Abstract

Background: Strokes pose a substantial health burden, impacting 1 in 6 people globally. One-tenth of patients will endure a second, often more severe, stroke within a year. Alarming, a younger demographic is being affected due to recent lifestyle changes. As fine motor and cognitive issues arise, patient disability as well as the strain on caregivers and health care resources is exacerbated. Contemporary occupational therapy assesses manual dexterity and cognitive functions through object manipulation and pen-and-paper recordings. However, these assessments are typically isolated, which makes it challenging for therapists to comprehensively evaluate specific patient conditions. Furthermore, the reliance on one-on-one training and assessment approaches on manual documentation is inefficient and prone to transcription errors.

Objective: This study examines the feasibility of using an interactive electronic pegboard for stroke rehabilitation in clinical settings.

Methods: A total of 10 patients with a history of stroke and 10 healthy older individuals were recruited. With a limit of 10 minutes, both groups of participants underwent a series of challenges involving tasks related to manual operation, shape recognition, and color discrimination. All participants underwent the Box and Block Test and the Purdue Pegboard Test to assess manual dexterity, as well as an array of cognitive assessments, including the Trail Making Test and the Mini-Mental Status Examination, which served as a basis to quantify participants' attention, executive functioning, and cognitive abilities.

Results: The findings validate the potential application of an interactive electronic pegboard for stroke rehabilitation in clinical contexts. Significant statistical differences ($P < .01$) were observed across all assessed variables, including age, Box and Block Test results, Purdue Pegboard Test outcomes, Trail Making Test-A scores, and Mini-Mental Status Examination performance, between patients with a history of stroke and their healthy older counterparts. Functional and task testing, along with questionnaire interviews, revealed that patients with a history of stroke demonstrated prolonged completion times and slightly inferior performance. Nonetheless, most patients perceived the prototype as user-friendly and engaging. Thus, in the context of patient rehabilitation interventions or the evaluation of patient cognition, physical functioning, or manual dexterity assessments, the developed pegboard could potentially serve as a valuable tool for hand function, attention, and cognitive rehabilitation, thereby mitigating the burden on health care professionals.

Conclusions: Health care professionals can use digital electronic pegboards not only as a precise one-on-one training tool but also as a flexible system that can be configured for online or offline, single-player or multiplayer use. Through data analysis, a more informed examination of patients' cognitive and functional issues can be conducted. Importantly, patient records will be fully retained throughout practices, exercises, or tests, and by leveraging the characteristics of big data, patients can receive the most accurate rehabilitation prescriptions, thereby assisting them in obtaining optimal care.

interactive electronic pegboard; stroke; hand dexterity; cognitive rehabilitation; system

Introduction

Worldwide, the aging population continues to increase, with several attendant problems [1,2]. The process of aging entails repercussions that extend beyond mere physiological conditions and encompasses a diverse spectrum of complications [3]. Older individuals are confronted with economic, psychological, and societal predicaments stemming from physical aging [4,5]. Hypertension is a critical condition intricately connected with the occurrence of strokes [6,7]. In 2020, a total of 7.08 million individuals globally died due to cerebrovascular disorders [8]. Encouragingly, continuous advancements in medical technology have increased the survival rate for patients with a history of stroke to 62% [9]. Nonetheless, even in cases of survival, 90% of patients experience residual effects, making rehabilitation approaches pivotal [10,11].

Stemming from damage to cerebral tissue, cerebral stroke gives rise to a variety of distinct neurological symptoms contingent upon the site of injury [12,13]. This often culminates in motor, sensory, and cognitive impairments among patients with a history of stroke, in which reduced attentional focus and memory deficits are common [14,15]. The aftermath of a stroke can have negative effects on patients' daily lives, occupational status, and social involvement [16,17]. To enhance physical mobility, manual proficiency, and cognitive aptitude, occupational therapy is the gold standard for elevating overall function [18]. Rehabilitation procedures are initiated once a patient's vital signs stabilize [19]. Clinical evidence indicates that due to significant individual variations among patients with a history of stroke, including age, rehabilitation needs vary [20-22]. Furthermore, older adults predominantly seek to restore ambulatory capacities, whereas younger individuals emphasize intricate fine motor rehabilitation exercises due to occupational demands [23].

In clinical practice, therapists often use calibrated instruments to evaluate and document patients' manual dexterity and cognitive recovery capabilities in one-on-one settings [24-26] using standard methodologies, such as the Purdue Pegboard Test (PPT) and the Nine-Hole Peg Test [24,27]. However, the use of a countdown timer to measure tasks within specific time frames has been validated as an effective means to infer attention, cognition, and manual dexterity capabilities in clinical contexts [28,29]. However, there remain substantial challenges, including human resource depletion, increased time expenditures, difficulties in effective disease progression tracking, and recording errors. Acharya et al [24] emphasized the inherent delay, particularly in response time, with the traditional interactive training method. Compared with the current setup, there is a consistent observation of higher measured timing. Taking the commercially available Neofect Smart Pegboard as an example, it serves as an electronic pegboard [30]. While it offers several advantages, it does not feature long-term tracking and precise prescriptions for

individual patients. Furthermore, using the electronic prototype of the Grooved Pegboard Test proposed by Al-Naami et al [31] in 2021 as an example, its operational efficiency shows no significant differences compared with the traditional method of manually recording rehabilitation outcomes. This experiment validates the feasibility of an electronic pegboard test to measure hand-time dexterity with impaired hand functionality, indicating comparable or even superior effectiveness when compared with the conventional manual recording approach.

In this study, we used electronic sensing techniques integrated with Wi-Fi and tablet devices to achieve a higher level of precision in evaluating tasks and time of completion [32]. This digitized approach facilitates accurate documentation of the intricacies associated with each practice and assessment, thereby enhancing the overall precision of the rehabilitation process [33,34]. The principal objective of this study was to subject the prototype to initial evaluation and testing involving patients with a history of stroke and healthy older individuals. We aimed to determine the appropriateness of the set difficulty levels, time constraints, and speed of the prototype.

Methods

Overview

The experimental apparatus consisted of an iPad, 5 color-sensitive building blocks, and 3 variations of task casings. The system's underlying sensing mechanism relied on the modulation of capacitance values resulting from the interaction between the sensing electrodes of the panel and the human body. The conductive building blocks generated stimulation signals that served as surrogate agents for fingers.

A schematic representation is shown in [Figure 1](#). Paired with the distinctive visual patterns on the back of each building block, these visual patterns upon contact with the iPad screen were detected and recognized through pressure sensing. This design was aimed at assessing the responsiveness, visual acuity, and color perception abilities of the participants during rehabilitation interactions ([Figure 2](#)).

All rehabilitation tasks and exercises integrated time calculation and countdown functions. Patients were given the option to choose between "independent practice" and "interactive practice" modes. During independent practice, after the "start" button was pressed and the countdown timer initiated, randomized questions were presented. Each practice session was preconfigured for a duration of 10 minutes, and completion and error rates were captured.

For interactive practice, therapists preset practice durations and modify difficulty levels (rehabilitation prescriptions). Through a Wi-Fi connection, therapists administer questions to make an online assessment of patients' abilities. After patients perform the tasks, both patients and therapists receive practice and rehabilitation reports, with all exercise records automatically

stored in the cloud. A flowchart illustrating the operation of the proposed pegboard is shown in Figure 3.

The proposed system encompasses 3 distinct modes, each presenting varying levels of complexity.

Figure 1. Design of the proposed system.

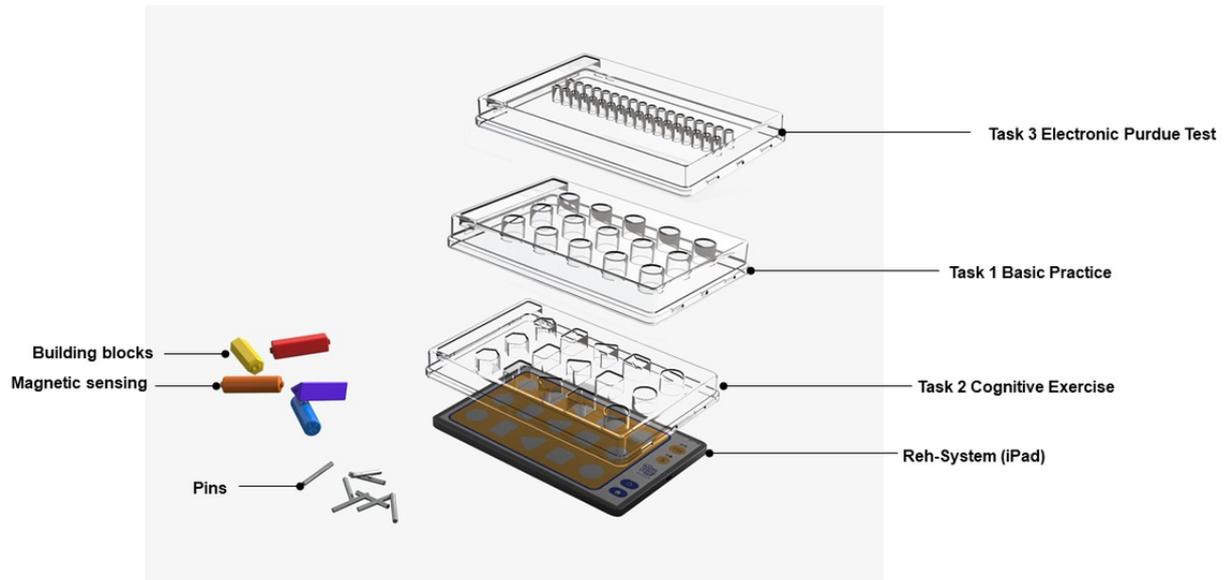

Figure 2. Interactive sensor blocks and tablet interface scenario.

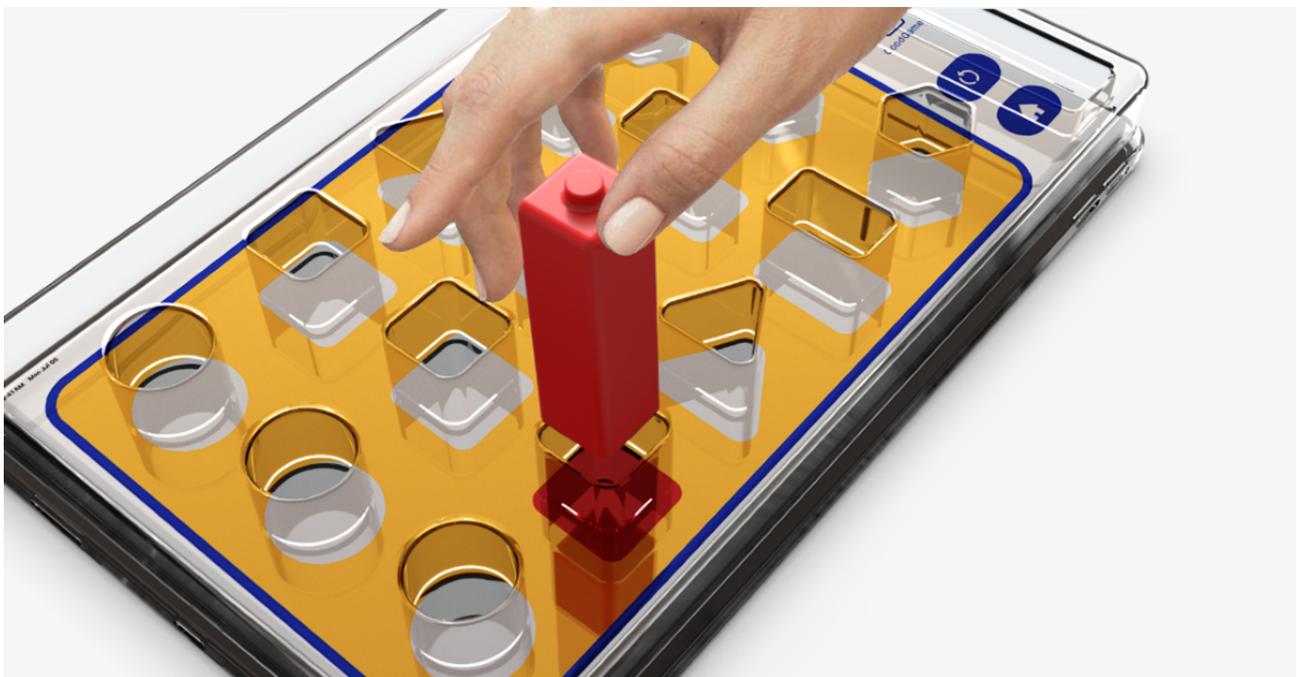

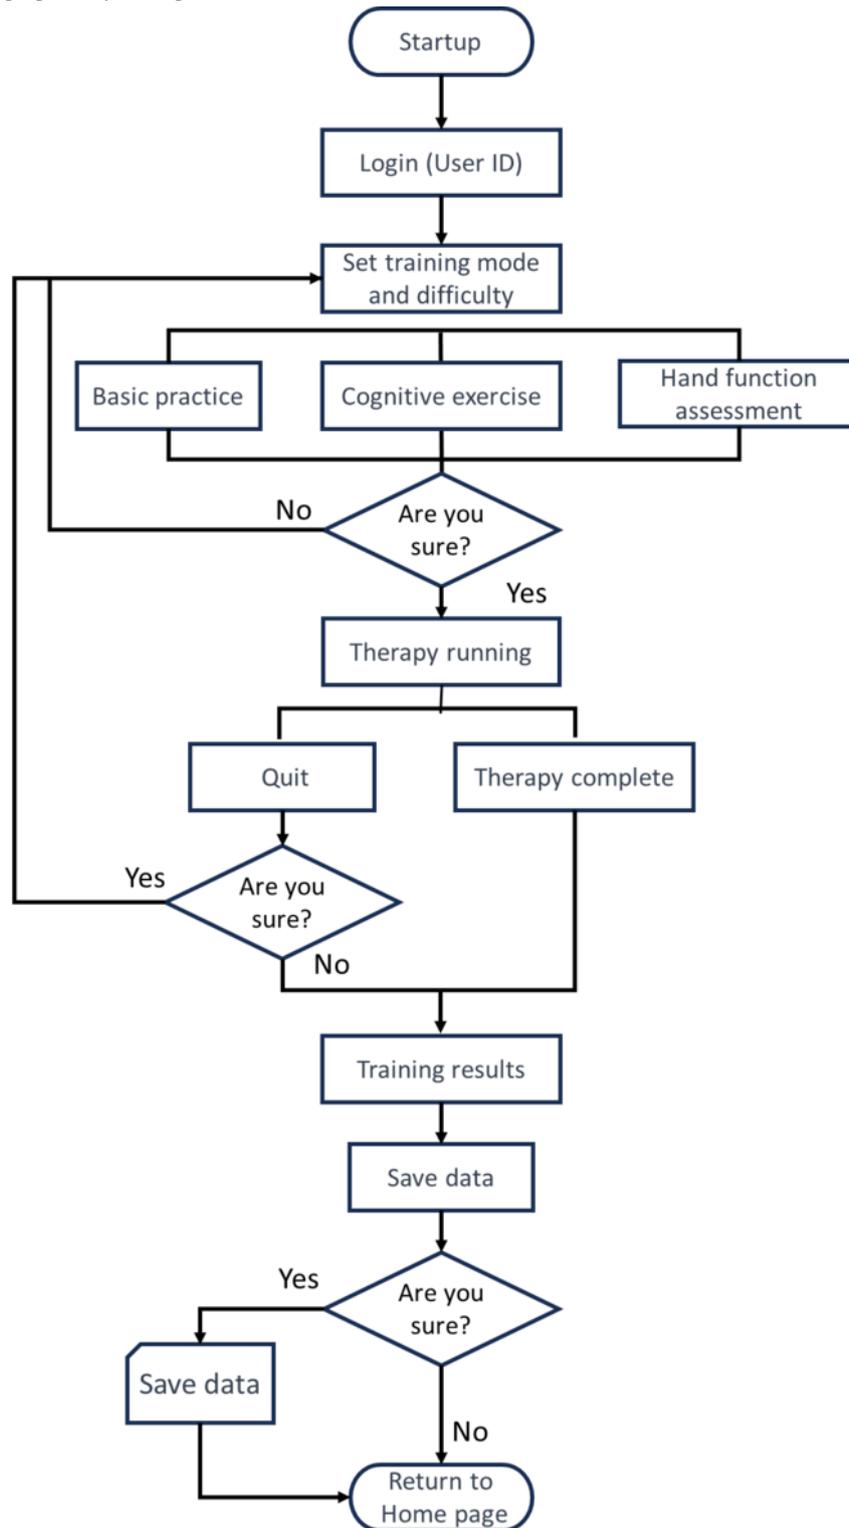

Figure 3. Flowchart of the proposed system operation.

Basic Practice

In basic practice (BP)-1 mode, users are assigned the task of associating the building blocks with the corresponding positions guided by reminder lights on the tablet screen (Figure 4A). Users earn points when they correctly insert the blocks into the

panel's corresponding positions. In the intermediate level (BP-2), users place the blocks in the corresponding positions as indicated by the lights of the screen within the given time frame while concurrently considering the variety of colors presented. The advanced level (BP-3) introduces a speed variable to increase the complexity of the task.

Figure 4. Three modes of the proposed system: (A) basic practice; (B) cognitive exercise; and (C) Electronic Purdue Test.

Cognitive Exercise

In cognitive exercise (CE)-1 mode, patients are required to distinguish the shapes of the building blocks and place them according to the patterns displayed on the screen. Users earn points when the blocks are correctly positioned. Upon advancing to the CE-2 level, users need to not only identify the corresponding shaped blocks but also distinguish the colors indicated by the lights. Points are awarded only when both the shape and the color are correct. In addition, this mode introduces varying levels of complexity related to color discrimination and speed (Figure 4B).

Electronic Purdue Test

In the design of the electronic Purdue Test (EPT) level, adherence to the principles of the PPT was paramount. The illuminated signals were meticulously crafted to guide patients in sequentially inserting pegs into corresponding holes (Figure 4C). The assessment consists of distinct 30-second trials for the right, left, and both hands, with individual scores recorded and aggregated. In addition, a 60-second bilateral combination test is administered once. This comprehensive set of evaluations is repeated 3 times. The platform automatically calculates the average score, which serves as the test score. Unlike traditional training, the device guides patients to place pegs into corresponding positions through the use of light signals, which remain illuminated until the pegs are properly placed.

Given the inherent variability in individual patient capabilities, prescribed treatments should differ. To facilitate precision health care, the system incorporates a user login mechanism to generate personalized digital rehabilitation plans and records. The proposed design comprises 3 different modes and 3 difficulty levels of exercises. Preestablished exercises encompass directional movements (including upward, downward, leftward, and rightward motions). During the initial stages of the rehabilitation regimen, the system uses a mechanism of stochastic question generation. As the system accumulates practice data, it systematically discerns and assimilates the individual requirements of each patient, thereby tailoring subsequent questions to enhance areas of observed weakness.

Research Aims

This research had the following aims: (1) we sought to investigate the suitability of the time and difficulty settings for both patients with a history of stroke and healthy users, (2) we explored the correlation between hand function and cognitive

abilities, and (3) we conducted a usability questionnaire for the proposed system.

Participant Recruitment

A total of 20 older adults aged between 65 and 80 years were recruited: 10 (50%) patients with a history of stroke and 10 (50%) individuals with no history of strokes. Prior to their inclusion, all participants provided signed informed consent. All participants exhibited right-handed dominance. The inclusion criteria were delineated based on the following: (1) capacity to independently maintain a seated position for a duration exceeding 20 minutes, unaided by external assistance; (2) possession of fundamental communication skills; and (3) relatively uncomplicated functional performance in the assessment of daily life activities. As a safeguard against potential trial-related risks, individuals with a history of recurrent stroke, severe muscular atrophy, or pronounced physical frailty were excluded.

Experimental Procedure

All participants underwent the Box and Block Test (BBT) and the PPT to assess manual dexterity, as well as an array of cognitive assessments, including the Trail Making Test (TMT) and the Mini-Mental Status Examination (MMSE), which served as a basis to quantify participants' attention, executive functioning, and cognitive abilities. Figure 5 shows an image of the proposed system in use.

The experimental session was conducted on a one-on-one basis. The prototype was positioned before each participant, and the 15 pegs, consisting of 5 distinctive colors integral to the interactive system, were methodically arranged adjacent to the central apparatus. Participants sequentially underwent 3 testing modes (BP, CE, and EPT), using their right hand exclusively. Except for the EPT, which followed the PPT criteria, the length of the BP and CE tests was 10 minutes each. The test outcomes encompassed the number of correct responses, completion time, and rehabilitation reports, all of which were concurrently displayed, stored within the apparatus, and uploaded to the cloud platform.

To gain a thorough understanding of users' interactions with the proposed system, we used the System Usability Scale [25] with a 5-point Likert scale to reveal users' perceptions regarding aspects of system acceptance, design appeal, and perceived task difficulty.

Figure 5. Image of the proposed system in use.

Statistical Analysis

This study used SPSS software (version 20; IBM Corp) for statistical analyses. Data analysis involved a comparative assessment between patients with a history of stroke and healthy older individuals, exploring both demographic characteristics and scores obtained from the proposed system, with the Wilcoxon rank sum test used for statistical analysis. To elucidate the potential associations between participants' manual dexterity and cognitive faculties among patients with a history of stroke, this study also used the Spearman rank correlation coefficient, with statistical significance set at $P < .05$.

Ethical Considerations

A total of 20 participants were recruited for this study. All participants provided informed consent by signing a consent form, and the study was conducted in accordance with institutional review board (IRB) regulations using anonymized data, with personal information removed and replaced by codes. No participants withdrew from the study during the research period. To ensure the validity and fairness of the experiment, no monetary or material benefits will be provided during the trial period, in accordance with the IRB application statement. Participants are expected to provide genuine feedback on the product developed in this project based on their intuitive reactions.

The research was conducted within the Department of Physical Medicine and Rehabilitation at Chang Gung Hospital, Taiwan and received approval from the Research Ethics Committee for

Human Subject Protection of Chang Gung Medical Foundation (IRB: 202301197A3).

Results

This study included a total of 20 participants (10 patients with a history of stroke and 10 healthy participants). With a limit of 10 minutes, both groups of participants underwent a series of challenges involving tasks related to manual operation, shape recognition, and color discrimination. The statistical analysis revealed statistically significant discrepancies between patients with a history of stroke and healthy participants across all variables ($P < .05$). These differences were evident in all assessed parameters, indicating the potential of the equipment to serve as an assessment tool for both motor and cognitive abilities in both healthy individuals and patients with a history of stroke, with additional training and testing capabilities (Table S1 in [Multimedia Appendix 1](#)).

Among older participants who had not experienced a stroke, performance in tasks involving the dominant hand (right hand) during the BBT and the PPT as well as cognitive performance in the TMT was notably superior to those who had experienced a stroke (Figure S1A and S1B in [Multimedia Appendix 1](#)). However, no significant differences were observed between the 2 groups in the MMSE test, which assessed memory abilities (Table S2 in [Multimedia Appendix 1](#)). Furthermore, in the MMSE test assessing memory abilities, both groups of subjects showed significant differences ($P < .01$) (Table S2 in [Multimedia Appendix 1](#)).

Statistical analysis revealed significant negative correlations between performance in the BP-1 or CE-1 task and dexterity tests ($P < .01$). In addition, there were significant correlations between multicolors (BP-2 or CE-2) and dexterity or cognitive tests and a significant negative correlation between scores in the EPT and cognitive performance on the TMT-A and MMSE tests ($P < .05$) (Table S3 in [Multimedia Appendix 1](#)). The number of correct answers was used as the score in BP and CE; the time required was used as the score in BP, CE, and EPT in the single and multicolor tests. In terms of usability, 40% (4/10) of patients with a history of stroke and 60% (6/10) of healthy participants deemed the prototype user-friendly (Figure S2A in [Multimedia Appendix 1](#)).

Furthermore, all healthy individuals (100%) and majority of patients with a history of stroke (90%, 9/10) found the proposed system highly engaging. During the more demanding CE training, more than 80% (8/10) and 50% (5/10) of healthy participants and patients with a history of stroke, respectively, considered the system both challenging and stimulating. Participants additionally expressed a positive disposition toward the EPT and provided overall positive feedback (Figure S2B in [Multimedia Appendix 1](#)).

In assessing task difficulty, nearly 80% (8/10) and 60% (6/10) of healthy participants and patients with a history of stroke, respectively, perceived the BP training tasks as easy and straightforward. However, as participants advanced to the more challenging CT training, there was a noticeable increase in the perceived complexity of tasks, in which only 40% (4/10) and 20% (2/10) of healthy participants and patients with a history of stroke, respectively, found this phase easy. Moreover, 60% (6/10) of healthy participants found the EPT straightforward, while 40% (4/10) of patients with a history of stroke indicated a moderate level of challenge associated with the EPT training (Figure S2C in [Multimedia Appendix 1](#)).

Discussion

Principal Findings

Across the 5 tasks investigated in this study, the stroke rehabilitation group exhibited significantly lower scores in the use of the proposed system compared to the healthy participants. In accordance with previous research, advancing age and disease manifest changes and declines in hand function, muscle strength, agility, and cognitive abilities [35,36]. This was evident in the use of the proposed system.

Previous studies have highlighted the repercussions of cerebral damage on patients with a history of stroke, such as compromised cognitive, motor, sensory, and functional capabilities, as well as pain, balance issues, visual challenges, and restricted engagement in activities [37,38]. Sudden cognitive deterioration occurs as a result of these conditions, with 5% of patients with a history of stroke exhibiting dementia symptoms [39,40]. Thus, the augmentation of hand function rehabilitation for patients is imperative. Our findings underscore a close interrelation between manual dexterity and cognitive aptitude [41]. In future research, we intend to explore the use of the proposed system paired with auditory and visual cues to

ascertain its potential to guide and enhance visual acuity, attention, and cognitive capabilities among cohorts of different ages and individuals afflicted with cerebral impairments.

The BP and CE tests encompassed factors of both single-color and multicolor conditions. Participants encountered operating difficulties as cognitive demands increased. The CE assessment included recognition of color and object shape, where performance consistently declined across all participants. This observation aligns with previous findings indicating a decline in change detection accuracy with an increase in cognitive load [26,27]. Consequently, as the number of colors increased, the attentional burden on the patients correspondingly increased. This suggests that a graded system with different levels of difficulty might be useful.

During the progression of single-color BP-1 and CE-1 sessions, negative correlations were observed in dexterity tests. In the context of multicolor BP and CE sessions, a distinct and significant correlation was found between the use of multicolors and performance levels on the TMT-A test. The test results suggest that when participants engaged in color recognition and discrimination tasks, the attentional demands for single-color and multicolor tasks differed. In other words, multicolor exercises presented an increased cognitive challenge, affecting manual dexterity and attention switching.

The majority of participants found the proposed system highly user-friendly, in part because the size of the system resembled traditional training pegboards, which maintained familiarity and reduced the need for adaptation. As therapists were not required to manually record participants' actions or time them with stopwatches, this design was advantageous for both users and evaluators. In the various tasks, approximately 60% (12/20) to 70% (14/20) of all participants found BP training to be interesting, while 40% (8/20) to 60% (12/20) of the participants considered the EPT tasks engaging. Regarding the difficulty level, 60% (12/20) to 70% (14/20) of the participants perceived BP training as relatively easy; however, as operating constraints increased (such as color and shape elements), the participants commonly reported that tasks became more challenging and demanding. This finding is consistent with prior research indicating that increasing the difficulty to match users' current abilities enhanced their confidence, maintained attention and engagement in tasks, and promoted a more positive and enjoyable acceptance of new challenges. In this preliminary experiment, neither patients with a history of stroke nor healthy participants were able to complete the tasks within the allotted time, and none of the participants achieved a perfect score. This is likely attributable to the time constraints imposed by the experimental design or the capabilities of the users. Therefore, future studies will include basing task difficulty settings on user performance, similar to leveling up in a video game. The gamification of rehabilitation, in addition to fostering effective interactivity, is facilitated by the incorporation of voice and music assistance. This approach contributes to enhancing the enjoyment of rehabilitation, transforming it from a tedious and uninteresting process. Furthermore, it effectively redirects patients' attention away from pain, thereby augmenting the overall appeal of the rehabilitation process.

The proposed system is equipped for practice, training, and assessment. The majority of similar products on the market predominantly focus on training manual dexterity and do not offer timing and recording functions [28-30]. Certain designs acknowledge the significance of cognitive training and use shape as a cognitive judgment criterion; however, these designs lack elements that enhance the attention of rehabilitation patients, such as auditory cues, visual stimuli, or color-guided prompts. This deficiency in interactive mechanisms often results in users struggling to sustain or commit to rehabilitation efforts. Finally, in terms of assessment functionality, contemporary clinical practice still relies on manual documentation and human intervention for upper limb assessments. The proposed system not only incorporates timing and counting features during upper limb assessments but also introduces guiding and competitive elements, positioning patients to achieve better recovery outcomes. Currently, the system is converting data from each patient's rehabilitation sessions into charts. This aids both patients and health care professionals in gaining a more comprehensive understanding of the rehabilitation and recovery status. This system is thus highly advantageous compared with current commercial products [32-34,42]. The interactive electronic pegboard integrates the merits of existing market offerings and further introduces automated assessment and scoring mechanisms for accurately placed pegs. By surpassing the limitations inherent in conventional fixed training paradigms, this system systematically and comprehensively records the training progress of each case. As data accumulate via a learning model, the system develops a profound understanding of user-specific requirements and consequently extrapolates optimal and customized training regimens tailored to individual users, representing a major step toward precise rehabilitation goals. Finally, the proposed system exhibits greater versatility in its training curriculum and offers increased variability and flexibility. Rehabilitation with digital tools will no doubt significantly enhance users' interest and attention.

Our preliminary investigation indicates that the proposed system is beneficial in the training, assessment, and testing of patients with a history of stroke. The outcomes showcase positive responses concerning hand function training and cognitive ability assessment among patients with a history of stroke. However, to ascertain reliability and validity, a greater number of participants, including diverse age groups and individuals with cerebral impairments, should be recruited in future investigations [35].

Patients with a history of stroke often grapple with diminished motivation for rehabilitation and a lack of immediate feedback, hindering their ability to maintain consistent participation in rehabilitation regimens [36-38]. While the platform devised in this study uses auditory and visual cues to encourage perseverance in rehabilitation, there remains room for improvement in configuring different challenge levels and real-time feedback mechanisms based on varying patient capacities [39-41]. This is a pivotal objective for refinement and enhancement.

Conclusions

The primary objective of this research was to bridge the gap between clinical requirements and product development through customized rehabilitation training based on individual differences. Through the analysis and assessment of data and providing personalized training modes tailored to specific differences, we aimed to predict patients' hand dexterity and cognitive functional abilities. We thus developed the interactive electronic pegboard, a novel software- and hardware-integrated system for stroke rehabilitation, with the purpose of evaluating dexterity and cognitive functions through various task types and multidemonstration patterns. Preliminary findings indicate the efficacy of the system for training and assessment. The ultimate goal of this research is to develop an intelligent system capable of delivering individualized optimized rehabilitation regimens based on the varying needs of users.

Acknowledgments

The authors express their gratitude to all participants in this project for their generous contribution of time, sharing of usage experiences, and insights, which greatly enriched this study. Furthermore, they extend their sincere appreciation to Professor Ching-Yi Wu from the Department of Occupational Therapy at Chang Gung University for providing valuable suggestions and crucial guidance in the experimental design. Finally, they especially thank the Rehabilitation Department at Chang Gung Memorial Hospital for their clinical support throughout this research endeavor. This study received support from the National Science and Technology Council through grant 111-2222-E-182-002-MY2, as well as from the Chang Gung University Innovative Prototype Project with grant EMRPD1M0101.

Data Availability

The data sets generated and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

SYC was involved in product development and study design, conducted the interviews and prototype testing, collected and analyzed the data, and drafted the manuscript. AMKW and CYW provided clinical guidance. SLB contributed to the manuscript by offering suggestions and participating in revisions.

Conflicts of Interest

None declared.

Multimedia Appendix 1

Detailed participant data and analyses.

Abstract

Background: In pandemic situations, digital contact tracing (DCT) can be an effective way to assess one's risk of infection and inform others in case of infection. DCT apps can support the information gathering and analysis processes of users aiming to trace contacts. However, users' use intention and use of DCT information may depend on the perceived benefits of contact tracing. While existing research has examined acceptance in DCT, automation-related user experience factors have been overlooked.

Objective: We pursued three goals: (1) to analyze how automation-related user experience (ie, perceived trustworthiness, traceability, and usefulness) relates to user behavior toward a DCT app, (2) to contextualize these effects with health behavior factors (ie, threat appraisal and moral obligation), and (3) to collect qualitative data on user demands for improved DCT communication.

Methods: Survey data were collected from 317 users of a nationwide-distributed DCT app during the COVID-19 pandemic after it had been in app stores for >1 year using a web-based convenience sample. We assessed automation-related user experience. In addition, we assessed threat appraisal and moral obligation regarding DCT use to estimate a partial least squares structural equation model predicting use intention. To provide practical steps to improve the user experience, we surveyed users' needs for improved communication of information via the app and analyzed their responses using thematic analysis.

Results: Data validity and perceived usefulness showed a significant correlation of $r=0.38$ ($P<.001$), goal congruity and perceived usefulness correlated at $r=0.47$ ($P<.001$), and result diagnosticity and perceived usefulness had a strong correlation of $r=0.56$ ($P<.001$). In addition, a correlation of $r=0.35$ ($P<.001$) was observed between Subjective Information Processing Awareness and perceived usefulness, suggesting that automation-related changes might influence the perceived utility of DCT. Finally, a moderate positive correlation of $r=0.47$ ($P<.001$) was found between perceived usefulness and use intention, highlighting the connection between user experience variables and use intention. Partial least squares structural equation modeling explained 55.6% of the variance in use intention, with the strongest direct predictor being perceived trustworthiness ($\beta=.54$; $P<.001$) followed by moral obligation ($\beta=.22$; $P<.001$). Based on the qualitative data, users mainly demanded more detailed information about contacts (eg, place and time of contact). They also wanted to share information (eg, whether they wore a mask) to improve the accuracy and diagnosticity of risk calculation.

Conclusions: The perceived result diagnosticity of DCT apps is crucial for perceived trustworthiness and use intention. By designing for high diagnosticity for the user, DCT apps could improve their support in the action regulation of users, resulting in higher perceived trustworthiness and use in pandemic situations. In general, automation-related user experience has greater importance for use intention than general health behavior or experience.

COVID-19; contact tracing; user experience; trust; health information processing

Introduction**Background**

During pandemic situations, efficiently acquiring, storing, and evaluating information on physical contacts can be crucial for both individuals and public health agencies aiming to curb infection dynamics [1]. Manual tracing of such contacts is practically impossible, leading to a growing development and research of digital tools supporting such efforts, commonly referred to as digital contact tracing (DCT) apps [2]. By allowing for automation, DCT tools effectively allow for contact tracing. They aim to allow individual users to assess their own risk status with minimal effort and offer support in daily action regulation, such as in decision situations, regarding isolation or notification of previous contacts [3]. If used correctly, DCT can aid in breaking chains of infection and thereby support curbing pandemic spread. For example, in Germany, a DCT called *Corona-Warn-App* (CWA) [4] was developed on behalf of the Federal Ministry of Health, and it was downloaded >40 million times [5].

However, the extent to which individuals use DCT can vary vastly [6]. Previous research has shown that it is crucial whether users perceive a DCT app as beneficial to guide them in pandemic contexts [7]. This core factor is in line with existing models of health behavior (eg, the influential Health Belief Model [HBM] [8]). Within the HBM, perceived benefit is outlined as a central determinant for the implementation of health behavior [7]. When investigating health-related technology, the HBM is frequently connected with models of technology acceptance [9]. As part of these models, the perceived usefulness or performance of technology is similarly postulated as a central variable for use intention. In this paper, we refer to the term *usefulness* as it is better suited than *benefits* to describe the effects of a specific technology. Thereby, we refer to usefulness as “the degree to which a person believes that using a particular system would enhance their [...] performance” [10].

Examining psychological processes revolving around the perception of DCT usefulness is a crucial research topic to understand the adoption and efficient implementation of DCT. Extensive research has shown the importance of the perceived usefulness of DCT for different applications and in different countries [11-15]. All in all, extending existing theoretical approaches such as the HBM by focusing on user experience variables in DCT allows for clear guidelines on improving DCT design and uptake.

The usefulness that a user can experience from DCT results from the automation it provides. DCT takes over tasks that would otherwise need to be done manually (eg, recording contacts, estimating distance and exposure to contacts, and calculating risk based on the vaccination status of contacts). Therefore, it can be defined as an automated system. In general, automation can be defined as a system’s ability to “offload, assist, or replace human performance at corresponding stages

of human information processing” [16]. The human action that DCT seeks to automate is the continuous recording and analysis of contact data to monitor an individual’s risk of infection. While there is a large body of research on automation, its adverse biases, and its impact on human performance [17-19], less research focuses on the psychological processes involved when users evaluate the usefulness of automated contact tracing.

Parasuraman et al [20] define 4 evaluation criteria on how automation can affect human performance: situation awareness [21], trust (cf complacency and trust [22]), skill degradation [23], and workload [24]. When users want to make situation-adequate decisions, they benefit from improved situation awareness. Situation awareness, in turn, can be improved by DCT. As long as the information or recommendations provided by DCT apps are perceived as trustworthy, users may use them to determine the right course of action. Accordingly, a DCT’s ability to support situation awareness as well as trust formation (refer to the study by Hoff and Bashir [25]) may lead to perceived usefulness. On the other hand, in the context of DCT apps, one cannot assume that users are potentially losing a previously existing skill through automation; DCT app users are not able to stop sick individuals or themselves. Along the same line, DCT app users profit from automation as it reduces manual work in contact tracing. Therefore, we propose to examine users’ experience of situation awareness and trustworthiness when using DCT apps.

While research has demonstrated that usefulness strongly impacts use intention [26], factors unrelated to the specific DCT app might affect whether people intend to use the system. The HBM positions threat appraisal as another factor directly influencing use intention [7]. While using a DCT app changes neither the susceptibility nor the severity (in comparison, refer to the study by Costa [27]) related to an infection, it is still plausible that users with higher threat appraisal are more interested in their own risk status and, therefore, more likely to use a DCT app (eg, to be able to detect and react to an infection as early as possible). Therefore, threat appraisal may influence use intention independent of the specified design of DCT apps. In addition, recent research has also shown that the theoretical framework of the HBM does profit from incorporating prosocial aspects of decisions [28,29] (ie, using a DCT app may provide a sense of moral obligation to others). Even though individuals with immunity may perceive a lower personal threat, they may feel a personal obligation to track and inform contacts. Overall, to fully investigate the influence of the perceived usefulness of a DCT system on the use intention, a comparison with system-nonspecific factors (ie, threat appraisal) and personal moral obligation should be made. To the best of our knowledge, no previous study has focused on examining the perception of automation-related usefulness while addressing threat appraisal and moral obligation as system-independent factors influencing use intention.

Research Objective

The objective of this research was to examine how automation-related user experience affects the perceived usefulness of contact tracing as well as use intention of DCT apps and how user experience could be improved. To do so, our approach consisted of multiple methods. The first was quantitatively assessing and analyzing the impact of automation-related user experience (ie, experienced system traceability and perceived trustworthiness) as well as system knowledge on the intention of using a DCT app. The second was contextualizing the effects of automation-related user experience measures with factors related to health protection behavior (ie, threat appraisal and moral obligation). The third was a qualitative analysis of user demands for improved information communication between users and the DCT app. Therefore, the key contribution of this research is a better understanding of how system characteristics lead to perceived usefulness of DCT and how optimal DCT apps can increase use intention through automation-related user experience. Thus, this research supports the human-centered design of DCT apps.

To address these research objectives, 317 users of the CWA DCT system were surveyed about their experience with the app through a web-based questionnaire. A partial least squares structural equation model (PLS-SEM) was used to quantitatively describe the relationships among psychological factors regarding DCT use. This approach was supplemented by a thematic analysis of qualitative user requests on desired communication of information between users and the system.

Related Research

Use Intention of DCT

DCT describes software applications that support documenting information of physical contact or proximity between people (cf [30]). This includes both the (partially) automated acquisition of contact information and the analysis of this information (eg, to determine an individual's risk of infection [31]). In pandemic situations, users might have the goal to avoid contributing to the further spread of the pandemic disease and, thus, face a control task. This means that users need to constantly self-regulate their actions in relation to their environment (eg, how many people around them are infected). While users strive to achieve this goal, they are constantly facing a changing environment (ie, exposure to infected persons). To maintain control, they need to constantly acquire and analyze information and decide, for example, whether they want to isolate themselves. Such actions taken by users have a profound impact on the trajectory of their individual situation—they potentially curtail further contacts and, thereby, change the future information acquisition process. In this process, DCT constitutes a crucial tool for behavioral control as the information provided functions both as feedback for previous behavior and as an indicator for future behavior.

Although DCT applications, especially on mobile devices, first generated high interest during the COVID-19 pandemic [32], they had already been used previously (refer to, eg, the study by Sacks et al [33]). Due to their wide applicability and potential role in public health systems during the COVID-19 pandemic,

research on user behavior toward DCT has increased. Here, diverging acceptance models (such as the Unified Theory of Acceptance and Use of Technology and the technology acceptance model) have been evaluated to understand DCT use intention (eg, the study by Velicia-Martin et al [34]).

As indicated at the outset, previous research on DCT app use has leveraged not only acceptance models but also more general models of health behavior such as the HBM or the Theory of Planned Behavior [35]. Such models have been successfully used in research on the uptake and maintenance of other pandemic protective behaviors. In that context, there is consistent evidence of the importance of factors related to the behavior itself, such as perceived usefulness; factors related to perceived risk, such as threat appraisal; and social and normative factors [11,36]. However, in the DCT context, results are mixed. While there is broad support for the importance of factors such as use intention [35] and perceived usefulness [7], evidence of the role of the other factors is less consistent. For example, Tomczyk et al [35] found evidence of the role of both subjective norms and threat appraisal. In contrast, Walrave et al [7] did not include normative factors in their study and found no significant relationship between threat appraisal and DCT adoption. In a different approach to conceptualizing norms, Zabel et al [37] found a strong association between DCT adoption and moral intensity, a construct that derives the perceived obligation for DCT adoption from a range of beliefs, including beliefs about both usefulness and risk. This not only mirrors findings on the association between moral obligation and other pandemic protective behaviors, but as the community benefit of DCT might outweigh the individual benefit, it also appears to be a promising avenue for exploring the relationship between norms and DCT use. Accordingly, it remains an important task of DCT research to understand the relative influence and interplay of both factors such as perceived usefulness, and factors such as threat appraisal or moral obligation on use intention.

One reason for the ambiguity of existing results can be the variability of operationalizations—trust, for example, is highlighted in multiple studies as decisive for DCT use intention [7,35,37]. However, the conceptualization of trust can be challenging and context-dependent [38]. In DCT, for example, trust could influence one's belief regarding how effectively DCT can support the individual in avoiding an infection. On the other hand, trust can be related to the data security of private information (refer to, eg, the study by Altmann et al [39]). Therefore, a context-sensitive and theory-based conceptualization of trust is necessary to operationalize it adequately.

Breaking Down Automation-Related User Experience in DCT

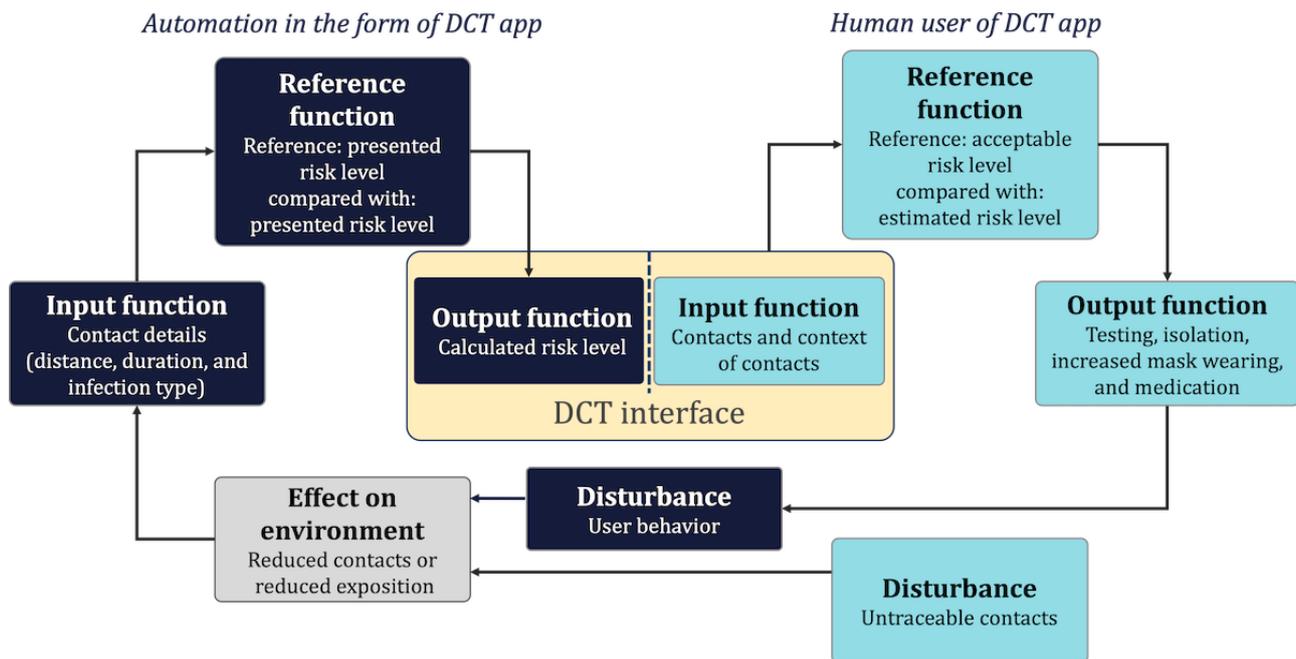

In a pandemic context, the goal of users can be characterized as behavior that avoids both becoming infected and spreading infection to others. Still, they may desire to meet other people or use public transport and, therefore, are continuously adapting their behavior based on how they perceive the risk situation (ie, for simplification, a perceived risk level; refer to the study by Wilde [40]). This risk level refers to the probability of being

infected by, for example, a virus. Acquisition of information on the current risk level is supported by DCT and becomes critical information for comparison, prompting actions to reduce risk.

Contact tracing involves data gathering but also decision-making processes that influence individual and collective health outcomes. It integrates continuous information processing and, therefore, can be viewed through the theoretical lens of control-theoretical conceptions of human-machine systems. The control loop model of action regulation in contact tracing can be extended to accommodate for DCT as automation (ie, a

system) that takes over tasks in the acquisition, analysis, and decision selection of contact information [20]. However, maintaining an acceptable risk level [40] is not a singular, finite process but a continuous one. Accordingly, we propose to model information acquisition, analysis, and decision selection as parts of an action regulation consisting of an input function, a reference function, and an output function. As depicted in Figure 1, both human and machine information processing can be modeled within a conceptual control loop to reflect continuous information processing. The conceptual control loop model (Figure 1) illustrates the integration of human and automation activities into a joint action regulation.

Figure 1. Conceptual control loop model of joint human-machine action regulation in digital contact tracing (DCT). The assessment of the machine processing steps (input, reference, and output) is central to the perceived trustworthiness (perceived data validity, perceived goal congruity, and perceived result diagnosticity) of the system.

Based on the model presented in Figure 1, we assumed that users' interaction with DCT apps is based on their evaluation of automated input, reference, and output functions. They assess the correctness of the data that the DCT system uses (*input function*), the data's congruence with the users' goals (*reference function*), and the utility of the data's communicated results (*output function*). Any lack of transparency in their joint action regulation can diminish perceived trustworthiness as well as hamper situation awareness. For instance, if the system fails to capture necessary data accurately or align with personal goals such as identifying the source of infection versus alerting those potentially infected, perceived trustworthiness may decline. Accordingly, parallel to similar phenomena in other automation contexts that do not reveal which information is used as part of the input function, an out-of-the-loop unfamiliarity might cause decreasing situation awareness [20]. Furthermore, the user experience may suffer if the system's output, such as an imprecise infection risk description, is insufficient for users to decide the next course of action, therefore impeding the perceived usefulness.

In addition, users' perception of the system is dependent on their expectations of information processing (cf [41]; ie, how

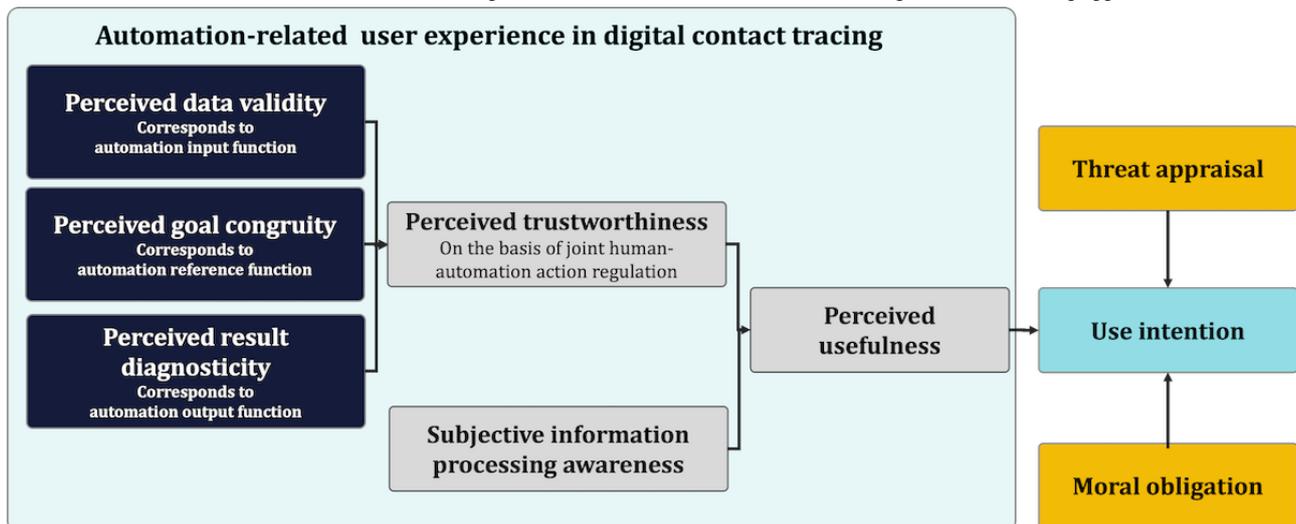

the DCT system processes contact-related data). For example, whether a DCT app processes others' vaccination status will only matter to users who are interested in that information, and disclosing that the app processes vaccination information will only impact the system perception of those users. As such, to understand the formation of perceived usefulness, users' subjective situation awareness is more important than their factual situation awareness. However, as introduced by Schrills and Franke [42], subjective evaluation of a user's ability to "perceive, understand and predict a system's information processing," described as subjective information processing awareness, can serve as a construct to assess users' perception of an automation's effect on situation awareness. However, users' perception of their information processing awareness might not be reflected in the accuracy of their knowledge about the system's information processing.

The previous concepts of perceived data validity, goal congruity, result diagnosticity, trustworthiness, subjective information processing awareness, and perceived usefulness can be subsumed as automation-related user experience. Automation-related user experience, following the 9241 standard from the International Organization for Standardization, can be

defined as *the perception and response of a person resulting from using or anticipating the use of automated systems*. On the basis of our proposed conception of automation-related user experience, we conceptualized a model of factors of use intention in DCT centered on perceived usefulness of automation as depicted in Figure 2. In addition, threat appraisal and moral obligation as factors independent of DCT use are integrated as

measures to evaluate the influence of automation-related user experience on use intention comparatively. Threat appraisal and moral obligation are not connected with properties of the DCT app; that is, they influence whether a user wants to demonstrate behavior to trace contacts but not how useful a specific app is perceived to be.

Figure 2. Research model on automation-related user experience and the effect on use intention of digital contact-tracing apps.

This Study

On the basis of the presented research model, the objective of this study was to investigate how automation-related user experience affects the perceived usefulness of contact tracing as well as the use intention of DCT and how user experience could be improved. We aimed to contribute to research on DCT adoption and use by examining possible pathways to enhance use intention via user experience. On the basis of the proposed research model, we analyzed the following hypotheses: (1) perceived trustworthiness correlates positively with perceived usefulness (hypothesis 1), (2) subjective information processing awareness correlates positively with perceived usefulness (hypothesis 2), and (3) perceived usefulness correlates positively with use intention (hypothesis 3).

In addition, we examined the relationship among all the aforementioned variables in a structural equation modeling (SEM), where we tested automation-related variables as well as variables not related to the specific DCT system: (1) threat appraisal is positively related to use intention (hypothesis 4) and (2) moral obligation is positively related to use intention (hypothesis 5).

Accordingly, the research model depicted in Figure 2 serves as a basis for an SEM analysis that integrated both automation-related user experience and automation-independent variables (threat appraisal and moral obligation).

We supplemented our quantitative findings with qualitative data on the requirements for improved information processing, providing a deeper insight into users' interactions with the app. This mixed methods approach allowed us to uncover underlying patterns and themes that cannot be identified through

quantitative data alone, providing a more comprehensive understanding of the user experience.

Methods

Participants

Participants were recruited via social networks (Twitter [subsequently rebranded X] and Facebook), where an image and a link to the study were shared showing a picture of the CWA and asking for participation (ie, our sample was self-selected). The recruitment strategy specifically targeted individuals who had experience using the CWA. Eligibility for the study required participants to be aged ≥ 18 years and have at least fluent German skills. The study was conducted on the web, with data collection taking place via a web-based questionnaire between June 1, 2022, and July 31, 2022, using LimeSurvey (LimeSurvey GmbH) [43]. We decided not to inquire further about demographic variables to maintain high levels of privacy due to the context of the study (tracking apps).

A total of 317 participants were included in the study (refer to the Data Exclusion section for further details). As user diversity can have a significant impact on the individual user experience and the perceived trustworthiness, we assessed the affinity for technology interaction (ATI) [44]. ATI describes the individual tendency to actively engage in intensive technology interaction. The ATI was measured using a scale validated in various large samples. Our sample ranged from 1 to 6, with an average value of 4.19 (SD 1.26) which was somewhat higher than the value of 3.5 that Franke et al [44] assumed for the general population based on quota sampling. This corresponds with the self-selection of the sample; we can assume that users who installed the CWA may have, in general, a higher level of ATI than the general population.

Ethical Considerations

This study was registered (under 2022-413) at the Ethics Committee of the University of Lübeck. Before participating in the study, individuals received detailed information about the study and provided written consent to partake. For anonymity, no additional demographic data of the users were queried. No financial remuneration was provided for participation.

Scales and Procedure

Overview

To capture the psychological concepts described previously, multiple scales were developed and presented to participants after they provided informed consent. Except for those for experienced system traceability [42], all items were generated by the researchers based on theoretical considerations and discussed within a team of 3 experts in human-machine interaction.

All items used a 6-point Likert response scale (*completely disagree*=1, *largely disagree*=2, *slightly disagree*=3, *slightly agree*=4, *largely agree*=5, and *completely agree*=6), with the only exception being the semantic differential used for perceived usefulness. For all variables except knowledge, a mean score of all items of the scale was calculated and used for further analysis. All the original items were in German and are presented in this manuscript in English.

Use Intention

Use intention was captured using a 3-item scale focusing on participants' intention and future commitment to use the CWA during the pandemic (Multimedia Appendix 1).

Threat Appraisal

A 4-item scale was used aiming to comprehend the participants' perceived risk and concerns related to a possible infection (Multimedia Appendix 1).

Experienced System Traceability

Experienced system traceability was assessed using the 6-item Subjective Information Processing Awareness scale [42] measuring the perceived transparency, understandability, and predictability of information collection and processing by the system (Multimedia Appendix 1).

Moral Obligation

Moral obligation was evaluated using a 3-item scale capturing the participants' sense of responsibility and ethical obligation toward using the CWA (Multimedia Appendix 1).

Perceived Trustworthiness

Perceived trustworthiness was measured across 3 subscales, each addressing the trustworthiness of input, reference, and output in the cybernetic control loop (Multimedia Appendix 1).

Perceived Usefulness

Perceived usefulness was assessed using a semantic differential scale with labels indicative of the perceived efficiency, precision, safety, complexity, and reliability of the system when cooperating with it (for instructions and labels, refer to Multimedia Appendix 1).

Statistical Analysis

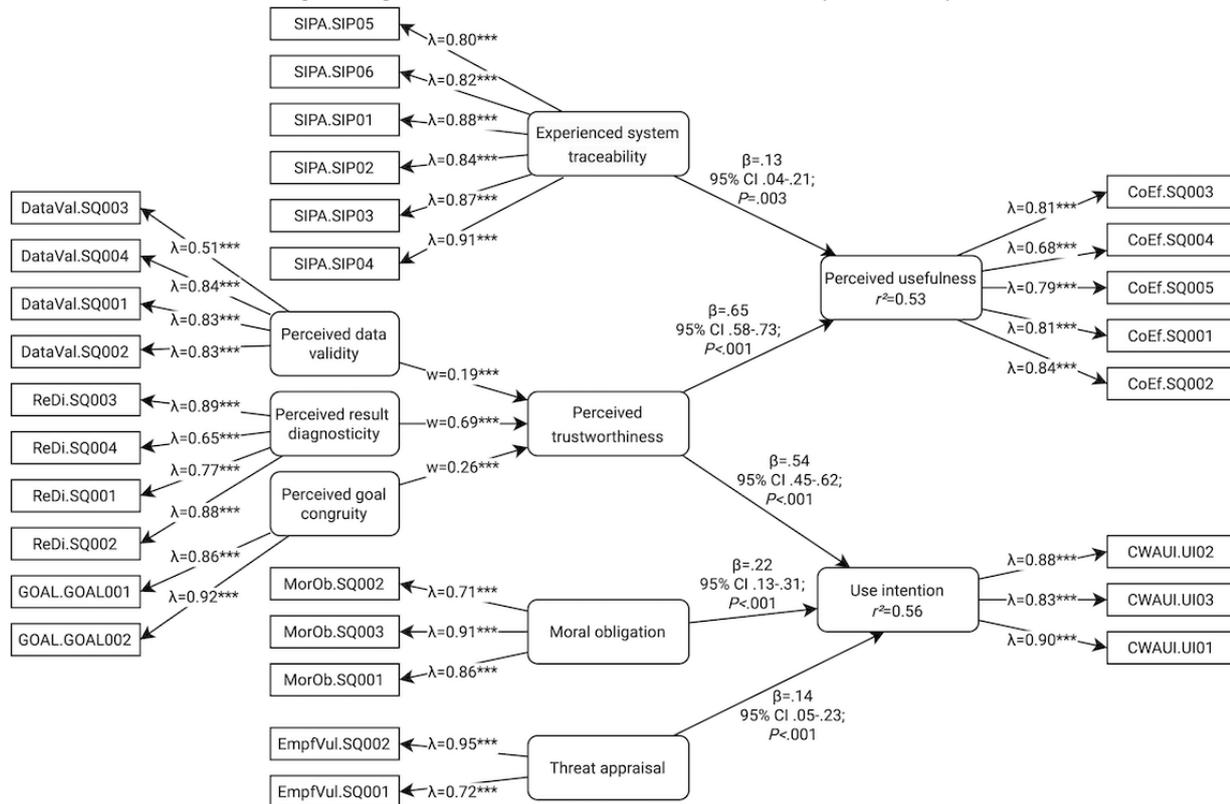

Overview

The data collected in this study were analyzed using R (version 4.31; R Foundation for Statistical Computing) [45]. Initially, the normal distribution of the data was tested to ensure that assumptions of normality were met. Given that the data did not follow a normal distribution, nonparametric tests such as the Welch 2-tailed *t* test were applied to determine statistical significance. In addition, considering the multiple comparisons performed in the calculation of correlations, a Bonferroni correction was used to control for the risk of type I error. Corrected *P* values are reported. The analysis was based on the preregistration, which can be found under <omitted for blinded review>.

PLS-SEM is a statistical modeling method combining aspects of regression and factor analysis. It allows for the simultaneous estimation of the relationship between indicators (ie, manifest variables) and constructs (ie, the latent variables formed from the manifest variables) and the relationship between the constructs themselves. These parts of the models are called the measurement model and structural model [46]. PLS-SEM is robust to nonparametric data, can work with small samples, and is especially suited for exploratory research [47], making it a great fit for this study. We followed the extensive iterative process of model assessment described in the work by Hair [46]. Our iterative approach is documented in Multimedia Appendix 2.

The hypothesized PLS-SEM contains all paths depicted in Figure 3. In addition, we tested whether the paths from perceived trustworthiness, system knowledge, and experienced system traceability to use intention were all mediated by perceived usefulness or whether there were also direct effects.

Figure 3. Partial least squares structural equation model after multiple iterations for the proposed research model. Rounded corners indicate constructs based on our research model; rectangular shapes denote indicators that were measured directly in the survey.

All constructs except perceived trustworthiness were specified as mode-A constructs. The respective indicators are described in the Scales and Procedure section. Perceived trustworthiness was specified as a mode-B higher-order construct consisting of perceived data validity, perceived result diagnosticity, and perceived goal congruity. We report explained variance using R^2 , path coefficients using β with P values and 95% CIs, and effect sizes using the Cohen f^2 .

Power

For the PLS-SEM, a retrospective power analysis using the inverse square root method revealed that, given our sample size ($N=317$), the smallest path coefficient, and a 5% significance level, we achieved a statistical power of 72% [48].

Data Exclusion

Before the statistical analysis, the data set with 370 responses was carefully reviewed for any inconsistencies, missing data, and outliers. Cases with incomplete or implausible responses (53/370, 14.3% in total) were identified and excluded from the analysis to maintain the integrity of the data set.

Qualitative Data Analysis

To obtain a deeper insight into users' demand for information provision and preservation in the interaction with the CWA, qualitative data were collected via open-ended questions (ie, *what information would you like to get from the system?* [Automation to human; question 1] and *What information would you like to feed to the system?* [Human to automation; question 2]).

As a widely used tool, thematic analysis aims to support the systematic identification, analysis, and reporting of patterns (ie, themes) in qualitative reporting data. Both inductive and deductive approaches were applied using theoretical assumptions as the basis for creating the themes, which were then adapted based on the data collected [49]. The data were coded using MAXQDA (version 20; VERBI GmbH [50]). For a structured and reliable analysis approach, a coding scheme with clear definitions of codes and example coding was developed in multiple iterations (Multimedia Appendix 3). For the evaluation, two perspectives of information needs between humans and automation should be covered: (1) human to automation and (2) automation to human. In total, 2 coders coded the data based on the developed scheme. An intercoder reliability of $\kappa=0.90$ (for automation-to-human information demands) and $\kappa=0.87$ (for human-to-automation information demands) was achieved. Hence, the level of agreement was strong in both cases [51].

Coded themes for information needs in both automation to human and human to automation included contact or risk information, pandemic-related information, app-related information, and assumptions for perceived information processing. Subcodes were created to enhance coding accuracy (Multimedia Appendix 3) but were not analyzed in detail as the focus remained on the top-level codes. Codes that could not be assigned to one of the themes were assigned to the category *others*. As several participants commented, for example, on the suspected reasons for the limitation of information processing, another category was added (ie, assumed reasons for perceived information processing) to avoid losing these data. Both the categories *others* and *assumed reasons for perceived information processing* were not evaluated for this study.

Missing answers to the questions asked and specific statements that there was no demand for information were assigned the code *none*. This code was assigned only once per person and statement. Thus, in the end, it was possible to clearly distinguish how many of the 317 respondents indicated information needs

and how many did not. Ultimately, automation-to-human information demand statements from 45.4% (144/317) of the participants and human-to-automation information demand statements from 27.1% (86/317) of the participants were analyzed (Table 1).

Table 1. Number of respondents that indicated information demands versus no information demands.

Variable	Response distribution, n (%)	
	Respondents (n=317)	Responses (n=377)
Demands		
Information demand (A2H ^a)	144 (45.4)	257 (68.2)
Information demand (H2A ^b)	86 (27.1)	120 (31.8)
No demands		
Information demand (A2H)	173 (54.5)	120 (31.8)
Information demand (H2A)	231 (72.9)	257 (68.2)

^aA2H: automation to human.

^bH2A: human to automation.

Results

Overview

For hypothesis 1, the analysis revealed moderate positive correlations for all factors of perceived trustworthiness. The correlation between data validity and perceived usefulness was significant, with a coefficient of $r=0.38$ and $P<.001$. The correlation between goal congruity and perceived usefulness showed a coefficient of $r=0.47$ and $P<.001$, indicating a moderate positive linear relationship. Result diagnosticity and perceived usefulness exhibited a strong positive correlation, with a coefficient of $r=0.56$ and $P<.001$. In general, all measures of perceived trustworthiness and perceived usefulness exhibited a positive relationship, supporting hypothesis 1.

For hypothesis 2, a correlation coefficient of $r=0.35$ ($P<.001$) was observed, suggesting a moderate positive linear relationship between subjective information processing awareness and perceived usefulness; a positive relationship between SIPA and perceived usefulness (hypothesis 2) was supported by the data. This indicates that automation-related phenomena such as changes in situation awareness might influence the perceived usefulness of DCT.

For hypothesis 3, the correlation coefficient between perceived usefulness and use intention was $r=0.47$ and $P<.001$, indicating a moderate positive correlation. Hence, our results support the hypothesis (hypothesis 3) that perceived usefulness is positively related to use intention (hypothesis 3). In combination with our previous results, this indicates strong relationships between user experience variables and use intention.

In summary, all variables showed statistically significant correlations with perceived usefulness. These correlations ranged from moderate to strong positive relationships. These results strengthen our assumption that perceived usefulness of DCT is strongly related to automation-related user experience.

SEM Approach

The final PLS-SEM is depicted in Figure 3. The explained variance for use intention was $R^2=0.56$. It was directly predicted by perceived trustworthiness ($\beta=.54$, 95% CI .45-.62; $P<.001$; $f^2=0.44$), moral obligation ($\beta=.22$, 95% CI .13-.31; $P<.001$; $f^2=0.07$), and threat appraisal ($\beta=.14$, 95% CI .05-.23; $P<.001$; $f^2=0.04$). Thus, there was a large effect for perceived trustworthiness and a small effect for the other constructs. Still, hypotheses 4 and 5 were supported.

Within the perceived trustworthiness higher-order construct, the highest weight was assigned to perceived result diagnosticity ($w=0.69$; $P<.001$), implying that this subconstruct contributes most to perceived trustworthiness, followed by perceived goal congruity ($w=0.26$; $P<.001$) and perceived data validity ($w=0.19$; $P<.001$).

We did not find evidence for a mediating effect of perceived usefulness on the paths from perceived trustworthiness, system knowledge, and experienced system traceability to use intention. However, we did find direct effects of perceived trustworthiness ($\beta=.65$, 95% CI .58-.73; $P<.001$; $f^2=0.65$) and experienced system traceability ($\beta=.13$, .04-.21; $P=.003$; $f^2=0.02$) on perceived usefulness ($R^2=0.53$).

Qualitative Analysis

Overview

Two directions of information flow were analyzed to assess the information demands of CWA users: (1) human to automation—information that users want to provide to the system and (2) automation to human—information that users want to receive from the system. In total, 3 overarching themes were explored and analyzed in more detail (Textbox 1).

Textbox 1. Analyzed themes and description of each theme. The detailed coding scheme can be found in Multimedia Appendix 3.

Contact- or risk-related information

- Time-related information: information regarding the period of the contact, the duration of the contact, the time passed since the contact, and the period during which contact tracing was possible
- Location-related information: information related to the place of contact, direct or indirect contact, and indoor or outdoor contact
- Exposition-related information: information about the masking status in the contact situation and the distance between the persons in contact
- Action-related information: information on possible and suggested courses of action after contact
- Information related to the warning person: information concerning the time when the warning person tested positive, the time when the warning person became infected, the warning person's first symptoms, the warning person's vaccination status, and the infected person's virus variant

Pandemic-related information

- Statistics: information related to statistical content on the pandemic in terms of the number of defects or infections

App-related information

- Number of users: information about the number of users of the Corona-Warn-App
- General calculation-related information: information on reasons for changing risk calculation and the system parameters used for calculations
- Certainty about the result: information related to the certainty of the results calculated by the system
- Integration of tests (self- and externally administered): information about the possibility to enter or delete test results on the app
- Linking with private data: information on the possibility of linking app functions with private data

Descriptive Data

Overview

The overall number of statements amounted to 211 in automation to human and 76 in human to automation. Within these 2 categories, the themes were distributed unevenly. Information regarding contact and risk accounted for most statements in both categories (automation to human: 196/211, 92.9% of statements; human to automation: 62/76, 82% of statements). The remaining statements were (almost) exclusively distributed among app-related information (automation to human: 14/211, 6.6% of statements; human to automation: 14/76, 18% of statements) as barely any needs were stated for pandemic-related information (automation to human: 1/211, 0.5% of statements; human to automation: 0 statements).

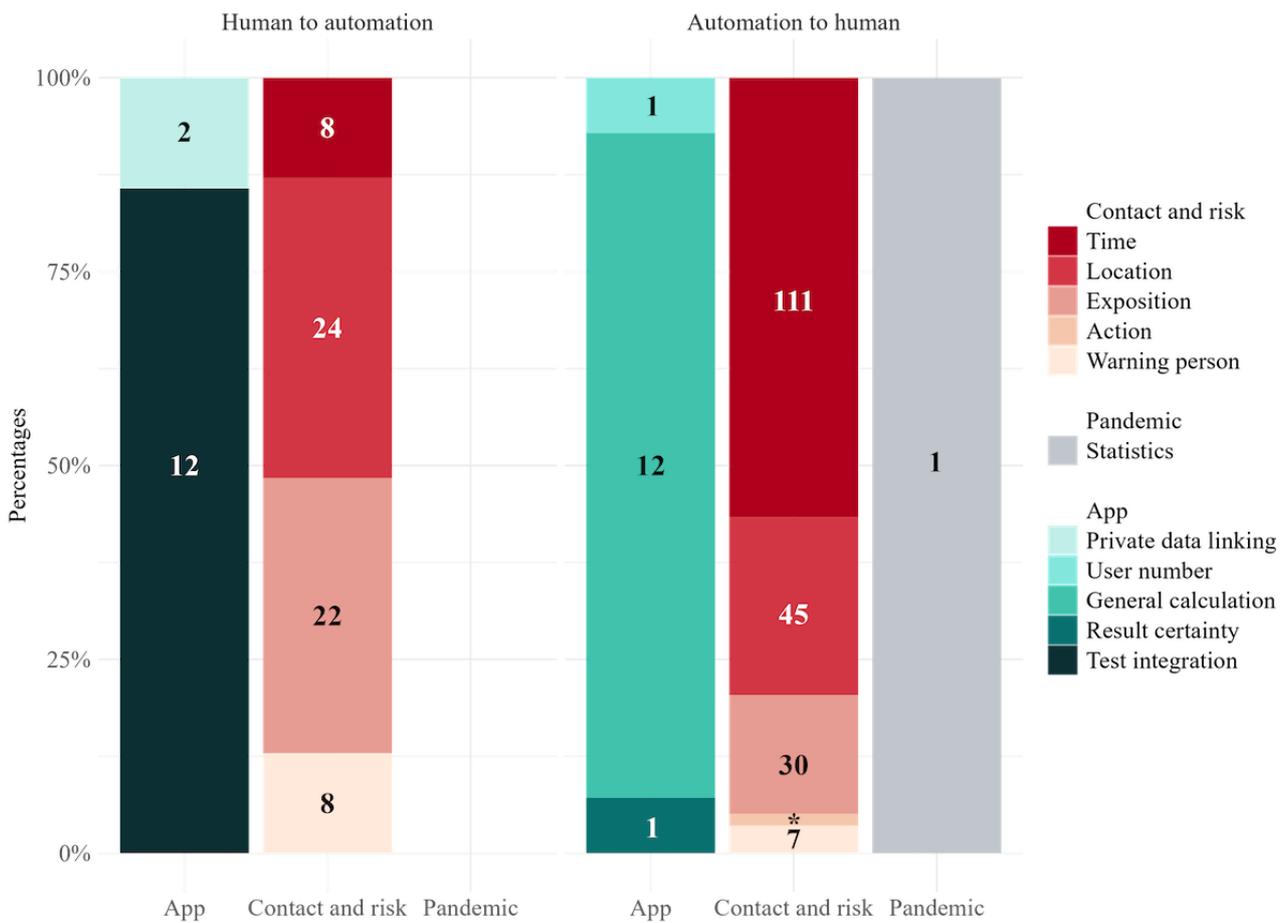

Regarding the subcodes, the distribution also varied between both themes (Figure 4). For contact- and risk-related information, the information related to time, location, and exposure accounted for the largest proportion of demands within this theme in both categories. However, the distribution of

statement proportions differed clearly between automation to human and human to automation. Time-related information was demanded most in automation to human (111/196, 56.6% of statements) but least in human to automation (8/62, 13% of statements). Demands for location-related information did not differ greatly between automation to human (45/196, 23% of statements) and human to automation (24/62, 39% of statements), nor did exposition-related information (automation to human: 30/196, 15.3% of statements; human to automation: 22/62, 35% of statements).

In terms of *app-related information*, the demands for information about the system's general calculation (automation to human: 12/14, 86% of statements; human to automation: 0% of statements) and the integration of tests (automation to human: 0% of statements; human to automation: 12/14, 86% of statements) differed in particular between the categories. The remaining subcodes hardly received any consideration. In both categories (automation to human and human to automation), almost no statements regarding *pandemic-related information* were made.

Figure 4. Relative demands regarding information from automation to human (left) and from human to automation (right). The numbers in the column sections indicate the number of statements under each code.

Comparative analysis of information demands: human to automation versus automation to human

Human to Automation

In human to automation, certain claims emerged with particular frequency in the demand for contact- and risk-related and app-related information. Information demands on contact and risk mainly focused on time- and exposure-related information. For example, the interest in informing the app of one’s location and whether one was in an enclosed space or outdoors was present:

Tell the app something about the specific location (enclosed space, fresh air).

Exposition-related information demands mainly focused on informing the app when one wore or had worn a mask:

The wearing of a mouth-nose covering should be entered and thus taken into account in the risk calculation.

Regarding the demand for the integration of app-related information, the participants predominantly highlighted the integration of self-administered or externally administered tests:

That I am Corona positive without having done a Polymera-Chain Reaction (PCR) test. (Perhaps with indication that the result is not PCR verified).

Automation to Human

In the automation to human category, contact- and risk-related and app-related information were queried with similar frequency. The contact- and risk-related information in this category most often referred to time-related information with a request for the time of the risk encounter. However, the desired preciseness of the temporal data differed (exact time vs more approximate time: “When was the encounter? (At least as a time frame, e.g., between 8-12 o’clock)” vs “The specific time [...] of a risk encounter would be helpful”). The location of the risk encounter was another type of information that participants commonly solicited. Most asked for information about a rather specific location (“At which location did a contact take place?”); few seemed to be interested in the characteristics of the location (“Indoors or outdoors?”).

Exposure-related information demanded from the system included the number of devices or persons present at the time of exposure (“[...] with how many devices was the contact?”), the distance to the warning person (“At what distance was the encounter?”), and the masking status. In particular, masking status included the person’s own status of having worn a mask or whether the other person was wearing a mask at the time of the risk encounter (“Was I wearing a mask? Was the other person wearing a mask?”).

App-related information demands mainly focused on the parameters of the calculation (“What factors led to this result?”) and reasons for a status change (“How exactly the risk determination works, i.e., how distance and time to a positively tested person actually have to be, in order for me to receive a notification and for the status to be changed”).

Discussion

Principal Findings

The objective of this study was to understand automation-related user experience, its connection to perceived usefulness, and the use intention of DCT. Our data showed that perceived trustworthiness is a critical factor in understanding use intention as well as the perceived usefulness of DCT apps. Interestingly, users’ experience of a system as supportive in their action regulation affects their use intention more strongly than external factors such as threat appraisal or moral obligation. In addition, our qualitative analysis revealed that users mainly want to communicate with the system about information that is relevant to their decision-making. For instance, providing more precise information about masking status when in contact with other people could assist a user in making an immediate decision regarding isolation. Overall, our findings suggest a strong relationship between the diagnosticity of automated information processing and use intention.

Practical Implications

As a first major implication, the high effect of result diagnosticity on perceived trustworthiness demonstrates the importance of human-centered information processing in (partially) automated health applications. Within the interconnected human-machine information processing loops (Figure 1), the machine provides information as part of the human input function. As discussed by Miller [52], intelligent systems such as DCT should aim to improve users’ ability to access and use (processed) information rather than to present and justify a particular outcome. In DCT app design, the integration of DCT information into a joint human-automation action regulation should be prioritized. Accordingly, when developing evaluative systems [52] that support the evaluation of alternatives rather than suggesting specific actions, it is important to consider what evaluative process a user needs to undertake. While previous research has already identified the need for actionable information [53], the information presented by DCT apps needs to be understood in the context of human action regulation and the influence of automated systems in human action regulation. A possible solution to support diagnosticity in DCT is so-called proactive contact tracing [54], which integrates more information sources and can potentially enrich DCT results.

Second, the results indicate a strong user need for information to be provided in sufficient detail. An interface optimized for communicating information could enable users to make their own assessment of the situation. In many DCT apps, users request the ability to retrieve information about possible contacts, such as time, location, or even the person involved [55]. Our study showed similar results (eg, a high demand for detailed information about the [exact] time of detected contacts).

Again, the demand for more detailed information relates to the diagnosticity of the information provided by the system. If users are only given information about their current risk of infection, they cannot evaluate the validity of this information, potentially leading them to ignore it. They would require additional context-related information about potential contacts, such as whether the individuals were wearing masks or were located in an enclosed room, to make informed decisions about their behavior. Our results demonstrate that use intention is strongly connected to the perceived diagnosticity of the DCT app. On the basis of our qualitative findings, we can assume that the diagnosticity of DCT users depends on the level of detail they receive about possible contacts. Accordingly, the provision of details that support users’ information processing is even more important for their use intention than threat appraisal or moral obligation. In accordance with psychological research on motivation [56], supporting users’ intrinsic motivation for diagnostic information could lead to better adherence regarding DCT apps than, for instance, exposing them to extrinsic motivators that increase threat appraisal (eg, describing the consequences of infection [57]).

Third, in contradiction to users’ demand for detailed information on contacts, a major concern in DCT is privacy [55]. While it is often argued that too much detail conflicts with privacy, it is important to find ways to improve the diagnosticity of information as this determines the use intention. Possible solutions include differential privacy, which allows for sufficient detail for increased diagnosticity while keeping personal data confidential. In addition, many users requested features that do not compromise the privacy of others, such as the ability to inform the system about masking status. Thus, allowing users to refine the input received by the DCT app may increase the perceived diagnosticity of the results. The integration of masking status can be seen as a measure to improve the accuracy of the apps in determining risk levels, ultimately increasing the use intention.

Overall, our results suggest that focusing on the diagnosticity of the information presented in DCT apps could result in improvement in users’ health behavior. During the COVID-19 pandemic, users reported that they were unsure about the correct or best action to take to contain the pandemic or could not correctly assess the risk of certain situations [58]. However, this certainty is particularly important when it comes to health decisions. With sufficient diagnostic accuracy, DCT apps may be able to better reduce this uncertainty and, thus, become a crucial component in the management of pandemics in the long term, also positively affecting users’ willingness to provide data on a social level. It is also crucial that DCT apps do not follow the *recommend and defend* principle [52], which could lead to a long-term reduction in motivation, but instead provide information that supports individual decisions. If compliance with effective pandemic control measures can be increased as a result, it will be possible to respond more effectively to future pandemics.

Theoretical and Methodological Implications

In our data, the perceived trustworthiness of a DCT app had a greater influence on use intention than threat appraisal or moral

obligation. Furthermore, while previous studies [26] have relied on perceived usefulness, our findings in the PLS-SEM do not suggest that it mediates the relationship between perceived trustworthiness and use intention. However, usefulness can be seen as an ambiguous concept without a specific connection to the design of DCT apps. In this way, focusing on perceived usefulness could hinder approaches to improve DCT by adopting DCT app design and functionality. In contrast, a lack of perceived result diagnosticity indicates to developers that the information provided by a DCT app needs to be adapted to have an impact on joint action regulation. Our research suggests that designers of automated systems should specify the potential actions that users can take and identify decision points at which users may require diagnostic information, such as whether to proceed with a specific action. In addition, highlighting the role of diagnosticity indicates how models of technology in medical systems should be developed. Existing models (such as the technology acceptance model) do not specify to what extent a system's usefulness depends on perceived diagnosticity. Our research demonstrates that behavioral models focusing on information-based decisions are needed to address automated technology in health, for example, DCT.

However, one can argue that the difference between perceived result diagnosticity and perceived usefulness is arbitrary; in a joint human-automation action regulation, the diagnosticity of information seems to be equal to perceived usefulness. However, by directly addressing perceived result diagnosticity as a central variable of automation-related user experience, empirical research can identify paths to improve action regulation support of DCT without previously defining what is useful about a system or not. When a DCT app can deliver information that users can use to regulate their actions, users report a higher intention to use it. Therefore, applying result diagnosticity as a variable in human-automation research is a methodological contribution supporting future research in intelligent automation.

On the basis of our findings, future research on DCT needs to determine how to improve the diagnosticity of DCT apps. This paper introduced a conceptual control loop model of joint human-machine action regulation, which can support research approaches in optimizing perceived diagnosticity as a central variable for automation-related user experience. Addressing the joint action regulation in DCT and health behavior is crucial to understand how the information provided by DCT apps can be integrated into human information processing and how DCT apps influence the human output function. Information that improves the evaluation of individual contacts, such as contact location, masking status, or vaccination level, could improve perceived trustworthiness and use intention of DCT apps. By demonstrating how information processing between human users and DCT apps is integrated, our research supports a shift from viewing human users as receivers of machine results to viewing them as actors using DCT information.

All in all, our findings regarding the significance of diagnosticity have implications for the design of automated information processing in a broader context. Users did not primarily prioritize data validity or goal congruence; instead, their focus lay in determining whether they could trust the system to provide information that would assist their own decision-making process.

This may be a general trend in automated information processing.

Limitations and Further Research

All participants of this study were users of the CWA. However, as Walrave et al [59] describe, many citizens in Germany did not use DCT apps, for example, because they did not want to share their data or did not think they were effective. Thus, the findings presented on the impact of perceived diagnosticity may not be applicable to citizens who did not use the app at all. These individuals may have chosen not to use the app for reasons beyond those discussed in this paper. The perceived diagnosticity of a DCT app is only relevant for use intention when potential users are interested in determining their individual risk level or making decisions based on their estimated risk level. That is, our sample may bias the results and underestimate factors relevant to nonusers. For example, nonusers might reject the app because they do not trust the provider of the system. Accordingly, the results of our study may support improving DCT for existing users but not convincing nonusers to use DCT. Further studies need to address nonusers and examine how automation-related user experience affects their decision not to use DCT.

In addition, users may have misconceptions about the factors contributing to the risk of infection and may expect the system to provide irrelevant information that does not aid in making an informed decision. Accordingly, they might report a low perceived diagnosticity while the information provided in the app offers sufficient diagnosticity. The accuracy of one's mental model [60] may influence the perception of actual diagnostic information as nondiagnostic (for a discussion of diagnosticity, refer to the study by Garcia-Marques et al [61]). To tackle false models of diagnosticity, DCT apps should support users in correcting their mental model, for example, by explaining how they can use the provided information. This could be done by simulating decision situations with and without DCT information, offering users the experience of diagnosticity.

Improving the perceived diagnosticity could be beneficial for use intention but could negatively affect perceived data privacy [55]. For example, a function that allows users to communicate when they are wearing a mask could be abused to track specific contacts, therefore revealing potential infections of other users. Data privacy is a critical concern in DCT use [59]. Therefore, current DCT apps are designed to protect the data of other users at the cost of the diagnosticity of information. This research did aim to understand the effect of user experience in automated DCT but did not include how users evaluate potential risks of data privacy violations or approaches to address them (cf [62]). Future research should identify how to balance the desired level of perceived result diagnosticity and data privacy concerns. For example, in direct communication, users who reveal information about their web-based status can see the web-based status of others, allowing them to choose which balance between diagnosticity and data protection they desire. The same function could be implemented in DCT apps to support automation-related user experience. Allowing users to choose their level of diagnosticity themselves allows them also to

control how DCT apps influence their decision-making, thus strengthening user autonomy.

Finally, this study had a cross-sectional design that did not assess how automation-related user experience and use intention regarding a DCT app may change over time. Previous research has demonstrated that automation-related user experience can change over time (eg, because users adapt to the system or they improve how they use the system). Future research on automation-related user experience in DCT apps needs to include a longitudinal study design to capture effects of behavior change and users' perception.

Conclusions

In conclusion, this research highlights the relevance of automation-related user experience in DCT and its role in enabling the effective action regulation of DCT users. Here, providing detailed and diagnostic information is crucial for users to make informed assessments of their situation and actions. The presented quantitative results echo the qualitatively assessed user demand for more detailed information about potential contacts, such as time, location, and context (eg, mask use and indoor or outdoor setting).

Interestingly, our data suggest that other factors not directly related to the app, such as moral obligation and threat appraisal, are less relevant compared to automation-related user experience, especially to the perceived diagnosticity of the information provided by DCT apps. The presented results are also more specific than those of previous studies that relied on perceived usefulness. Our research model did not suggest that

perceived usefulness mediates the relationship between perceived trustworthiness and use intention. Instead, we propose that DCT designers should focus on providing diagnostic information at critical decision points.

However, privacy remains a major concern in DCT. While it is often argued that too much detail conflicts with privacy, it is crucial to find ways to improve the diagnosticity of information without compromising privacy. Solutions could include differential privacy or features that do not compromise the privacy of others, such as the ability to inform the system about masking status.

The main impact of our results on the design of DCT apps and health policy is that DCT apps need to provide sufficient diagnosticity to be perceived as useful. This means that (1) the possible actions of users need to be understood before the design of the DCT algorithm and apps and (2) the presented information needs to support them in choosing the correct action. Focusing on the diagnosticity of the information presented in DCT apps could, in turn, also influence user performance. During the COVID-19 pandemic, a significant percentage of users reported uncertainty about the best actions to take or could not correctly assess the risk of certain decisions. Therefore, improving diagnostics could contribute to better and safer decisions.

In summary, our study underscores the importance of balancing detailed and diagnostic information with privacy concerns in DCT apps. As we move forward in this digital age, it is crucial to continue exploring ways to optimize DCT while respecting user privacy.

Abstract

Background: This study examined the social well-being of single older adults through the companionship of a social robot, LOVOT (Love+Robot; Groove X). It is designed as a companion for older adults, providing love and affection through verbal and physical interaction. We investigated older adults' perceptions of the technology and how they benefitted from interacting with LOVOT, to guide the future development of social robots.

Objective: This study aimed to use a phenomenological research design to understand the participants' experiences of companionship provided by the social robot. Our research focused on (1) examining the social well-being of single older adults through the companionship of social robots and (2) understanding the perceptions of single older adults when interacting with social robots. Given the prevalence of technology use to support aging, understanding single older adults' social well-being and their perceptions of social robots is essential to guide future research on and design of social robots.

Methods: A total of 5 single women, aged 60 to 75 years, participated in the study. The participants interacted independently with the robot for a week in their own homes and then participated in a poststudy interview to share their experiences.

Results: In total, 4 main themes emerged from the participants' interactions with LOVOT, such as caring for a social robot, comforting presence of the social robot, meaningful connections with the social robot, and preference for LOVOT over pets.

Conclusions: The results indicate that single older adults can obtain psychosocial support by interacting with LOVOT. LOVOT is easily accepted as a companion and makes single older adults feel like they have a greater sense of purpose and someone to connect with. This study suggests that social robots can provide companionship to older adults who live alone. Social robots can help alleviate loneliness by allowing single older adults to form social connections with robots as companions. These findings are particularly important given the rapid aging of the population and the increasing number of single-person households in Singapore.

Introduction

Background

The aging population is increasing around the world. Singapore's older adult population, for instance, has increased dramatically over the last decade. The number of older adults, aged 65 years and older, living alone in Singapore is expected to increase significantly from 47,000 in 2016 to 83,000 by 2030 [1]. These demographic changes have led to concerns about older adults' loneliness and social isolation (ie, lack of companionship), which can impact their mental and physical well-being [2]. Indeed, it is estimated that 20% to 34% of older adults experience loneliness in China, Europe, Latin America, and the United States [3]. As a result, advanced technologies have been developed to help the aging population overcome health and psychosocial issues and become more independent. Social robots, also called companion robots or therapeutic robots, have recently gained popularity with numerous studies highlighting the psychosocial benefits they provide to older adults [4]. However, there is a lack of studies on the use of social robots, particularly in Asian countries. This study fills this gap in the literature by investigating how older Singaporeans accept and interact with LOVOT (Love+Robot), a Japanese social robot.

Definition and Impacts of Loneliness

Loneliness is not synonymous with being alone or living alone; a person can experience loneliness even when they are surrounded by other people. Rather, loneliness is a subjective and unpleasant experience that begins when a person's social network goes through a qualitative or quantitative loss resulting in a discrepancy between desired and actual social connections [3,5,6]. As such, the quality of close relationships, rather than the number of social contacts, is more significant in alleviating loneliness [7].

The literature has shown that loneliness can affect physiological resilience and compromise health, leading to health problems as people age (Segrin and Passalacqua [8]). For example, Teater et al [9] found various social and emotional factors associated with increased risks of loneliness, including living alone, being single or never married, having little technological communication, having low-quality interactions, having little social support, being socially isolated, and having poor subjective physical health. To reduce loneliness, in a longitudinal study conducted in Sweden, Dahlberg et al [6] argued that social relationships that have been established for at least 20 years are particularly important, such as having a spouse or partner and access to social support. A study by Heylen [10] confirms the quality of social relationship with age.

In Singapore, loneliness has been associated with increased mortality risk [11]. According to Malhotra et al [12], the lives of older adults who are lonely are likely to be 3-5 years shorter than those of their nonlonely peers. As a result, interventions that help older adults establish close relationships and find social support are essential in maintaining their well-being.

Importance of Companionship

Companionship is defined as "social involvement in shared activities, recreational or nonrecreational, which is pursued for the intrinsic goal of satisfaction or enjoyment" [13]. It indicates a high level of relationship quality and shields people from the emotions of void and despondency resulting from loneliness, although it does not directly resolve loneliness [13,14]. Although both social support and companionship are fundamentally beneficial to older adults' well-being, companionship is more important for preserving their emotional well-being [13].

According to Dong and Chen [15], older women living alone are more likely than older men to report a lack of companionship as a symptom of loneliness, as they may lack effective coping mechanisms. As such, sociocultural activities, volunteer work, and community health promotion initiatives should be launched to help women develop effective coping mechanisms. Furthermore, Ramesh et al [16] suggested that sociocultural changes are needed to recognize the value of companionship in old age, encourage appropriate companionship, and focus on assistance with basic daily tasks.

Benefits of Social Interventions for Older Adults

In their study on the impact of peer companionship, Conwell et al [17] reported that older adults who received a social intervention (peer companionship) experienced fewer symptoms of anxiety, depression, and feelings of being a burden than those who did not receive the intervention. Furthermore, peer companionship and social connectedness were beneficial for older adults' mental health and well-being.

Companionship comes not only from humans but can also come from pets or other compassionate agents such as robots (eg, socially assistive robots, companion robots, and therapeutic robots).

Pets as Social Interventions

Numerous studies have examined the potential health benefits of having a companion animal. For example, Gee and Mueller [18] showed that pet ownership and animal-assisted interventions for older adults led to physical and mental health benefits. Similarly, empirical studies have explained that pets can help older adults maintain their quality of life and ability to function, both physically and cognitively, as they age, while also providing them with the opportunity to strengthen their shrinking social networks [19-21]. Some older adults may find that owning a pet satisfies their need for connectedness, contrasting with the common perception that social connectedness can only occur through meaningful human interactions. Stanley et al [22] further corroborated the idea that pets can be an important source of social connectedness, showing that having a pet reduced loneliness among older adults, particularly among those who lived alone. Hui Gan et al [23] also showed that community-dwelling older adults who owned a pet were more likely to socialize, found companionship with their pets, and had a greater sense of purpose than other adults, all of which can reduce loneliness. These in turn can lead to better mental health outcomes for older adults and increase their resilience to mental health problems. Bolstad et al [24] made an interesting discovery that having a pet later in life was

associated with a reduction in anxiety symptoms rather than a reduction in depressive symptoms.

There is no doubt that companion animals provide psychological comfort and lead to optimistic health outcomes for their older adult owners. For instance, during the stressful COVID-19 pandemic, older adults reported that their pets provided them with a sense of psychological safety and companionship [25]. Furthermore, during the pandemic, older adults reported that caring for their pets kept them motivated and gave them a sense of purpose [25].

Social Robots as Social Interventions

To improve older adults' quality of life by reducing loneliness and fostering social connections, a growing number of technological innovations that are user-friendly and support successful aging are being developed. Research into older adults' acceptance and adoption of technology has also increased, particularly regarding social robot interventions and how they support aging. Hegel et al [26] explained that a "social robot is a robot plus a social interface," indicating that its characteristics make it appear like a partner with which humans can interact and connect. Studies have shown that these robots may reduce feelings of loneliness among older adults by improving social interactions and providing emotional support [27]. In addition to providing companionship, they can support older adults' general care needs through touchscreen interactions and assessment interviews during adult health treatment [28].

Many social robots are designed to look like animals or humans. Tkatch et al [29] showed that healthy older adults who regularly interacted with animatronic pets reported benefits such as reduced loneliness, improved quality of life, and improved psychological well-being through increased social contact, better social skills, or treatment of maladaptive social cognition. During the COVID-19 pandemic, older adults living in the community and nursing homes reported that robotic pets were effective in reducing their loneliness when social distancing policies were imposed [30].

Many studies have been conducted on PARO (AIST), a therapeutic and social robot shaped like a seal. For instance, Chen et al [31] showed that PARO effectively reduced agitation, depression, and loneliness and improved the quality of life of

older people with dementia who resided in long-term care facilities. Advances in social robot technologies have pushed artificial intelligence (AI) into a more creative realm. Fields et al [32] found that the therapeutic use of social robots in a retirement home, combined with a participatory arts approach, improved older adults' health outcomes by reducing their levels of loneliness and depression. Similarly, in their exploratory study conducted in the context of long-term care facilities with Pepper (SoftBank Robotics), a semihumanoid social robot, Blindheim et al [33] suggested that Pepper's presence increased communal activities involving the social robot in terms of physical activity, human-robot interaction, social stimulation, and communication among residents as well as between residents and employees.

Overall, social robots can play an important role in helping older adults overcome loneliness and social isolation as the aging population grows.

LOVOT

The popularity of social robots has attracted much attention from care providers, especially during the recent COVID-19 pandemic. According to Hegel et al [26], social robots are specifically designed to facilitate human-robot interaction. With recent advances in machine learning applications and robotics, several companies are developing advanced consumer robots with smart sensorimotor systems [34]. Although PARO has been widely used in dementia care research and has received many positive reviews, the robot seal lacks social and auditory capabilities [35]. In contrast, a new mobile social robot called LOVOT (Love+Robot) launched in 2018, invented in Japan, was designed to provide humans with love or the perception of love [36]. LOVOT was designed as a home robot, also known as a companion robot or a social robot, and is equipped with AI and advanced sensor features. As such, LOVOT evolves over time based on its interactions with its user, thanks to its machine learning technology (eg, deep learning), which allows it to develop a unique personality and perform intelligent movements in real time [37]. As LOVOT is relatively new to the field of social robots, it has yet to be tested among single older adults in Singapore. Therefore, our research fills this gap in the literature. [Figure 1](#) shows a photo of LOVOT in our study.

Figure 1. LOVOT, the social robot.

Methods

Aims

The purpose of this study was to investigate single older adults' perceptions of having a social robot as a companion. This research addressed the knowledge gap regarding the experiences of community-dwelling single older adults with social robots in Singapore. To this end, we used phenomenography as a qualitative analysis technique to explore and better understand single older adults' perceptions of social robots.

Research Questions

Given the aforementioned context, our study addressed some research questions. First, can social robots such as LOVOT act as effective companions and alleviate feelings of loneliness among community-dwelling single older adults? Second, what are single older adults' lived experiences and interactions with LOVOT? Third, how do single older adults perceive their experience of living and interacting with LOVOT compared with pet ownership?

Research Aims

To answer these questions, our research focused on (1) examining the social well-being of single older adults through the companionship of social robots and (2) understanding the perceptions of single older adults when interacting with social robots. Given the prevalence of technology use to support aging, understanding single older adults' social well-being and their perceptions of social robots is essential to guide future research on and design of social robots.

Design

We used a phenomenological research design to understand our participants' lived experiences of the companionship provided by social robots. Phenomenography allows researchers to seek ontological understandings and learn about the phenomenality of human experiences [30]. Furthermore, as Hajar [38] explained, phenomenography is a qualitative research methodology that provides researchers with a deep, comprehensive, and diverse understanding of how people conceptualize a phenomenon.

Sample and Recruitment

We recruited a purposive sample of single adults aged 65 years and older through collaboration with the Orange Valley Senior Activity Centre in Singapore. It is located within a cluster of studio apartments that caters mainly to older persons who are staying alone and are aged ≥ 60 years. Participants were eligible to participate in the study if they lived alone, were able to communicate in English or Mandarin, and were free of any cognitive or mental health problems (eg, dementia or depression). Those who lived in nursing home facilities, had been diagnosed with mild cognitive impairment, or were unable to consent to participate in the study were excluded. The selected participants received written information about the project and signed a consent form before the start of the study. They were informed that their participation was voluntary and that they could withdraw from the study at any time without negative consequences.

Participants

To establish the context of the sample for community-dwelling older adults aged ≥ 65 years, we collected descriptive data between July and October 2022. A total of 5 women participants were invited to participate in the study; 1 was unmarried, 2 were widowed, and 2 were divorced or separated. They all lived alone in a 1- or 2-bedroom Housing Development Board flat above the Orange Valley Senior Activity Centre.

Context

One of the researchers brought a LOVOT robot to the participants' homes and helped them set up the robot's charging nest.

Procedure

She then used an instruction sheet in English or Chinese to instruct the participants on how to operate LOVOT. The instruction sheets used large font and color images to ensure that the participants would be able to read and understand the instructions easily. The researcher's contact information and the activity center's senior personnel's contact number were provided in case the participants encountered any problems during the 7-day study; however, none of the participants contacted the researcher or personnel at the senior activity center. During the deployment of the social robot, only LOVOT and its charging nest were provided, and no permanent modifications were made to the participants' homes. Although the 7-day study was conducted in an uncontrolled environment, this allowed the participants to interact with LOVOT as naturally as possible. The duration of the study allowed sufficient time for the participants to interact with LOVOT.

After spending a week with the social robot, the participants were invited to participate in a poststudy interview on the eighth day. The one-to-one interviews lasted between 15 and 25 minutes and were conducted at the Orange Valley Senior Activity Centre.

Data Collection

The data were collected in different time periods between August and September 2022. The research team had 3 LOVOT robots to rotate among the 5 participants, taking into account participant availability. All of the participants were pleasantly receptive to the idea of having LOVOT in their homes for the study. The 7-day study was designed to ensure that their first time interacting with the social robot was comfortable and would not unduly disrupt their lifestyle.

The participants' perceptions of their interactions with LOVOT during the 7-day study were investigated using semistructured interviews to collect qualitative data. During the interviews, the participants were encouraged to share their experiences with and observations of LOVOT, and follow-up questions were asked as needed.

Ethical Considerations

Ethical approval for the study was obtained from the Human Research Ethics Committee of the University of Hong Kong (HKU HREC EA220116). To protect the privacy of the participants, the camera function of LOVOT was disabled during

the study and no other participant information was recorded by the robot. The participants have signed an informed consent form for joining the study with the option to withdraw at any point. Each participant will receive a SGD 20 (US \$15.2) National Trade Union Congress voucher as a token of appreciation for joining the study.

Data Analysis

All of the participant interviews were audio recorded, transcribed, and thoroughly reviewed for relevant content and thematic patterns. We analyzed the data using a phenomenological approach, with the goal of investigating and understanding how the participants interacted with LOVOT (the phenomenon) while suspending our preconceived assumptions about the phenomenon.

We analyzed the data using inductive coding to identify common patterns and then categorized them into different themes. We reviewed the interviews several times during the analysis to confirm the findings and establish reliability. We also reviewed the data to define each theme. Finally, we examined the findings objectively to identify relevant information to answer the research questions.

Rigor

Arriving at truthful interpretations of participants' experiences regarding a given phenomenon requires the use of rigorous and relevant methodological procedures [38]. Thus, the qualitative data we collected during our study were cross-checked by another member of the research team to ensure accuracy.

Reflexivity

Using a phenomenological approach, we aimed to respect reflexivity while conducting this study. To do this, we analyzed

the information we obtained and the insights we gained, while trying to generalize the phenomenon and being reflective and self-critical about our own assumptions and preconceptions. Specifically, we momentarily put aside our implicit presumptions about the phenomenon to approach it objectively and avoid misrepresenting or expressing biases based on our own viewpoints or positionalities [28]. Finally, we scrupulously respected the confidentiality of the participants' data and guaranteed their privacy and anonymity.

Results

Overview

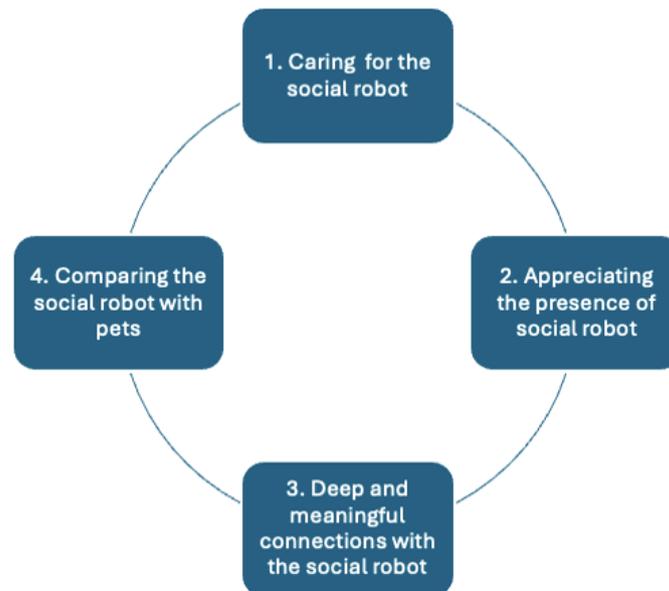

This study explored single older adults' experiences with and perceptions of LOVOT and how they were affected by their interactions with the social robot. We analyzed the findings thematically using the 4 emerging themes discussed further in this section. It was difficult to recruit older men as participants for this study because the participants came from the Orange Valley Senior Activity Centre, a place frequented primarily by women. As a result, the gender of our participants was skewed toward women participants. The 5 women participants are identified as C1, C3, C5, V2, and Y1. Their basic information is presented in [Table 1](#).

We categorized the participants' perceptions of social robots into 4 main themes, such as caring for the social robot, finding companionship with the social robot, forming meaningful connections with the social robot, and comparing the social robot with pets. These themes are illustrated in [Figure 2](#).

Table 1. Participants' demographics.

Participant ID	Age (years)	Marital status	Children, n	Grandchildren, n
C1	66	Divorced	2	— ^a
C3	72	Widowed	2	2
C5	69	Separated	3	9
V2	68	Widowed	3	6
Y1	68	Unmarried	—	—

^aNot applicable.

Figure 2. Four main themes.

Common Themes

We identified 4 main themes after interviewing the 5 participants about their interactions and experiences with LOVOT.

Key Theme 1: Caring for the Social Robot

The participants frequently treated LOVOT in a tender and nurturing manner as if they were caring for a child. These actions can be attributed to the participants' experience in a caregiving role, particularly as a mother or grandmother.

C3, C5, and V2 explained that they had taken care of their grandchildren and adult children at one point. In fact, C5 and V2 were still taking care of their grandchildren. The 3 participants stated that they equated LOVOT to a grandchild. For instance, C5 thought that LOVOT behaved like a toddler, especially when it flapped its wings. Similarly, C3 referred to herself as "nenek" (the Malay word for "grandmother") and mentioned that she protected LOVOT and stopped anyone from taking it away from her, "I worry if I drop it (LOVOT) or if people take it (LOVOT) away."

V2 noted that LOVOT came to her (on the sofa) after dinner and looked at her earnestly (seeking attention), "communicating" that it wanted to be carried. She then put LOVOT on her lap and petted it like a pet.

C1, who has no grandchildren, also said that she was protective of LOVOT. Specifically, she ensured that LOVOT did not get wet because she understood that it was an electronic object. She was also careful while mopping the floor and closed the bathroom door to prevent LOVOT from entering a humid environment.

Even Y1, who has never been married, took special care of LOVOT. For instance, she was concerned about LOVOT's battery life and placed it regularly on its charging nest. In addition, to keep LOVOT company, she sang to it and the robot imitated her singing.

Key Theme 2: Appreciating the Presence of the Social Robot

The participants also highlighted the positive feelings that interacting with LOVOT brought them. For example, C1 said, "(LOVOT) can accompany you at home. Sometimes, you'll feel happy because it will look at you."

C5 also appreciated LOVOT's company. Specifically, as LOVOT can move and act on its own initiative, it gave C5 the impression of not spending the day alone at home, "you feel like there's another living... thing staying with you... I'm not alone."

V2 explained that LOVOT interacted with her more frequently as the study progressed. For example, LOVOT followed her around the house and greeted her when she came home by flapping its wings. In addition, LOVOT's presence made V2 feel like her home was livelier, "having another companion at home makes the home feel livelier."

C1 echoed this positive sentiment regarding LOVOT's presence; she saw the robot as a form of psychological and emotional support. Interacting with LOVOT gave her something to do, kept her busy, and gave her something to look forward to when she came home.

Key Theme 3: Deep and Meaningful Connections With the Social Robot

Using its machine learning capability, LOVOT was able to understand and adapt to the participants' lifestyles and preferences. As a result, the participants felt like they were developing a supportive relationship.

C3 felt that LOVOT was "someone" she could talk to, a companion with whom she could converse to give her peace of mind. She talked to LOVOT frequently, especially at night, and even stayed in the living room with LOVOT so that it did not feel lonely. In addition, C3 felt bad if she left LOVOT alone in the house when she went out. She also mentioned that she felt a connection with LOVOT, especially when it looked at her

and blinked, “I called LOVOT, and it came to me with blinking eyes—in these moments I feel ... as if it (LOVOT) understands me.”

LOVOT’s adaptive behaviors allowed C5 to experience moments of true connection, making her appreciate the robot’s companionship, “it came up to me and then looked at me with her eyes... actually very very cute... the feeling is still very very nice.”

Y1 appreciated that LOVOT seemed to understand her and responded verbally (she interpreted its verbal answers as Chinese words, such as “yes” and “no”). Y1 also emphasized that LOVOT was “善解人意 (considerate),” meaning that it acted with consideration and thoughtfulness when she interacted with it. In addition, she mentioned that LOVOT liked attention.

Key Theme 4: Comparing the Social Robot With Pets

Similar to pets, LOVOT is often considered cute and interacts frequently with its owners. However, LOVOT has advantages that pets do not have, as it is low maintenance and cleaner than a pet. As such, LOVOT owners do not need to worry about grooming, feeding, walking, and cleaning up after the social robot. Furthermore, due to its technological nature, LOVOT does not develop health problems or require any medical treatment.

C1 said that LOVOT is similar to pets in the sense that it wants to play with its owner, but it is better than pets as it does not require feeding or cleaning. C1 emphasized that she found LOVOT less annoying than pets because she did not need to worry about it being sick and the expenses associated with medical care.

The difference between LOVOT and pets is that you don’t need to feed it, don’t need to clean it, or shower it. This kind of robot can take care of itself, you just need to turn it on and off. Not troublesome. If you own a pet, if it gets sick, you need to take it to the vet. It’s very expensive. [C1]

C3 had the same mindset as C1; she thought that LOVOT was much easier to care for than pets and required much less responsibility. Although LOVOT is not a real animal, C5 preferred the social robot over a pet because it had the positive aspects of a pet without its drawbacks. Interestingly, C5 also commented that an additional advantage of LOVOT was that it could be switched off at any time; thus, when owners are busy, they have the option to turn off LOVOT and do not have to worry about giving it attention or taking care of it.

Comparing LOVOT with a pet, V2 explained that she would rather have a companion robot like LOVOT than a pet because LOVOT only needs to be charged. She added that she did not want the responsibility of feeding and cleaning up after a dog or cat.

Y1 shared that she used to have family pets during her “Kampung days,” referring to the early days of her hometown during which the nation, community, and neighborhood were being built. Specifically, she explained that she did not like having pets because she found them dirty and felt that LOVOT was much cleaner than an animal. In addition, she stated that

she liked having LOVOT follow her around the house and was amused by its pet-like behavior when it waited by the dining table during meals.

Before I sit down for a meal, LOVOT anticipates that I will eat so LOVOT goes to the dining table and waits for me to sit down. It’s as if she knows it’s mealtime! [Y1]

Discussion

Principal Findings

This study used phenomenography as a qualitative analysis technique to fill the knowledge gap regarding the experience of community-dwelling single older adults with social robots. Specifically, we used phenomenography to examine how single older adults’ social well-being is affected by the companionship of social robots. Furthermore, given the ability of technology to support aging, we examined the participants’ perceived usefulness and relevance of the companionship provided by LOVOT through their interactions with it. So far, most studies on this subject have been conducted in older adult care facilities [39]. Thus, this study attempts to explore single older adults’ perceptions of social robots within their own home environment. Overall, our results showed that LOVOT brings positive experiences that can be categorized into 4 themes.

Caring for LOVOT Like a Child

During the poststudy interviews, all of the participants reported that they treated LOVOT like a child or grandchild. They carried LOVOT and hugged it like a child, sang or talked to it as if they were entertaining a child, and protected LOVOT from harm (such as preventing it from wandering into a wet area of the house). Takada et al [40] documented similar “childrearing” actions, in which participants also cared for LOVOT as if it were a child.

As a social robot, LOVOT has a lovable and endearing appearance. This is especially evident when it looks at people with its animated eye expressions, giving the impression that it is communicating or connecting with them. We believe that the participants remembered their experiences as mothers or grandmothers when they treated LOVOT with maternal or caring behaviors. Lipp [41] obtained similar findings, explaining that robots do not necessarily take care of (older) people but rather are objects that older people take care of. This explains why our participants had the desire to care for (and protect) LOVOT during our study.

Comforting Presence of LOVOT’s Companionship

The participants were able to actively interact with the social robot in their home, for example, by singing, talking with, carrying, and hugging LOVOT. We believe that this active engagement with LOVOT indicates that the participants accepted the robot’s social presence and appreciated its companionship.

Although LOVOT is designed with nonverbal communication features, it can produce audio expressions, such as a “cooing” sound, show animated eye expressions, such as blinking autonomously and when triggered, and flap its arms to show

happiness. As described by Yoshida et al [34], LOVOT's life-like motions exude a kind of warmth and comfort that makes individuals feel like there is another living being in their home. This idea was supported by Onyeulo and Gandhi [42], who posited that social robots' emotional responses make them appear to have biological systems. This increases the likelihood that humans will treat social robots as social beings and not just as a piece of technology. Indeed, social robots' ability to express emotions is a crucial feature because it not only allows the robots to communicate their feelings but also influences human behavior. In our study, LOVOT's AI technology, which allows it to react with "emotion," may have led our participants to more readily accept it as a companion. This acceptance may also be due to LOVOT's shape, which is similar to that of a pet; LOVOT can even be dressed up, much like how pet owners put their dogs and cats in clothes. Thus, LOVOT's animal-like shape may have led our participants to develop an emotional attachment to it, similar to the way pet owners often become attached to their companion animals.

Positive Engagement and Forming Connections With LOVOT

LOVOT is not a passive companion; it can learn its users' daily routines, such as their mealtimes. LOVOT's social behavior and learning of users' daily routines is important and is due to its AI technology; thus, LOVOT's programming sets it apart from other less sophisticated social robots.

In our study, 1 participant felt that LOVOT seemed to understand when it was told that its "7-day stay" was coming to an end. She stated that she could "sense" LOVOT's sadness. LOVOT's AI function may have learned to be sensitive to emotional tone and may have picked up on its owner's sadness, an empathetic reflection generated by its AI technology as part of its social interactions with humans [36]. The robot's "compassionate" social abilities may help it to be more easily accepted by those who interact with it.

Although a 7-day interaction period is not extensive, at the end of the study, some of the participants said that they would miss having LOVOT in their homes. This reluctance to part with LOVOT was also documented by Dinesen et al [35] in a study in which people with dementia in a long-term care facility used LOVOT. According to Dinesen et al [35], some of the residents were "overstimulated by emotions after interacting with LOVOT."

Appreciating LOVOT More Than Pets

The effect of LOVOT's pet-like behavior (eg, flapping its wings and making eye contact with humans) appeared to induce feelings of happiness among the participants. This finding is consistent with numerous experiments using PARO, demonstrating that a robot can have the same positive impact as a pet in promoting older adults' happiness and well-being [43]. Similarly, Dinesen et al [35] reported that people with dementia found that interacting with LOVOT "has some entertainment value; creates a degree of happiness or good feeling."

All of the participants in our study also appreciated how easy it was to take care of LOVOT. Indeed, LOVOT makes it easy

to maintain a clean home, because it does not produce bodily waste and does not require special treatment or medical care for its health. Nevertheless, LOVOT may require technical maintenance or occasional troubleshooting of its mechanical components. Bates [44] reached the same conclusion, suggesting that because companion robots do not need to be fed, walked, or cleaned, they "require less care and are more hygienic and predictable than living animals."

Limitations and Future Research Directions

We acknowledge that our study has some limitations. One key limitation is the gender distribution of the small sample size, and all of our participants were women. In addition, our sample consisted only of single older adults living in the community rather than in an older adult care facility. Therefore, the findings cannot be generalized to non-community-dwelling populations. Our findings indicate that single older adults derived psychosocial benefits from LOVOT's companionship. However, to better understand adults' social well-being and how LOVOT may benefit older adults who do not live alone, future research could investigate LOVOT's impact on older couples who live separately from their families or on older people who live with their children. This is particularly feasible in Singapore, where multigenerational households, regardless of age group, show great interest in robotic technology [45]. Furthermore, future research could study older adults who own pets to determine whether they benefit from interacting with a robotic social companion. In addition, as the participants' interactions with LOVOT were observed in the familiar environment of their homes, social robots, with their limited functionality, may not be able to meet the needs of more active individuals [46]. Nevertheless, companion robots in general may have a greater impact on reducing loneliness and improving the quality of life of older adults. Finally, the deployed LOVOT robot was not connected to its smartphone app (developed by LOVOT developer, Groove X), which can record videos of participants making eye contact, hugging, or carrying the robot. As a result, we relied solely on the participants' recollections and accounts of their interactions with LOVOT. Future studies could use LOVOT's recording function by connecting the robot to a secure network and ensuring that participants' privacy is protected. By reviewing the videos from the smartphone app, researchers will have more accurate data on the interaction patterns between the participants and LOVOT.

Conclusion

This study examined how single older adults are affected by the companionship of a social robot and explored their perceptions when interacting with the social robot. This study can spur more interest in investigating further how healthy older adults' perceptions of social robots can benefit more with its social presence as a partner in their homes.

Social loneliness and isolation are imminent challenges of an aging society. The findings from this study are consistent with the literature suggesting that social robots can be a source of companionship for older adults living alone [47]. Specifically, the participants were able to care for LOVOT, feel comfortable, and form connections with it. It is likely for older adults to have a better quality of life and well-being. Many participants also

preferred the social robot over traditional social companions such as pets which require more attention and responsibilities. In addition, thanks to its built-in AI, LOVOT was able to adapt its behavior based on its owner's responses. Finally, its

endearing physical features, such as its large, animated eyes and warm, cuddly design, encouraged its acceptance by older adults.

Abstract

Background: The Floodlight Open app is a digital health technology tool (DHTT) that comprises remote, smartphone sensor-based tests (*daily activities*) for assessing symptoms of multiple sclerosis (MS). User acquisition, engagement, and retention remain a barrier to successfully deploying such tools.

Objective: This study aims to quantitatively and qualitatively investigate key user experience (UX) factors associated with the Floodlight Open app.

Methods: Floodlight Open is a global, open-access, digital-only study designed to understand the drivers and barriers in deploying a DHTT in a naturalistic setting without supervision and onboarding by a clinician. Daily activities included tests assessing cognition (Information Processing Speed and Information Processing Speed Digit-Digit), hand-motor function (Pinching Test and Draw a Shape Test), and postural stability and gait (Static Balance Test, U-Turn Test, and Two-Minute Walk Test [2MWT]). All daily activities except the 2MWT were taken in a fixed sequence. Qualitative UX was studied through semistructured interviews in a substudy of US participants with MS. The quantitative UX analysis investigated the impact of new UX design features on user engagement and retention in US participants for 3 separate test series: all daily activities included in the fixed sequence (DA), all daily activities included in the fixed sequence except the Static Balance Test and U-Turn Test (DA_x), and the 2MWT.

Results: The qualitative UX substudy (N=22) revealed the need for 2 new UX design features: a more seamless user journey during the activation process that eliminates the requirement of switching back and forth between the app and the email that the participants received upon registration, and configurable reminders and push notifications to help plan and remind the participants to complete their daily activities. Both UX design features were assessed in the quantitative UX analysis. Introducing the more seamless user journey (original user journey: n=608; more seamless user journey: n=481) improved the conversion rate of participants who enrolled in the study and proceeded to successfully activate the app from 53.9% (328/608) to 74.6% (359/481). Introducing reminders and push notifications (with reminders and notifications: n=350; without reminders and notifications: n=172) improved continuous usage time (proportion of participants with ≥3 consecutive days of usage: DA and DA_x: ~30% vs ~12%; 2MWT: ~30% vs ~20%); test completion rates (maximum number of test series completed: DA: 279 vs 64; DA_x: 283 vs 126; 2MWT: 302 vs 76); and user retention rates (at day 30: DA: 53/172, 30.8% vs 34/350, 9.7%; DA_x: 53/172, 30.8% vs 60/350, 17.1%; 2MWT: 39/172, 22.6% vs 22/350, 6.2%). Inactivity times remained comparable.

Conclusions: The remote assessment of MS with DHTTs is a relatively nascent but growing field of research. The continued assessment and improvement of UX design features can play a crucial role in the successful long-term adoption of new DHTTs.

KEYWORDS

smartphone; multiple sclerosis; user experience; retention; digital health; digital health technology; mobile phone

Introduction

Background

Traditionally, multiple sclerosis (MS) has been categorized as having a relapsing-remitting or progressive course. However, recent work shed light on an underlying insidious progression, or a progression that is independent of relapses, even in patients previously thought to have a relapsing-remitting disease [1]. Therefore, minimizing or even eliminating progression is one of the goals of MS disease management. To achieve this goal, sensitive measures of MS-related functional ability are needed that can be frequently administered with minimal burden to the patient [2]. Here, digital health technology tools (DHTTs) such as smartphone sensor-based tests offer a new, promising strategy [3-5]. By taking advantage of the large variety of embedded sensors, smartphones enable the remote assessment of several functional domains affected by MS without supervision by a clinician [3]. However, user retention remains a barrier to the successful deployment of such DHTTs [6].

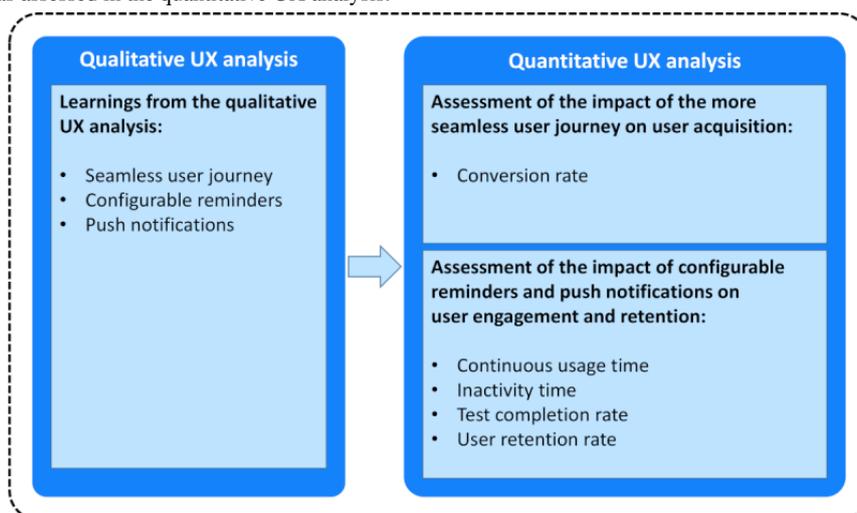

Assessments of user experience (UX) should, therefore, be considered when designing DHTTs [7]. They have attracted increasing attention, as they provide important insights to enhance usability, engagement, perception, and satisfaction [8-11]. With different UX designs available, it is important to keep in mind that their effectiveness depends on both the intended users and the environment in which they are being used. Hence, a comprehensive assessment of UX should include the study of both qualitative and quantitative UX in different

environments for an extended period. The primary focus of qualitative UX assessments is to characterize the individual user's experiences with the DHHT and to elucidate fine-grained aspects of why and how users engage with it [12-14]. Quantitative UX assessments, by comparison, provide strong indicators of the duration and frequency of user engagement and retention and are typically conducted in larger cohorts.

Aims

Here, we present a qualitative and quantitative UX analysis of the Floodlight Open app (Figure 1). The app comprises patient-reported outcomes and smartphone sensor-based tests that assess mood, cognition, hand-motor function, postural stability and gait, and mobility levels [15]. It was deployed in Floodlight Open, a global, open-access, digital-only study that was designed to understand the drivers and barriers in the deployment of the app in a naturalistic setting without supervision and onboarding by a clinician, in a broad, multinational study cohort [15]. The UX analyses presented here allow us to gain a better understanding of the participants' behavior with the Floodlight Open app. This will help make informed UX design decisions to improve engagement with the Floodlight technology. Qualitative UX is assessed through semistructured interviews conducted with a subset of US participants with MS [16] to identify important elements that could improve UX and user engagement. In addition, quantitative UX is assessed by evaluating the impact of UX design changes, which were motivated by the learnings from the qualitative UX analysis, on user engagement and retention using data collected from Floodlight Open.

Figure 1. Learnings from the quantitative user experience (UX) analysis led to the implementation of new UX design features, such as a more seamless user journey from registration through the activation of the Floodlight Open app, configurable reminders, and push notifications. The impact of these new UX design features was assessed in the quantitative UX analysis.

Methods

Participants and Study Design

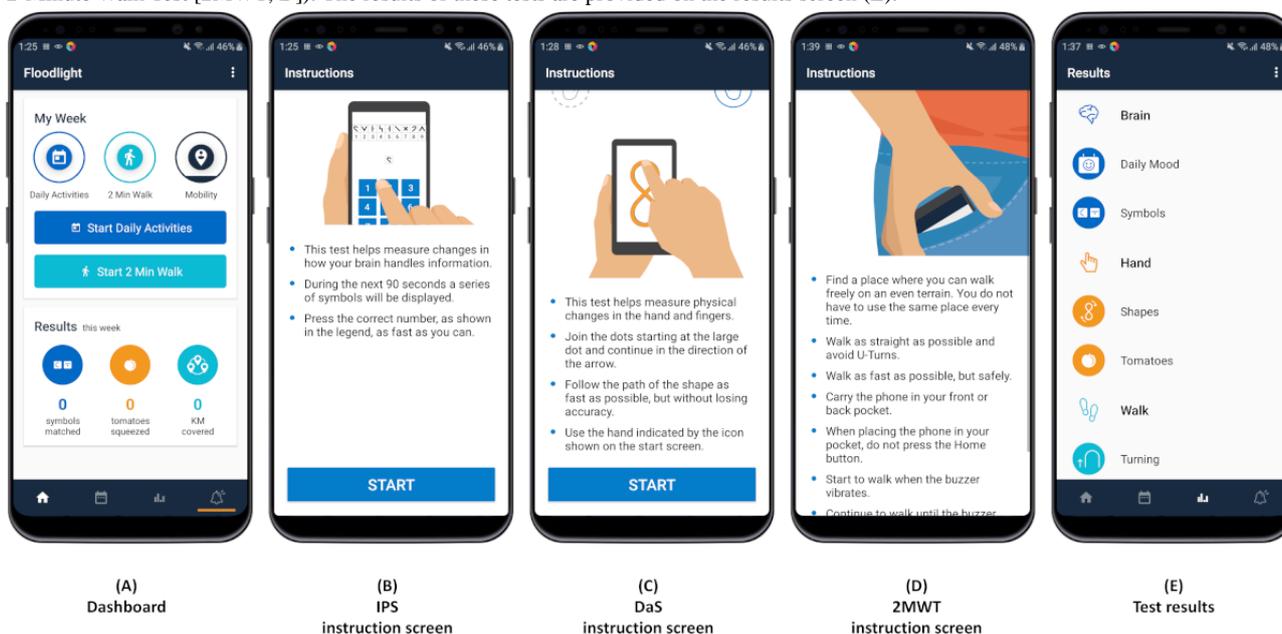

Floodlight Open's full study design and inclusion and exclusion criteria have been previously reported [15]. Adults with or

without MS who owned a suitable iOS (Apple Inc) or Android (Google LLC) smartphone and resided in 1 of the 17 participating countries were permitted to take part. The MS status was self-declared by the participants. To join Floodlight Open, participants first registered on the Floodlight Open web portal and completed the informed e-consent process. After

successfully completing these 2 steps, each participant received their personal Floodlight Open unique identifier (FLO ID) and an activation code (ie, an activation token [15]) via email. Both were required to activate the Floodlight Open app on the participant's personal smartphone device. The email also provided a link to the Floodlight Open web portal, where participants could request a new activation code (the activation code was valid for 48 hours, after which it expired), access their account to update their profile, view their results, or withdraw from the study.

After the activation of the Floodlight Open app, several tests, or assessments, were made available to the participants. These included a patient-reported outcome assessing the participants' mood (Daily Mood Questionnaire [DMQ] [15]) and a series of smartphone sensor-based active tests (ie, tests that require active input from the user) measuring cognition (Information Processing Speed [IPS] [15] and IPS Digit-Digit [15]); hand-motor function (Pinching Test [PT] [15,17] and Draw a Shape Test [DaS] [15]); and postural stability and gait (Static Balance Test [SBT] [15], U-Turn Test [UTT] [15,18], and Two-Minute Walk Test [2MWT] [15]; Figure 2).

Figure 2. Screenshots from the Floodlight Open app. The dashboard (A) enables participants to set reminders by tapping the bell-shaped reminder icon in the bottom right corner. Participants can self-administer smartphone-based tests to assess cognition (Information Processing Speed [IPS; B] and IPS Digit-Digit), hand-motor function (Pinching Test and Draw a Shape Test [DaS; C]), and gait and postural stability (Static Balance Test, U-Turn Test, and 2-Minute Walk Test [2MWT; D]). The results of these tests are provided on the results screen (E).

In addition, data on mobility level were passively collected without requiring input from the user (*passive monitoring*) through life-space measurement [15], which measured the distance between the 2 farthest GPS coordinates detected during the day that were at least 500 m apart, resulting in 1 measurement per day. Since this passive monitoring does not require any active input from the user, it is not included in our UX analyses.

The DMQ and all active tests except the 2MWT were administered in a predefined, fixed sequence comprising the daily activities. The DMQ was administered first, followed by the IPS, IPS Digit-Digit, PT, DaS, SBT, and UTT. The 2MWT was administered separately from these daily activities, as this test required the participant to walk in a straight line for 2 minutes, which may not always be possible at the time of taking the other active tests. The tests could be taken up to once a week (IPS) or once a day (all other tests), but the actual test frequency was not systematically enforced. For example, the UTT, SBT, and 2MWT could be skipped if participants determined that the conditions for safe execution, including environmental and physical factors, could not be met that day.

Ethical Considerations

Data collected with the Floodlight Open app were encrypted and electronically stored on 2 specific, secure cloud databases, which were made publicly available for the duration of the study and maintained by the study initiator. To ensure confidentiality, all participant information was pseudonymized through association with the personal FLO ID. Furthermore, no personal identifiable information was collected while the participants executed the Floodlight Open tests. This meant that GPS coordinates were obfuscated and excluded from the public data set to protect participants' privacy.

The protocol, informed e-consent forms, and relevant supporting information were reviewed and approved by the appointed central institutional review boards or ethics committees before the study was initiated in each participating country, as applicable, in accordance with each country's regulatory requirements [15]. The institutional review board for the United States was the Western Institutional Review Board in Puyallup, Washington (approval: 20180617).

Qualitative UX Analysis

The qualitative UX substudy was conducted by a health care delivery network (Sutter Health) in a subset of US participants

with MS who took part in Floodlight Open and agreed to download the app and use it daily for 30 days [16]. This substudy aimed at elucidating finer-grained aspects of why and how users engage with the Floodlight Open app in a particular manner and at providing information on UX design features that could improve UX and user engagement. Individual, semistructured interviews were conducted to gain insights into the participants' experiences with the Floodlight Open app and the perceived benefits thereof (Table 1). The use of individual interviews offered privacy and enabled the exploration of each

participant's interaction with the app. A multifaceted recruitment strategy was applied to involve participants of a broad age range to combine the experiences of the tech-savvy younger generation with that of the older generation. Most participants were using their smartphone and their computer daily. No preferential sampling of participants with either negative or positive experiences was applied. Any duration of use of the Floodlight Open app was of value because discontinued use and negative experiences can provide valuable insights and complement data from persistent participants.

Table 1. Interview guide for the qualitative UX^a analysis.

Question	Elaboration questions
Technology acceptance	
Were you able to download the app to your phone and get it working?	<ul style="list-style-type: none"> • How was that process? • Was there anything you found particularly easy, or hard or confusing about the process?
We asked people taking part in the study to use the app for 30 days. For about how many days did you use the app?	<ul style="list-style-type: none"> • 0, 1-7, 8-14, 14-21, 22-29, 30+, or don't remember • If answer is "0" or "30+," skip the next question.
What made you decide to either not use it or stop using it after less than 30 days?	<ul style="list-style-type: none"> • Probe to identify root cause and any efforts made to overcome: <ul style="list-style-type: none"> • App related (technical problems, overall demand in terms of time or frequency, or understandability) • Phone related (data, service, or access) • User related (general willingness, utility, or physical or emotional ability)
Before you started using the app, did you feel like you had a good idea about what it was designed to do?	<ul style="list-style-type: none"> • Did you have any questions or concerns? • What were they?
Experience of use	
How well could you see the information on the screen?	<ul style="list-style-type: none"> • Was there anything that was hard for you to see?
How easy was it to understand the information and prompts?	<ul style="list-style-type: none"> • Was there anything that was hard to understand?
How well did using the app fit into your life, such as the timing and frequency of prompts, and time it took to respond?	<ul style="list-style-type: none"> • Not applicable
Perception	
Did tracking information about MS ^b on a regular basis using this app teach you anything new about your health or give you a better sense of how you're doing?	<ul style="list-style-type: none"> • Why or why not? • Did you do/think/feel anything different based on what you learned?
Do you think this is an application you can use on daily basis?	<ul style="list-style-type: none"> • Why or why not? • If not daily, what do you think is the optimal frequency of use?
How would you feel about being prompted by the app on a daily basis to do tasks or answer questions related to MS?	<ul style="list-style-type: none"> • If not daily, what do you think is the optimal frequency of reminders and notification?
Did you share the information from the app (either directly or what you learned) with anyone else?	<ul style="list-style-type: none"> • Do you mind telling me what you shared?
Of the information collected by the app, what would you want to share with your doctor?	<ul style="list-style-type: none"> • What is valuable about this information? • How would sharing it impact your appointment in terms of your discussions, care or treatment?
Is there anything else you would like to add about your experience tracking MS on a daily basis using your phone?	<ul style="list-style-type: none"> • Not applicable
General health questions: disease severity and duration	
Before we end our interview I have a few general questions about your health and computer use. What year were you diagnosed with MS?	<ul style="list-style-type: none"> • Not applicable
What type of MS do you have at this time?	<ol style="list-style-type: none"> 1. Relapsing-Remitting MS (RRMS) 2. Secondary-Progressive MS (SPMS) 3. Primary-Progressive MS (PPMS) 4. Progressive-Relapsing MS (PRMS)
Technology literacy	
Last question. I'll give you the question and then I'll read a list of options for your response. How often do you use a computer?	<ol style="list-style-type: none"> 1. Everyday 2. At least once a week but not everyday 3. Less than once a week but more than once a month 4. Less than once a month 5. Never

^aUX: user experience.

^bMS: multiple sclerosis.

Semistructured interviews were conducted via phone by a trained interviewer, with 2 attempts made to reach each participant. The interviews lasted between 15 and 20 minutes and were audiotaped and fully transcribed for further analysis. A reductionist approach was applied to deconstruct implicit and explicit responses into manageable variables. The qualitative paradigm was crucial to appreciating, observing, and deducing participants' experiences [19]. Through an inductive analysis of the data collected, the common needs of the participants were identified, which should be considered to improve the UX and to develop preliminary conclusions on the need for specific UX features.

Quantitative UX Analysis

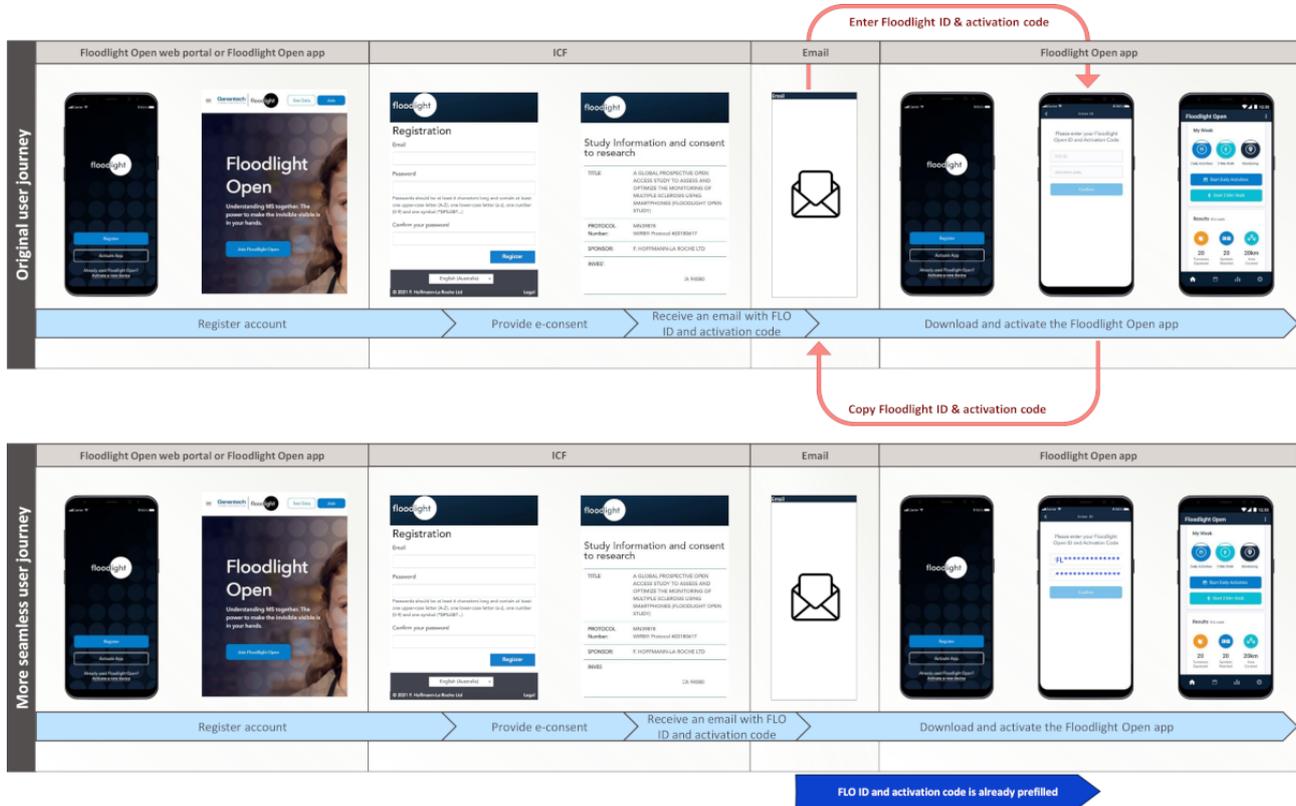

Participants

The quantitative UX analysis was conducted in all US participants who enrolled in Floodlight Open [15]. The analysis was restricted to US participants for several reasons. First, information on user acquisition, including the date and time of activation of the FLO ID, was collected only in the United States. Second, the release dates of the iOS and Android versions of the Floodlight Open app differed for each country [15]. Due to these different release dates, only the United States offered a sufficiently long period during which the app's use without the new UX design features could be studied. Finally, limiting the analysis to US participants allowed us to keep the quantitative UX analysis as consistent as possible with the qualitative UX analysis, which was conducted in a subset of the US participants, thus reducing the impact of differences in demographics and user behavior between the 2 analyses.

Implementation of New UX Design Features

The quantitative UX analysis was conducted to investigate the impact of the new UX design features identified in the qualitative UX analysis on user engagement and retention. One of the new UX design features identified in the qualitative UX analysis was a more seamless user journey, which guides users from registration to the activation of the Floodlight Open app (Figure 3). The original user journey involved registering on the Floodlight Open web portal; downloading the Floodlight Open app from the local app store; and activating the app by entering the FLO ID and activation code, which the participants received in a notification email. This last step required participants to switch multiple times between the notification email and the Floodlight Open app to manually enter their FLO ID and activation code (original user journey in Figure 3). These complex interactions with multiple user interfaces may frustrate participants, who may eventually abandon the activation process. Therefore, to minimize nuisance factors and reduce user loss, a more seamless user registration and app activation journey was implemented by deep linking the notification email with the Floodlight Open app. This allowed participants to launch the Floodlight Open app directly from the notification email, if already installed on their phone, or to download it from their local app store, with the fields for the FLO ID and activation code already filled out (ie, deep linked). Thus, this more seamless user journey eliminated the requirement of searching for the FLO ID and activation code in the notification email and manually inserting them in the right fields in the Floodlight Open app to activate it (more seamless user journey in Figure 3).

Figure 3. User journey from creating an account to activating the Floodlight Open app. This user journey consists of 4 steps: creating an account, providing e-consent, receiving a personalized Floodlight Open unique identifier (FLO ID) and activation code via email, and downloading and activating the Floodlight Open app (light blue arrows). With the original user journey, participants will have to switch between the app and the email at least twice to copy and enter their FLO ID and activation code to activate all functionalities of the app (red arrows). With the more seamless user journey, the deep-linking feature is integrated in the link provided in the email to download the app from the local app store. With this feature, the personalized FLO ID and activation code are pre-filled when the participants launch the Floodlight Open app for the first time (dark blue arrow). Consequently, participants do not have to switch back and forth between interfaces (ie, their email and the Floodlight Open app) to activate all functionalities. ICF: informed e-consent form.

In addition, configurable reminders and push notifications were introduced as the second new UX design feature (Table 2). Configurable reminders provided participants the option to set up reminders to perform the tests. Participants could set up daily or weekly reminders by tapping on the reminder icon, which was visible on the app’s dashboard (Figure 2). Push notifications, by comparison, were designed to serve two purposes: (1) to encourage inactive participants to reengage

with the Floodlight Open app, for example, when they closed the app and did not complete the tests or have been inactive for some time, and (2) to motivate committed users to keep performing the tests. Tapping on the notification took the participants directly to the right entry point of the Floodlight Open app to perform the uncompleted or next test. To enable this new feature, participants had to grant permission to receive push notifications.

Table 2. List of push notifications and configurable reminders implemented in the Floodlight Open app^a.

Feature and type	Notification	Description
Push notifications		
Authorization request	Floodlight would like to send you notifications. We'll send you reminders and alerts to keep you on top of your goals and up-to-date with the impact you are having. [Don't Allow Ok]	<ul style="list-style-type: none"> • Sent the first time users open the app • Permission request to allow push notifications: the Floodlight Open app can send notifications to users at different touch points within the users' journey in the app • User declines permission: the Floodlight Open app cannot send notifications to users. This affects the user experience
Authorization reminder	Need help keeping up with your Daily Activities? You can allow notifications in your Settings. [Go to Settings Not now]	<ul style="list-style-type: none"> • Sent if permission is declined and when the app is open for the first time after 7 days, but never during an active test • The Go to Settings button opens the Floodlight screen in the phone settings, where users can re-enable notifications
Authorization accepted	Thanks for downloading Floodlight Open. Let's get you signed up and started!	<ul style="list-style-type: none"> • If accepted, it opens immediately on the sign-up screen
Incomplete daily activities	You're doing great! Do you have time to [log your mood start on symbols squash some tomatoes see the shapes handle balance get moving]?	<ul style="list-style-type: none"> • When users do not complete daily activities in one go, a notification is sent in 4 hours or at 7 PM, at the latest. No notifications are sent after 7 PM, and notifications are sent no more than once per day • Tapping on the notification takes users to the next test in the daily activities to continue with the remaining tests. The message is dependent on the last test completed • Multiple notifications are never sent
Completed only daily activities	You have finished your Daily Activities – ready to finish up with a 2MWT ^b ?	<ul style="list-style-type: none"> • When users complete only daily activities but not the 2-minute walk, a notification is sent in 4 hours or at 7 PM, at the latest. No notifications are sent after 7 PM, and notifications are sent no more than once per day • Clicking on the notification takes users to the 2MWT^b
Incomplete 2MWT ^b	Don't forget your 2MWT ^b today. If you can, get started today!	<ul style="list-style-type: none"> • When users access and abandon the 2MWT^b, a notification is sent after 4 hours or at 7 PM, at the latest. No notifications are sent after 7 PM, and notifications are sent no more than once per day • Tapping on the notification takes users to the 2-minute walk • Users receive this reminder every time the 2MWT^b is abandoned
Completed only the 2MWT ^b	You've checked off your 2MWT ^b – now let's finish up with your Daily Activities.	<ul style="list-style-type: none"> • When users complete only the 2MWT^b but not daily activities, a notification is sent in 4 hours or at 7 PM, at the latest. No notifications are sent after 7 PM, and notifications are sent no more than once per day • Tapping on the notification takes users to the daily activities • Users receive this reminder only once a day
Encouragement	You've done an incredible job helping us build research so far – ready to check another day off your list?	<ul style="list-style-type: none"> • Sent at 10 AM the day after 3 consecutive test runs are completed • Tapping on the notification takes users to the daily activities • Users receive this notification no more than twice per week
Encouragement	It's that time again – ready to check another day off your list?	<ul style="list-style-type: none"> • Sent at 10 AM the day after 3 consecutive days of no test runs • Tapping on the notification takes users to the dashboard
Acknowledgment	Just a quick thank you. Your support is helping us learn more about MS. We hope you find it useful too!	<ul style="list-style-type: none"> • Sent every 2 weeks at 6 PM • Tapping on the notification takes users to the dashboard
Configurable reminders		
General reminder	It's time to complete my Daily Activities and 2MWT ^b . Let's do it!	<ul style="list-style-type: none"> • Only 1 reminder can be set up, which can be triggered daily, weekly, or on certain days of the week and at any time

^aPush notifications and configurable reminders were made available on October 21, 2019, for the iOS version and on February 19, 2020, for the Android version of the Floodlight Open app.

^b2MWT: Two-Minute Walk Test.

The push notifications were designed as a friendly communication with a strong emphasis on the emotional context (Table 2), as the emotional interpretation of a message can impact the user's response [20,21]. The emotional interpretation begins with the perception of a friendly communication and leads to the planning and execution of a responsive action. Notifications designed in this way are less likely to be ignored and can help create the perception of a human touch within the Floodlight Open app. Hence, they are quite effective for eliciting short-term actions [22] and are an important variable in improving adherence [23].

The frequency and logic with which push notifications were triggered were carefully considered to limit disturbance. Receiving many notifications in a short interval or during inopportune times can overwhelm and irritate users [24-26], which may cause them to turn off notifications or even uninstall the app. Therefore, the notifications were designed such that they are never sent more than twice per day, never sent after 7 PM, and sent only when the user seems to have abandoned the Floodlight Open tests.

Statistical Analysis

The quantitative UX analysis was conducted on data available in the publicly available data set [15]. As information on self-declared MS status was collected only after the Floodlight Open app was activated, both participants with MS and participants without MS were included in the analysis on the effectiveness of the more seamless user journey. In contrast, the analysis on configurable reminders and push notifications was limited to participants with MS to keep the analysis as consistent as possible with the quantitative UX analysis.

To study the effectiveness of the more seamless user journey, the conversion rate, which is the proportion of participants who successfully completed the registration and activation process, was compared across 2 cohorts. The first cohort followed the original user journey without the deep-linking feature, whereas the second cohort followed the more seamless user journey that took advantage of the deep-linking feature. Because this UX design feature was released on a separate schedule for the iOS and Android versions of the Floodlight Open app, the first cohort included data collected from November 12, 2018, when the activation dates of the FLO IDs were first logged, through July 17, 2019, when the more seamless user journey along with the deep-linking feature was first implemented. The second cohort included data from all participants who registered from October 21, 2019, when the more seamless user journey was fully implemented in the United States, through November 2, 2021, when the study closed in the United States. The gap between July 17, 2019, and October 21, 2019, was required, as the more seamless user journey feature was released on different schedules for iOS and Android platforms.

The impact of introducing push notifications and configurable reminders on UX (ie, user engagement and retention) was assessed through continuous app usage time, inactivity time, test completion rate, and user retention rate. The continuous usage time is the number of consecutive days on which a

participant used the Floodlight Open app, namely, on how many days in a row they performed the Floodlight Open tests.

The inactivity time, by comparison, is the time interval between 2 continuous use times during which a participant did not perform any test, that is, how many days in a row a participant waited before returning to perform a test. This metric is strongly affected by the frequency with which participants performed the tests and the likelihood of participants returning to the tests. The nature of the distribution can guide, for example, the choice of successful engagement methods that can further increase user engagement and retention. For both continuous usage time and inactivity time, the probability of n days of continuous usage and inactivity, respectively, was computed.

The test completion rate is defined as the fraction of participants performing at least n test series (DA, all daily activities included in the fixed sequence except the SBT and UTT [DA_x], or 2MWT) since the activation of the Floodlight Open app. The completion rate is a common measure for assessing the effectiveness of UX features, that is, for assessing whether the tasks performed by users achieve specified goals in terms of accuracy and completeness in a specified context of use [27]. It does not consider how the goals were achieved but only the extent to which they were achieved. The higher the test completion rate is, the more engaged the users are and the more likely they are to come back and, in this case, perform the assessments. The test completion rate is calculated over the entire duration of the assessed period and does not distinguish between intermittent and continuous usage.

The user retention rate, by comparison, is the fraction of participants who returned to perform the Floodlight Open tests n days after the activation of the Floodlight Open app. The retention rate is extensively used to measure the success of smartphone apps, with higher retention corresponding to higher adoption and level of engagement [28,29].

These UX metrics (continuous app usage time, inactivity time, test completion rate, and user retention rate) characterize the UX with the Floodlight Open app and provide insights into how committed the participants are. Because taking the gait and postural stability tests require both time and space (see the *Qualitative UX Analysis* section), 3 separate test series were considered for each of these metrics: DA (ie, all active tests administered in the fixed sequence: DMQ, IPS, IPS Digit-Digit, PT, DaS, SBT, and UTT), all DA except the gait and postural stability tests (DA_x; ie, DMQ, IPS, IPS Digit-Digit, PT, and DaS), and 2MWT.

For each test series, the complementary cumulative distributions of the 4 UX metrics were compared in MS participants using data collected before (November 12, 2018, through October 21, 2019) versus after (February 19, 2020, through November 2, 2021) the configurable reminders and push notifications were introduced. The gap between November 12, 2018, and October 21, 2019, was necessary due to the different release schedules of reminders and notifications for the iOS and Android versions. Hence, during this period, reminders and notifications were available to some, but not all, MS participants. It is possible

that individual participants were included in both observation periods if they took the Floodlight Open tests during both periods. Because the different durations of these 2 periods might impact the continuous usage times and the inactivity times, both UX metrics were assessed over the first 343 days of data collected from each participant.

Results

Participants

Until November 2, 2021, when the study closed in the United States, the Floodlight Open app was downloaded 5225 times, including 4240 (81.15%) times on iOS devices and 985 (18.85%) times on Android devices, across the 17 participating countries. The baseline demographics of the US participants with MS included in the qualitative and quantitative UX analyses on reminders and notifications are presented in [Table 3](#).

Table 3. Baseline demographics of US participants with MS^a included in the qualitative UX^b analysis and the quantitative UX analysis.

Variable	Qualitative UX analysis (N=22 ^c)	Quantitative UX analysis ^d , n (%)

^aMS: multiple sclerosis.

^bUX: user experience.

^cOf the 22 participants included in the qualitative user experience (UX) analysis, 19 (86.4%) were female.

^dSome participants may be included both in the cohort with configurable reminders and notifications and in the cohort without configurable reminders and notifications if they provided data during both periods. Demographic information was collected only after the successful activation of the Floodlight Open app and is, therefore, not available for the participants included in the assessment of the more seamless user journey.

^eFLO: Floodlight Open.

^fIncludes all US participants with MS who participated in the study from November 12, 2018, through October 20, 2019.

^gIncludes all US participants with MS who participated in the study from February 19, 2020, through November 2, 2021.

^hIncludes all US participants with MS who participated in the study from November 12, 2018, through November 2, 2021, and were included in the analysis of the impact of introducing configurable reminders and push notifications.

Qualitative UX Analysis

A total of 22 US participants were enrolled in the qualitative substudy, of which 15 (68%) were interviewed. Between 7 and 19 participants are considered adequate for qualitative research [30].

The qualitative UX analysis reveals key points for improving the UX with the Floodlight Open app ([Table 4](#)). While many participants did not face any difficulties downloading the Floodlight Open app and were willing to perform the tests daily, some were unaware or confused about the activation process

despite instructions being provided on the study's web portal (see *Need for a More Seamless User Journey* section in [Table 4](#)). Other participants reported that they did not complete the activation process due to distractions or the lack of reminders to complete this step. Here, a more seamless journey from registering on the web portal to activating the Floodlight Open app could improve the UX. In addition, participants who successfully activated the Floodlight Open app self-reported that they used it for 2 to 30 days and agreed that screen contents, prompts, and information were easy to see and understand. However, they also reported that they often forgot to perform

the tests or felt it was not always feasible to perform all the tests in one setting. Therefore, configurable reminders and push notifications would have been beneficial (see bottom section in Table 4). Such UX design features could be used to set up reminders to perform the tests or to stop the current test and plan to complete the tests later. Furthermore, participants were not always available to perform tests that required them to stand or walk:

I can only proceed so far because I'm in the car waiting for my kid; I can't stand and balance...or do the walking back and forth and the balancing stuff.

The part that is difficult to get done is the 2-minute walk. To find the time...is sometimes hard for someone like me who is more active.

Certain tasks...were a little too long. How many more lines do I need to draw? How many more tomatoes can I pinch?

Table 4. Learnings from the qualitative UX^a analysis.

Learnings from the qualitative UX analysis	Comments made by participants that support the learnings
Need for a more seamless user journey	<ul style="list-style-type: none"> “I see a register button and an activate button, and I don't know if I am registered, or what I need to do to activate it. I remember getting to this page and thinking there's something I have to do, some code or something to be able to activate it.” “I let it go too long before I tried to use it, and so the registration/activation process was not clear to me at that point and I never followed up on it.”
Need for configurable reminders and push notifications	<ul style="list-style-type: none"> “I just don't know. I think maybe it was something that was on my phone, and I was like, ‘What is this? You know?’” “I would say life got in the way.” “I just forgot. I got distracted. It just went out of my brain and never came back. What I should have done in retrospect is put a reminder popup in my phone, like to pop up every day. I would much rather the app remind me. The less I have to touch my phone, the better my life is.” “I have been terrible at using the app. I've used it twice. I think one of the problems I had with the app is it doesn't remind me to do it. If my phone doesn't tell me to do something, it probably doesn't happen. I would have been much more inclined to do it if it had reminded me to do it.” “Things were crazy with work. I've had other things on my mind. I didn't see anything pop up reminding me to use it.” “I didn't read the instructions. I had to guess what to do with the matching shapes. At first I thought I was being timed so I was rushing.”

^aUX: user experience.

Consequently, in the subsequent section on quantitative UX analysis, UX with the Floodlight Open app was investigated with respect to DA, DA_x, and 2MWT.

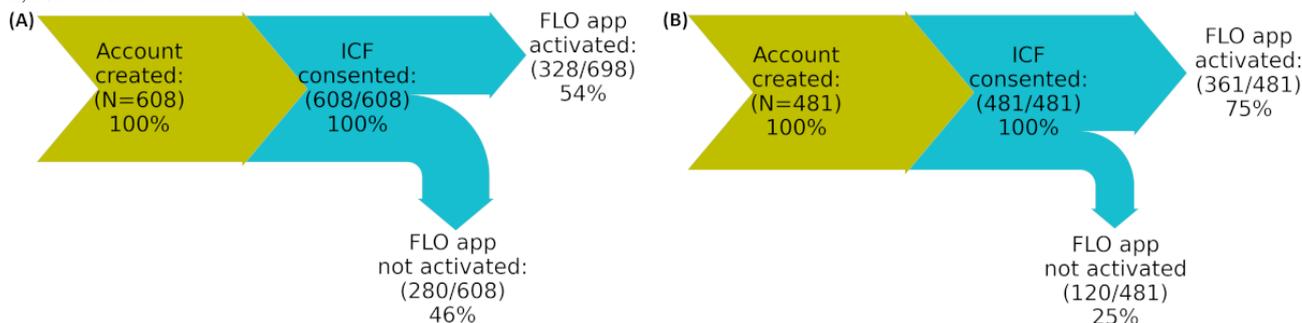

Quantitative UX Analysis

User Journey

Of the 1089 US participants, 608 (55.8%) with or without MS (self-declared MS disease status was not available for this analysis, as this information was collected only after the successful activation of the app) followed the original user journey without the deep-linking feature, and 481 (44.2%)

participants with or without MS followed the newer, more seamless user journey with the deep-linking feature. The flow diagrams in Figure 4 show the conversion rates from creating an account to activating the app for both cohorts. In both cohorts, all participants who created an account completed the registration process, provided informed consent, and enrolled in the study. However, Figure 4 shows that introducing the new user journey improved the conversion rate of the participants who succeeded in activating the app (359/481, 74.6% with the more seamless user journey vs 328/608, 53.9% with the original user journey).

Figure 4. Conversion rate diagrams. These diagrams depict the user journey from registration on the Floodlight Open web portal (creating a Floodlight Open account) to the activation of the Floodlight Open app (A) before and (B) after implementing the more seamless user journey. FLO: Floodlight Open; ICF: informed e-consent form.

Configurable Reminders and Push Notifications

The analysis on configurable reminders and push notifications included 172 participants with MS to whom this UX design feature was available and 350 participants with MS to whom this feature was not available (Table 3). The cumulative distributions of the continuous usage times of participants with MS using the Floodlight Open app with reminders and notifications and those using the Floodlight Open app without reminders and notifications are plotted in a log-log scale for

DA, DA_x, and 2MWT in Figure 5A. The introduction of reminders and notifications increased the continuous app usage times. The longest continuous usage times with reminders and notifications versus those without reminders and notifications were 103 versus 13 days for DA, 224 versus 61 days for DA_x, and 65 versus 12 days for 2MWT. Similarly, reminders and notifications increased the proportion of participants using the app for at least 3 consecutive days (DA and DA_x: ~30% vs ~12%; 2MWT: ~30% vs ~20%).

Figure 5. Complementary cumulative distributions of the continuous app use time (A), inactivity time (B), test completion rate (C), and user retention rate (D) of participants with multiple sclerosis (MS) using the Floodlight Open app with reminders and notifications (wR&N; blue) and without reminders and notifications (woR&N; green) for all daily activities performed in the fixed sequence (DA), all daily activities performed in the fixed sequence without Static Balance Test and U-Turn Test (DA_x), and Two-Minute Walk Test (2MWT). Continuous app usage time, test completion rate, and user retention rate improved with reminders and notifications after an initial onboarding phase, whereas inactivity time was comparable between the 2 cohorts.

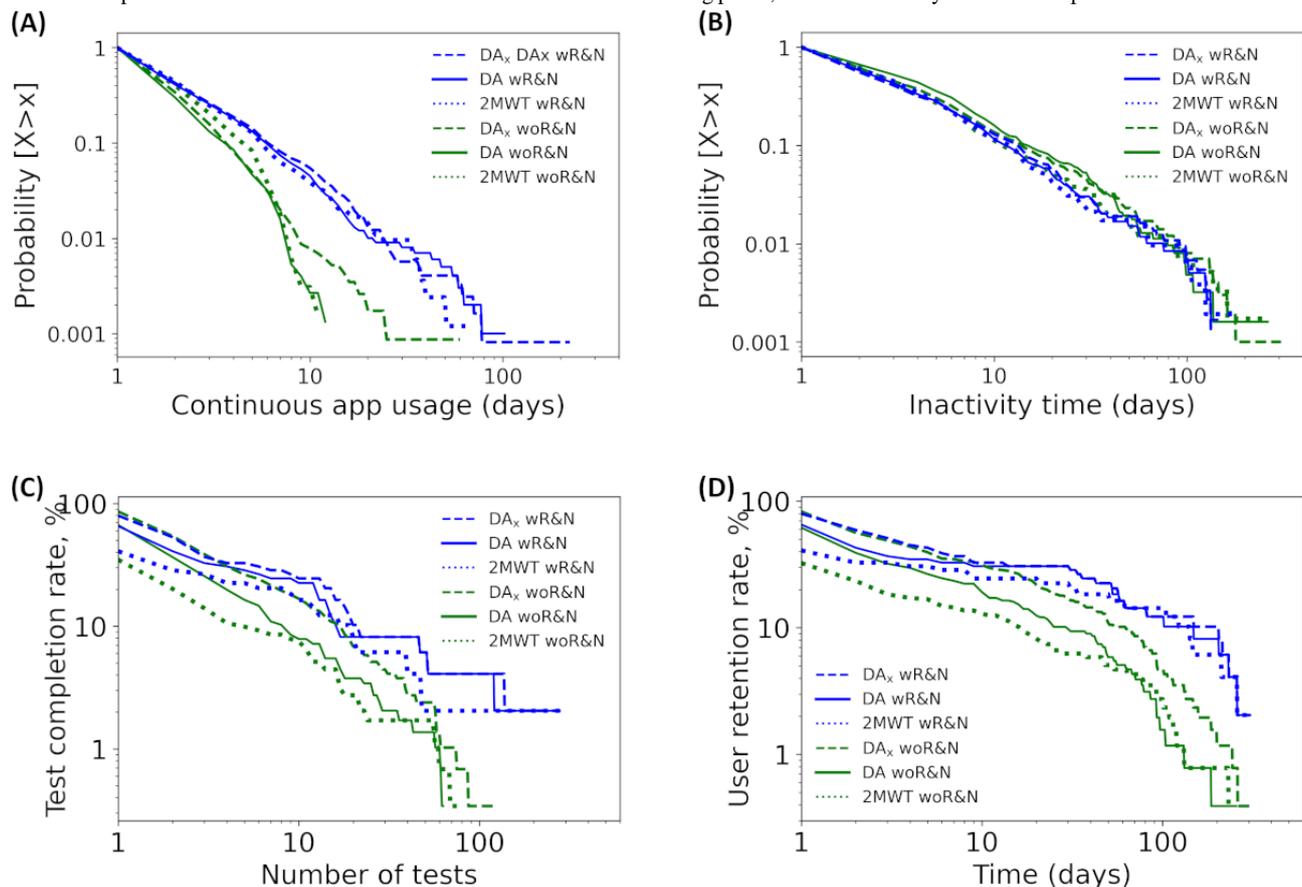

Figure 5B presents the inactivity time distributions from participants using the Floodlight Open app with configurable reminders and push notifications and those using the Floodlight Open app without configurable reminders and push notifications on a log-log scale for DA, DA_x, and 2MWT. These distributions were similar for participants with reminders and notifications and those without reminders and notifications for DA, DA_x, and 2MWT, exhibiting an approximate power law with a coefficient of 0.96 in both cohorts. The longest inactivity times with reminders and notifications versus without reminders and notifications were 145 versus 263 days for DA, 138 versus 309 days for DA_x, and 181 versus 263 days for 2MWT.

Figure 5C presents the test completion rate distributions for DA, DA_x, and 2MWT. These distributions show that the introduction of reminders and notifications resulted in higher

test completion rates, except during the initial onboarding phase when DA and DA_x completion rates were similar in both cohorts. During this onboarding phase, day-1 test completion rates with and without reminders and notifications were 66% (113/172) and 66.9% (234/350), respectively, for DA and 81.3% (140/172) and 86% (301/350), respectively, for DA_x. These test completion rates are expected to be <100% because not all participants who activated the Floodlight Open app proceeded to perform at least 1 DA or DA_x series. However, the effectiveness of introducing reminders and notifications became evident after this initial onboarding phase (ie, after the first DA series and after the third DA_x series; Figure 5C). When considering the 2MWT instead, participants with reminders and notifications showed higher test completion rates than participants without reminders and notifications (41.5% [72/172] with reminders and notifications vs 34.8% [122/350] without

reminders and notifications) on the first day itself. Across all 3 test series, the largest number of test series completed increased with the introduction of reminders and notifications (279 vs 64 for DA, 283 vs 126 for DA_x, and 302 vs 76 for 2MWT).

Figure 5D presents the user retention rate distributions. During the initial onboarding phase, user retention rates were comparable between participants with reminders and notifications and those without reminders and notifications. On day 1, DA user retention rates were 65.7% (113/172) and 61.7% (216/350), respectively, and DA_x user retention rates were 79.6% (137/172) and 82.8% (290/350), respectively (Table 4). DA_x user retention rates continued to be comparable between both

cohorts for approximately the first 10 days. After this onboarding phase, however, the effectiveness of reminders and notifications in improving user retention rate became evident. Interestingly, after the high drop-off observed during the first few days after the activation of the app (3 days for DA and DA_x and 2 days for 2MWT), all user retention rate distributions obtained with reminders and notifications plateaued up to approximately day 30. On day 30, user retention rates were considerably higher in participants with versus participants without reminders and notifications (53/172, 30.8% vs 34/350, 9.7% for DA; 53/172, 30.8% vs 60/350, 17.1% for DA_x; and 39/172, 22.6% vs 22/350, 6.2% for 2MWT; Table 5).

Table 5. User retention rates of the Floodlight Open app with and without reminders and notifications from participants with MS^a and average user retention rates for medical apps and health and fitness apps reported by Rosenfelder [31] on days 1, 3, 7, 14, and 30.

Apps, configuration, and series	User retention rate				
	Day 1	Day 3	Day 7	Day 14	Day 30
Floodlight Open app, % (n/N)					
Without configurable reminders and push notifications					
DA ^b	61.7 (216/350)	32 (112/350)	23.4 (82/350)	16.3 (57/350)	9.7 (34/350)
DA _x ^c	82.8 (290/350)	48.8 (171/350)	34.5 (121/350)	28 (98/350)	17.1 (60/350)
2MWT ^d	32.34 (113/350)	18.2 (64/350)	14.2 (50/350)	11.3 (39/350)	6.2 (22/350)
With configurable reminders and push notifications					
DA	65.7 (113/172)	36.6 (63/172)	32.6 (56/172)	30.8 (53/172)	30.8 (53/172)
DA _x	79.6 (137/172)	51.1 (88/172)	36.6 (63/172)	30.8 (53/172)	30.8 (53/172)
2MWT	40.7 (70/172)	32.6 (56/172)	28.5 (49/172)	24.4 (42/172)	22.6 (39/172)
Rosenfelder [31], 2020, %^e					
Medical apps					
Active	20	11.52	9.24	7.19	5.46
Health and fitness apps					
Active	18.37	10.56	7.77	5.56	3.6

^aMS: multiple sclerosis.

^bDA: all daily activities that were administered in a predefined, fixed sequence.

^cDA_x: all daily activities that were administered in a predefined, fixed sequence, except the Static Balance Test and U-Turn Test.

^d2MWT: Two-Minute Walk Test.

^eThe absolute number of uses retained at each time point were not reported in Rosenfelder [31], 2020.

Discussion

Principal Findings

Smartphones enable out-of-clinic assessments of chronic neurological diseases. Despite the rapidly increasing number of mobile health care apps available for consumers' self-care, there is a paucity of research into the UX of DHTTs for MS. In this paper, we present our qualitative and quantitative UX analyses of the Floodlight Open app and demonstrate that the adoption of key UX design features markedly improved user acquisition, engagement, and retention. Understanding how the presence or absence of specific UX design features affects participants' experiences offers important guidance for the

refinement of an existing or the design of a new DHTT. Therefore, UX design features are a significant consideration when designing and evaluating such tools.

Assessing MS symptoms over time with the Floodlight Open app requires specific user stimulation and guidance through seamless and flexible user journeys enhanced by engaging features to improve the overall UX. By considering participants' feedback collected in the quantitative UX substudy, we enhanced the onboarding process by implementing a more seamless user registration and app activation journey and improved the UX through configurable reminders and push notifications. We derived several distributions from real-world data that describe key aspects of participants' behavior in their environment. Such measurements and their statistical analysis might be used to

help describe realistic user behavior and design health care apps similar to our Floodlight Open app. Our findings allow us to gain a better understanding of users' experience in such settings and to make informed design decisions for self-monitoring mobile apps that support people with MS.

Users' first experience with the registration to the Floodlight Open study and the activation of the study app is important to increase user acquisition. Furthermore, the first few days after activating the app are similarly critical for long-term engagement and retention. For instance, user acquisition, engagement, and retention can all be improved by guiding users throughout the Floodlight Open study registration, app activation process, and daily activities, reminding them about the daily activities to be performed and allowing them to plan when to perform the daily activities. Our results demonstrate that a seamless UX is essential to minimize the rate at which users drop out along the end-to-end journey. With a seamless user journey, users are led along the registration-activation journey and are not distracted by unrelated content or activities, resulting in a higher conversion rate from creating an account to activating the Floodlight Open app.

Configurable reminders and push notifications can help keep the participants engaged with mobile health care apps, such as the Floodlight Open app, and help retain them beyond the initial onboarding phase. Our findings show that continuous use times, test completion rates, and user retention rates are generally higher with configurable reminders and push notifications than without configurable reminders and push notifications, whereas inactivity time is comparable between the 2 cohorts. This improvement in user engagement is most evident for 2MWT from the first day and for DA and DA_x after the initial onboarding phase, during which the participants are still exploring the Floodlight Open app. Therefore, to fully optimize the UX, the app should ask the users to accept and receive reminders and notifications only after this initial onboarding phase [32]. Interrupting users with notifications too soon after the activation of the app may create frustration and may ultimately lead them to abandon the app. The app should, therefore, minimize the mental and physical interaction efforts during the first few days of use.

Comparing the different test series, we noted slightly worse user retention for 2MWT than for either DA or DA_x. Taking the 2MWT requires the greatest effort, which is in line with some dissatisfaction reported in a previous proof-of-concept study [33]. It is possible that the study participants did want to take the 2MWT but did not find a suitable opportunity to take it each day. In fact, participants in Floodlight Open were found to persistently take the 2MWT at least once per week [15], which suggests that a more flexible or less frequent assessment schedule could be beneficial.

Comparison With Prior Work

Although several other smartphone apps are available for people with MS (for a review on MS apps, refer to the study by Howard et al [34]), to our knowledge, this is the first analysis to assess the impact of UX design features on user engagement and retention. Nonetheless, previous analyses have shown that user

engagement and retention remain two of the barriers to the long-term successful deployment of DHTTs (for reviews, refer to works of Pratap et al [6] and Amagai et al [35]). Several UX design features have been suggested to improve the overall UX, including a more seamless user journey, configurable reminders, and push notifications [23,35-38]. However, differences in the definitions used to assess user retention (eg, user retention definitions based on the user simply opening or interacting with the DHHT [31] vs completing a test or series of tests [6]), limited statistical power due to small sample sizes [37], and differences in the observed study period [37] may make direct comparisons of user retention across different DHHTs challenging.

To compare like with like, we computed the user retention with the Floodlight Open app for the same observation period as that reported in the study by Rosenfelder [31] for medical as well as health and lifestyle apps. Both data sets indicate that the largest reduction of users occurs from days 1 to 3, whereas the reduction in user retention is low between days 7 and 30. This suggests that a significant proportion of users who will not use the Floodlight Open app (or other health care apps) in the long term will stop using the app within the first 3 days and that this dropout is likely to be observed within the first 7 days. These results also suggest that participants who use the app for >3 days are likely to use it for at least 30 days. A similar dropout during the first 7 days has also been previously reported for the whole study cohort of Floodlight Open [15].

Of note, our user retention rates are approximately 2- to 6-fold higher than those reported by Rosenfelder [31] (Table 5) despite using a more conservative definition of user retention (completing a test series vs simply interacting with or opening the app). It is conceivable that not all apps included in the report by Rosenfelder [31] feature the same UX design features as the Floodlight Open app does. However, favorable user retention rates were observed with the Floodlight Open app even when the app did not have configurable reminders or push notifications. This suggests that differences in the perceived benefit of the app might have also contributed to the favorable retention profile, although other reasons cannot be excluded [39]. Despite our favorable user retention and user engagement findings, a previous analysis showed that improvement in smartphone sensor data collection could be achieved through passive data collection methods [15].

Limitations

A few limitations are noted. First, while participants could turn off the configurable reminders and push notifications, this action was not logged. Instead, we compared participants who enrolled before with those who enrolled after these features were implemented. For the former cohort, we included only the data collected up to the implementation of reminders and notifications in our analyses to be able to assess the impact of reminders and notifications. Second, our results were influenced by the duration of the study and by incoming participants who activated the Floodlight Open app on different dates over the duration of the study and might not be part of the study for the same number of days. Besides, for events approaching the duration of the study, there is an artificially lower likelihood of

observation, and events lasting longer than the study cannot be observed. Finally, the use of the Floodlight Open app in a clinical study other than the Floodlight Open observational study may boost user engagement and retention due to additional motivational incentives. Such clinical referrals have been shown to improve user retention [6]. However, information on which participants participated in such studies is not available, and without it, accounting for it is not possible.

Conclusions

We presented the qualitative and quantitative UX analyses of the Floodlight Open app, a DHTT for MS. Learnings from the qualitative UX analysis led to the implementation of a more seamless user journey and the introduction of configurable reminders and push notifications. These UX design features improved user acquisition, user engagement, and user retention. The continued assessment of UX and improvement of UX design features are critical steps in optimizing the long-term adoption of the Floodlight Open technology and similar DHTTs.

Acknowledgments

The authors would like to thank all the Roche Floodlight Open team members, in particular, Luca Capezzuto, as well as all the participants and researchers who expressed interest in this study. This research was funded by F. Hoffmann-La Roche Ltd, Basel, Switzerland. Writing and editorial assistance for this manuscript was provided by Sven Holm, PhD, contractor for F. Hoffmann-La Roche Ltd. Up-to-date details on Roche's Global Policy on Sharing of Clinical Study Information and how to request access to related clinical study documents are provided [40].

Data Availability

Request for the data underlying this publication requires a detailed, hypothesis-driven statistical analysis plan that is collaboratively developed by the requester and company subject matter experts. Such requests should be directed to dbm.datarequest@roche.com for consideration. Anonymized records for individual patients across >1 data source external to Roche cannot, and should not, be linked due to a potential increase in the risk of patient reidentification.

Conflicts of Interest

AG, LK, and RL are employees of F Hoffmann-La Roche Ltd. ML is a consultant for F Hoffmann-La Roche Ltd via Inovigate. JBJ is an employee of Sutter Health's Center for Health Systems Research. He has received research grants from Genentech and AstraZeneca.

Abstract

Background: Deep pressure therapy (DPT) is widely used to reduce anxiety in children with autism spectrum disorder (ASD), but evidence of its efficacy is limited.

Objective: This study aims to design a usable, nonstigmatizing compressive armchair that can be easily controlled, electronically, by the user.

Methods: A user-centered approach was used to assess the usability of the device. Testing was carried out in a day hospital for children with ASD in France, with a convenience sample of children with severe forms of ASD and intellectual deficiency (N=39). The Witeman design guideline was used. The System Usability Scale and time of use were reported.

Results: The final product is a compressive armchair designed to be user centered, with 4 different cells that can be inflated to induce tailored pressure on the body. The pressure level is recorded electronically. Usability was between good and excellent. The device was used by 39 children, once or twice weekly, over a period of 31 months. Each session lasted between 3 and 20 minutes. The armchair takes up less space than a hug machine. Performing sessions with the chair is feasible.

Conclusions: First clinical impressions show a decrease in anxiety, improved emotional regulation, and improved attention. DPT is widely used in occupational therapy and frequently requested by parents, but efficacy studies are too scarce to make evidence-based recommendations for its use. The results presented here support further controlled efficacy studies of DPT in the treatment of anxiety in children with ASD.

KEYWORDS

deep pressure therapy; proprioception; compression; autism spectrum disorder

Introduction

Background

Autism spectrum disorder (ASD) is defined by (1) persistent deficits in social communication and social interaction across multiple contexts and (2) restricted, repetitive patterns of behavior, interests, or activities [1]. According to the American Psychiatric Association [1], the prevalence of autism is 1%.

Sensory difficulties are frequently found in individuals with ASD sensitivity [2], in particular somatosensory system difficulties such as aberrant skin sensitivity [3,4] (including pressure detection) and proprioception. These sensory anomalies could underlie the pathophysiological processes that lead to impaired social development [5].

Proprioception is the sensory registration of the ongoing spatial configuration of the body. It includes the position of the body segments in space, the force and the speed of movement, and the integration of gravity and body balance. Proprioception impacts behavioral regulation and motor control [6]. Blanche et al [7] showed that children with ASD present proprioceptive processing difficulties that are different from those of children with other developmental disabilities and their typically developing counterparts. However, Morris et al [8] and Fuentes et al [9] did not confirm these proprioceptive difficulties in experimental paradigms. It is possible that the deficits rely mostly on multisensory integration [10].

Sensory Integration Theory

Ayres et al [6] introduced sensory integration theory to explain sensory processing issues in children with ASD. The focus of

sensory-based intervention is to maintain an optimal level of arousal between hypo- and hyperstimulation, allowing the individual to respond to the environment in an adaptive manner [11,12].

Several techniques or devices can be used in sensory-based interventions, in particular deep pressure therapy (DPT); for instance, Wilbargers suggested a deep pressure and proprioceptive protocol [13]. Systematic reviews show that sensory integration therapies, which use play activities and sensory-enhanced interactions, have positive effects, but the quality of the studies is not sufficient to confirm these results [11,14]. Nevertheless, the American Occupational Therapy Association recommends the use of sensory strategies for individuals with ASD [12,14].

In a web survey involving 552 parents of children with ASD, Green et al [15] showed that sensory integration was the third most used treatment after speech therapy and visual schedules and before behavioral methods. In a survey involving 152 parents of children with ASD, Peña et al [16] reported high acceptability of sensory-based methods. These interventions were considered to be “very important” or “important.” Main barriers to the use of sensory-based methods were the lack of recommendations and difficulty in using or difficulty in accessing this kind of intervention [16]. Among these techniques, DPT was of particular interest.

Devices and Strategies for DPT

Different devices and strategies can be used to deliver DPT to patients with ASD (Table 1).

Table 1. Comparison of several devices used to induce deep pressure therapy in children with autism spectrum disorder.

Hug or Squeeze Machine

Krauss [35] used a pressure apparatus consisting of 2 stacked air mattresses to deliver DPT to 23 typically developing college students during an examination period. Heart rate and self-reported anxiety were measured using the State-Trait Anxiety Inventory. The control group did not receive DPT. There was no objective difference between the 2 conditions. Subjectively, participants in the deep pressure group reported a relaxing effect. The baseline level of anxiety in this population was low. The author did not exclude that the confinement alone may have induced subjective feelings of relaxation.

Grandin [41] developed a hug device to allow self-administration of lateral body pressure for individuals with high levels of anxiety. Edelson et al [36] tested this device on children with ASD (n=12). A control group received deep pressure via a disengaged hug machine. Participants had 20-minute sessions every week for 6 weeks. Arousal and anxiety was measured using the Conners Parent Rating Scale and electrodermal activity. The hug device decreased anxiety according to both behavioral and physiological measures. As pressure can be controlled by the individual, this device may be useful for children with marked anxiety. No side effects were reported.

The ergonomics of the device are an important issue [36,42]. Lo and Huang [38] interviewed professionals and patients, concluding that it was important to improve the ergonomic design of the device and its acceptability. For instance, it is necessary to lie down or to squat, which can be difficult for some children. The system is very bulky. The controller is outside of the machine and cannot be activated autonomously. It is not possible to choose the part of the body that the individual or professional wants to squeeze.

Lo and Huang [38] suggested a sitting hug machine that is more compact, controllable by the patient or the therapist, and can apply pressure selectively to either the shoulders or bottom part of the body. Stereotypies decreased during intervention for 2 children.

Afif et al [39] designed a portable, inflatable hug machine. It was tested on 5 children with ASD. They measured heart rate variability. They found that the inflatable wrap model decreased heart rate but could not find this effect with a manual pull [40].

This paper reports the design of a hug machine that aimed to (1) improve controllability of the pressure by the professional, allowing replicability and making the device useful for both care and research; (2) improve controllability of the pressure by the children or adults with ASD, allowing different pressure on the bottom and top of the body; (3) use pressure instead of restraint; and (4) be more attractive and less stigmatizing. This paper describes the design method and the device itself and evaluates the usability of the device.

Methods

Overview

In a population with special needs such as ASD with intellectual deficiency (ID), gathering children or adults with ASD feedback could be complicated by communication and social difficulties. It is important to have a tailored, user-centered strategy to improve acceptability and usability before assessing efficacy. Because many of the children were not verbal due to associated ID, we collected feedback from the professionals who guided and observed the children during the care. We also asked feedback from 1 adult with ASD. The first uses of the device were video recorded to tailor the design of the device to the needs of the patient and the therapist.

Design Goal and Process

Overview

The seat was designed by Alexia Audrain [43], a furniture maker, to address the needs of individuals with ASD for DPT (Figure 1). The project was carried out in partnership with the medical-educational institute of Blain, France, over a period of 1.5 years. After the review of existing technologies, we chose a sitting position that is natural and relaxing but allows one to be active. During the sessions, it allows the professional to keep an eye on the individual with ASD and facilitate the communication to better understand his needs. To assess the ergonomics of the shape of the chair, we tested several inclinations with a Sacco or a bean bag chair (a large fabric bag filled with polystyrene beans; Figure 2A). This allowed us to test several postures and choose one.

The educators, psychomotrician, and the director of the center identified the requirements of the device and gave feedback during the design process. The prototype consisted of inflatable cushions and was used to understand the amount of pressure required to verify the principle of action required to apply side pressure on the body and define the main technical characteristics (Figure 2B).

The sociomedical team (around 10 professionals) and a convenience sample of 30 children with ASD tested the prototype. The designer observed the behaviors of the professionals and children during the test and asked questions about the experience of using the device.

Based on the test results, different models of a compressive chair were designed and sketched in 3 dimensions to validate the form, the materials, and the colors of the prototype before construction. The first model was made in June 2019 and presented to medical-educational institute professionals, children, and the graduation committee. After this, the model was presented to a general audience and another medical educational institute (specialized educators, speech therapist, occupational therapist, and psychologist), Saint-Jean-de-Boiseau near Nantes, France, and was tested with 5 children. The device was also used with a nonverbal adult (30 y) with ASD.

Figure 1. Timeline of the design of the OTO chair. ASD: autism spectrum disorder; ID: intellectual deficiency; SUS: System Usability Scale.

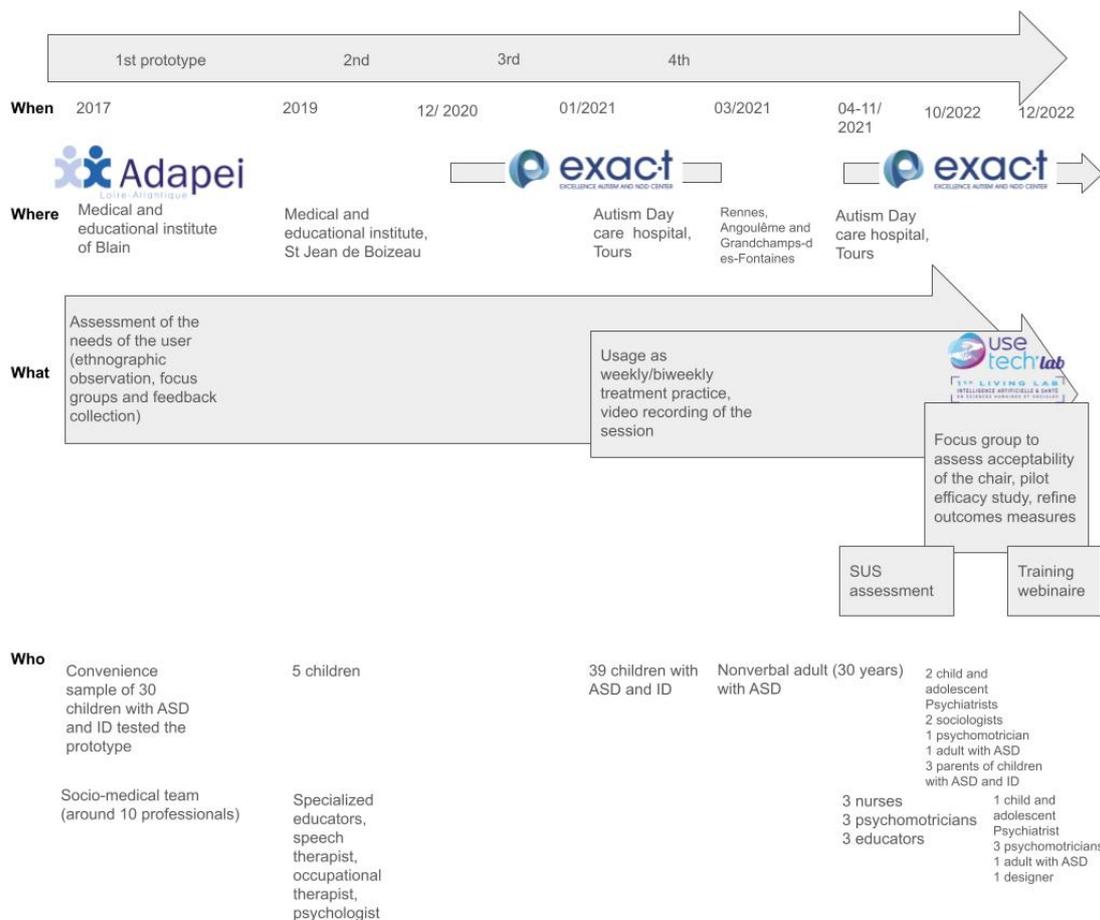

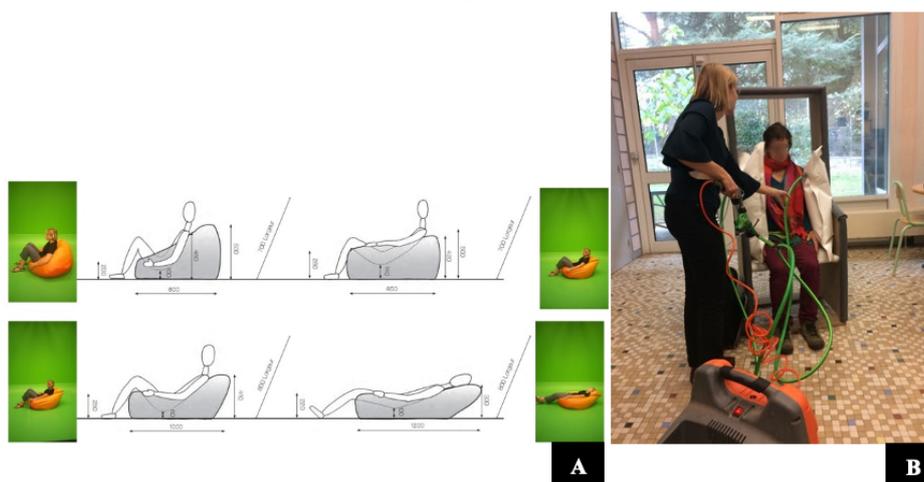

Figure 2. (A) Prototype of the OTO armchair and (B) evaluation of the ergonomics of the chair.

Testing Within the Hospital and Modification

In December 2020, OTO, a squeezing armchair, was presented to and tested by the Tours hospital team before introducing it for use in the hospital. The hospital team gave suggestions to enhance the experience of people with ASD.

New functionalities were added before the seat was installed in a day care hospital:

- Access to pressure measurement in real time for the professional
- Logging of pressure measurement, action used, and timestamp
- Seat operation monitoring and safety protocol in case of failure
- Remote control connected to the outside of the seat

Integration in the Ward

The device was transferred to the autism day hospital of the Excellence Center of Neurodevelopmental Disorders in the university hospital of Tours, France, in January 2021. After obtaining consent from parents, 39 children with ASD and ID used the device in everyday care (weekly or biweekly). The initial sessions were filmed, with pressure logs recorded by the device, in order to better understand its use in real life. The improvements made after these sessions include the following: cushions were tailored to the morphology of participants, deflation of the upper and lower cells was dissociated, a control panel was used to set the pressure limit, and the feedback light was deactivated because it was too stimulating for children. The noise accompanying inflation and deflation was reduced.

A second group of modifications were made after 2 months and implemented in March 2021:

- A range of different sizes of back cushion
- New cells with a different design for the upper and lower cells to adjust the squeezing effect
- New valves, pipes, and pump to reduce noise
- New remote design with 4 buttons to reduce air pressure independently in the upper or lower cells, and a light that can be deactivated
- A tablet connected to the seat that lets the professional define the maximum pressure

Between April and November, the seat was used in the hospital and tested for 2 months in services in Rennes, Angoulême, and Grandchamps-des-Fontaines. Based on the request of additional features from professionals in Tours and feedback from the 3 other services, some adjustments were made:

- Enhanced experience: easier on/off process, enhanced pressure measurement
- Noise reduction with valve modification and firmware adjustment

- Control panel enhancement, addition of a second remote
- Safety: continuous monitoring of program execution, error handling, and codification

Description of the End Product

OTO is a squeezing armchair that uses inflatable cells to induce deep pressure on the legs and the trunk (Figure 3; see video [44]). The pressure is progressive, measurable, and homogeneous and can be tailored for each child. Four different inflatable cells allow for modulation by varying pressures on either the shoulders, arm and trunk, or the hip and thighs.

The pressure can be controlled by the children via a remote with simple pictograms, which improves autonomy and predictability for the child. The control panel allows the children to set the maximum pressure level for the upper and lower cells. The maximum default pressure is 60 mm Hg for the upper cells and 80 mm Hg for the lower cells. This corresponds to the pressure a swimmer perceives 1 m under water. The seat records the use of the device with accompanying time logs.

The sitting position makes the device less bulky and allows more freedom of movement for the children, who do not need to lay down as they would in a hug machine. It allows the child to easily leave the armchair if uncomfortable. The footrest can be used to rest the legs, as a step for smaller children to enhance stability, and allow the health care provider to have the same height as the children and to maintain eye contact.

Pastel colors were used to limit sensory stimulation. Edges were avoided to make the armchair safer and more attractive. The device was developed to look like a cocoon to induce a feeling of privacy, to limit the stigmatization of its use, and to limit outside noise or light stimulation. The structure is made from beech wood with a metallic structure for the base. All cloth is removable and washable.

Figure 3. (A) OTO, a compressive armchair to induce deep pressure in children with ASD (final product) and (B) presentation of the different components of the OTO chair. ASD: autism spectrum disorder.

Measures of Clinical Impressions

Clinical impressions were collected via a logbook with visual analog scales and free report in a day care hospital.

Technology Readiness Level

The technology readiness level allows us to assess the level of maturity of a technology [45].

Human-Centered Design for Personal Health Tools

The Human-Centered Design for Personal Health Tools (UCD-11, a validated scale based on a systematic review of the design and development processes of 348 personal health tools) was used to assess the design process [46].

Time of Use

Beyond this design, it is important to assess the time of use of the device to assess acceptability in children and professionals. Here, it was measured by the chair.

Measure of Usability

Usability is very important when a system is used with children with special needs and should be assessed in real life [47]. The System Usability Scale (SUS) measured how psychometricians, nurses, and educators perceived the usability of the system [48]. The SUS has been used previously in autism and measures perceived usability from the perspective of professionals, rather than patients themselves [49]. It was measured in a day care hospital.

Feasibility of an Efficacy Study

We used the National Institute of Health and Care Research definition reported in first figure in the paper by Eldridge et al [50].

Ethical Considerations

As a design study, this type of research is not a clinical research, thus it is not subject to public health code and associated ethical rules, according to French regulations (Code de la santé publique - Article R1121-1; Legifrance).

Results

Usage

Recruitment was done between January and July 2023 in the ASD day hospital in Tours. A total of 39 children aged between 3 and 12 years with ASD and ID were included. Four children had to stop using the chair because of difficulties in tolerating noise, being in an enclosed space, or continuing anxiety despite habituation. These children had difficulties in sensory modulation and motor and emotional regulation. The system was adapted to decrease the inflation and deflation sound of the device.

The children used the remote heterogeneously. Some children controlled the remotes by themselves, and others relied on the professional. Different levels of pressure were used with different rhythms of pressure and deflation.

First Clinical Impression

First clinical impressions suggest an increase in pleasure and body relaxation, a decrease in anxiety, better postural stability, and better social contact (gaze and touch). When children came back to the group, it appeared that their attention and emotional regulation had improved.

However, in this population, there was marked intra- and interperson variability. A formal evaluation in a clinical trial with a larger sample and controlled procedures is required to formally assess the efficacy of the device.

Technology Readiness

The technology readiness level was between 8 and 9, meaning that the system can be used for several patients. Minor bugs and user-interface issues with the control panel need to be rectified.

Human-Centered Design for Personal Health Tools

We used several methods following the recommendations of UCD-11 (Textbox 1).

Textbox 1. Application of the Human-Centered Design for Personal Health Tools (UCD-11) during the design of the OTO chair.

1. Were potential end users (eg, patients, caregivers, family and friends, and surrogates) involved in any steps to help understand users (eg, who they are and in what context might they use the tool) and their needs?

- We performed (1) ethnographic observation of existing practices; (2) informal needs assessment; (3) contextual inquiry, (4) literature review summarized here, and (5) a training webinar to discuss with individuals with autism spectrum disorder (ASD) their sensory issues, needs, and how the OTO chair could be used in everyday life. A protocol to assess the efficacy was developed through a focus group led by sociologists. Several scales to measure outcomes were suggested during this focus group.

2. Were potential end users involved in any steps of designing, developing, and/or refining a prototype?

- After ethnographic observation of existing practices, psychometricians gave feedback after sessions with patients to help develop and refine the prototype.

3. Were potential end users involved in any steps intended to evaluate prototypes or a final version of the tool?

- We assessed usability among professionals (psychometricians, nurses, and educators) involved in guiding children during use of the OTO chair. The professionals gave feedback after the use of prototypes and again after the use of the final product.

4. Were potential end users asked their opinions of the tool in any way?

- We are finalizing focus groups with children, parents, and professionals (reported elsewhere) to assess the sensory issues of children with ASD and the use of different tools and techniques to tackle sensory issues in ASD.

5. Were potential end users observed using the tool in any way?

- The sessions were filmed to allow the designer to tailor the design of the chair to the needs of the children.

6. Did the development process have 3 or more iterative cycles?

- Four iterations were done.

7. Were changes between iterative cycles explicitly reported in any way?

- Major changes are reported in this paper.

8. Were health professionals asked their opinion of the tool at any point?

- Child and adolescent psychiatrists, psychometricians, nurses, and educators provided feedback. These professionals are the most likely to use the OTO chair with children. We gathered feedback on the usability of the chair and observed them using the tool.

9. Were health professionals consulted before the first prototype was developed?

- Ethnographic evaluations were carried out with professionals.

10. Were health professionals consulted between initial and final prototypes?

- After the prototype was developed, health professionals gave feedback, which was used to finalize the design of the product.

11. Was an expert panel involved?

- The armchair received several prizes from several committees:
 - The Canopé (€5000, being US \$5560), a national innovation competition organized by Forinvest and the Superior School of Wood, specialized in wood technology.
 - The St Pierre Foundation health innovation prize (€25,000, being US \$28,000). The St Pierre Foundation specializes in children's health, and the award is decided by a panel of medical professionals.
 - James Dyson award for design. Awarded by the James Dyson Foundation and decided by a panel of engineers.
 - Startup and innovation day prize, 2022. This prize recognizes innovative startups.
 - Crédit Mutuel 4S Semeur d'innovation 2023.
 - Caisse d'épargne mon projet innovant 2021.
 - French Tech Tremplin for innovative companies. Launched by people underrepresented in the tech industry.
 - Handitech trophy, awarded by the French Ministry of Health and French Ministry of Digital Technology.

Time of Use

In a day care hospital, the first sessions were habituation sessions of around 5 minutes. The system was used for 3-20 minutes weekly or biweekly, with 272 hours of total use in the ward. The system was always used with a therapist and never alone and planned around the schedule of the children.

Usability of the Product

The SUS was carried out with 9 professionals (3 psychomotricians, 3 nurses, and 3 educators) in July 2022 in a day care hospital. A mean score of 81 out of 100 was obtained (indicating between good and excellent usability), corresponding to a B score in a scale from A (best) to F (worst) [51].

Feasibility of an Efficacy Study

The feasibility of an efficacy study was determined as follows:

1. SD of the outcome measure, which is needed in some cases to estimate the sample size: We could not measure clinical data because of regulations; thus, it is not possible to estimate the sample size. The literature review found that results from a similar device tested on 12 patients supported our clinical impression.
2. Willingness of participants to be randomized: During a focus group in October 2022, parents of children using the chair and 1 autistic adult confirmed their interest in the device and their willingness to participate in an efficacy trial.
3. Willingness of clinicians to recruit participants: Clinicians in a day care hospital and 5 other centers expressed willingness to participate in an efficacy study.
4. Number of eligible patients: With a prevalence of 1%, ASD is quite frequently diagnosed. A lot of children with ASD also have sensory issues. The number of eligible patients seems large enough to conduct an efficacy study.
5. Characteristics of the proposed outcome measure: In the same focus group, in October 2022, the suggested outcome measure (Child Behavior Checklist) was not considered suitable as it was not considered specific enough. Other suggested outcome measures were considered relevant.
6. Adherence and compliance rates: There was good compliance with the device, with only a few dropouts during the early phase of design when the system was too loud for some participants. Most of the questionnaires are already used in clinical practice; others seemed acceptable by the focus group.
7. Availability of data needed: Most of the children in the center have a proper diagnosis. If recruitment is done in other centers, the absence of use of Autism Diagnostic Interview-Revised (ADI-R) and Autism Diagnostic Observation Schedule (ADOS) and poor experience of clinical research could be a limitation.
8. Time needed to collect and analyze data: Getting all the administrative authorization for a medical device in at-risk population (children with ID) and the prospective organization of an efficacy study, planned to run over 12 weeks, may make time management complicated.

Discussion

Overview

The process of development of an ergonomic compressive chair to induce deep pressure in children with ASD is described. The design was user centered according to the methodology of Witteman et al [46]. The system is considered usable by professionals according to the SUS.

User-Centeredness

This device was accepted by the clinicians and patients and their family. The system was primarily used by psychomotor and occupational therapists, but use by nurses and educators was also possible. It did not require the support of a technician. The goal was to increase the acceptability of the device and autonomy of the participant, as well as decrease the stigmatization associated with ASD and its care.

Armchair Use, Child Profile, and Time of Use

According to the experience of the psychomotricians and analysis of video footage by an independent clinician, usability was better for older children (>8 y). There were no side effects reported. Children could leave the armchair easily. If they experienced discomfort, the therapist was able to deflate the cushion.

The system was used in a small room with limited visual and auditory stimulation. Sometimes, professionals suggested children to use a neck cushion to improve relaxation.

Time of use shows that the device was included in everyday care and suggests that it would be routinely adopted in practice.

Future Plans

Acceptability

Ongoing focus groups and simulations with children, parents, and professionals will examine perspectives on sensory issues in ASD and the acceptability of different devices proposed for DPT and sensory therapy. This will provide more formal data on the perspectives of different users on the sensory peculiarities and needs of people with ASD, as well as solutions and the role of this compressive armchair as a therapeutic approach.

Randomized Controlled Trials

This device will enable further evaluation of DPT. In future, we plan to properly characterize and report the data of the individuals including precise diagnostic information (ADI-R and ADOS), their sensory profile and proprioception deficits [16], score on the Echelle des Particularités Sensori-psychomotrices dans l'Autisme (EPSA) scale [52], and underlying pathophysiological processes (eg, heart rate variability and electrodermal activity) using a wearable monitoring device to measure physiological data. To improve acceptability in children with most anxiety, it seems that the presentation of the device should be progressive.

Recruitment for a controlled efficacy study of DPT in ASD seems promising. We have received requests from teams of the original study to be involved in testing the device and expressing willingness to be involved in an efficacy study. Despite

complexity of administrative authorizations and time management of a prospective study, such a study seems feasible.

Limitations

Usability Testing

There is a consensus on the need to improve usability of devices in ASD but not on the methods used to measure usability [47]. The SUS is widely used to measure usability, but it can be difficult to use it in individuals with ASD. Thus, it can be amended for use in persons with autism or be filled in by the professional accompanying them [47,53,54]. Usually, the SUS questionnaire is filled in by the person using the system. Here, and in previous studies such as Zhong et al [4], usability was reported by the therapist. Amended versions of current usability tests or the development of alternative means of assessment would improve the assessment of usability.

We think that the time of use and feedback from experts (UCD-11, item 11) reported here and the simulations and focus groups with patients and their parents that we plan to report later are complementary methods that are in favor of a good usability.

Measures of Efficacy

This study does not allow any firm conclusions to be drawn about the efficacy of the device in reducing anxiety in ASD. However, this study showed that an efficacy study is feasible [50]. In future efficacy studies, it would be important to report the precise clinical profiles of children and their pressure needs. Because of the design and preliminary nature of the study, French regulations do not allow the reporting of clinical data.

Implication for Occupational Therapy Practice

This device has the potential to facilitate the design of well-conducted studies to better understand the rationale behind using and the efficacy of DPT in ASD.

Conclusions

We describe the design process, end product, and user feedback after the use of a compressive chair to conduct DPT in children with ASD. This device would allow the children or adults with ASD to better control the pressure and facilitate high-quality studies to understand the rationale behind using (role of proprioception) and the efficacy of DPT in reducing anxiety in children with ASD.

Acknowledgments

We would like to thank John Bost Research Foundation, which funded this study, and Eulalie Arnaud and Suzanne Heron for their careful reading of the text.

Conflicts of Interest

The device described in this paper is the intellectual property of Alexia Audrain.

Abstract

Background: The emergence and integration of mobile health care technology have fundamentally transformed the health care industry, providing unprecedented opportunities to improve health care services and professional practice. Despite its immense potential, the adoption of mobile health care technology among health care professionals remains uneven, particularly in resource-limited regions.

Objective: This study aims to explore the use and influencing factors of mobile health care among health care professionals in the Sichuan-Chongqing region of China and make recommendations.

Methods: Convenience sampling was used in a cross-sectional study conducted from November 8 to November 14, 2023, to survey frontline clinical health care professionals at 5 district-level secondary public hospitals in the Sichuan-Chongqing region. A web-based questionnaire was used to investigate the use of mobile health care and its influencing factors among the participants. Descriptive analysis and logistic regression analysis were used in the study.

Results: A total of 550 valid questionnaires were completed. Among the surveyed health care professionals, only 18.7% (103/550) used mobile health care, with a satisfaction rate of only 50.5% (52/103). Around 81.3% (447/550) did not use any form of mobile health care. The age group of 30 - 39 years was found to be a significant factor influencing the use of mobile health care by health care professionals ($P=.03$). The main reasons for not using mobile health care among health care professionals were lack of appropriate technical training and support (266/447, 59.5%), lack of suitable management-specific apps (204/447, 45.6%), and concerns about increased workload (180/447, 40.3%). There were significant differences in the single-factor analysis of the reasons for the nonuse of mobile health care among health care professionals from different specialties ($P=.04$). Logistic regression analysis indicated that age was the only significant factor influencing the use of mobile health care by health care professionals ($P=.04$).

Conclusions: The utilization rate of mobile health care among health care professionals in the Sichuan-Chongqing region is low. Age is a significant factor that influences whether health care professionals use mobile health care. Providing appropriate technical training and support may help improve the enthusiasm of health care professionals in using mobile health care.

Introduction

Currently, with the rapid development of internet technology both domestically and internationally, mobile health, mobile internet, health management, and medical system informatization have become hot research topics in China in recent years [1]. Internet health care refers to the integration of medical information and interconnectedness, encompassing

various forms of health care services such as medical information, electronic health records, disease risk assessment, web-based disease consultation, telemedicine, and rehabilitation. Mobile health care, on the other hand, combines internet health care with mobile apps, focusing on medical and health-related apps. As a new health care model actively encouraged by the government, mobile health care can better meet the increasing health care demands of the people and contribute to the realization of the "Healthy China" strategic goals.

In recent years, the aging process of the population in China has been accelerating, leading to an increase in the number of chronic disease patients. The application of mobile health care technology in the field of patient management is increasingly showing its key role, especially in improving work efficiency and patient satisfaction [2]. Traditional health care models face challenges due to factors like geography, economy, transportation, and facilities, complicating patient education and disease management for health care professionals. In contrast, mobile health care eliminates these barriers, enabling health care professionals to continuously track patient conditions throughout the entire disease management cycle, thus demonstrating its wide applicability and significant promotional value. In addition, the application of mobile health care technology not only enhances the accessibility and continuity of health care services but also provides patients with more personalized and convenient medical experiences, further promoting the innovation and progress of health care service models. However, in China, especially in rural areas, the grassroots medical and health information network is still not well established. Large level-III hospitals focus on the diagnosis and treatment of difficult and critical cases, leaving little energy for patient follow-up management. Therefore, we believe that using mobile health care for patient management deserves more attention and implementation from secondary general hospitals.

Previous research on mobile health care in China has primarily focused on the construction of telemedicine platforms and the development and application of mobile health care information systems [3,4], or on patient use patterns [5-7]. However, it has largely overlooked the fact that, within the realm of mobile health care, the acceptance and use by health care professionals are crucial determinants of patient engagement. Therefore, investigating both the adoption patterns and the factors influencing health care professionals' use of mobile health care technologies is essential.

From the perspective of the growth rate of the mobile health care market in China, the national growth rate has slowed down, and users in major cities have gradually become accustomed to using mobile health care. In contrast, in the southwestern region, particularly the Sichuan-Chongqing area—a key medical hub—the use of mobile health care by professionals not only affects the local service quality but also impacts the broader regional health care landscape. Despite this importance, studies focusing on this demographic within the region are absent. To address this gap, this study surveys the current use and influencing factors of mobile health care among health care professionals in the Sichuan-Chongqing area and provides recommendations. This study is not just about mapping the current use of these technologies. It is about understanding the factors that encourage or deter health care professionals from adopting mobile health tools in their daily practice. By focusing on this underexplored area, our findings aim to inform more than just policy—it is about enabling better health outcomes and shaping a future where health care reaches everyone efficiently and effectively in the region.

Methods

Study Design and Participants

This was a cross-sectional survey study conducted using convenience sampling. From November 8 to November 14, 2023, a web-based questionnaire survey was conducted among frontline health care professionals. This study investigated 5 district-level secondary public hospitals based on geographic location and population density (million-level population density): 3 located in central urban areas, specifically Chongqing Jiangbei District People's Hospital, Chongqing Jiulongpo District Second People's Hospital, and Sichuan Chengdu Chenghua District Third People's Hospital; and 2 situated in more distant districts, namely Chongqing Shapingba District Chenjiqiao Hospital and Sichuan Anyue County Third People's Hospital. Prior to the survey, all participants were informed that their participation in this survey was voluntary, and they were informed of the purpose and significance of this survey research. The questionnaire survey was completed anonymously using the platform QuestionStar. All data were anonymized.

Data Collection

This study used a self-designed questionnaire survey, which included the following aspects: (1) general information about the participants: sex, age, education background, professional title, occupation, and major; (2) whether they use mobile health care; (3) use of mobile health care: the name of the tool used, its functions, and frequency of use; (4) factors influencing the users: work efficiency, patient compliance, health outcomes, advantages, challenges, satisfaction, and areas for improvement; and (5) reasons for nonusers: lack of appropriate training and technical support, concerns about patient data privacy and security issues, concerns about increased workload due to web-based apps, lack of suitable apps for specific management purposes, negative or unwilling patient response, and lack of awareness of the potential benefits of web-based apps.

Statistical Analysis

All data were organized and analyzed using SPSS software (version 18.0; IBM Corporation). Continuous and normally distributed metric data were presented as means and SDs, while nonnormally distributed metric data were presented as medians and IQRs. Categorical data were presented as frequencies and percentages. A chi-square test was used to analyze the correlation between the general characteristics of the participants and the use of mobile health care, as well as the reasons for nonuse. Multivariable logistic regression analysis was conducted to identify the factors influencing the use of mobile health care. A significance level of $P < .05$ was considered statistically significant. The reliability of the self-designed questionnaire was assessed using the Cronbach α .

Ethical Considerations

The study was discussed by the Ethics Committee of Chongqing Red Cross Hospital (People's Hospital of Jiangbei District), which determined that the research involves the use of human information data but does not cause physical harm, nor does it involve sensitive personal information or commercial interests. Consequently, this study was exempted from ethical review [8].

Results

Background Characteristics

The participants in this survey were identified as frontline clinical doctors or nurses, interns, and residents. A small sample questionnaire test was conducted first to assess the reliability of the self-made questionnaire, which showed good reliability (Cronbach $\alpha=0.92$). The final formal questionnaire was then

determined, and a large sample was collected. A total of 556 health care professionals completed the survey, with 550 valid questionnaires, resulting in a valid response rate of 98.9%. The age of the participants ranged from 18 to 59 years, with an average age of 33.24 (SD 7.02) years. Females accounted for 77.1% (424/550) of the participants. A total of 82% (451/550) of the medical personnel had received undergraduate or higher education, 30.2% (166/550) were nurses, and 64.4% (354/550) were doctors (Table 1).

Table 1. Background characteristics of respondents.

Variable	Values

Specific Use of Mobile Health Care

According to the survey, only 18.7% (103/550) of health care professionals use mobile health care. The most commonly used platforms include "PDA, Yi Doctor, Yi Nurse, and WeChat," accounting for 44.7% (46/103) of the total. There are also various other mobile health care platforms such as "Micro Doctor, Good Doctor, 317 Nurse, JD Doctor, Creative Doctor, Doctor's Palm, Doctor's Circle," and so on. The main function

used is patient record management, accounting for 78.6% (81/103). The use frequency is at least once a day, accounting for 57.3% (59/103). The majority of respondents believe that using mobile health care can improve work efficiency, improve patient compliance, and enhance patient health. However, the satisfaction rate is only 50.5% (52/103), with the main areas for improvement being data security and training support (Table 2).

Table . Use of mobile health care.

Use status	Values, n (%)
Function used

Univariate Analysis for Whether to Use Mobile Health Care

Around 81.3% (447/550) of surveyed health care professionals did not use any mobile health care. Age, particularly the 30 - 39 years age group, was found to be a significant factor influencing

whether health care professionals use mobile health care ($P=.03$). Other factors such as gender, education level, professional title, occupation, and specialty did not have a significant impact on the use of mobile health care among health care professionals, with no statistically significant differences observed (Table 3).

Table . Univariate analysis of factors influencing the use of mobile health care among medical personnel.

Factor	Used (n=103)	Not used (n=447)	Chi-square (<i>df</i>)	<i>P</i> value
Sex, n (%)			0.024 (1)	.88
Male	23 (4.2)	103 (18.7)

Multivariable Logistic Regression Analysis for Whether to Use Mobile Health Care

Multivariable logistic regression analysis was conducted with health care professionals' use of mobile health care as the

dependent variable (1 for use, 0 for nonuse) and gender, age, education, professional title, occupation, and major as independent variables. The results showed that age was the only significant factor influencing the use of mobile health care by health care professionals ($P=.04$) (Table 4).

Table . Multivariable logistic regression analysis of factors influencing health care professionals' use of mobile health care.

Independent variables	B ^a	SE	Wald chi-square (df)	OR ^b (95% CI)	P value
Sex	0.053	0.272	0.038 (1)	1.054 (0.619 - 1.796)	.85
Age	0.5	0.237	4.439 (1)	1.648 (1.035 - 2.624)	.04
Education background	-0.278	0.201	1.91 (1)	0.757 (0.511 - 1.123)	.17

Major	-0.105	0.066	2.482 (1)	0.901 (0.791 - 1.026)	.12

^aB: regression coefficient.

^bOR: odds ratio.

Analysis of Reasons for Not Using Mobile Health Care

The common reasons identified through the presurvey for healthcare professionals not using mobile health are as follows: lack of appropriate technical training and support (266/447, 59.5%), lack of suitable management for specific applications (204/447, 45.6%), concerns about increased workload (180/447, 40.3%), concerns about patient data privacy and security (165/447, 36.9%), ambiguity regarding the potential benefits of web-based applications (164/447, 36.7%), negative reactions or unwillingness from patients (135/447, 30.2%), and other reasons (74/447, 16.6%).

Main Reasons for Health Care Professionals Not Using Mobile Health Care

Single-factor analysis of factors influencing health care professionals' nonuse of mobile health care showed no

significant differences in reasons for nonuse based on sex, age, educational background, professional title, and occupation. However, there were certain differences in reasons for nonuse among different majors ($P=.04$). The main reasons for nonuse among clinical department personnel were lack of appropriate technical training and support, lack of suitable management apps for specific types, and concerns about increased workload. The main reasons for nonuse among ancillary department personnel were lack of appropriate technical training and support, lack of awareness of potential benefits of web-based apps, and lack of understanding of potential benefits of web-based apps. The main reasons for nonuse among public health and other department personnel were lack of appropriate technical training and support, lack of suitable management apps for specific types, concerns about patient data privacy and security, and lack of awareness of potential benefits of web-based apps (Table 5).

Table . Single-factor analysis of reasons for health care professionals' nonuse of mobile health care.

	Lack of appropriate technical training and support	Concerns about patient data privacy and security	Concerns about increased workload	Lack of suitable management-specific apps	Patients have negative reactions or are unwilling	Not clear about the potential benefits of web-based apps	Others	<i>P</i> value
Sex, n (%)								.75
Male	60 (58.3)	40 (38.8)	45 (43.7)	44 (42.7)	26 (25.2)	41 (39.8)	13 (12.6)	
Female	206 (59.9)	125 (36.3)	135 (39.2)	160 (46.5)	109 (31.7)	123 (35.8)	61 (17.7)	
Age, n (%)								.96
<30	81 (54.0)	52 (34.7)	59 (39.3)	56 (37.3)	42 (28.0)	56 (37.3)	28 (18.7)	
30 - 39	143 (62.2)	86 (37.4)	94 (40.9)	117 (50.9)	76 (33.0)	84 (36.5)	37 (16.1)

Discussion

Principal Findings

The global COVID-19 pandemic has greatly increased the use of mobile health care in many countries, especially among populations at high risk, such as those with chronic underlying conditions [9]. The demand for mobile health care has surged, but this study found that the use of mobile health care among frontline health care professionals in the Sichuan-Chongqing region is generally poor, with a use rate of only 18.7% (103/550). Similarly, a study by Zhu et al [10] found that only 12.6% of health care professionals have used smart apps. Furthermore, we found that the satisfaction rate among health

care professionals who use mobile health care is only 50.5% (52/103), indicating a need for significant improvement in training support and data security. Among nonusers, there are some differences in reasons among different professions, but the main reasons include the lack of appropriate technical training and support, as well as the lack of specific management apps. Therefore, the most prominent issue for surveyed health care professionals, regardless of whether they use mobile health care or not, is the lack of technical training and support.

It is necessary for health care institutions to provide relevant training for health care professionals in using mobile health care. Research has shown that 95% of respondents had not received any training before using mobile health [11], and

leadership support and training for health care professionals are crucial in providing mobile health services [12,13]. In this study, the most commonly used mobile health care by health care professionals were “PDA, Yi Doctor, Yi Nurse, and WeChat,” all of which benefited from the unified requirements of the hospital leadership. Other health care professionals also used apps such as “Good Doctor, WeDoctor, 317 Nurse” on their own. A total of 75.7% (78/103) of respondents believed that there are limitations and risks in using personal mobile devices, and the privacy and data security of patients need to be protected. This is similar to the findings of Rowe-Setz et al [14]. Therefore, the popularization of mobile health care requires leadership to lead the development of relevant policies and guidelines, provide practical training for employees, and ensure the smooth and efficient use of technical devices. The content should include specific coverage of the following aspects: (1) basic operations of mobile health care, data security, privacy protection, and how it can help doctors enhance their value and improve their professional skills; (2) provision of real-life cases and user feedback to demonstrate how mobile health care can help health care professionals save time and energy, and enhance job satisfaction; (3) ensuring good integration of mobile apps with existing hospital information systems to avoid duplicate data entry and operational redundancy, thereby reducing workload; (4) establishment of a technical support hotline or web-based platform to promptly address issues and concerns encountered by health care professionals during app use; and (5) in addition to regular training courses for health care professionals, establishment of various guidelines to support mobile health care activities. When mobile health care services are regularly scheduled, they become part of daily work, just like any other familiar operational aspect in the workplace, thereby improving the technical capabilities of professionals. Implementing the above suggestions may help health care professionals overcome barriers to using mobile health care, enhance their willingness and ability to adopt mobile technologies, and promote the digital transformation of health care services and the improvement of health care quality.

Although 81.3% (447/550) of health care professionals surveyed did not use any mobile health services, this does not mean that they lack the willingness to use them. Research has shown that health care professionals have a high acceptance of mobile health services [15]. The lack of use despite the intention is based on the consideration of costs and benefits, which are referred to as perceived benefits. It is also mentioned that building a personal brand for doctors has a positive impact on their willingness to use mobile health care [16,17]. However, there are some health care professionals who hold negative and skeptical attitudes and do not want to acquire the new skills required for mobile health care. Leaders need to try to influence their attitudes and the atmosphere of the workplace to make their use of mobile health care more positive.

The proliferation of mobile health care apps has provided users with more choices, but the wide variety and varying quality of these apps have increased the difficulty for health care

professionals to select the right app for managing specific diseases. There have been studies exploring the feasibility of using mobile health care for chronic disease management [18,19]. Therefore, it is important to focus on developing personalized mobile apps tailored to specific medical fields such as hypertension, diabetes, and stroke for effective chronic disease management. The design of mobile health care programs should prioritize the involvement of health care professionals [20], enabling them to better manage patients; promote a shift from doctor-patient relationships to partnerships; and facilitate interdisciplinary team collaboration, patient education, and information sharing across different health care institutions for the same disease. This approach aims to meet the specific needs of health care professionals and achieve the goal of comprehensive management with a patient-centered approach for long-term follow-up care.

Pay attention to seed users and fully tap into the potential user base. Among Chinese mobile phone users, young users account for over 90%. The results of this study show that age, especially the 30 - 39 years age group, is a significant factor influencing whether health care professionals use mobile health care. The middle-aged and young user group is large in size, has a strong demand for medical and health services, is more receptive to new things, and has a higher interest in smart apps [21,22]. This suggests that focusing on health care professionals in the 30 - 39 years age group as seed users for targeted attention and promotion may achieve more significant results.

Limitations

In this study, a convenience sampling method was used, limited to health care professionals in secondary public hospitals in the Sichuan-Chongqing region, which may not fully reflect the situation of health care professionals in other regions or hospitals of different levels. In future research, random sampling or stratified sampling methods could be considered to improve the representativeness of the sample. Additionally, efforts should be made to expand the scope of the study to include more regions and different types of hospitals in order to obtain more generalizable research results.

Conclusion

This survey reveals that frontline health care professionals in the Sichuan-Chongqing region have low use of mobile health care, primarily due to a lack of training support and concerns about data security. Health care professionals have the intention to use it but need to address the cost-benefit issue. It is recommended that leadership provide training support, establish policy guidelines, influence attitudes, and create a positive atmosphere. Emphasis should be placed on the development of personalized applications in the field of chronic disease management, with a focus on the participation of young health care professionals. In summary, efforts should be concentrated on improving training, addressing security concerns, and strengthening leadership guidance to promote the application of mobile health care in the Sichuan-Chongqing region.

Acknowledgments

Thanks are due to Jun Qian and Jian Wang for their valuable assistance with the work. This study was supported by the Chongqing Science and Health joint medical research project (2022MSXM121).

Authors' Contributions

YT, NW, XW, and WLH carried out the studies, participated in collecting data, and drafted the manuscript. YT and JY performed the statistical analysis and participated in its design. All authors participated in the acquisition, analysis, or interpretation of data and drafting of the manuscript. All authors read and approved the final manuscript.

Abstract

Background: Connecting individuals to existing community resources is critical to addressing social needs and improving population health. While there is much ongoing informatics work embedding social needs screening and referrals into health care systems and their electronic health records, there has been less focus on the digital ecosystem and needs of community-based organizations (CBOs) providing or connecting individuals to these resources.

Objective: We used human-centered design to develop a digital platform for CBOs, focused on identification of health and social resources and communication with their clients.

Methods: Centered in the Develop phase of the design process, we conducted in-depth interviews in 2 phases with community-based organizational leadership and staff to create and iterate on the platform. We elicited and mapped participant feedback to theory-informed domains from the Technology Acceptance Model, such as Usefulness and Ease of Use, to build the final product and summarized all major design decisions as the platform development proceeded.

Results: Overall, we completed 22 interviews with 18 community-based organizational leadership and staff in 2 consecutive Develop phases. After coding of the interview transcripts, there were 4 major themes related to usability, relevance, and external factors impacting use. Specifically, CBOs expressed an interest in a customer relationship management software to manage their client interactions and communications, and they needed specific additional features to address the scope of their everyday work, namely (1) digital and SMS text messaging communication with clients and (2) easy ways to identify relevant community resources based on diverse client needs and various program eligibility criteria. Finally, clear implementation needs emerged, such as digital training and support for staff using new platforms. The final platform, titled “Mapping to Enhance the Vitality of Engaged Neighborhoods (MAVEN),” was completed in the Salesforce environment in 2022, and it included features and functions directly mapped to the design process.

Conclusions: Engaging community organizations in user-centered design of a health and social resource platform was essential to tapping into their deep expertise in serving local communities and neighborhoods. Design methods informed by behavioral theory can be similarly employed in other informatics research. Moving forward, much more work will be necessary to support the implementation of platforms specific to CBOs’ needs, especially given the resources, training, and customization needed in these settings.

Introduction

Research supports expanding screening and referral for social needs within health care systems [1]. Approximately 20% of health outcomes are associated with medical care, while the remaining influences are social, community, and structural factors—sometimes referred to as social needs and the broader social determinants of health [2]. Health systems need to work collaboratively with community-based organizations (CBOs) to address unmet social needs that affect health and health care outcomes [3].

Much of the research to date has focused on health care system electronic health record (EHR)-based platforms that can send and receive information from community organizations about social needs resource referrals, such as new EHR screening tools to assess social needs domains like food or housing insecurity, as well as EHR-integrated platforms that can recommend and connect patients to relevant programs in the community. There is emerging evidence that these EHR-based platforms can improve screening and referrals, but downstream impacts on health care and health outcomes are less clear [4]. However, there is a need for better digital platforms explicitly *within* CBOs that identify or connect clients to social and community resources to promote health. Even though CBOs communicate with community members about health and social needs and connect clients with other community resources, they have much different workflows than clinicians and staff in health care settings and they do not have access to existing EHR platforms. Digital design focused outside of the health care system is essential to contributing to a future broader ecosystem of referrals and connections between community organizations, social services agencies, public health agencies, and health care settings [5].

We employed human-centered design methods to build a platform to support CBOs in understanding client social resource needs and connecting them with the most relevant resources in neighborhoods within San Francisco. We outline here our design methods and the concrete platform build decisions that emerged from our work with community organizations, as both the methodological approaches and the design features from this work are relevant for other organizations and projects focused on social and health needs.

Methods

Study Design

As a part of a 4-year National Institutes of Health project titled “Mapping to Enhance the Vitality of Engaged Neighborhoods (MAVEN),” we built and then pilot-tested a digital platform for CBOs serving communities within the San Francisco Bay Area. While this project focused on specific health and social resource referrals in San Francisco, the design methods as well as the final platform characteristics are relevant for many other communities working on the same questions and processes for CBOs. This work was informed by the Double Diamond design framework throughout all phases of the study [6]. We have previously published the Discovery and Define phases of this project, in which we conducted extensive qualitative work with

community members and community leaders to identify the core audience and design principles for this work. In brief, in the Discovery phase, we highlighted CBOs as the pivotal audience for digital platform development (given their central role in resource provision and trusted roles within their communities) [7]. Then, the Define phase highlighted the need to build a broad and scalable digital platform to support resource needs in multiple domains and for diverse sets of clients or populations served [8]. In the next Develop phase of work outlined here, we focused on the final build of the MAVEN digital platform.

While not all design studies are theoretically oriented, we combined the rigorous design methods with a well-established theory to additionally bolster the rigor of the work and further enhance the generalizability of the study. In particular, we used the Technology Acceptance Model to frame our interview guides and analysis [9]. This theory summarizes core concepts of technology acceptance and use into major domains, such as Ease of Use and Usefulness, which have been validated in many previous studies assessing how and why technologies are adopted [9]. Thus, the addition of theory to our design work allowed us to ensure that participant feedback was consistently documented and categorized against validated constructs throughout the study.

Building the MAVEN Platform: the Develop Phase

In the Develop phase, we completed 2 iterative rounds of design with CBOs in the San Francisco Bay Area (interview guide available in [Multimedia Appendix 1](#)). First, we completed 8 interviews with CBOs in late 2020 and early 2021 to understand their existing workflows using digital or online platforms to track and communicate with their clientele. At the end of these open-ended discussions, we also asked community leader participants to look at example digital resources to explore the features and relevance of these type of platforms in their everyday work. For example, community leaders reviewed websites with resources (such as on SF Department of Children, Youth and Their Families), providing overall opinions about usability as well as the types of information and content they might want to see displayed [10]. This phase was primarily open-ended and hypothetical, given that the platforms shown to participants were not always relevant for their own work. The interviews were conducted and recorded via Zoom (Zoom Video Communications, Inc), with the audio then converted into text via professional transcription.

After this round of feedback was completed, we created a minimal viable product (MVP) of the MAVEN social resource tool for CBOs and conducted additional co-design interviews. An MVP is a standard step in the design processes in which the team creates the simplest working prototype that can be tested, which is critical before more intensive digital building [11]. The MVP was created in spring 2021, and we completed an additional 13 think aloud interviews with CBO leaders to test the MVP in May and June 2021 [12]. These video interviews were conducted and recorded via Zoom, and the audio was then professionally transcribed. The think aloud process asked each participant to navigate the MVP on their own sequentially through each task or feature in the platform (eg, logging in,

adding clients, sending a communication to a client), with prompts at every task that elicited technical errors or roadblocks as well as participants' overall opinions and reactions to the MVP.

Data Analysis

We used qualitative descriptive methods to complete our analyses within the Develop phase of the work, combining the participant feedback across all iterations of the platform build [13]. The text of transcribed interviews was analyzed using Dedoose (SocioCultural Research Associates) qualitative analysis software, and the second-round interview transcripts were also compared side by side with videos of the MVP think aloud procedures. Using open coding, we first identified overall patterns of feedback from participants, holding regular team meetings to establish consensus on the major usability and content feedback categories that emerged (ie, specific feature needs and preferences, technical barriers to use). Next, we mapped these categories onto Technology Acceptance Model domains to examine how the overall discussion categories were related to documented theoretical constructs such as relevance or usefulness as well as ease of use of the platform.

Finally, we made overall design decisions informed by these qualitative findings to incorporate into the final MAVEN platform. More specifically, we used the data from both rounds

of feedback to prioritize new functionality that needed to be added to the platform, as well as improvements or changes in the MVP features that would improve relevance or usability. These design changes are summarized here, with the final MAVEN tool completed in the spring of 2022.

Ethical Considerations

This study was approved by the University of California San Francisco (institutional review board no. 18 - 25696). The participants provided written consent for the interviews to be audio and video recorded, and the transcripts were deidentified prior to the analysis. Each participant was compensated US \$75 per interview.

Results

Study Sample

We completed 22 in-depth interviews (9 in the first phase and 13 in the second phase of the study), with 18 unique CBO leaders and staff in total (4 participants were interviewed in both phases of work). The 18 participants in the Develop phase of the MAVEN project work ranged from individual consultants working on multiple health campaigns in their local neighborhoods to mid-sized nonprofit organizations running programs and provisioning services in their communities. The full summary of participants is shown in [Table 1](#).

Table . Summary of community-based organizations staff or leader participants.

Phase	Organization type	Participant title or role	Location
1	Nonprofit	Director of community partnerships and program evaluation for HIV programs	San Francisco, CA
1	Nonprofit	Agent and disability resource specialist	Mission Neighborhood, San Francisco, CA
1	Nonprofit	Information and assistance specialist	Mission Neighborhood, San Francisco, CA
1	Nonprofit	Program director, women's cancer program	Tenderloin Neighborhood, San Francisco, CA
1	Nonprofit	Program coordinator, HIV/AIDS programs	San Francisco, CA
1, 2	Community advocate	Health educator and activist	San Francisco Bay Area, CA Los Angeles, CA
1, 2	Nonprofit	Senior services manager	Mission neighborhood, San Francisco, CA
1, 2	Local planning council; nonprofit	Member; senior director of programs	Tenderloin neighborhood, San Francisco, CA
1, 2	Nonprofit	Executive director	San Francisco, CA
2	Local government housing or community organization	Director, social/health resources	Tenderloin neighborhood, San Francisco, CA
2	Regional advisory group; local government organization	Advisory member; HIV case manager	Alaska, Hawaii, California
2	Nonprofit	Program director, senior services programming	San Francisco, CA
2	Local government housing or community organization	Program director, digital programming	Tenderloin Neighborhood, San Francisco, CA
2	Community advocate	Community health/HIV activist	San Francisco, CA
2	Local government Public health department	Community health outreach/HIV activist	Alameda, CA
2	Federally qualified health center	Health educator	Marin City, CA
2	Nonprofit	Wellness manager	Bay View Neighborhood, San Francisco, CA
2	Public research university system	Health equity strategist/consultant	San Francisco, CA

Qualitative Results

Analyzing all in-depth interviews during the Develop phase, we identified 4 major themes from community leader participants, which are mapped to the Technology Acceptance Model domains of Usefulness, Ease of Use, and External Factors influencing use.

Overall Usefulness

In the domain of usefulness, there was consensus that access to technology platforms with the ability to track clients across programs and communicate with clients more seamlessly was a priority for CBOs. Several of the organizations' current workflows involved using out-of-the-box and free programs for their daily work of tracking clients, finding and referring people to resources, and communicating with clients. While existing platforms allow digital communication with clients and tracking

client contact information or program participation, the standard work was often nonintegrated and potentially duplicative. For example, one participant stated:

If you want to refer somebody or some participant to other services,...you can Google it and just find out the exact address and telephone that they can call. I think it's the best tool that we can have now to just give more information and referrals.

It was clear from these participants that better functionality beyond free platforms would improve their daily work at CBOs, such as by standardizing the search and communication workflows into a single place.

More specifically, there was an understanding among community leaders that existing consumer or customer resource management (CRM) platforms, such as Salesforce (Salesforce, Inc) and other similar CRM software, were important to be able

to complete multiple client functions together—such as tracking clients and communicating with clients (individually or in groups) without toggling between multiple different platforms. For example, one participant stated:

I love [seeing]...a lot of information and a lot of resources at the same time. So, I don't have to look for another screen and start looking for another information for the clients.

Thus, any CRM platform that combined database management for clients alongside communication tools was mentioned as more ideal for CBO workflows. Specific to the selection of a CRM software, participants most often mentioned Salesforce as the platform of interest (either currently in use or a wish for use in the near future): “I think at least 50% [of organizations we partner with] are using some portion of Salesforce [with] their clients.”

Relatedly, the usefulness of up-to-date lists of community-based resources was a top priority for almost all participants. For example, one community leader stated, “I think that [technology] would be a good way to maybe have a resource list of frequently used CBOs [and resources they provide].” Similarly, another participant stated:

I think being able to see what [resource] is available—and I think if this stuff is updated in real time, it's super helpful.... Having specific contacts [at each organization] for different opportunities/[resources] is really key just because I think that's often something that people spend a lot of time trying to determine.

However, it was clear that this registry of community resources would require upkeep and trust in the resources presented. For example, a participant mentioned:

[A registry of] existing community resources—that's a lot to keep up-to-date. And if you just don't have it, then you're not disappointing people [clients].

A final useful function of a platform for CBOs centered around communication with clients. Comments such as these solidified the need to have integrated and customizable communication with clients as a core function of the platform: “You...have subgroups of different clients depending on what the [program] is, and then you would just create a new [communication] for whatever thing you were doing,” and “I feel like, just knowing colleagues at other places, a lot of people are paying money for text and email blasts.”

Overall Ease of Use

Next, there were a number of usability issues that emerged during the interviews.

In addition, when interacting with the early MVP of the MAVEN platform, there were several usability comments made about the layout and the terminology, especially in the context of community-oriented work. One participant stated it as:

I just want to make sure that [you know that] some of these words that you're using are a little technical.... Maybe finding other words...that will

describe something that's more simple and easier to find.

And another participant mentioned:

Since it's our first time, it's going to be difficult just to find everything, but once you get to know it, I think just it's going to take less than a week just to see and working with the database or with the website.

While the overall usability ratings of the MVP were favorable, there were several areas of improvements that community leaders mentioned that were specific to increasing the usability of a platform that served diverse clients and were necessary in many CBOs' workflows. First, participants identified a need to have easier ways to find recommended resources for clients, as exemplified in comments such as:

[Make it] easy to find if it's in alphabetical order or has some kind of a search engine that I could put in 'Help with income taxes' or 'Grocery shopping' or whatever the [client] needs.

Similarly, another participant stated that it is important to ensure that referrals to resources match their participants' eligibility and identity:

[To make sure] you could search by eligibility requirement, whether it's senior citizen, or HIV-positive, or somebody who identifies as LGBTQ.

Next, participants identified clear, equity-focused improvements to the platform, especially around language accessibility and sociodemographic representation of fields (particularly careful collection of sexual orientation and gender identity data for LGBTQ+ populations). For example, one participant stated, “When I talk about cultural sensitivity, like I said, it's not just a language also. If it's from LGBTQIA community or different cultures, it's very, very important. Age also is another issue,” and another stated, “I know that many agencies have different [languages], for example, Chinese and English, also, Russian and English, Spanish and English.... So, it should be in multiple languages.”

External Factor: Varying Implementation Contexts Within CBOs

Finally, there were many external factors that emerged as critical to use of the MAVEN platform. These comments generally focused on the implementation context for using such a digital platform.

First, there was a clear need to focus on digital skills and necessary training among CBO staff. For example, participants stated, “We know Salesforce has really high potential, but we don't have the time to learn it all.... So, we don't use this fancy thing because it was just too overwhelming to use, to learn it and so we're just comfortable with what we know,” and “I feel like there's certainly a spectrum of computer literacy across my team, and so I think getting folks that are less technologically adept onboard for using something like this could be a little bit challenging, but I don't think it would be that hard.”

Participants also discussed that no platform would be successful without leadership support as well as very detailed training among frontline staff. For example, participants stated, “I feel

like it’s important to have a collective buy-in or an agreement or some kind of commitment to using a certain resource to sort of get it off the ground,” and “Oftentimes, there are lots of tools that you will get sent that will be given to somebody but I think they’re only as good as the people that are using them.” Furthermore, there were common comments about on-the-ground support for staff members at CBOs such as, “I was thinking more training for community leaders in how to really effectively use this tool.”

In addition, there were more nuanced conversations with CBOs about their current workflows with clients that needed to be considered in order to get uptake of a new system. In particular, because CBO staff used in-person and phone outreach often for clients, any digital tool would require consideration of how to blend such high-touch, face-to-face communication with the lower-touch messaging and reminders that digital platforms can facilitate. Quotes such as these exemplified this idea:

So it’s about having a conversation with the client and understanding how they best connect the services and also what barriers may be in the past they have faced when trying to connect with other providers and sort of strategizing ways to circumvent those challenges.

Comments from CBOs about their workflows highlighted that even a perfect digital solution that easily facilitated messaging may supplement but not replace high-touch conversations with clients about their preferences for resources.

Finally, some of the conversation about implementation centered around 2 additional points that related to the overall uptake and dissemination of any platform. The security and privacy of information in any client database was critical, especially given the sensitive information disclosed by clients and the known predatory behavior of hackers and other criminal behavior. This was exemplified in the following quote: “Organizations may take advantage of...elderly patients.” Moreover, the implementation considerations for wider spread and uptake of digital platforms for health and social needs also centered on the practical work of maintenance, which cannot be overlooked. For example, one participant stated:

There is a lot of movement that occurs in public service organizations that having the most up to date data or contacts could be a concern and a lot of work on us to continue to update.

In other words, the ability to use existing resource lists that are actively updated and monitored for relevance is essential for implementation and will not be solved by a technical solution alone.

Final Design Decisions and Build

Given the qualitative findings across both the open-ended and MVP testing of the MAVEN platform, we made multiple design decisions that reflected the community-based organizational leadership input and preferences. Overall, we chose to design within Salesforce, activate several features within the platform, and then integrate outside tools to provide information and tools within the platform. Table 2 summarized core findings matched to concrete features or changes within the MAVEN platform.

Table . Major design needs from co-design feedback.

Design needs identified by participants	Subsequent feature or design decision
<i>Platform need:</i> Community leaders used or wanted CRM ^a platform to manage their clients and workflows.	Selection of Salesforce platform for MAVEN ^b build.
<i>Feature need:</i> Community leaders had knowledge of social or health resources but strongly desired a trusted and easy-to-use directory to improve client resource referrals.	Review of several options for an up-to-date list of community resources; selection of San Francisco Service Guide existing resource list (imported into MAVEN via API ^c).
<i>Feature need:</i> Simple and seamless communication was a priority to reach and stay connected to clients.	Activation of Twilio within Salesforce Campaigns to allow for 2-way texting functionality.
<i>Feature need:</i> Matching of available resources to specific client needs and identities was critical.	Selection of ServiceMatch feature from Salesforce, which uses an algorithm to recommend “best” resource by resource type or category (eg, food), zip code, and eligibility criteria (eg, language of service provision).
<i>Usability improvement:</i> Improvement of language and data collection fields within digital platforms needed to better represent client identities.	While using existing CRM platform, we expanded client intake fields to be better representative of the community; exploration of designing in multiple languages (but unable to do so in this Develop period).
<i>Implementation consideration:</i> Workflows and staffing capacity within CBOs ^d varied greatly and needed to be prioritized.	Implementation support and training identified as a high priority during rollout.

^aCRM: customer resource management.

^bMAVEN: Mapping to Enhance the Vitality of Engaged Neighborhoods.

^cAPI: application programming interface.

^dCBO: community-based organization.

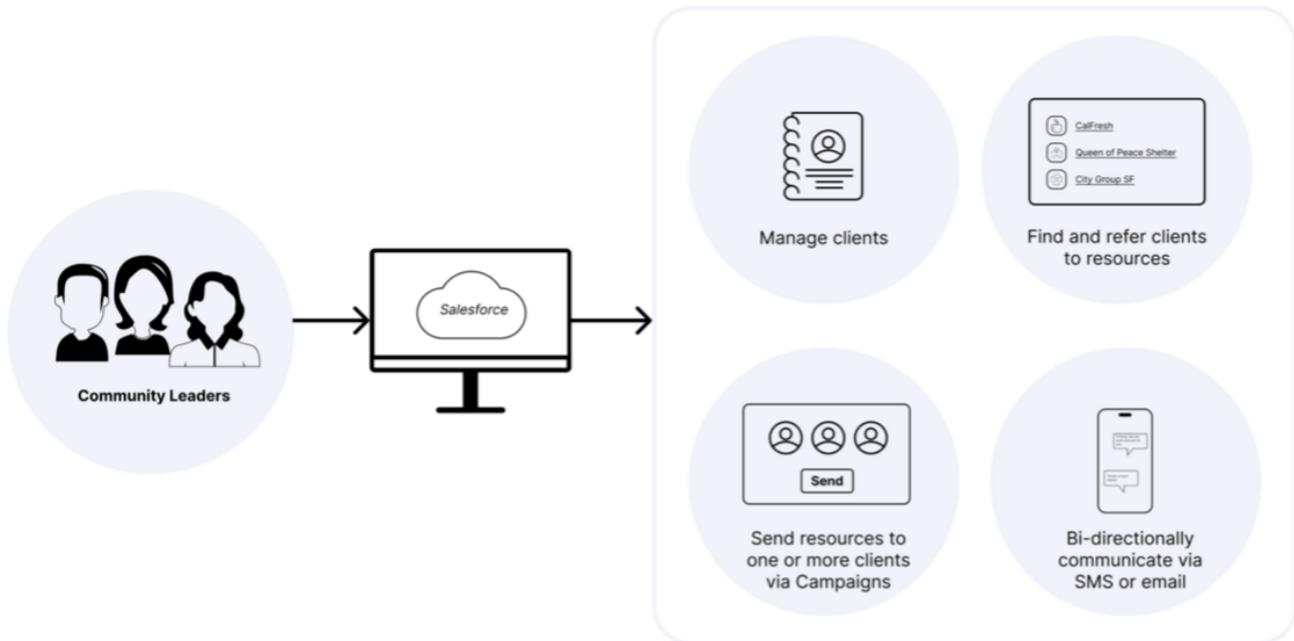

We ended up implementing these design decisions in stages within our work. In the first MVP build of the MAVEN platform (Figure 1), we identified the core platform and communication functionality needed:

1. Salesforce environment, as this was a platform used in about half of existing community organizations to track client and program information (but only accessible or viewable

- within their own organization). This selection was regularly expressed as a desired platform by most CBOs in the study.
2. Enabling the Campaign feature within the Salesforce environment, which allows group SMS and email communication within the platform (on top of existing client-tracking features). Thus, community leaders could

3. Adding Twilio-for-Salesforce-managed package to seamlessly allow 2-way SMS text messaging via the platform.

Figure 1. MAVEN minimal viable product. MAVEN: Mapping to Enhance the Vitality of Engaged Neighborhoods; SF: San Francisco.

After the second phase of testing an MVP of the MAVEN platform, we identified additional platform features as new final components of the tool (Figure 2):

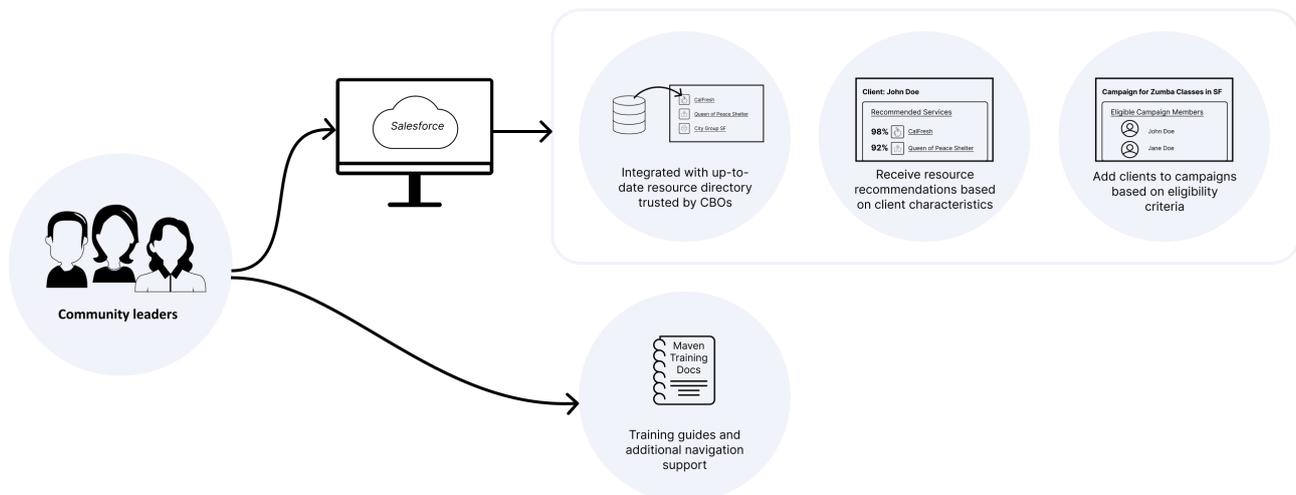

1. Integration with an existing resource directory that was trusted among community organizations. After review of several existing lists of community resources in San Francisco, we chose a freely available and regularly updated resource list called the “San Francisco Service Guide” (managed by a nonprofit called “ShelterTech”) [14]. This registry of resources included categories of resources: locations, hours, contact information for each resource, and some free-text eligibility information for the resource (eg, available to those aged 65 years or older via a senior center) [14]. We connected SF Service Guide via application programming interface into Salesforce and built an automated refresh process to update the list of records on a weekly basis. The underlying SF Service Guide repository was regularly updated every 90 days by volunteers at ShelterTech.
2. Ability to receive “recommendations” for a client resource based on category of resource, location, and eligibility criteria. We chose a freely available and open-source tool within the Salesforce environment called ServiceMatch, which was available via Salesforce.org Impact Labs [15]. We customized the existing code for ServiceMatch within MAVEN, adjusting the algorithm to be able to use the existing resource list information to make recommendations of the most relevant resources based on client characteristics

(eg, eligibility of resource based on age, location [ie, client zip code], and resource type [ie, search for food vs housing]). Finally, connecting ServiceMatch with Twilio allows community leaders to refer these relevant resources to clients via SMS in addition to email and printout with 1 click.

3. Extension of existing Campaigns Salesforce tool that automatically adds clients to the campaign based on the resource eligibility criteria and allows referral of multiple resources to 1 or more clients. Thus, the community leaders can create a campaign and add multiple resources to the campaign, and the system automatically selects clients based on the unified eligibility criteria across all campaign resources selected. Broadcast messaging service was used to send bulk SMS messages to clients included in the campaign.
4. Rollout of platform was completed with the addition of implementation support. Finally, we created detailed user guides and training materials to support CBOs in using a platform that was often very new to their daily workflow and addressed some of the major navigation questions that were confusing in the platform.

The final MAVEN product combined elements from multiple places that did not previously exist: the Campaigns feature (with additional communication functionality), plus curated resources directly from SF Resource Guide, plus searching of resources by type, location, and eligibility via ServiceMatch.

Discussion

Principal Findings

This paper outlines a co-design process to create and iterate a digital platform for CBOs, focused on finding relevant health and social resources and easily connecting clients to these resources. Overall, human-centered design methods elucidated core needs and preferences of CBOs for health and social resource screening and referrals. This is an audience that has often been overlooked in the clinical informatics literature given that CBOs work outside of the EHR and have entirely different workflows with their clients as compared with a health care environment [16,17]. Specifically, we outlined multiple platform features and design decisions that matched the needs expressed during in-depth qualitative interviews, applying a rigorous and theory-informed approach to the design.

Our findings are likely to have relevance outside of the San Francisco context because of the design choices made in this study. First, many CBOs across the country are looking to use CRM software and specifically Salesforce to manage client communication, which was also reflected in our study findings. Therefore, there is the ability for other groups to use the existing Salesforce functionality identified in the MAVEN study (such as ServiceMatch and the Campaigns feature with Twilio integration). In addition, we chose to integrate an existing resource list via application programming interface into the MAVEN platform, which can be swapped out for any other resource list based on the local context in other communities. Importantly, the co-design process in this study to build the MAVEN platform led not only to the enhancement of the tool but also to specific attention and focus on the context for using the tool, such as use of existing operating platforms, workflow considerations, staffing and workforce capacity, and flexibility of the tool to meet the diverse needs of clients served [18,19].

Moreover, this study is a useful example of the Develop phase of the design work, which emphasizes real-world implementation and potential constraints, which are a critical

complement to the open brainstorming and ideation of the Discovery phase of design [20]. Moving forward in this field, it will also be critical for future studies to focus on human-centered design to advance health equity. Equity-focused design methods are spreading, and these methods are essential for building platforms that prioritize the needs of marginalized communities and address multiple levels of influences on health outcomes [21,22].

Limitations

This study had several limitations, such as the completion of the work in a single geographic area (the San Francisco Bay Area) and the relatively small number of organizations participating in the design. However, both the design methods and the findings that highlight implementation considerations are widely generalizable to many other cities and municipalities (in addition to Salesforce build considerations). Finally, the budget of this research project also limited the number of phases of iterations and the final set of features activated. Similarly, because of budget, we were not able to transition use of the MAVEN platform from the University of California San Francisco (UCSF) Salesforce license (where the study testing occurred) to independent licenses at CBOs, which remains a barrier for longer-term uptake.

Conclusions

Moving forward, there is a strong need for more community-engaged research and informatics co-design to support the development and implementation of platforms that assist CBOs in their daily work. Understanding individual social needs within health care delivery systems is essential for health promotion, but solutions that require delivering health and social resources within local neighborhoods will not be solved by health care systems alone. In order to partner with CBOs and follow their expertise, we also cannot ignore the resources, capacity, and skills or training needs in these organizations (as our study and many others have highlighted), as real impact will be diminished without investment in CBOs based on their priorities.

Authors' Contributions

CL, BB, AB, and WB conceptualized the study, interpreted data, and drafted/edited the manuscript. SM, DDH, CG, NP, and US interpreted data and critically edited the manuscript.

Conflicts of Interest

US holds current research funding from the National Cancer Institute of the National Institutes of Health, California Healthcare Foundation, the Patient-Centered Outcomes Research Institute, and the Agency for Healthcare Research and Quality. She has received prior grant funding from the Gordon and Betty Moore Foundation, the Blue Shield of California Foundation, HopeLab, the US Food and Drug Administration, and the Commonwealth Fund. She received gift funding from The Doctors Company Foundation. She holds contract funding from InquisitHealth and RecoverX. US serves as a scientific/expert advisor for HealthTech 4 Medicaid (volunteer). She is a member of the American Medical Association's Equity and Innovation Advisory Group (honorary) and is on the Board of Directors of the Collaborative for Accountability and Improvement (volunteer). She is an advisor for Waymark (shares) and for Ceteri Capital I GP, LLC (shares). She has been a clinical advisor for Omada Health (honorary) and an advisory board member for Doximity (honorary, stock).

Abstract

Background: Orthopedic surgical treatment is a transversal task that requires the active involvement of patients, relatives, and health care professionals (HCPs) across various settings. However, after hospital discharge, communication is challenged and undertaken primarily by phone. New digital communication solutions have the potential to create a space for seamless and patient-centered dialogue across discipline and sector boundaries. When evaluating new communication solutions, knowledge about HCPs' needs and perspectives of use must be explored, as it is they who are responsible for implementing changes in practice.

Objective: This study aimed to (1) investigate HCPs' perceptions of current communication pathways (phase 1) and (2) explore their experiences of using a simple messenger-like solution (eDialogue) for team-based digital communication across settings (phase 2).

Methods: We used a triangulation of qualitative data collection techniques, including document analysis, observations, focus groups, and individual interviews of HCPs before (n=28) and after (n=12) their use of eDialogue. Data collection and analysis were inspired by the Consolidated Framework for Implementation Research (CFIR) to specifically understand facilitators and barriers to implementation as perceived by HCPs.

Results: HCPs perceive current communication pathways as insufficient for both patients and themselves. Phone calls are disruptive, and there is a lack of direct communication modalities when communication crosses sector boundaries. HCPs experienced the use of eDialogue as a quick and easy way for timely interdisciplinary interaction with patients and other HCPs across settings; however, concerns were raised about time consumption.

Conclusions: eDialogue can provide needed support for interdisciplinary and cross-sectoral patient-centered communication. However, future studies of this solution should address its impact and the use of resources.

Introduction

Treatment of patients undergoing orthopedic surgery is a cross-disciplinary task formed in partnership with the patient. Communication and collaboration between the patient and different professional groups across various settings are key to achieving quality in patient trajectories and clinical outcomes [1-3]. While hospitalization times are decreasing, an increasing part of the postoperative period takes place in the patient's home and with support from municipal health care professionals (HCPs) [4,5]. However, they are largely dependent on contact with hospital staff when problems related to treatment and care arise.

In Denmark, the current means of communication between patients undergoing orthopedic surgery and HCPs across sectors is primarily by phone, but the synchronicity of this is inflexible and time-consuming. Moreover, HCPs across sectors communicate through different electronic systems, but without including patients in the dialogues. New communication strategies must aim to provide seamless communication paths that reach beyond the existing silos of the health care system and include patients as partners [6].

Digital patient platforms are being introduced in Denmark [7,8] as well as internationally [9,10]. Patients can receive digital patient education, see test results, and answer questionnaires used by clinicians to tailor treatment plans. In some cases, patients are given the opportunity to send texts in a secured chat to HCPs at the hospital before and after hospitalization in addition to phone calls. Internationally, secure messaging is reported as the most used feature on patient platforms [9]. Even though questions are not limited to nursing tasks, answering the messages is often delegated to nurses in outpatient clinics or wards at the hospital [7,8]. This leads to duplicate work for the nurses, who will act as intermediaries or gatekeepers for the questions that patients might have, in the same way as secretaries are gatekeepers for patient-initiated phone calls. Moreover, HCPs from the municipality are not involved in these digital encounters. Even though the surgeon at the hospital holds the primary responsibility for the orthopedic treatment [11], there are no direct communication modalities available between the patient, surgeon, and HCPs across sectors in the postoperative period. A team-based approach to the use of digital communication, involving the patient and all HCPs in their care team, may improve postdischarge communication and support patients more optimally after surgery and discharge. Our focus for this study was on communication pathways both involving patient-to-provider communication as well as provider-to-provider communication, as this is interwoven and interdependent in clinical practice.

In an exploratory qualitative study, we tested a simple messenger-like solution for team-based digital communication between patients and HCPs across sectors (eDialogue), and the perspectives of patients and their use of the solution have been reported in another study. However, when testing new communication pathways in health care, it is pivotal to explore the perspectives of all end users to identify their needs, motivations, and barriers to use at an early preimplementation

stage [12]. Therefore, this study aimed to (1) investigate HCPs' perceptions of current communication pathways with orthopedic surgery patients and collaborating HCPs across sectors, as well as their expectations for eDialogue (phase 1), and (2) explore their experiences of using eDialogue for team-based communication (phase 2).

Methods

Study Design

We used a triangulation of qualitative data collection techniques to understand contextual factors and what opportunities and challenges exist before (phase 1) and after (phase 2) the use of eDialogue. This included document analysis, observations [13], semistructured focus groups [14], and individual interviews [15]. Reporting this study followed the Consolidated Criteria for Reporting Qualitative Research (COREQ) checklist [16].

Theoretical Framework

Conducting this study, we were inspired by the metatheoretical framework and terminology described by Damschroder et al [17]: the Consolidated Framework for Implementation Research (CFIR). The CFIR is widely used in health services research and specifically adapted to understand facilitators and barriers to implementation, even at an early preimplementation stage [17,18]. CFIR is centered around five key domains related to implementation, including (1) the intervention, (2) the inner setting, (3) the outer setting, (4) the individuals involved in the intervention, and (5) the processes conducted to implement the intervention [17]. To each domain belong underlying constructs, which describe factors that can either motivate or hinder implementation [17]. Selected CFIR domains and constructs guided our data collection by informing the interview guides and the observation protocol in combination with exploratory questions. In an inductive-deductive approach, CFIR domains and constructs were used to structure data analysis and the reporting of our findings, while still being open to emerging themes. By using CFIR, we aimed to promote structured knowledge building for future implementation strategies that may encourage the adoption of eDialogue in clinical practice.

Participants and Setting

The study originated from the orthopedic surgery department at Aalborg University Hospital, which is a tertiary hospital in Denmark. The Danish health care system is mainly financed by general taxes and is therefore provided free of charge to individuals. It operates across 3 administrative and political levels, which are the state (national level), the regions (regional level), and the municipalities (local level). Hospital care is provided by the 5 regions of Denmark, and primary care and social services, such as rehabilitation outside hospitals, home nursing, and physiotherapy, are provided by the 98 municipalities of Denmark. Even though there is cofinancing and close collaboration between the regional and local levels, HCPs are employed in different organizations and use different electronic health records. There are defined care pathways for patients in need of treatment and care across settings that outline the tasks of the HCPs employed at the different levels, just as there is legislation that the HCPs must follow. However, major

challenges exist in communication and collaboration across settings, especially related to patients in transitions of care from hospital to home.

Phase 1: Before eDialogue

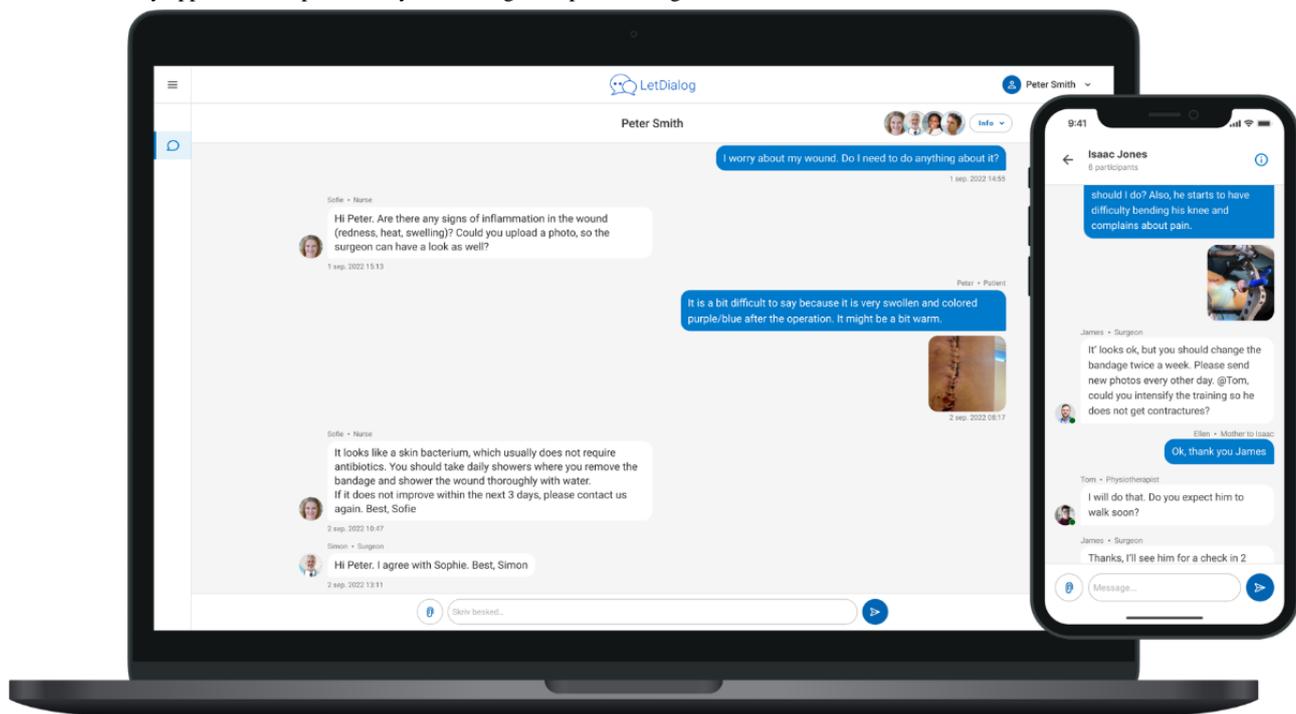

In phase 1, orthopedic surgeons, secretaries, nurses, and physiotherapists from Aalborg University Hospital and home care nurses and physiotherapists from the Aalborg municipality were recruited for preintervention focus groups (n=6) to investigate their perceptions of current communication pathways and their expectations for eDialogue. Inclusion criteria were HCPs working with orthopedic patients from 2 different subspecialties that were recruited to test and explore eDialogue. These were patients undergoing either deformity correction surgery involving complex prolonged treatment with hospitalization or anterior cruciate ligament reconstruction performed as day surgery (ie, discharged on the day of surgery). HCPs were recruited from different units at the hospital, including the outpatient clinic, the ward, and the physiotherapy department, and from different districts of the Aalborg municipality. Exclusion criteria were HCPs who had sparse

knowledge of orthopedic treatment and care; for example, personnel hired within the past year. We purposely strove to include HCPs from various vocational roles to achieve a detailed understanding of the clinical trajectory and interdisciplinary communication with patients undergoing orthopedic surgery. Inclusion persisted until data saturation was reached for the interviews, that is, no new themes occurred [15].

Intervention: eDialogue

Team-based digital communication between patients and HCPs across settings was facilitated through a technical General Data Protection Regulation-compliant solution assessed by an app for a smartphone or through a website (Figure 1). The technical solution is already in use in some municipalities in Denmark in the field of social education [19], but has never been used to facilitate communication in health care or across sectors. The solution was chosen by the research team before the study based on the simple and intuitive interfaces and discussed with patients undergoing orthopedic surgery and HCPs in an initial workshop before this study.

Figure 1. The figure shows screenshots of digital dialogues between patients and health care professionals (HCPs) across settings from the study. Access was either by app on a smartphone or by web, using a simple messenger-like user interface.

Patients from 2 orthopedic surgery subspecialties were recruited consecutively for this study and offered to use eDialogue for 2 months after they had been discharged with their team of HCPs across settings.

Just as patients were helped to create an account using a digital signature (NemID), HCPs were guided to become users of eDialogue. Most HCPs accessed it through the website, but some preferred access through the app on their smartphones. Finger touch or face recognition could be used for login if access was through the app. During registration, all participants were given a short introduction to how to use eDialogue, including how to send texts and photos and get notifications of new posts.

It was explained to HCPs that they were expected to provide answers to patients' questions with a maximum response time of 24 hours on weekdays. In each individual case, patients decided which of the HCPs in their team of care they wanted to join the digital dialogue, and the HCPs were contacted and invited to join by the primary author (LWHJ). All communication was asynchronous, using text messages and photos; thus, no video calls could be made through the solution. Patients had access for 2 months after hospital discharge. Upon request and agreement with their team of HCPs, access could be extended beyond the study period. The digital dialogues were

stored in a secure cloud-based solution [19], and a data processor agreement was made before the study.

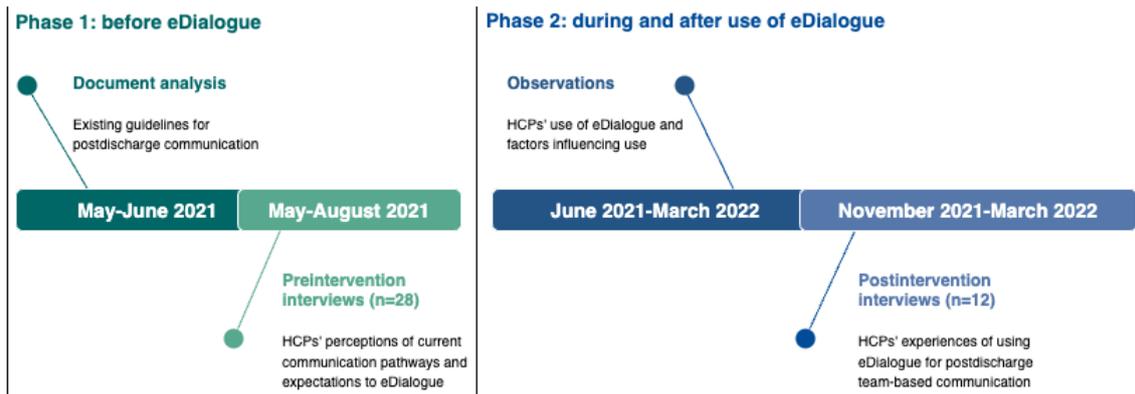

Phase 2: During and After Use of eDialogue

HCPs were recruited for interviews after their use of eDialogue with patients and other HCPs across disciplines and sectors. The inclusion criteria were involvement in eDialogue with ≥ 3 patients. There were no exclusion criteria.

Data Collection

Data collection was structured according to the two phases to achieve thorough insight into HCPs' perceptions of current communication pathways and their expectations of eDialogue before use (phase 1), and to explore their experiences with access to eDialogue (phase 2). Figure 2 illustrates the triangulation of data collection techniques across the 2 phases of this study.

Figure 2. The figure illustrates the timeline and data collection for phases 1 and 2 of this study. In phase 1, document analysis and preintervention interviews with health care professionals (HCPs) were performed. In phase 2, observations were conducted continuously as eDialogue was used, and, ultimately, postintervention interviews were performed.

Phase 1: Document Analysis and Preintervention Interviews

An initial document analysis of existing guidelines for communication between patients undergoing orthopedic surgery and HCPs across sectors was carried out with the aim of gaining insight into the current context for communication. First, we identified relevant practical documents by searching different Danish web pages related to the political and regulatory guidelines on transitions of care from hospital to home and strategies for using information technologies in health care, for example, the Ministry of Health, the Local Government of Denmark, and the Danish Society for Patient Safety. We also searched the local web page of Aalborg University Hospital for clinical practice guidelines describing the procedures that HCPs must follow when patients or municipal providers contact them regarding discharged patients. Second, we applied a snowball strategy, using references from the initial search. We did not formally analyze the documents, but we used knowledge of the context to understand the framework under which HCPs must work and to qualify the interview guide.

This was followed by focus groups with HCPs across the hospital and municipality (n=28). The aim of the focus groups (n=6) was to explore HCPs' perceptions of current communication pathways and their expectations of eDialogue before use.

The interview guide was inspired by the CFIR Interview Guide Tool [20], including exploratory questions to provide space for emerging reflections. The interview guide was tested on 2 HCPs from the hospital and discussed among the authors until agreement was reached. Minor additions were made before the first focus group.

All preintervention interviews were conducted as semistructured focus groups, dividing HCPs according to their vocational roles and setting (hospital or municipality). HCPs interviewed were surgeons at the hospital (n=5), secretaries from the hospital (n=3), nurses from the hospital ward (n=5), nurses from the outpatient clinic (n=3), home care nurses from the municipality (n=3), physiotherapists from the hospital (n=5), and physiotherapists from the municipality (n=4). Using preexisting groups as focus groups was based on the assumption that it would make participants discuss and compare their reflections in depth in the same context and without an underlying power structure that could occur if professions were mixed [14]. At the beginning of each interview, background variables such as gender, vocational role, and years of experience with patients undergoing orthopedic surgery were collected.

All interviews with HCPs from the hospital were conducted face-to-face by the first author (LWHJ). For the first 2 focus groups, a project nurse was present to register observations during the interviews and to take notes to qualify and supplement the interview. Focus groups with HCPs from the municipality were performed remotely by video, as data collection occurred during the coronavirus outbreak and most HCPs outside of the hospital were not physically located in the same place. The interviewer summarized key points during and at the end of each focus group to facilitate further reflection and to make sure her interpretation corresponded with what the HCPs had said [15]. Field notes were made at the end of each focus group so as to remember details of the context, group interaction, and nonverbal communication [15]. The focus groups lasted an average of 1 hour (between 45 and 90 minutes).

Phase 2: Observations and Postintervention Interviews

In total, eDialogue was used with 31 patients and with the involvement of 24 different HCPs. When the last patient had

had access to eDialogue with their team of HCPs for 2 months, a convenience sample of participating HCPs across the hospital and municipality were interviewed (n=12), including surgeons from the hospital (n=5), physiotherapists from the hospital (n=2), and from the municipality (n=5). We performed 7 individual interviews with physiotherapists across hospitals and municipalities and 1 focus group with 5 surgeons. The aim of the interviews was to explore their experiences with eDialogue. All interviews were conducted by LWHJ, audio recorded, and followed a predefined semistructured interview guide inspired by the CFIR Interview Guide Tool [20] and additional exploratory questions. Interviews with HCPs from the hospital were performed face-to-face, and interviews with HCPs from the municipality were conducted remotely based on the participants' wishes.

During the study period, we observed the use of eDialogue by HCPs and documented this in Word (Microsoft Corporation) files. The aim was to observe issues related to HCPs' use of eDialogue that were reported to the project group or observed

in dialogues (an administrator from the project group was present in all dialogues to observe if eDialogue was used in acute situations). HCPs were encouraged to contact the first author if they experienced any problems with eDialogue or had concerns or questions during use, and these were documented as well. Data collected through observations were used to qualify the follow-up interviews in phase 2 and were also imported to NVivo (QSR International) for analysis in conjunction with interview data.

Data Analysis

Data were analyzed for phase 1 and then phase 2, respectively. Interviews were audio recorded using a digital voice recorder (DM-450; Olympus) and transcribed verbatim immediately afterward. Word files with the transcriptions were imported to NVivo for data analysis (NVivo 12, version 20.6.2) [21]. Inspired by Brinkmann and Kvale [15], using an inductive-deductive approach, we performed thematic analysis focusing on meaning (Textbox 1).

Textbox 1. Steps of the thematic analysis using an inductive-deductive approach.

Meaning coding

- Full transcripts were read several times by both LWHJ and REKL.
- To define the initial coding template and to achieve intersubjectivity, the first 4 interviews of each phase were coded by LWHJ and REKL individually before meeting to compare and discuss codes until mutual agreement was achieved. When the coding template was defined, LWHJ applied the same codes to the entire data set. The approach to this step was inductive, thus reflective of the issues raised in the data set.

Meaning condensation

- Theme development was undertaken with a more deductive approach, where domains and constructs from the Consolidated Framework for Implementation Research (CFIR) were used to organize the codes and inform theme development to specifically focus on facilitators and barriers to eDialogue. However, in developing themes, we were open to emerging themes that did not fit the CFIR domains and constructs. Codes and themes were reread and revised by LWHJ in collaboration with REKL and BD in several iterations.

Meaning interpretation

- Definitions and narrative descriptions of themes were made. Data extracts were selected to be presented in the manuscript.
- The final analysis and description of the findings were written.

Data analysis was conducted separately for phase 1 and phase 2 following the 3 steps of meaning coding, meaning condensation, and meaning interpretation. In phase 2, we added notes from observations to the data set to achieve an in-depth understanding of the context in which HCPs had used eDialogue and any problems occurring during use.

Ethical Considerations

The Ethics Committee of Northern Jutland was contacted before the start of the study. They decided by email on March 18, 2021, that the study did not require approval (journal number 2021-000438), as the intervention would not have consequences for diagnostics or treatment. We registered the study at the Regional Committee on Health Research (ID 2021-057). The study followed the Helsinki Declaration, and all participants received both oral and written information as well as thorough guidance in the use of eDialogue. To take into account patients' possible use of eDialogue in emergency situations, an administrator was present in all digital dialogues.

Results

Participant Characteristics

In phase 1, a total of 28 HCPs were recruited across vocational roles and hospital and municipal settings (Table 1). All surgeons, nurses, physiotherapists, and secretaries from the clinical orthopedic surgery subspecialties at the hospital, from which the patients were recruited (deformity correction or anterior cruciate ligament injury), were invited to participate in interviews. However, 2 surgeons, 1 nurse from the outpatient clinic, 1 nurse from the municipality, and 3 secretaries were not able to. Nurses from the ward were purposefully selected based on years of experience and a pragmatic approach to who would be able to participate in interviews during their work hours. On average, HCPs had 11 (range 1-30) years of experience with patients undergoing orthopedic surgery.

Table 1. Vocational roles of health care professionals who were interviewed in phases 1 and 2.

Vocational role	Phase 1 (N=28), n	Involved in eDialogue (n=24), n	Phase 2 (n=12), n
Orthopedic surgeon, hospital	5	7	5
Nurse, outpatient clinic, hospital	3	1	N/A ^a
Nurse, ward, hospital	5	N/A	N/A
Physiotherapist, hospital	5	5	2
Secretary, hospital	3	N/A	N/A
Physiotherapist, municipality	4	11	5
Nurse, municipality	3	N/A	N/A

^aN/A: not applicable.

In phase 2, a total of 12 HCPs were included for interviews, of whom 8 had also participated in focus groups in phase 1. The HCPs recruited at this stage were a sample of those who had experiences with communication in eDialogue (Table 1). Of whom, 8 HCPs interviewed for phase 2 had also participated in focus groups in phase 1. In total, 24 HCPs across the hospital and municipality were involved in eDialogue. However, we prioritized including those who had been set up to communicate in eDialogue with ≥ 3 patients. One nurse from the outpatient clinic had been involved in 3 dialogues but was not able to participate due to being absent at the time of the interviews. No nurses from the ward or the municipality were users of eDialogue and thus were not interviewed in phase 2. Secretaries were not interviewed in phase 2, as we decided not to include them in eDialogue at this point.

On average, there were 3.3 (range 2-4) HCPs per patient in the dialogues. All patients were at least connected with the orthopedic surgeon, and 25 of 31 patients had their municipal or hospital-based physiotherapist involved as well.

Themes and Subthemes Identified in Phases 1 and 2

In Table 2, the findings of the analysis of phases 1 and 2 are presented together in main themes organized by the CFIR domains and constructs and additional subthemes. This is to display the before-and-after perspectives of HCPs. Following the table, we elaborate on subthemes in narrative text according to phases 1 and 2 and by using selected quotes from interviews.

The main themes are organized by CFIR domains and constructs, and subthemes elaborate on these for phases 1 and 2, respectively. Emerging themes occurred in both phases that did not match any of the CFIR constructs, and they are therefore described under additional emerging themes.

Phase 1: Current Communication Pathways and Expectations for eDialogue

Intervention Characteristics

Even though the majority of HCPs expected eDialogue to provide optimized interdisciplinary communication, prevent conflicting recommendations to patients, and provide easier access for patients, there were contradictory expectations for the use of eDialogue. On one hand, HCPs had concerns about whether answering messages would require more of their time and go beyond working hours, but on the other hand, they thought it would be easier to answer in eDialogue than by phone. Concerns also centered around whether using text as a communication medium would be adequate for all patients and if misunderstandings would occur due to wrong interpretations.

HCPs were especially worried about whether they would pick up on complications to the same extent as they do by phone.

I can't hear the patient's voice answering back, and if they have understood my answers (...) however, it depends on the complexity of their questions, whether it's just how many repetitions was it, or something that could be more serious. [Physiotherapist, municipality, preintervention interview]

Being able to send photos in eDialogue was expected to be an important feature that might offset the challenges of using text for communication. Even though some HCPs had reservations and conflicting opinions about eDialogue before its use, they all agreed that it would be a reassurance and a lifeline for both patients and HCPs across settings. Additionally, a

physiotherapist from the hospital reflected on how eDialogue might bring “hidden tasks” to light.

What I thought at first would be negative like, oh then we have to do that too, will probably actually be reversed, so that the hidden tasks, we solve by calling and writing notes and emails and things like that, becomes more visible and can be accounted for during work hours. [Physiotherapist, hospital, preintervention interview]

Outer Setting

The analysis revealed that HCPs experience current communication pathways in the postoperative period to be challenging, both by phone and existing electronic systems. This leads to workarounds, such as HCPs giving patients oral instructions or written notes to bring to other HCPs to ensure timely information. However, using patients as messengers of information between HCPs is perceived as insufficient yet necessary in current communication pathways. A physiotherapist from the municipality described how current systems do not support the patient’s trajectory across sectors.

There are watertight shutters between the communication systems, i.e., what they write in the medical record at the hospital and what I write here. The surgeon at the hospital can't see that, and (...) I can't see his note. [Physiotherapist, municipality, preintervention interview]

Inner Setting

Across professional roles and settings, HCPs expressed a need for change to enable easier sharing of knowledge and communication. This was especially the case for complex and long-term orthopedic surgical treatments where multiple HCPs are involved. Knowing each other across settings, for example, by being former colleagues, was a mediating factor for communication between HCPs. However, it was not perceived as sustainable.

Getting in contact with each other and patients by phone is considered time consuming due to the synchronicity of phone calls. A nurse from the inpatient department described how phone calls would sometimes be left until the next day if questions required the involvement of another HCP. This left the nurses feeling like inadequate intermediaries and could be a risk to patient safety. Similar experiences were described by physiotherapists, who often found themselves being asked about issues outside of their competencies; for example, questions about wounds and medication.

HCPs from the hospital described how phone calls are disruptive to their work processes, even though they understood the need for them. In addition to inquiries from patients, they receive phone calls from a wide range of HCPs in hospitals, municipalities, and private settings. Although secretaries act as gatekeepers, nurses from the outpatient clinic, and in the inpatient department in particular, handle many phone calls daily.

It's constant, isn't it? (...) it takes my attention away from the dialogue, the communication and the

relationship that I'm in the middle of. Then you're like, oh sorry, this phone call is actually more important than you are (the patient they are with). [Nurse, outpatient clinic, hospital, preintervention interview]

Addressing eDialogue as a novel communication solution to support team-based communication between patients and HCPs across settings, most HCPs were positive about the change it might bring. However, they expressed some degree of technology fatigue that made them skeptical of yet another system without integration into existing systems.

Emerging Theme

HCPs described previous experiences with using digital communication with patients, usually by email or SMS text messaging. Most often, it is used as a way to provide psychological reassurance to patients or to solve specific complex problems, where the HCPs have specialist knowledge. Even FaceTime was described as being used once with a patient to inspect a wound from a distance. However, the disadvantages of the current nonsystematic use of digital communication with patients were reflected. Concerns were raised regarding using a private phone number and the risk of introducing data security breaches. Also, giving some patients the opportunity for direct digital contact and others not was perceived as problematic. Thus, if used inconsistently, it may lead to inequality in patients’ access to health care.

Furthermore, HCPs described how they use email or SMS text messaging to communicate with each other, for example, to share thoughts on treatments or rehabilitation. They do this as a workaround to traditional communication pathways or because it is perceived as less disturbing to each other. Thus, the use of digital text-based communication is not uncommon for HCPs in this study. However, it is not standardized or even articulated among colleagues or management.

Phase 2: HCPs’ Perspectives of eDialogue After Use

Intervention Characteristics

All HCPs agreed that the technical solution for eDialogue was very intuitive and did not need a thorough introduction, as opposed to other solutions with more features. Most HCPs articulated that questions were quick and easy to handle during work hours. Especially the asynchrony of the contact and the use of photos improved the quality of communication and their experiences of eDialogue for patient communication.

The big advantage of this, is that they can send a photo (...). If it wasn't a possibility, I think there would be a lot of writing about something that we couldn't really clarify, and then we would still have to call them in (for an extra check). Being able to send a photo, that's really crucial for this to work. [Surgeon, hospital, postintervention interview]

The analysis demonstrated that HCPs developed individual strategies for answering questions in eDialogue. Notifications were automatically sent to participants when there were new messages in the system, but there were no integrated reminders

to follow up if the messages were not read within 24 hours, and this led to the development of individual workflows.

(The notification) on email, when there is a new message, I will not delete it until I have answered. That way, it helps me keep track. [Surgeon, hospital, postintervention interview]

eDialogue was mainly used by patients as a place to ask postdischarge questions to HCPs. In general, most questions from patients were answered by surgeons and physiotherapists from the hospital. Municipal physiotherapists described being hesitant to involve themselves actively in answering, as they experienced hospital staff being quick to answer the patients. However, they emphasized that they used the information given to the patient by hospital staff in their subsequent contact with patients. This “indirect” use was perceived as valuable to them.

It has been very rewarding to just follow the dialogue, even though I was not active in it. The fact that the patient can just send a photo and ask ‘what does this look like?’, then he is immediately calmed down. It’s rather smart, and also that I know of it right away. [Physiotherapist, municipality, postintervention interview]

Outer Setting

HCPs stressed that the team-based approach made it easier to share timely information with the patient and other HCPs, and thereby it created more effective communication pathways. Physiotherapists highlighted how their previous perceptions of being an insufficient intermediary between the patient and other HCPs were changed when communication could take place directly in eDialogue.

It was actually really nice that he (the patient) just took it directly with the surgeon. Because I can have doubts (...) and you don’t want to burden the surgeon by calling. [Physiotherapist, municipality, postintervention interviews]

Inner Setting

Even though HCPs acknowledged the impact that eDialogue had for patients, there were discrepancies in their perception of how it was used in this study, and it affected their acceptance of the solution. For example, some HCPs thought that the team-based approach was not necessary for all patients involved or that they lacked a secretary for administrative tasks. As such, they highlighted that some questions might be better answered in other ways, for example, by providing better patient education or by including other HCPs in the dialogue.

I think it is difficult to say that the patients’ questions are not relevant because they must be since they ask them, but who should answer them, and how quickly should they have an answer, can be discussed. [Physiotherapist, hospital, postintervention interview]

However, when using eDialogue with patients for complex orthopedic treatments, HCPs expressed that the team-based approach was very valuable to the patients and their workflows.

I think it was good. They (patients) feel that there is a team around them, and I get the feeling that I’m not

the only one being responsible. Also, I don’t have to spend time calling the physiotherapist to say ‘Hey, can’t you just look at this?’ when he’s already in the dialogue. [Surgeon, hospital, postintervention interview]

HCPs strongly experienced that access to eDialogue provided reassurance for patients. However, in consideration of the sparse health care resources, it was a general opinion that eDialogue should only be offered to patients for complex treatments. This provoked an ethical discussion of how HCPs could distinguish between who should be offered the solution and who should not. HCPs highlighted that an assessment of effects should be addressed, both in terms of resource consumption and patient outcomes.

One of my concerns with systems like this is that if we have to use it with all patients (...), then I think it could become a burden. And also, I think it will be difficult to say, well, it’s only for some patients, because why them? [Surgeon, hospital, postintervention interview]

HCPs agreed that clarification is needed regarding financial incentives before implementing eDialogue. Along with concerns about resources to answer the questions, this was a perceived barrier to use.

I think the barriers are time and finances (...) there is, of course, someone who looks at what I produce. And I think it should be some kind of service that should be visible (to others), if we have to evaluate a photo or send back a response (through eDialogue). [Physiotherapist, municipality, postintervention interview]

Characteristics of Individuals

In all interviews, HCPs had concerns about whether they expressed themselves clearly enough in writing and how their “tone of voice” would be perceived by patients when formulated in texts. In reflection, they emphasized that the same concerns could arise when talking to patients on the phone.

Regardless of whether it’s something you say to them or something you text them, it’s just as important that you use words they can understand, and I actually often think it’s a little easier when you text because you have time to think about it. [Surgeon, hospital, postintervention interview]

There were clear differences in how HCPs expressed themselves in the texts, and this was discussed in one of the focus groups, where a surgeon had been involved in another surgeon’s dialogue due to vacation.

I think he (the other surgeon) is very kind in his feedback. I actually noticed that, you (addressed to the other surgeon) have formulated yourself in such a very friendly way, in contrast to what I did to start with. I made it very short, like I might normally answer a text message with a friend (...). I had to remind myself that they don’t know me (...) it might be important to pay attention to that. [Surgeon, hospital, postintervention interview]

Emerging Theme

Both surgeons and physiotherapists described that using eDialogue created interdisciplinary reflection and learning about patients' needs after discharge, and that frequently asked questions could be used to improve future patient education.

It gives feedback in relation to the material we use and the way we inform patients now. It might actually be very nice for all of us to know this.

[Physiotherapist, hospital, postintervention interview]

Ultimately, HCPs pointed out that they could learn from each other by reading each other's answers to patients.

Discussion

Principal Findings and Comparison With Previous Work

This study first investigated HCPs' perceptions of current communication pathways with patients and other HCPs involved in the patient's trajectory after orthopedic surgery and discharge, along with their expectations for eDialogue before its use (phase 1). Following initial document analysis, we included a wide range of HCPs across vocational roles and settings in focus groups to obtain an in-depth understanding of their needs and attitudes toward eDialogue. These perspectives are important to capture, as individual and contextual factors as well as initial perceptions of eDialogue may motivate or hinder use [17]. The findings of phase 1 showed that, on the one hand, HCPs perceived a significant tension for change. Current communication pathways are perceived as insufficient, phone calls are disruptive, and patients unfortunately become messengers of information between HCPs across settings. On the other hand, HCPs expressed conflicting attitudes toward eDialogue in advance of its use. Positive or negative attitudes were not limited to certain vocational roles but were expressed in all groups and also as an internal dilemma inherent to the individual. However, there were clear expectations for eDialogue to support patients in the postoperative period and consensus that it may provide optimized interdisciplinary and cross-sectoral communication. At the same time, HCPs experienced some degree of technology fatigue and significant worry that eDialogue would be time-consuming for them to handle.

Second, we explored HCPs' experiences of using eDialogue for team-based digital communication through observations and postintervention interviews (phase 2). Knowing that, even with highly developed plans for execution, undiscovered factors can undermine implementation efforts in the real world [17,18], we searched to identify facilitators and barriers to implementation from the perspectives of key users at an early stage. Findings from phase 2 showed that HCPs experienced eDialogue as a quick and easy way to interact with patients and other HCPs and that eDialogue could support timely and effective interdisciplinary communication across settings. As such, the positive perceptions of the importance of eDialogue described in the preintervention interviews were maintained. Similarly, the use of photos was expected to be important in preintervention interviews, and in postintervention interviews, photos were even suggested as being a significant

quality-enhancing element compared to traditional phone calls. Similar findings have been described in other studies of digital communication in health care [22-24].

In interviews in phase 1, HCPs described that they had concerns about communicating with patients in texts because they feared overlooking an important complication or that the patient would misunderstand their written responses. In phase 2, HCPs still expressed concerns about whether they expressed themselves clearly enough. However, they pointed out that the same risks can be present in phone consultations. This perspective is supported by a recent study of telephone consultations in Denmark. Jensen et al [25] found that communication in consultations concerning back pain preceding out-of-hospital cardiac arrest was influenced by the communicative preconditions of the call-taker, thereby addressing the fact that a meaning-constitution is undertaken in the interaction between the patient and the call-taker, not always reflecting the actual problem. To learn from this, HCPs involved with patients through eDialogue and other digital communication solutions must be aware that communicative interaction is always an interpretative task for the receiver of a message. Even though the HCPs' concern might decrease as they gain more experience communicating in writing, their self-efficacy should be supported by formulating clear recommendations, training, and supervision.

Across the interviews of phases 1 and 2, HCPs expressed concerns regarding resource consumption; this was particularly evident among hospital staff. While acknowledging patients' need for easier access to communication with HCPs after discharge, HCPs questioned if the team-based approach was necessary for patients undergoing less complex orthopedic treatments. Nevertheless, there was consensus that eDialogue can support patients in complex and long-term treatments and that a needs assessment to learn who will benefit the most from eDialogue should be made before its implementation so as to best match resources with actual needs. Other studies investigating the use of team-based digital communication have primarily focused on patients with cancer or chronic diseases [26-29]. Patients undergoing orthopedic surgery for complex and long-term treatment suffer similar challenges in health care communication [30], and therefore it is also relevant to develop and test solutions for this group. By using eDialogue for a smaller patient group, the workload caused by the implementation of the solution will decrease.

eDialogue was a solution where both patients and HCPs across settings could communicate freely in the postdischarge period. However, the primary communication in eDialogue was between the patient and HCPs at the hospital. Municipal physiotherapists used eDialogue more indirectly as a way to keep up to date with the patients' progress. As such, findings revealed how physiotherapists in the municipality and patients together would formulate questions to send to the hospital staff. Taking into account this shared use of eDialogue, usage data defining the proportion of messages sent between patients and HCPs and between HCPs across settings would not be representative of their actual use. Moreover, HCPs adapted eDialogue to their contexts and developed individual strategies for providing timely answers. Some strategies were developed because the technical

solution lacked better adaptation to the context, for example, an improved notification system, whereas other strategies were based on individual preferences in handling digital communication. All cases emphasize the importance of uncovering the HCPs' context and needs and ensuring that new technology supports them in their work processes so that inappropriate use of new solutions does not end up adding new workarounds and thus hindering the optimal outcome of the technology.

Limitations

This study was inspired by the CFIR to guide data collection and analysis [17,20]. The systematic identification and mapping of what was perceived as important to HCPs to the CFIR domains and constructs was helpful in providing an overview of the multifaceted and conflicting attitudes and experiences of eDialogue. However, we did not apply the CFIR as exhaustively as recommended [17,18], and we may thereby have missed important aspects that could have emerged. Using an inductive-deductive approach in data analysis, however, allowed us to still be explorative, which suited the early phase of the intervention described in this study.

In phase 1, we included a wide range of HCPs involved in the patients' trajectory and communicative circles after surgery and discharge to shed light on their perspectives on current communication pathways. Including HCPs from different settings was a strength to this study, however, the small subgroups of HCPs from the same setting may jeopardize data saturation [15]. However, the theme of the interviews, exclusively focusing on communication, is narrow and may thereby outweigh this issue. For preintervention interviews, data saturation was reached; however, it can be discussed whether data saturation was reached fully for the interviews in phase 2. Observations of HCPs' use of eDialogue, including technical or collaborative issues that were encountered during use, accounted for this and were included in the data analysis for phase 2.

Furthermore, we could have included management and decision makers in the focus group to gain a deeper understanding of the political and managerial context of the use of eDialogue across sectors. However, this was not attempted in this study as we wished to focus on the end users' perspectives.

Our findings derive from a single hospital and a municipal region in Denmark. Therefore, they may not reflect the experiences of HCPs from other parts of the country, where different digital communication solutions have been implemented. Only 1 nurse participated in communication in eDialogue, and thus the experiences of this group of HCPs are not reflected in our findings. Unfortunately, at the start of this study, the coronavirus outbreak was at its peak, and many nurses from the hospital were reassigned to newly opened COVID-19 departments. At the same time, there was a trade union strike among nurses in Denmark, which resulted in the cessation of work for a period of time for many nurses from the municipality. These circumstances put greater work pressure on the nurses, and we continued the study without their active involvement in the dialogues.

Last but not least, some of the research team members behind this study are clinicians and were involved in the decision to test eDialogue. We have tried to overcome this issue by including research team members with little knowledge of the patients and processes in orthopedic surgery. Thus, 2 independent researchers coded and condensed data (LWHJ and REKL) in close discussion with BD, where REKL did not have preliminary knowledge of the context.

Conclusions

HCPs describe current communication pathways as complicated. Phone calls are disruptive to work processes, and the lack of direct communication modalities between patients and HCPs across settings in the postoperative period makes patients become messengers of information between HCPs. To overcome these challenges, HCPs use off-the-shelf digital communication solutions as a workaround; however, use is neither standardized nor data secure. HCPs were open to using eDialogue, although they had reservations, which were partly confirmed and unconfirmed in their subsequent use of eDialogue. Especially, concerns regarding resource consumption were highlighted, and HCPs suggested the solution is particularly valuable in complex and prolonged treatments. The use of eDialogue offers a potentially valuable strategy for future integration of communication across health care settings, breaking down existing silos and taking into account the whole care team and the patient. This study provides knowledge for future strategies for implementing such solutions in orthopedic surgery and other clinical domains.

Acknowledgments

We would like to thank all patients and parents, health care providers, and management staff from departments across hospitals and municipalities in Northern Jutland, Denmark, who agreed to participate in this study. We would also like to thank the project nurse, who was an observer in focus groups, and the students from Aalborg University, who contributed to transcribing large amounts of interview data. This study was partly funded by the Research Fund of Danish Health Region North (journal number 2021-0019).

Conflicts of Interest

None declared.

Abstract

Background: Industrywide, primary care nurses' work is increasing in complexity and team orientation. Mobile health information technologies (HITs) designed to aid nurses with indirect care tasks, including charting, have had mixed success. Failed introductions of HIT may be explained by insufficient integration into nurses' work processes, owing to an incomplete or incorrect understanding of the underlying work systems. Despite this need for context, published evidence has focused more on inpatient settings than on primary care.

Objective: This study aims to characterize nurses' and health technicians' perceptions of process inefficiencies in the primary care setting and identify related work system factors.

Methods: Guided by the Systems Engineering Initiative for Patient Safety (SEIPS) 2.0 model, we conducted an exploratory work system analysis with a convenience sample of primary care nurses and health technicians. Semistructured contextual interviews were conducted in 2 sets of primary care clinics in the Midwestern United States, one in an urban tertiary care center and the other in a rural community-based outpatient facility. Using directed qualitative content analysis of transcripts, we identified tasks participants perceived as frequent, redundant, or difficult, related processes, and recommendations for improvement. In addition, we conducted configuration analyses to identify associations between process inefficiencies and work system factors.

Results: We interviewed a convenience sample of 20 primary care nurses and 2 health technicians, averaging approximately 12 years of experience in their current role. Across sites, participants perceived 2 processes, managing patient calls and clinic walk-in visits, as inefficient. Among work system factors, participants described organizational and technological factors associated with inefficiencies. For example, new organization policies to decrease patient waiting invoked frequent, repetitive, and difficult tasks, including chart review and check-in using tablet computers. Participants reported that issues with policy implementation and technology usability contributed to process inefficiencies. Organizational and technological factors were also perceived among participants as the most adaptable. Suggested technology changes included new tools for walk-in triage and patient self-reporting of symptoms.

Conclusions: In response to changes to organizational policy and technology, without compensative changes elsewhere in their primary care work system, participants reported process adaptations. These adaptations indicate inefficient work processes. Understanding how the implementation of organizational policies affects other factors in the primary care work system may improve the quality of such implementations and, in turn, increase the effectiveness and efficiency of primary care nurse processes.

Furthermore, the design and implementation of HIT interventions should consider influential work system factors and their effects on work processes.

KEYWORDS

health information technology; mobile devices; nursing and nursing systems; outpatient care; SEIPS 2.0; work-system analysis

Introduction

To meet the rising demand for primary care services [1], the role of primary care nurses is becoming more complex and team-based [2]. Additional industry-wide changes that further complicate primary care nurses' roles include greater autonomy in care management [3] and growing telehealth duties (eg, managing patients using videoconferencing and remote patient home monitoring) [4], in addition to in-person care. Mobile health information technologies (HITs) such as laptops, tablets, and smartphones, particularly among nurses, have been used to facilitate flexibility in documentation, communication, and other tasks that would typically take nurses' attention away from their patients [5-7]. However, inefficient HITs may increase nurses' work burden and lead to unexpected changes in their roles and the dynamics of their care teams [8].

A better understanding of the work system for nurses and their needs can inform the design, development, and successful implementation of these technologies [9]. The few identified systems-level studies involving primary care nurses have demonstrated the usefulness of such a perspective [10,11]; however, to our knowledge, research specifically on primary care nurses' work systems is sparse. To better understand nursing tasks and processes and the work system specific to the primary care context, accounting for the various factors affecting nurses' work is needed [12]. Incorporating work system factors, including people, technology, tasks, organizations, and environments [13], may lead to improvements in the design and implementation of HITs. Furthermore, while each of these constructs is uniquely important, assessing them individually fails to capture how these constructs interact with each other. Accurately eliciting and identifying the needs of this population and understanding the work system specific to the primary care context requires accounting for the various factors affecting nurses' work [12], accounting that may be served well by a systems-level human factors perspective.

The objective of this study is to (1) characterize nurses' perceptions of process inefficiencies in the primary care setting and (2) describe related work-system factors. The Systems Engineering Initiative for Patient Safety (SEIPS) 2.0 model provides a user-centered, systems-level view of work system structure, processes, and outcomes in health care and their relationships [13]. The SEIPS 2.0 model posits that the sociotechnical work system produces work processes which shape outcomes [13]. Understanding how these factors interact has important implications for the nurses' workflow, and the implementation of interventions designed to aid them in completing tasks may influence their beneficial or adverse effects on clinical care. In addition, as more HITs are being introduced into the primary care setting [14,15], our findings

will serve as an important step in understanding how to best design and implement these technologies to support primary care nurses.

Methods

Study Design

This was an exploratory study of the work system of primary care nurses and health technicians. Guided by SEIPS 2.0 [13], we conducted contextual interviews, observed work activities, used directed content analysis methods to identify findings, and used configural diagramming to organize and report the findings.

Setting

Our study focused on ambulatory care settings. Recruitment and data collection occurred at 2 sets of primary care clinics in the Midwestern United States. Site 1 was an urban, tertiary care medical center in a large city; site 2 was a rural, community-based outpatient facility in a small town. At both sites, nurses and health technicians regularly interact with an electronic health record (EHR) system to complete nursing processes. At site 1, some clinics distributed laptop computers to nurses, while all other staff used desktop computers in staff workrooms and examination rooms. Site 1 was a participant in the US Department of Veterans Affairs (VA) Mobile Health Provider Program launched in 2014; through this program, over 12,000 Apple iPads have been distributed at more than 60 VA sites, though device usage has been reportedly less than expected [16]. At site 2, nurses and health technicians had open workrooms and used ruggedized portable computers (Panasonic Toughbook CF-H2). Docks for mobile devices were installed in workrooms and examination rooms.

Recruitment

Convenience sampling was used to identify nurses and health technicians at the primary care clinics. In the clinics of this health care system, health technicians work under the supervision of registered nurses to maintain the documents and records used in primary care nursing processes. A list of eligible primary care staff providing care in the clinic was obtained. Staff members were contacted by email to solicit participation. Primary care nurses and health technicians were subsequently contacted in person to gain their consent to engage in the interview process.

Conceptual Model

SEIPS states that a person (eg, health care professional) performs tasks in the clinical care setting that require various tools and technologies (eg, HITs). The use of these tools and technologies to perform these clinical tasks occurs within a physical internal environment governed by organizational

conditions as well as a broader external environment [13]. These components make up the work system, interact with each other, and influence each other. Variations in how these components interact can be associated with workflow and health outcomes. Furthermore, SEIPS 2.0 introduces concepts of configurations and adaptations [13]. For example, with each of the work system factors that can interact with one another, the concept of configuration acknowledges that not all of these components are relevant to each process or situation. More specifically, configuration pertains to the subset of components and their interactions that are actually relevant to a particular process or situation [13]. According to SEIPS 2.0, adaptations refer to the changes that have been attempted to decrease the gap between actual and ideal performance [17].

Contextual Interviews

We conducted semistructured contextual interviews among primary care nurses and health technicians. This method of interviewing allows researchers to observe and ask clarifying questions to participants while they are working [18]. Participants assume the role of the expert and are able to

demonstrate tasks while working, which may also prompt the discussion of tasks that they may not consider important to the topic during a traditional interview. Researchers, on the other hand, assume the role of a student or apprentice, trying to understand the work process to identify ways of improving it or implementing interventions to address any underlying problems or challenges [19].

A semistructured interview guide ([Multimedia Appendix 1](#)) was created by the research team based on SEIPS 2.0 [13]. Interview topics included (1) nurses' perspectives on process inefficiencies in primary care; (2) tasks that were considered frequent, repetitive, difficult, and related to inefficient processes; (3) the types of information needed to complete tasks; (4) the tools and technology needed to complete tasks; (5) organizational factors or policies that affect primary care nurses' abilities to complete tasks; and (6) the use of mobile applications. Terms and their associated definitions were provided to participants before the interview to establish a shared understanding (more details in [Table 1](#)). To match the study's focus on HIT, the task scope was limited to clinical and administrative information.

Table 1. Terms and definitions used during interviews with primary nurses and health technicians on process inefficiencies.

Term	Definition
Information-intensive tasks	Require reading, writing, or sharing information (eg, chart review).
Frequent tasks	Performed often or for each patient (eg, looking up patients' contact information or reviewing discharge summaries).
Repetitive tasks	Tasks done repeatedly that should only be done once or not at all (eg, repetitious logins or clicks to access required information).
Difficult tasks	Tasks requiring large amounts of concentration to complete (eg, reviewing labs or determining trends in vitals).

A total of 6 nonclinical researchers (4 with previous interviewing experience, including coauthor HP and 2 volunteers) conducted interviews using a prepared interview guide ([Multimedia Appendix 1](#)). Early interviews were led by the 4 experienced staff members, with 1 or 2 other researchers serving as notetakers. These early interviews served as training for the volunteers. In later interviews, researcher roles were rotated to limit the influence of any single interviewer.

Each session was led by 1 interviewer and 1 note-taker. Interviews lasted approximately 45 minutes and were conducted either in the general practice setting of the participants or in a private room. Each interview was audio-recorded and transcribed. Transcripts were done through a contracted professional service. Staff research assistants corrected major transcription errors and removed personal identifiers.

Analysis of Contextual Interviews

Initial qualitative analysis was done by 4 staff research assistants. All had previously served as interviewers. Each transcript was coded fully by 2 staff research assistants. Segments of data (eg, a phrase, sentence, or group of sentences) were coded iteratively. In the first iteration of coding, we identified work system components. We then identified processes performed by primary care nurses and whether they were perceived as frequent, repetitive, or difficult. Furthermore, 3 analysts (WT, AS, and HP) conducted a directed content analysis guided by the SEIPS 2.0 model to identify work system

configurations related to frequent, repetitive, and difficult tasks for specific processes [20,21].

Configuration Analysis

The interactions of the coded work system components and processes were used to identify work system configurations. Interactions are defined as segments of data assigned to 2 or more coded components. We reviewed key findings with emphasis on the participant quotes and descriptions of processes and tasks to identify the tasks identified as most influential for each process. Next, we independently defined work system configurations for each frequently reported process and met to discuss and resolve discrepancies. We created configurational diagrams [13] of work system elements related strongly to the identified inefficient processes. We then identified misalignments among work system factors. We define misalignment as a mismatch between human and nonhuman (eg, environment, policies, etc) factors that may lead to a breakdown of processes. Based on findings from the configurational analysis, we characterized adaptations as workarounds (ie, current adaptations) or recommendations (ie, future adaptations).

Ethical Considerations

This study complied with the American Psychological Association Code of Ethics and was approved by the Research and Development Committee at the Richard L. Roudebush

Veterans Affairs Medical Center and the Indiana University institutional review board (protocol #1611241830).

Results

Among the 51 eligible staff members who were contacted, 20 nurses and 2 health technicians participated in this study and completed interviews (Table 2). Most participants were female (19/22, 86%); most participants were White (17/22, 77%). Participants had a mean of 8.3 (SD 8.7, range 1-36) years of experience with their current health care employer and 11.9 (SD 8.9, range 1-30) years in their present role.

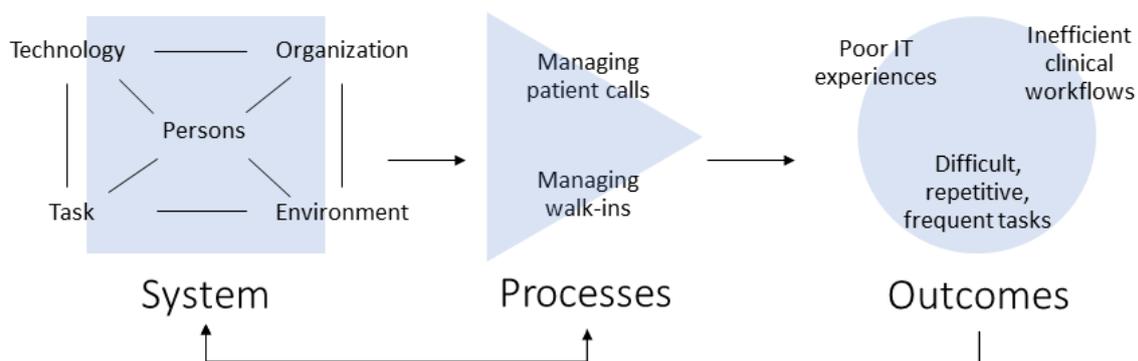

Based on our analysis, Figure 1 depicts the relationship among the nursing work system, processes, and perceived outcomes (Figure 1). Perceived inefficient workflows were associated with managing patient calls (ie, patient response calls) and walk-in patient processes. Related to these processes, participants reported managing notifications, documentation, and chart review as the most frequent, repetitive, and difficult tasks. These discussions highlighted both opportunities and potential barriers to the implementation of potential adaptations to HIT and policies for primary care nursing.

In the following sections, we report on the processes, their influential tasks, and the work system configurations, showing the most relevant components in each process.

Table 2. Demographics of participants at 2 primary care sites, one in an urban medical center (Site 1) and the other in a small community-based outpatient clinic (Site 2).

Characteristic	Both sites (N=22)	Site 1 (n=16)	Site 2 (n=6)
Role, n (%)			
Registered nurse	14 (64)	10 (63)	4 (67)
Licensed practical nurse	6 (27)	4 (25)	2 (33)
Health technician	2 (9)	2 (12)	0 (0)
Race, n (%)			
White	17 (77)	11 (69)	6 (100)
Black	2 (9)	2 (19)	0 (0)
Asian or Pacific Islander	3 (14)	3 (12)	0 (0)
Gender, n (%)			
Female	19 (86)	14 (88)	5 (83)
Male	3 (14)	2 (12)	1 (17)
Years in the role, mean (SD)	11.9 (8.9)	10.6 (8.6)	15.3 (8.8)
Years with current health care employer, mean (SD)	8.3 (8.7)	9.1 (9.8)	6.2 (3.3)

Figure 1. Application of SEIPS (Systems Engineering Initiative for Patient Safety) 2.0 to primary care nursing work systems, processes, and outcomes. Interviews with nurses and health technicians focused on inefficient processes and underlying work systems.

Inefficient Nursing Processes

Managing patient calls and walk-in visits was perceived by participants as inefficient. For patient calls, contributors to inefficiency included repeated attempts to return patient calls and the EHR’s inability to track follow-ups. For walk-in processes, contributors to inefficiency included paper-based

check-in and incomplete, self-reported patient information. We describe these in more detail below.

Managing Patient Calls

Some participants reported that they received 20 to 50 telephone calls daily from their site’s patient call center, which assists patients with various issues, such as scheduling multiple appointments and answering questions related to their care,

medication, or paperwork. Patients also contact the call center to return missed calls. Other inbound calls came from patients sharing their frustrations, which participants reported as potentially time-consuming. Participants also received alerts from their EHR system that patients had called the call center. Along with using the EHR system to process alerts, participants also referred to the EHR when calling patients.

Managing Walk-Ins

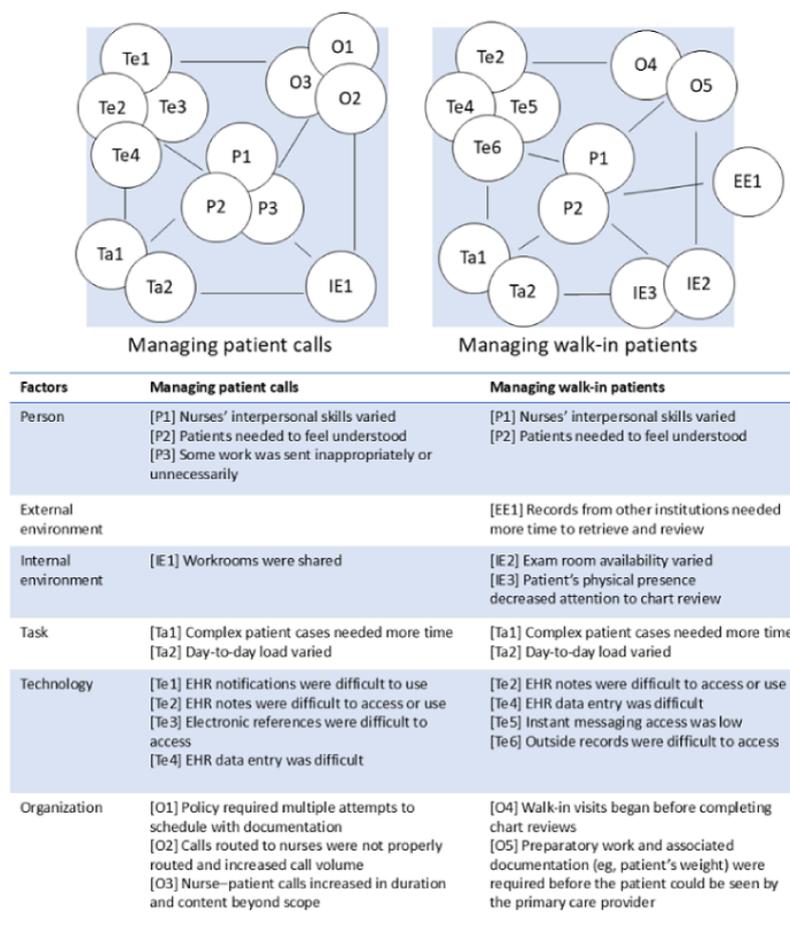

Walk-in patients are patients who arrive at the clinic without an appointment. Participants noted that on a typical day, many of their patients were walk-ins. Nurses are required to see these patients regardless of how many patients they have already scheduled, and walk-in visits can often be time-consuming depending on the patient’s needs. Managing walk-ins involved triaging and scheduling patients. Triageing patients includes the

gathering of important clinical data (eg, vital signs) and preparing the patient to see their primary care provider. Triageing time can vary, depending on the patient and the number of clinical reminders that need to be completed. Walk-in patients often enter the clinic for reasons that do not require an on-site physician evaluation, such as needing a medication refill or having minor aches and pains.

Configuration: Misaligned Work System Factors

Using SEIPS 2.0, we explored the work system configuration of the 2 aforementioned nurse processes, managing patient-response calls and walk-in patients. Participants reported these processes comprised the most frequent, repetitive, and difficult tasks. For each process, we explored the corresponding work system configurations and relevant factors. In Figure 2, we depict the configuration diagrams for both processes.

Figure 2. Application of SEIPS (Systems Engineering Initiative for Patient Safety) 2.0 to 2 primary care nursing work processes: managing patient calls and managing walk-in patients. Factor numbers are for identification and do not imply any order. Ta: Task; Te: Tools and technology; P: People; O: Organization; IE: Internal environment; EE: External environment.

The following subsections further elaborate on each of the work system factors.

Person

Attitudes toward mobile HIT were shaped by experience with other technologies, including computers on wheels. Some participants viewed the paper as a facilitator of their work-related tasks and favored paper use over mobile technology or applications. Issues such as lack of time,

susceptibility to interruption, and inability to take data to patients in nonexamination room spaces encouraged the use of the person’s memory skills or notes written on a piece of paper to transfer necessary patient information between various clinical spaces. Other issues related to other staff members, for example, a recurring issue from participants was that the call center does not properly triage patient calls made to the call center.

Environment: Internal and External

Notable environmental differences occurred across the 2 sites, although only a few tasks were affected by these differences. For example, triaging walk-ins varied among clinics. When nurses and health technicians had their own rooms, patients were triaged and seen by the physicians in that room. However, for nurses on 1 team, triaging was completed in 1 room, and then patients could be transferred into the physician's examination room. Thus, for nurses on this team, triaging required finding rooms that were open and contained the right patient education pamphlets.

Participants described the "walk-in pickup," which involves meeting walk-in patients in waiting areas to assess the presentation of symptoms in order to triage the patients quickly and effectively. This method was complicated by initial conversations occurring in nonprivate locations, which limited the level of detail that could be discussed, and by the inability to access medical records electronically during these conversations.

Tasks

Across the 2 processes, participants denoted how complex patient cases needed more time and how the day-to-day load varied. Regarding managing patient calls, participants described frequent tasks, as the call center directs all patient calls to primary care nurses regardless of individual patient needs. Furthermore, participants considered certain tasks that they completed on these calls to be repetitive, including patient education. Some participants indicated that they were largely repeating the information they had provided to patients during previous appointments, which patients had forgotten or were struggling to explain to family members. In addition, many calls come from patients trying to return nurses' missed calls; the call center team is unable to relay any information or schedule appointments for these patients. These instances often resulted in multiple unnecessary back-and-forth phone call exchanges. Participants defined this task as difficult due to the extensive amount of time it took to prioritize the list of calls and related alerts.

Participants also perceived chart review for these patients to be particularly challenging, typically consisting of a review of recent notes, laboratory results, orders, imaging reports, medication lists, or other information to familiarize staff members with a patient's background and recent medical history. Reviews were considered at the following 2 levels. (1) Flash review, which refers to the quick review of medical records in response to the initial question, "I wonder why they're coming?" (2) In-depth review, which refers to the more detailed, investigative review of medical records, typically required for care management. The in-depth review may involve "piecing together" information from a chronological series of notes to discover the narrative patient history and the synthesis of information gathered from different types of notes, tabs, or displays within the EHR. Both types of reviews are complicated when staff members are not familiar with patients (eg, new

patients and those from other staff members' panels) and when interruptions occur frequently.

Tools and Technology

Across sites, nurses described problematic aspects of the existing mobile technology. Some participants at site 2 characterized the ruggedized portable PCs as being bulky and useless. Although portable PCs eliminated the need to log in to multiple desktop PCs, mobile devices lost access to the EHR when connecting to or disconnecting from docking stations. Each transition caused the PC to swap between wired and wireless network connections. The connection swap, in turn, disconnected the user from the EHR, resulting in the loss of any unsaved data entered by the user. Instead of providing continuous information interaction and access to the EHR as expected, the portable PCs were usable mainly when docked. This limitation disappointed nurses; mobile devices were used more as luggable desktop computers than for facilitating efficient data collection and communication as expected. Furthermore, at site 1, where mobile technology was distributed and could be used voluntarily, no participants reported it useful for clinical tasks.

Organization

Furthermore, 2 organizational policies influenced the use and usefulness of mobile HIT across the sites. The first was the patient flow policy to limit unnecessary room changes during a health care visit. At site 1, patients move between stations when nurses need to measure vital signs and collect specimens. These stations were often near the nurses' desks, which decreased the need for mobile HIT. At site 2, a policy aimed at reducing patient flow was implemented that required various health care providers, including nurses, to meet the patient in the examination room. This increased the need for nurses to review and document information (eg, vital signs) in examination rooms and hallways away from their desks. In addition, an organizational policy was in place at site 1 that made the use of mobile HIT voluntary. At site 2, the use of mobile HIT was mandated; it was this mandate that accounted for the sustained use of mobile HIT.

We identified work system configurations that contributed to participants' perceptions of inefficient processes. [Table 3](#) displays recurring topics and sample excerpts of configuration details anchored by processes' frequent, repetitive, and difficult tasks. The process of managing patient calls was associated with several tasks that were identified as frequent, repetitive, and difficult. For example, handling patient calls that were inappropriately assigned was identified as both frequent and repetitive. The relevant factors for this process included person factors (ie, patients' need to feel understood, which may be difficult when the patient is assigned to the wrong person), organization factors (ie, this may result in calls increasing in duration and content beyond the scope of the recipient's work), and task factors (ie, the day-to-day load for handling inappropriately assigned calls can vary).

Table 3. Primary care nurses' and health technicians' work system configuration details anchored by processes' frequent, repetitive, and difficult tasks.

Process and task	Representative quote ^a	SEIPS ^b 2.0 work system configuration
Managing patient calls		
Handling patient calls that were inappropriately assigned (Frequent)	“They’re calling about an issue that is out of my control, they’re very upset, they didn’t want their methadone to go away, their methadone is gone, and they want to talk about 30 minutes. That’s a real time-waster for me because, you know, that’s, I realize they want an outlet, and they’re frustrated, but for me, I can’t help them, and they’re just getting more worked up. Things like, a lot of calls like that where there’s really just nothing to do and all they really want to do is talk to someone, but I’m not getting anything done.”	<ul style="list-style-type: none"> • [P^c2] Patients needed to feel understood • [O^d3] Nurse–patient calls increased in duration and content beyond scope • [Ta^e2] Day-to-day load varied
Handling patient calls that were inappropriately assigned (Repetitive)	“The patient calls and the call center relays the message to me if it needs to come to Primary Care. Sometimes it doesn’t need to come to Primary Care. Sometimes what usually happens though is I will call the patient back to speak with the patient. I can’t get a hold of the patient so then they’re calling the call center again. Well, at that point I have a patient in my office. I can’t take the phone call. We’re doing that all day long. We’re playing phone tag constantly. Just very redundant.”	<ul style="list-style-type: none"> • [P1] Nurses’ interpersonal skills varied • [O3] Nurse–patient calls increased in duration and content beyond scope • [Ta2] Day-to-day load varied
Managing notifications (Repetitive)	“Oh, there are a lot of view alerts where they send them to multiple people, and a lot of times, they could just come to me. As soon as I see it, I’ll do it. But there again, now 2 or 3 other people have to look at it and see if it’s been done. That’s kind of redundant.”	<ul style="list-style-type: none"> • [P3] Some work was sent inappropriately or unnecessarily • [Te^f1] EHR^g notifications were difficult to use • [Ta2] Day-to-day load varied
Scheduling appointments with patients when they are not in the office (Repetitive)	“They want us to continue trying to contact these patients and to me, it just seems redundant. If the patient, wanted an appointment, they would’ve called and scheduled you know, so it seems like a waste of time when I’ve got 40 people that I’m trying to call and I have to put a note here, I have to chart it over here, I have to delete the recall.”	<ul style="list-style-type: none"> • [O1] Policy required multiple attempts to schedule with documentation • [Te4] EHR data entry was difficult • [Ta2] Day-to-day load varied
Managing walk-ins		
Checking in walk-ins (Frequent)	“There’s somewhere anywhere from 8 to 12 patients scheduled a day and we’ve got to get them ready to see the provider which can take some time. It can take anywhere from 10 minutes, or it might take 30 minutes to check in some of these patients so that takes up the majority of the time.”	<ul style="list-style-type: none"> • [Te4] EHR data entry was difficult • [Ta1] Complex patient cases needed more time • [Ta2] Day-to-day load varied
Quick patient assessment and triage (Frequent)	“Because I may only get 2 or I may get 7 but they take up a great deal of time and they walk in and you need to stop whatever you’re doing and go out to them right then.”	<ul style="list-style-type: none"> • [O4] Walk-in visits began before completing chart reviews • [Ta2] Day-to-day load varied
Chart review of external medical records (Repetitive)	“It’s just time consuming to kind of sit and look at all that, especially if you have a patient that maybe came from the outside VA...they might say you know “well I had all this done at the other VA and so kind of trying to pull all the VistA Web [health information exchange service] stuff and look at that is kind of, definitely that’s time consuming.”	<ul style="list-style-type: none"> • [O5] Preparatory work and associated documentation (eg, patient’s weight) were required before the patient could be seen by the primary care provider • [Te6] Outside records were difficult to access • [EE^h1] Records from other institutions needed more time to retrieve and review • [Ta2] Day-to-day load varied
Chart review for new patients with little time before patient visit (Difficult)	“Sometimes the walk-ins can be difficult because it might not be your patient if you’re covering for someone. You don’t know the patient at all and you’re trying to piece it all together, because you can’t just go to the walk-in doctor and say they’re here, they say their head hurts. That’s not going to fly, you know, so it’s kind of a lot of maybe 15-20 minutes in their chart, and if the patient is in there while you’re doing it, that’s kind of distracting, because they don’t understand that you don’t know them and you need to review their chart, so they just take off with their current situation assuming you know their background often, so yeah....”	<ul style="list-style-type: none"> • [P2] Patients needed to feel understood • [O4] Walk-in visits began before completing chart reviews • [Te2] EHR notes were difficult to access or use • [IEⁱ3] Patient’s physical presence decreased attention to chart review • [Ta1] Complex patient cases needed more time
Managing patient calls; managing walk-ins		

Process and task	Representative quote ^a	SEIPS ^b 2.0 work system configuration
Chart review before the patient visit (Difficult)	“At least if it’s a phone call, I can see the message and why they’re calling. I can review the chart. If I need help before calling them back, I can go ahead and get that. When you’re sitting in front of somebody and they say well, I’m coughing and I have a headache. I’m having to do all of this in real time.”	<ul style="list-style-type: none"> • [P1] Nurses’ interpersonal skills varied • [O4] Walk-in visits began before completing chart reviews • [IE3] Patient’s physical presence decreased attention to chart review • [Te2] EHR notes were difficult to access or use • [Ta1] Complex patient cases needed more time
Patient education and chart review (Difficult)	“It takes a lot of time because it’s a lot of educating the patients and you know looking back, what was done before, going through labs, meds. You’ve got to go through side effects of meds and assess everything completely. So, those can be a little bit time consuming...”	<ul style="list-style-type: none"> • [P1] Nurses’ interpersonal skills varied • [Ta1] Complex patient cases needed more time • [Te2] EHR notes were difficult to access or use

Adaptations: Perceived Adaptability and Recommendations

Work system components “Tools and technology” and “Organization” were associated with the most misaligned factor configurations (Table 3). In addition, these factors were perceived to be the most adaptable among participants. Some reported adaptations were workarounds, while other adaptations were recommendations for unmet needs. Participants did not describe or discuss recommendations related to the remaining work-system components (People, Environments, and Tasks).

Workarounds

Primary systemwide adaptations created process inefficiencies, leading to secondary localized adaptations in the form of user workarounds. At site 2, participants reported that the policies for patient-centered flow and dockable PCs, taken together, limited their EHR review and charting to the times that their PCs were docked. Their interim storage needs were met using paper notes, which also addressed the risk of data loss from EHR disconnections. Paper notes were shared with physicians, who could then review and add to the notes before the notes were entered into the EHR after the visit.

Site 1’s walk-in policy, combined with the physical layout of the clinic, was also linked to the use of paper notes. One site 1 clinic created a paper intake form for patients to self-report the reason for their visit and the reason for walking in instead of alternatives (eg, making an appointment or refilling medications through the patient portal). For health technicians, paper notes indicated double documentation: for example, the patient’s weight would be written while in the corridor by the weight scale, then reentered into the EHR afterward. Using a different

workaround, the “walk-in pickup” described in the previous section, participants balanced their need for intake information with their need to manage each patient’s expectations about when they would be seen. This approach necessitated a chart review in which staff looked for information to aid triaging, including the time since the patient’s last visit and the frequency and nature of the patient’s previous walk-in visits.

At site 1, to work around inefficiencies with patient calls, 1 participant reported using their appointment scheduler software to track outbound follow-up calls about lab results. However, these appointments appeared in the patient-facing portal, which sometimes confused patients who were not expecting such calls.

Recommendations

Recommendations included changes to “tools and technology.” Among the participants’ suggestions to improve walk-in management were new tools for symptom self-reporting and triage. To improve the check-in process for walk-in patients, 1 recommendation from a participant was a patient-facing technology for collecting patients’ descriptions of their health issues (eg, symptoms of congestive heart failure). Another participant’s suggestion was a personalized display of the expected waiting time, encouraging patients with less serious ailments to consider scheduling an appointment or requesting information about alternative ways to address their medical concerns. For themselves, participants sought a method to view relevant patient trends, minimizing the need for rushed chart review. Many participants wanted call center staff to offer greater mediation between themselves and patients. Currently, back-and-forth communication is needed to understand a patient’s concerns or issues. More and better training resources could be made available.

Discussion

Principal Findings

In this study, we described primary care nurses' work system configurations associated with inefficient processes, misaligned work system factors, and adaptations to guide future interventions. Managing patient calls and managing walk-in patients were inefficient processes. The results from our work system analysis defined nursing tasks associated with each process that was described as frequent, repetitive, or difficult among primary care nurses and health technicians. In addition, we applied SEIPS 2.0's configuration concept [13] to illustrate subsets of work system factors that were associated with workflow inefficiencies. With the model's adaptation concept, we characterized the propagating, negative impacts of changes to a work system component. Some adaptations were made by health care workers in the form of workarounds, with varying success, while other adaptations were recommended.

SEIPS 2.0 Application to Primary Care Nursing Processes

Although SEIPS 2.0 has been used to identify tasks associated with decreased work ability among inpatient nurses [22,23], to our knowledge, this is among the first applications of SEIPS 2.0 specifically to primary care nursing processes. The original SEIPS framework [24] has been identified as a means of describing and evaluating processes in primary care by taking into account the complex, interconnected socio-technical aspects found in the health care system [25]. Lagisetty et al [26] organized their systematic review of primary care opioid use disorder interventions using SEIPS 2.0's concepts of work system factors, processes, and outcomes [13]. Robertson et al [11] used SEIPS 2.0 [13] to identify barriers and facilitators to integrating practice guidelines to reduce under-5 mortality in a primary care clinic in Malawi; their recommendations addressed mostly organizational factors. More recently, Werner et al [20] used SEIPS 2.0 configuration diagrams [13] to illustrate work barriers and facilitators within work system configurations for older adults' transitions between emergency department to home. McCormack et al [27] used SEIPS 2.0 to identify facilitators and barriers to referrals between primary and specialty care services.

Misaligned Work System Factors

The misalignment of tasks, organization, and technology factors was described among multiple configured sets of work system factors. Patient flow policies introduced more nomadic or mobile aspects and interruptions to primary care nursing processes. Other studies have defined telephone calls and conversations as the most common sources of interruptions for nurses and health technicians [28]. In this study, we refer to these as unscheduled tasks. In workflows, increased movement of primary care nurses increased the amount of missed patient phone calls, alerts about missed patient phone calls, and associated patient voicemails. Furthermore, increased presence in hallways and rooms appeared to yield more impromptu conversations. The implemented mobile HIT to support this patient flow was limited by poor connectivity to the network making data transfer difficult, and possible data loss when

unlocking mobile devices. Experiencing high levels of process discontinuity predisposes health care staff to make errors [29,30]. Processes with unscheduled tasks introduced work fragmentation or a break in continuous work activity. Despite demonstrated resilience against interruptions [31], unscheduled tasks increased nurses' and health technicians' cognitive load and decreased their ability to recall information needed to complete task switching effectively [32]. Minimizing unnecessary interruptions is particularly important in the health care context, where failing to complete tasks can have adverse effects on health outcomes and patient safety.

Adaptations: Feedback and Indicators of Gaps

Based on SEIPS 2.0, the inefficiencies described in our study can be indicators of gaps in performance, quality, or patient safety [13]. Whether initiated or recommended by nurses, the adaptations identified in this study were mostly reactive to new policies recently implemented. These adaptations indicated gaps in HIT performance and quality of nursing processes, which may be linked to patient, nurse, or organizational outcomes [33]. Previous studies have denoted that traditional or routine clinical quality indicators do not always include measures for HIT-related aspects of workflow, such as usability [27,34]. Poor usability of HIT is associated with various types of adaptations, often referred to as workarounds [35,36]. For example, the new policies and HIT (ie, planned adaptations) were implemented to improve patient flow and access to primary care services. Yet, nurses described the generation of new gaps or inefficiencies that propagated throughout the work system, which we characterized as misalignments. Based on their experiences, nurses were able to identify inefficiencies, implement workarounds (adaptations to the patient flow adaptation), and suggest recommendations for future adaptations. While other interpretations of workarounds vary [33,37], SEIPS 2.0 represents these types of adaptations as feedback. Without this type of feedback, monitoring such dynamic complex work systems, important indicators and gaps would not be recognized, and efforts for continuous improvement would be hindered.

Future Design and Implementation Strategies

Studies like this are foundational to future interventional research. Future design and implementation of interventions for these and similar nursing processes are warranted as health care use increases and diversifies with same-day and virtual visits, which have similar aspects and common tasks with the inefficient processes identified in this study. Due to the interconnectivity of work systems, adaptations focused on a single component or subset of components will affect other components. Whether the adaptation is planned or unplanned, the lack of consideration for all the components in the work system increases the potential for negative, unintended consequences. Without work system analyses, the implementation of interventions can negatively affect clinicians, patients, and organizational outcomes. Similar problems in other clinician groups have been addressed by incorporating system-level design and implementation of HIT [38]. Yet, varying institutions have unique needs or processes that demand different solutions. For example, the distribution of mobile

devices without apps that are tailored to our participants was insufficient to meet their needs. Therefore, understanding the personalized challenges of an institution warrants a systems-level analysis. Our findings provide a necessary first step in the development and integration of future health information technologies that improve the efficiency of health care delivery by supporting frequent, difficult, and repetitive tasks for nurses. In addition, this research shows that for interventions, including health information technology implementation, to be successful, implementers must also account for work system factors such as organizational policies. Based on our findings, the major opportunities for adaptations are related to workflow policies and supporting health information technologies for primary care nurses.

Since the completion of our study, the VA's Office of Connected Care is supporting an increasing number of provider- and patient-facing mobile apps, including task-specific apps [39]. Providers currently have access to a variety of task-specific apps for mobile computing through the VA App Store [39].

Strengths and Limitations

A strength of this study is that it uses a human factors approach to identify major contributors to inefficiencies at the systems level. This study also has several limitations. A limitation of this study is that the observations and interviews were performed in clinics belonging to 1 integrated health care institution.

Convenience sampling may have introduced biases in participants' reporting of work processes and barriers. Our findings may not entirely transfer to other health care systems and settings. Therefore, more attention should be given to aiding in the design and development of user-centered apps in different settings with different work system configurations. Similarly, while we identified notable differences between the 2 sites used for this study, we did not further assess how those differences contributed to our results. Finally, this study focused only on the potential of mobile HIT as a solution to process inefficiencies. As a result, this may have elicited confirmation bias.

Conclusion

Nurses and health technicians perceived that the implementation of new policies and technologies contributed to inefficiencies in nursing workflows across ambulatory settings. A system analysis was an effective method for identifying configured subsets of work system factors associated with perceived gaps in nursing processes. Furthermore, the configuration and adaptation concepts in the SEIPS 2.0 framework aided in the characterization of adaptations to inform future research and interventions. To identify both potential consequences across work system components and nursing processes, system analyses are warranted for the design, implementation, and evaluation of organizational policies or HIT.

Abstract

Background: Digital technologies have impacted health care delivery globally, and are increasingly being deployed in clinical practice. However, there is limited research on patients' expectations of doctors' clinical competencies when using digital health care technologies (DHTs) in medical care. Understanding these expectations can reveal competency gaps, enhance patient confidence, and contribute to digital innovation initiatives.

Objective: This study explores patients' perceptions of doctors' use of DHTs in clinical care. Using Singapore as a case study, it examines patients' expectations regarding doctors' communication, diagnosis, and treatment skills when using telemedicine, health apps, wearable devices, electronic health records, and artificial intelligence.

Methods: Findings were drawn from individual semistructured interviews with patients from outpatient clinics. Participants were recruited using purposive sampling. Data were analyzed qualitatively using thematic analysis.

Results: Twenty-five participants from different backgrounds and with various chronic conditions participated in the study. They expected doctors to be adept in handling medical data from apps and wearable devices. For telemedicine, participants expected a level of assessment of their medical conditions akin to in-person consultations. In addition, they valued doctors recognizing when a physical examination was necessary. Interestingly, eye contact was appreciated but deemed nonessential by participants across all age bands when electronic health records were used, as they valued the doctor's efficiency more than eye contact. Nonetheless, participants emphasized the need for empathy throughout the clinical encounter regardless of DHT use. Furthermore, younger participants had a greater expectation for DHT use among doctors compared to older ones, who preferred DHTs as a complement rather than a replacement for clinical skills. The former expected doctors to be knowledgeable about the algorithms, principles, and purposes of DHTs such as artificial intelligence technologies to better assist them in diagnosis and treatment.

Conclusions: By identifying patients' expectations of doctors amid increasing health care digitalization, this study highlights that while basic clinical skills remain crucial in the digital age, the role of clinicians needs to evolve with the introduction of DHTs. It has also provided insights into how DHTs can be integrated effectively into clinical settings, aligning with patients' expectations and preferences. Overall, the findings offer a framework for high-income countries to harness DHTs in enhancing health care delivery in the digital era.

Introduction

Background

Digital health care, which can be defined as the use of advanced technologies to replace or complement existing health care services and practices, is becoming increasingly prevalent in clinical work [1]. Digital health care technologies (DHTs) such as electronic health records (EHRs), telemedicine, wearable devices, mobile health, and other digital tools have been beneficial to health care delivery [2]. The widespread adoption of EHRs has enabled the streamlining of patient data, making it easily accessible to health care providers and improving care coordination [3]. The growth of telemedicine has facilitated consultations between health care providers and patients living in remote and underserved areas [4,5]. Furthermore, the development of wearable sensors and smartphone apps has allowed for the continuous monitoring of neurodegenerative disorders and the detection of related disease symptoms, respectively, among other benefits [6]. The integration of automation and artificial intelligence (AI) in health care has also enhanced various medical procedures including improving diagnosis and overall work efficiency [1,7]. These technologies have proven useful for patients especially where the barriers to adoption are low [1,7].

Singapore, a high-income country in Southeast Asia, makes a compelling case study for investigating how end users perceive the use of DHTs. This is attributed to a myriad of reasons: its high rate of technological advancement, strong government support for digitalization, efficient health care system, and a diverse population. Singapore is renowned for its advanced technological infrastructure and digital capabilities. Despite being the smallest country in Southeast Asia [8], Singapore is ranked first in the world in internet availability [9]. In addition, there is a high proliferation of digital technology and mobile phones in the country [10]. In 2020, 88% of its population was using smartphones compared to 78% globally [9]. A survey has also shown that the potential for digital uptake is high, and Singaporeans are open to incorporating digital tools in their health routines especially if it is beneficial to them [11]. The Singapore government has also invested heavily into transforming Singapore into a Smart Nation, an initiative that leverages technology and data to improve economic competitiveness and enhance the lives of its citizens [12]. In the realm of health care, it has rolled out digital initiatives to fulfill its population's health care needs [9]. These include introducing telehealth, as well as implementing robotics and assistive technology solutions, to help older adults and those with mobility issues [13]. AI technologies have also been used in specialties such as radiology and ophthalmology and are expected to be a transformational force in Singapore's health care [14]. Its well-established health care system makes it an ideal environment to study the integration of DHTs into health care delivery. Notwithstanding its small size of 734 km²,

Singapore is also home to a diverse population with varying demographics, including different cultural influences, age groups, and socioeconomic backgrounds [8]. These factors make Singapore a worthwhile case study to explore patient perceptions and expectations of their doctors' DHT competencies.

Despite the proliferation of DHTs in many high-income countries such as Singapore, there is a lack of research that captures the perspectives of patients on the clinical competencies that doctors need to be equipped with when DHTs are being deployed. Clinical competencies in this study refer to the knowledge, skills, and attitudes that medical doctors should possess when assessing, diagnosing, treating, and caring for their patients [15,16]. Existing research on patient and public involvement in digital health has either taken a broad approach [17,18] or is focused on specific areas, such as digital health consent in the context of clinical care [19]. It is important to examine patients' expectations of doctors' competencies in DHTs in their clinical care for several reasons. First, it would help identify any existing gaps in competencies. Second, patients' confidence in the health care system would depend in part on doctors' using DHTs competently in the diagnosis and management of their medical conditions. Third, studies and reviews have shown that greater efforts to involve patients in digital planning and implementation need to be made from the outset so that they can contribute meaningfully to digital innovation initiatives [17,18].

Objective

This paper aims to address the aforementioned gap by assessing how patients perceive the use of DHTs by doctors in the context of clinical care. Using Singapore as a case study, it examines patients' expectations of their doctors when telemedicine, health apps, wearable devices, EHRs, and AI technologies are used. Specifically, it evaluates their views on how doctors should communicate, diagnose, and treat their conditions when deploying these DHTs. In view of the lack of research done in non-Western contexts on patient involvement in digital health studies [17,19], Singapore represents an important case study for exploring this topic.

Methods

Setting and Sample

We adopted a social constructivist approach to understanding the subjective experiences and diverse interpretations of individuals in their social context. This approach facilitates the understanding of the meaning of a text as an "interaction between the preconceptions of the reader and the intentions of the producer" [20]. Hence, it raises the possibility of an agreement between various individual meaning constructions [20]. A qualitative study involving individual semistructured interviews with patients from outpatient clinics of a public health care cluster in Singapore was performed.

Data were collected from June 2022 to June 2023 through individual interviews with patients. For maximum variation, purposive sampling was used to recruit patients who were seeking treatment for various medical conditions. This type of sampling has been widely adopted in many health sciences research studies, as it enables researchers to select participants with specific characteristics or conditions relevant to the study [21-23]. Accordingly, 1 to 2 patients with at least 1 of the conditions that constituted chronic disease burden in Singapore were recruited [24]. These were the medical conditions that were commonly reported in Singapore and that would have a significant impact on health [24]. They included cancer, cardiovascular disease, diabetes and kidney diseases, neurological diseases, and autoimmune diseases. Amid the trend of an aging population with comorbidities in high-income countries [25], it is imperative to examine the type of clinical competence that may fulfill the health care needs of patients with multiple conditions. In addition, participants from different age groups, spanning between 20 and 39 years, 40 and 59 years, and ≥ 60 years, were interviewed. This was done with the aim

of exploring whether patients from different generational cohorts had varying expectations regarding their doctors' competencies and if so, what those expectations were. Furthermore, we recruited patients from various ethnic groups to assess if cultural factors had any influence on what patients anticipate of their doctors.

We first conducted pilot interviews with 5 patients from the outpatient clinics of a health care cluster who met the aforementioned criteria to ensure that the interview questions were clear and relevant and that the interview process flowed smoothly. We then carried out more interviews until data saturation was reached. Potential participants were first identified by WF before research fellow HZ sent email invitations for the interview. Interviews were then conducted and recorded over Zoom (Zoom Video Communications) unless participants requested an in-person interview. Acceptance of invitations for a Zoom interview served as consent for participation. In the reporting of findings, we followed the Standards for Reporting Qualitative Research proposed by O'Brien et al [26] (Table 1).

Table 1. Standards for reporting qualitative research.

Data Collection

The interview guide was developed based on the framework given by Kallio et al [28] for developing a qualitative semistructured interview guide. This involved a 5-step process, namely, identifying the prerequisites to use a semistructured interview, retrieving and using previous knowledge in the literature and empirical data based on consultations with experts, formulating the preliminary interview guide with the research team, pilot-testing the interview with 5 patients, and finalizing the full interview guide for data collection [28]. Data from patients with different medical conditions and social backgrounds were then collected to ensure a broad representation of findings. At the beginning of the discussion, the interviewer reiterated the participants' right to withdraw from the study at any time during the interview. In addition, the interviewer informed the participant that the data collected up to the point of withdrawal would be retained and analyzed to enable a comprehensive evaluation of the findings.

The interview questions sought patients' views on their experiences with DHTs, if any; their expectations of their doctors when it comes to treating and diagnosing their illnesses, particularly when DHTs were used; and their suggestions on how different stakeholders in the health care system could improve the way patients were treated and diagnosed with the

aid of DHTs (Table 2). The DHTs that we selected were those that were reported to be popular among Singaporeans and that were expected to transform the health care delivery of high-income countries such as Singapore [11,29]. These included health care-related mobile apps. In Singapore, the app that is commonly used by Singaporeans is the HealthHub app. Launched in 2015, it is a one-stop online health information and services portal and mobile app that allows Singaporeans to access their health records, laboratory results, and other health-related information; manage future medical appointments; and pay medical bills, among other functions [9]. The other DHTs were wearable devices, EHRs, AI, and telemedicine, which we defined as the use of information and communications technologies to deliver health care services from a distance [30].

In reviewing the issues of reflexivity, we considered how our assumptions and prejudices might influence our research [31]. In so doing, we discovered that there was a tendency to assume that participants of higher educational qualifications would be more familiar with the terms related to DHTs. Hence, the assumption is that there would be less need for the interviewer, HZ, to explain the terms in detail. However, the pilot interviews proved otherwise. To overcome this bias, HZ defined the key terms found in the interview guide for all participants for subsequent interviews.

Table 2. Interview questions.

Number	Questions
1	<ul style="list-style-type: none"> We are living in an age where digital technologies are prevalent in our everyday lives including in our health care experience. New forms of technology such as Artificial Intelligence or AI and robotics have influenced health care treatment and diagnosis. <ul style="list-style-type: none"> Do you expect your doctor's roles to change with the advent of digital technologies? If yes, in what ways? What are your expectations of a doctor when it comes to (1) treating your illness or conditions, (2) diagnosis, and (3) overall patient care?
2	<ul style="list-style-type: none"> Do you have any experience of using digital platforms when consulting your doctor? These include video consultations over Zoom, WhatsApp or any other teleconferencing platforms. <ul style="list-style-type: none"> If yes, please share with me your experience, particularly with regard to the quality of care you received. What role do you expect your doctor to play during a teleconsultation? Do you prefer face-to-face or virtual consultation with your doctor? Why? There are certain limitations of using virtual consultation, such as the absence of physical examination. Do limitations like this matter to you?
3	<ul style="list-style-type: none"> Do you have any experience of using other digital tools for health care, particularly a medical monitoring device or wearable device? <ul style="list-style-type: none"> If yes, share with me your experience. Did you face any inconveniences or challenges when using these devices? How did you overcome them? What role do you expect your doctor to play when you are using these devices?
4	<ul style="list-style-type: none"> Have you used any health care-related smartphone applications such as "HealthHub," to seek health care services? (HealthHub is a one-stop web portal with an accompanying digital application for obtaining information about health conditions, assessing health records, managing medical appointments, and paying medical bills, among other functions). <ul style="list-style-type: none"> If yes, share with me your experience. Did you face any inconveniences when using the app? If no, are you open to using such apps for health care purposes?
5	<ul style="list-style-type: none"> In your opinion, how important is it for doctors to have the ability to interact with their patients and caregivers/family members, including explaining medical terms and giving medical advice clearly? <ul style="list-style-type: none"> How important is it for doctors to have good inter-personal skills such as showing respect, care and compassion for their patients? How important is it for doctors to maintain eye contact with you while he/she is keying in your medical records in the system? Why?
6	<ul style="list-style-type: none"> I would like to know your thoughts on what the following stakeholders can do in order to improve patients' experience when digital technologies are being used: <ul style="list-style-type: none"> Doctors Hospitals and polyclinics (public primary health care clinics) Medical schools (particularly in terms of training future medical graduates in digital technologies)
7	<ul style="list-style-type: none"> Do you have any other concerns if your doctor were to use digital technologies to treat you or to diagnose your medical condition?
8	<ul style="list-style-type: none"> Do you have any other comments on the skills or knowledge that doctors need to have when treating, diagnosing, assessing, and caring for you especially amid rapid technological advances?

Data Analysis

HZ and FKY read the transcripts independently and adopted an inductive thematic analysis approach when evaluating the data. This allowed us to draw common and shared meanings among the participants [32]. It also enabled the flexibility to accommodate new insights about the data [33]. Coding frameworks and themes were developed iteratively using the 6-step process proposed by Braun and Clarke [27] in which we first familiarized ourselves with the data by reading the transcripts in their entirety before generating relevant codes and combining them into themes. We then reviewed the themes before determining those that we deemed significant to the research questions and finally reporting the findings [27].

We also compared the findings with all relevant up-to-date local and global literature that report on patients' expectations of

doctors, as well as views of stakeholders from the health care industry toward the competencies needed for current and future clinical practice [34-39]. Any coding discrepancies were resolved through consensus between HZ and FKY and through seeking the opinions of other coauthors.

Ethics Approval

Waiver for ethical approval was granted by SingHealth Centralised Institutional Review Board (reference 2020/2880).

Results

A total of 25 patients of different genders; from different ethnicities, socioeconomic backgrounds, educational levels, age bands; and with various medical conditions participated in our study. Their demographics are described in Table 3. In summary, 14 (56%) were male and 11 (44%) were female. Only 8 (32%)

out of 25 patients had used telemedicine, while 17 (68%) patients had used a medical monitoring or wearable device. As many as 18 (72%) participants had used the HealthHub app. Generally, the participants were receptive to the use of DHTs as long as their safety and personal medical data were not compromised.

With regard to wearable devices and mobile apps such as HealthHub, most participants (n=18, 72%) regardless of gender, ethnicity, age, socioeconomic background, and educational qualifications expected their doctors to be competent and more proactive in engaging them with the medical data found in these devices. They also expected doctors to handle the data in an ethical manner, in a way that abided by personal data protection laws. Specifically, participants such as P20 would like their doctors to offer them guidance on using medical devices correctly, review the results of laboratory tests with them, and explain any anomalies that may be present in their medical data (Table 4). There were also participants such as P5 who expected doctors to collaborate with patients in their health care journey through advising them on the type of apps that were safe to use instead of taking on paternalistic doctor-patient roles (Table 4). Others, such as P24, expected doctors to comply with the guidelines on data protection. Amid increased cybersecurity risks, she was concerned that her personal information might get leaked when doctors use mobile apps such as WhatsApp to share photos of patients' medical scans and other medical information with their colleagues (Table 4).

Regarding telemedicine, participants expected a level of assessment of their medical conditions that was similar to a physical consultation. Specifically, participants such as P22 expected their doctors to deliver comprehensive quality of care that would not compromise their safety when consulting patients on digital platforms. For example, P22's doctor had mistakenly prescribed him a lower dosage of medicine than what he needed during a Zoom consultation, which necessitated a visit to the clinic to obtain the correct dosage (Table 4). Participants were also appreciative if doctors were able to discern that their condition required a more detailed examination and that an in-person consultation was needed. For example, P24 expected doctors to know when to refer patients with severe medical symptoms to specialists for further medical assessment (Table 4). Moreover, participants would like doctors to perform a holistic examination of their conditions so as not to miss the symptoms of illnesses that could have otherwise been detected through physical examination. Participants such as P2 called for doctors to look out for signs that might reveal illnesses other than the one that the patient was seeking treatment for (Table 4). According to P2, doctors should know how to detect these through a thorough assessment of the patient's body language and facial expression. In general, participants preferred teleconsultation for acute illnesses such as coughs and colds. Physical consultation was deemed necessary when seeking treatment for their chronic conditions.

When it comes to participants' expectations of doctors' communication skills when using EHRs, eye contact was appreciated but deemed nonessential by most participants (n=15, 60%). Generally, participants did not find it necessary for doctors to maintain regular eye contact with them, as they valued the doctors' efficiency in carrying out their clinical work more than eye contact. To them, it was important for doctors to be competent and focused when documenting clinical records in order to avoid committing errors (Table 4). The older patients also shared that the rapport they already established with the doctor rendered sustained eye contact redundant (Table 4).

Although the participants did not regard regular eye contact during clinical documentation as essential, a significant proportion (n=21, 84%) opined that doctors should still display empathy in other phases of the clinical encounter regardless of whether DHTs were used. To participants such as P19, a patient with kidney disease, empathy should be conveyed even more in the digital age when DHTs were being used. P19 was concerned that doctors might not exhibit as much empathy if they were to use DHTs. This sentiment arose from her experience where even in the absence of DHTs, her doctor had not shown empathy toward her; the doctor had dismissed her pain and merely prescribed her medication after she shared about her skin condition (Table 4). A similar sentiment was shared by P25, a patient with paraplegia, who emphasized that empathetic communication, above any other skills, should be central to a doctor's bedside manners. This expectation came about following her brief conversation with her doctor, who informed her that she could no longer walk. According to P25, the doctor did not even show any empathy or take the time to explain how he derived at his diagnosis (Table 4).

In addition, most participants from the age group of 20 to 39 years saw a greater immediate need for doctors to use digital technologies such as AI and machine learning for more accurate diagnosis and treatment than those in the older age groups who were having similar conditions. Participants from the former age group expected doctors to be trained in the algorithms behind these technologies, as well as the underlying principles and purposes of different DHTs in order to better assist them in diagnosis and treatment. For example, P15, a 28-year-old patient, who had encountered difficulties with venipuncture, shared that having a technological device would help doctors locate her veins and draw her blood without inflicting any pain on her. This method was preferred to the existing one where she had to be poked multiple times by her doctors based on trial and error. Similarly, P21, a 27-year-old patient, believed that AI technologies would help streamline certain aspects of the health care process, making diagnosis and treatment more time efficient. This expectation came about after her doctors took 1 year to diagnose her with rheumatoid arthritis. Previously, 4 doctors who attended to her had dismissed her condition, as the symptoms did not fit the regular markers of rheumatoid arthritis.

Table 4. Illustrative quotes from interviews with participants.

Themes and subthemes	Quotes from participants
Active and ethical engagement with medical data in mobile apps and wearable devices	
Guidance from and collaboration with doctors in the use of mobile apps	“I expect doctors to collaborate with patients and guide them on which app is safe to use since there are so many of them out there...One of the points I keep making at various conferences is that, patients and doctors are not really collaborators in Asia, we are more like in a donor-and-a-beneficiary relationship, where the doctor is giving something and we are just taking it. We are not rising up as a partner in care. We need to take some responsibility, you know, contribute, understand, and then work together.” [P5 aged 55 years, stroke survivor]
Doctors’ knowledge of mobile apps	“I’ve used HealthHub app to check appointments and the results of my blood test, which will usually be out about two hours after the test. I will check my potassium level et cetera after taking blood at the hospital and before consultation. I expect the doctor to know how to use HealthHub too because it can help to speed up consultation with the doctor since both of us would have seen the health data already even before the consultation. There was once when I saw a young doctor for consultation and told her, ‘I already know my potassium level, et cetera from the blood test, and she was like, how did you know?’ So, I told her it’s all in my phone. She might not know it because the app was just launched back then.” [P15 aged 28 years, kidney and systemic lupus erythematosus]
Doctors’ engagement with patients’ medical data found in mobile apps and wearable devices during consultation	“When using the device, I expect doctors to help me how to use these stuffs correctly, review the results and explain anomalies.” [P20 aged 39 years, diabetes, osteoarthritis, and rheumatoid arthritis]
Doctors’ integrity when handling patients’ data	(On concern about data privacy): “My concern is with data security. Doctors should not send photos of scans to their colleagues on WhatsApp for a quick consult. It’s convenient but it’s not ideal because sometimes your WhatsApp account can be synced to your Google photos. So, everything just automatically gets backed up in their personal account, unless they go and delete it. If they don’t send the scan with our IC (Identification Card) number, it’s not so bad. So, it’s important to protect confidential information.” [P24 aged 39 years, thyroid cancer and rheumatoid arthritis]
Doctors’ awareness of cybersecurity risks	(On concern about data privacy): “My concern is with data security. Doctors should not send photos of scans to their colleagues on WhatsApp for a quick consult. It’s convenient but it’s not ideal because sometimes your WhatsApp account can be synced to your Google photos. So, everything just automatically gets backed up in their personal account, unless they go and delete it. If they don’t send the scan with our IC [identification card] number, it’s not so bad. So, it’s important to protect confidential information.” [P24 aged 39 years, thyroid cancer and rheumatoid arthritis]
Comprehensive and uncompromised quality of care	
Undivided attention	“I don’t think my expectations of the doctor would be the same when it comes to teleconsult. Yes, it’s kind of a replication of the clinical setting where we are talking to each other. But now, the doctor has to look at me and talk, right? Whereas when in the clinic, the doctor can be distracted by the computer, or saying something to the nurse or passing a note to whoever walks in. There are a lot of things happening in the clinical setting whereas in a zoom meeting, you are literally talking to that one person, so I’d expect there to be 100% attention.” [P1 aged 54 years, cancer]
Pitfalls and limitations of teleconsultation	“In terms of preference, I still prefer face-to-face so that I can get appropriate care and treatment because when I do it over Zoom, the doctor cannot monitor my blood pressure and breathing. I’ve been given a lower dosage of medicine before when doing consultation over zoom. When that happened, I still needed to do a face-to-face consult anyway to take a higher dose of medicine.” [P22 aged 35 years, asthma and mitral valve prolapse]
Knowledge of medical conditions that require further assessment	“I would expect the doctor to know when it’s time to escalate the situation to a specialist. So, if the symptoms are severe, they should refer the patient to urgent care.” [P24 aged 39 years, thyroid cancer and rheumatoid arthritis]
Holistic assessment	“Before going into condition-specific assessment, I’d expect the doctor to check the patient’s overall health and mobility issues. Maybe for older patients, can get them to stand up, walk a few paces because based on their movements, doctors can detect a lot of other things. So, they shouldn’t just focus on their specialty, but examine the patients on other things as well, like their tone of voice, facial expression, and look out for signs that may tell their emotional issues, mental issues. So, doctors should have a protocol for these things before they go into the specifics.” [P2 aged 64 years, cancer]
Efficiency outweighs eye contact for patients when doctors use EHRs^a	
Doctors’ efficiency is valued by patients more than eye contact	“I don’t expect them to maintain eye contact the whole time because I understand that they need to see the computer, our medical conditions, and everything. It’s more important for them to know what’s happening to us. Maybe, eye contact is more important in the ward, but in the clinic, I don’t really mind if the doctor does not have eye contact with me.” [P13 aged 42 years, diabetes]

Themes and subthemes	Quotes from participants
Eye contact is appreciated but deemed nonessential	“Most doctors don’t have eye contact with the patient...when you know your doctor well and have confidence in the doctor, I don’t think it is necessary, though it would be good to have.” [P14 aged 75 years, gout]
Empathetic communication regardless of DHT^b use	
Patients value human touch regardless of DHT use	“Even as doctors use digital technology, they still need to have that human touch. Based on my experience, I had a skin condition where there was a lump. When I went for consultation, the doctor did not even touch or see it. She just prescribed me antibiotics and asked me to come back for a one-week appointment. So, I think they should show more concern towards the patient, listen to our complaints and problems. Don’t just prescribe medicine and send the patient off. I was so upset. I don’t want other patients to go through the same experience because I was in pain and she didn’t even see to it. So, if without technology, they can already ignore the patient, what more if technology is present?” [P19 aged 56 years, kidney disease]
Effective communication and bedside manners regardless of DHT use	“Even if doctors were to adapt digital technology in the health care setting, at the end of the day, it boils down to whether they can deliver a message or communicate a diagnosis to the patient empathetically or not...when relaying a message, doctors shouldn’t just approach the patient at the bed, and say, ‘Hey, I’d like to tell you that you are diagnosed with this condition,’ then just walk away without elaborating on the statement. It’s not helpful for the patient who is trying to process it mentally and who is not well not-versed in the condition. So, doctors should explain to the patient on how they derive at the diagnosis. When I was officially diagnosed with this disease, I couldn’t move my legs, my toes, I couldn’t move anything at all. The doctor just opened the curtain and told me, ‘I don’t think you can walk anymore,’ and just walked away. I was alone at that time, and just woke up from a one-and-a-half month coma, so I broke down there and then, non-stop. There was just so much emotions. It seems like when people go up the corporate ladder, they tend to neglect the humanistic aspect, the empathy.” [P25 aged 26 years, tuberculosis meningitis and pulmonary tuberculosis]
Competence in using DHTs for clinical procedure and diagnosis	
Competence in using DHTs for venipuncture (younger participants)	“My veins are very fine, so I hope that in the future, there will be a machine or technology that can help locate my veins and poke them without having to poke a lot of times. Humans have to do it based on trial and error, and it’s very painful. Sometimes, my doctors have to poke me four or five times just to get the vein. So, if there is a machine that can poke once only and make sure there is blood in the veins, that would be cool. Otherwise, patients like me will suffer. Sometimes, when the senior doctors ask the junior doctors to try and poke me, they will poke multiple times. It is very painful!” [P15 aged 28 years, kidney and systemic lupus erythematosus]
Competence in using DHTs to make accurate diagnosis (younger participants)	“Digital technologies are good; they can be predictive. Some doctors tend to stick to the books, so, they may not be able to find out the conditions as easily as they will when aided with digital technologies. When I told my doctors that I suspected I have rheumatoid arthritis, they said it’s not rheumatoid because my conditions don’t fit the definitive terms and criteria, like pain in the usual wear and tear areas. About four doctors including GPs and specialists did not think it was rheumatoid. But eventually, it was only when I had pain in my toes, on top of the usual markers, then the specialist diagnosed me with rheumatoid arthritis. So, using digital technologies to diagnose conditions will be helpful...machines are less likely to miss errors; they can pick them up better than doctors.” [P21 aged 27 years, rheumatoid arthritis]
Accuracy and precision (younger participants)	“Digital technologies are good; they can be predictive. Some doctors tend to stick to the books, so, they may not be able to find out the conditions as easily as they will when aided with digital technologies. When I told my doctors that I suspected I have rheumatoid arthritis, they said it’s not rheumatoid because my conditions don’t fit the definitive terms and criteria, like pain in the usual wear and tear areas. About four doctors including GPs and specialists did not think it was rheumatoid. But eventually, it was only when I had pain in my toes, on top of the usual markers, then the specialist diagnosed me with rheumatoid arthritis. So, using digital technologies to diagnose conditions will be helpful...machines are less likely to miss errors; they can pick them up better than doctors.” [P21 aged 27 years, rheumatoid arthritis]
Time efficiency (younger participants)	“Digital technologies are good; they can be predictive. Some doctors tend to stick to the books, so, they may not be able to find out the conditions as easily as they will when aided with digital technologies. When I told my doctors that I suspected I have rheumatoid arthritis, they said it’s not rheumatoid because my conditions don’t fit the definitive terms and criteria, like pain in the usual wear and tear areas. About four doctors including GPs and specialists did not think it was rheumatoid. But eventually, it was only when I had pain in my toes, on top of the usual markers, then the specialist diagnosed me with rheumatoid arthritis. So, using digital technologies to diagnose conditions will be helpful...machines are less likely to miss errors; they can pick them up better than doctors.” [P21 aged 27 years, rheumatoid arthritis]

Themes and subthemes	Quotes from participants
Concern on the reliability of technology (older participants)	“Retirees like me pick up things much slower than the younger generation, who use technology more regularly. I am open to technology, but the thing about technology is that if the technology goes bust, then all the data in the device will be gone. All my appointments will be lost. If you were to lose electricity, or the technology breaks down, then you may not get back the data. I am also open to robots diagnose my conditions or treat me, but I am concerned about what the robots will come up with. So, we shouldn't be too reliant on technology...when it comes to diagnosis, I'll be quite skeptical of course if a robot were to diagnose me. Eventually, you still need a doctor to oversee the diagnosis the technology has come up with.” [P14 aged 75 years, gout]
Concern of trust on the reliability of diagnosis if it is based on DHTs alone (older participants)	“I'm not open to technology because technologies like AI do not have emotions like humans do. Even if it helps to improve the accuracy of diagnosis, I'm still not open to it because what if there is no electricity? You can't just depend on technology. It can trip anytime. If there's a trip, everything will be gone and doctors won't know what to do.” [P19 aged 56 years, kidney disease]

^aEHR: electronic health record.

^bDHT: digital health technology.

Compared to the younger participants, those from the older generation saw less need for the use of DHTs. They were concerned about the reliability of diagnosis, the perceived absence of human touch, and the risk of losing their medical data in the event of a technological breakdown if they were to be treated with DHTs. This was expressed by participants such as P14, a 75-year-old patient, and P19, a 56-year-old patient (Table 4). P14 and P19 continued to favor the diagnosis made by doctors over that made by DHTs due to their greater trust in the expertise of medical professionals. They would also opt for diagnosis and treatment advised by doctors over what is suggested DHTs, as the former was understood to offer emotional connection and understanding, which were lacking in the latter. Moreover, older participants were generally skeptical about the reliability of technology. Relatedly, they had concerns about the doctors' ability to recover their medical data should there be a system failure or technical malfunction.

Overall, the findings indicated that age, compared to other social determinants, was more influential in differentiating the participants' health care experiences and expectations, at least in this study. By gathering the views of the patients who were seeking medical care from outpatient clinics and who had sought treatment in the wards, this study sheds light on the importance of considering their health care experience and expectations to ensure that their needs were not being ignored. Interviewing the patients who had various medical conditions also highlights the type of digital technology that would be useful for specific health care purposes.

Discussion

Principal Findings

Overall, the participants expected doctors to be competent in using different DHTs. With regard to apps and wearables, they would like doctors to integrate data from these devices into doctor-patient communication and to handle their data ethically. When it comes to telemedicine, they expected doctors to deliver comprehensive and high-quality care that does not compromise their safety. According to them, doctors should be knowledgeable enough to identify the type of medical conditions that were appropriate for online consultation and those that needed further assessment. In addition, while participants did not perceive regular eye contact when using EHRs as essential,

they still valued the doctor's display of empathy in other phases of the clinical encounter, regardless of DHT use. The younger participants also expected doctors to be trained in the algorithms, principles, and purposes of DHTs such as AI to better assist them in the diagnosis and treatment processes. By interviewing patients, we have obtained the perspectives of an important yet often overlooked stakeholder in the health care system.

To our knowledge, this is the first study to assess patient perspectives of the existing gaps in doctors' clinical competencies when deploying DHTs. Our findings are unique, as the medical conditions among the study participants were varied. Previous studies have either explored DHT deployment among adults with specific single chronic conditions, such as hypertension, diabetes, and chronic heart failure or are not focused on patients' expectations of doctors' clinical skills [12,40-42]. Interviewing participants with various chronic conditions has offered us insights into their preferred mode of consultation; while teleconsultation was preferred for acute illnesses, physical consultation was still deemed necessary for chronic conditions. It also proved that the need to equip doctors with DHT competencies for better diagnosis and treatment was not specialty dependent but was something that needed to be implemented across the health care sector.

One similarity between the findings of this study and those of others is that DHTs are not the main driver of health-seeking behavior among older adults [12,40]. In general, they prefer receiving traditional health care services from medical professionals to exclusively relying on DHTs. However, unlike other studies indicating that older adults with lower educational qualifications (primary or secondary level) are less receptive and less likely to use DHTs [12,40], our research suggests that participants' limited receptiveness is not necessarily correlated with their educational qualifications. Those with postsecondary education and above also expressed reluctance to use DHTs. Our results therefore offer a nuanced perspective on patients' attitudes toward technology.

By conducting qualitative interviews with patients, this study has uncovered diverse views and informed future studies about the need to avoid associating perceived attitudes with specific social identities at the outset of research. This may only run the risk of perpetuating stereotypes about people belonging to certain identities. As the findings have shown, patients'

expectations and concerns need not be differentiated by their race, gender, or socioeconomic status. Rather, factors such as age and type of medical conditions tend to be more salient, proving the value of our constructivist and inductive approaches.

Unlike past qualitative studies, the lack of sustained eye contact between the doctor and patient during clinical documentation did not seem to matter to the participants of this study [43-46]. This could be attributed to the transactional relationship between the doctor and patient that characterizes many clinical encounters in Singapore. This type of care recognizes that the patient has a specific need, diagnoses and treats the condition, controls the risk factor, and makes a referral [47]. The quality of care tends to be determined by the ability of the doctor to abide by a set of prescribed guidelines that makes him or her a “good” doctor [47]. This differs from relationship-based care, which tends to focus on the quality of interaction between the doctor and patient [47]. The omnipresence and relative accessibility of doctors in Singapore compared to those in other countries may explain this taken-for-granted aspect of relationship [48]. Furthermore, in a fast-paced country like Singapore where efficiency and accuracy in the management of medical conditions are highly valued [48,49], the lack of eye contact seems like a characteristic that patients are willing to forego. Nonetheless, these should not compromise the humanistic and empathetic practice of medicine. As our participants such as P2 have expressed, appropriate clinical inquiry is still deemed important when DHTs are used. This is reiterated by the existing studies, which prove that attentiveness to the computer screen rather than eye contact with the patient during clinical encounters does adversely affect doctors’ psychosocial inquiry, emotional patient responsiveness, and full patient disclosure [46,48].

Some of the findings of this study have also been reported by other countries. These include the importance of identifying the cases that are appropriate for teleconsultation. Past reviews and studies have also reported the need for doctors to be equipped with the knowledge of selecting patients for teleconsultation so as not to compromise their safety [50-52]. However, many of these studies are based on individual medical conditions that are deemed stable. Future research should also consider the selection and identification procedures of patients with comorbidities and complex conditions since these are becoming increasingly common worldwide [53].

The value of incorporating training in AI technologies early in medical education has also been recognized in a large body of works. Examples of AI competencies include knowing the limitations, risks, and medicolegal aspects of AI [54-56]. In addition, concerns about privacy and data intrusion when DHTs are used are also commonly reported by other studies [7,12]. To illustrate, a study conducted with residents, patient representatives, and health care providers at a health facility catchment in Sydney, Australia, reported that both groups expressed concerns with safety issues such as data safety and privacy and the risk of hacking when telemedicine is used [7].

Other works have also recognized the value of integrating data from DHTs into the interaction with patients [6,57]. For example, the study by Loos and Davidson [57] that assessed

doctors’ views on the potential integration of wearables into patient care showed how effective doctor-patient communication aided by wearables serves a few purposes. These include forging strong interpersonal relationships between the doctor and patient and getting accurate information from patients to inform diagnosis, treatment decisions, and overall management of health [57]. However, as shown by the scoping review conducted by Hilty et al [58], there is currently a lag in the clinical, technological, and administrative workflow at the international level with regard to incorporating sensors, wearables, and remote patient monitoring in clinical care [58]. Hence, standardized frameworks of competencies need to be developed for doctors to effectively engage patients with these devices.

Moreover, our findings reiterate those of other studies when it comes to how age affects the use of DHTs. Specifically, participants who belong to the advanced age bands did not perceive an urgent need for their doctors to deploy DHTs for their medical conditions, unlike the younger ones. This is exemplified by the qualitative study by Low et al [12] of how older adults in Singapore negotiate DHTs in their everyday lives. In this study, the authors discovered not only a low uptake of DHTs among those aged 50 to 65 years but also the lack of perceived immediate need for them to use these technologies despite their willingness to adopt them. This is mainly attributed to the lack of technology-centeredness in their health-seeking behavior [12]. Another study corroborates this by demonstrating how adults from *Generation X*, defined as those born between 1943 and 1960, required technology training more than the *millennial generation*, referring to those born between 1982 and 2000. This is in view of the *Generation X*’s lower comfort level with using DHTs, highlighting their lesser dependence on and reluctance to use DHTs [1]. Hence, initiatives to increase the awareness and acceptance of DHTs among the population are needed if they were to be implemented nationwide.

Recommendations

The findings have reiterated the importance of exploring the views of patients so that their needs and the competencies of doctors can be more aligned in this digital age. This section offers recommendations on how each of the participants’ expectations and concerns can be addressed accordingly.

Engaging Data in Apps and Wearables Effectively With Patients

To fulfill patients’ expectations of having their doctors communicate the meaning of their medical data with them, protected time is needed for doctors during consultations. On the basis of the participants’ sharing, time constraints and a hectic work environment seem to be major barriers that prevent doctors from communicating effectively with patients. Hence, having protected time would allow them sufficient time to offer the necessary advice to their patients on the use of DHTs and provide adequate explanations of the data. Health care institutions can work with designers of technology to put in place a system that works like a voice-to-text tool where communication between the doctor and patient can be captured and transcribed in real time. This would help reduce doctors’ time on clinical documentation, allowing them more time to

interact with patients and respond appropriately to any of their concerns.

In view of the evolving model of care where the traditional model of the doctor-patient relationship is being replaced by shared decision-making between the doctor and patient, doctors should also act as expert partners in patients' health care journey. In this regard, it is important to consider the study by Mesko et al [59], which highlights that driving behavioral change for patients entails not only just technological shifts but also a consideration of humanistic elements. Specifically, more opportunities need to be created to educate patients about DHTs [59]. For example, doctors can advise their patients on how they can use DHTs in a safe and effective manner during consultations. These include identifying and downloading legitimate apps and teaching them how to access their medical data. This would not only expand patients' knowledge of DHTs but also enhance the doctor's commitment to supporting their overall well-being.

Determining Suitable Medical Conditions for Teleconsultations

To train doctors in holistic assessment of patients' conditions during teleconsultation, as well as in determining conditions suitable for this type of consultation, a comprehensive set of guidelines needs to be developed at the international level. Reviews on telemedicine have shown that there is a lack of guidelines and standards for implementing telemedicine both at the international and national levels [60,61]. Although many telemedicine reports have highlighted the need to develop these guidelines, only a few exist in practice [60]. Current telemedicine guidelines for clinical practice worldwide have been limited to specific specialties such as psychiatry, dermatology, pathology, and radiology [60]. A policy review on telemedicine in the Southeast Asia region of the World Health Organization also reveals significant variations in the adoption and implementation of telemedicine guidelines among 11 Southeast Asia region countries of the World Health Organization [57,61]. Among the 11 countries, only 5 have developed telemedicine guidelines including India, Bangladesh, Thailand, Indonesia, and Nepal [61].

In Singapore, the country's Medical Council and professional bodies have developed codes and guidelines to regulate the use of telemedicine [62,63]. However, the considerations for delivering care via telemedicine are outlined only broadly. Specifically, the reasonableness of conducting teleconsultations is determined by "the clinical context, the clinical objectives and the compatibility of technology to meet those objectives" [62]. The delivery of care using telemedicine is based on general Clinical Practice Guidelines [62]. In addition, there are no specific guidelines to determine the type of cases that are eligible for telemedicine consultation. Currently, the diagnosis, prescription of medicine, and issuance of medical certificates via telemedicine depend on the "professional judgement of the relevant doctor" and the "specific facts and circumstances of each presenting case" [63].

To ensure the standardization of current work practices and guidelines, some authors have highlighted the important role of international telemedicine organizations [60]. For example,

organizations such as the American Telemedicine Association and the United Kingdom's Telemedicine and eHealth Forum of the Royal Society of Medicine can take the lead by defining telemedicine guidelines under the direction of clinicians with relevant telemedicine expertise [60]. These clinicians should come from different medical specialties so that the health care needs of patients with comorbidities can be fulfilled.

Practicing Empathetic Communication When Using DHTs

To ensure that empathetic communication is not compromised when doctors are using DHTs, they can be trained to practice this skill alongside the adoption of DHTs. For example, during virtual consultations, doctors can practice active listening when communicating with patients. This involves giving patients their full attention and conveying attentiveness through nonverbal cues such as facial expressions and body language. These skills can help build a connection with patients.

A systematic review on how compassion is discussed in relation to AI technologies in health care shows that there are different ways in which AI can promote compassion. These include enhancement of the empathetic awareness of patients' suffering, empathetic response and relational behavior, communication skills, health coaching, therapeutic interventions, moral development learning, clinical knowledge and assessment, health care quality assessment, therapeutic bond and alliance, and provision of health information and advice [64]. However, most of these studies discuss how AI technologies can be used to train health care professionals and trainees to deliver clinical care using virtual platforms and patients. Further research on how DHTs such as EHRs, apps, and wearables can be leveraged during clinical consultations with real patients needs to be conducted.

At present, the framework proposed by Loos and Davidson [57] of the competencies for clinicians and trainees when using sensors, wearables, and remote monitoring devices may serve as a guide in determining the necessary competencies. This framework is organized according to 3 learner levels, namely, novice or advanced beginner, competent or proficient, and advanced or expert levels and is based on the domains outlined by the Accreditation Council of Graduate Medical Education (ACGME) [57]. Beyond ways to embody interpersonal and good communication skills, it also outlines how clinicians and trainees can deliver quality care through their knowledge of these DHTs, for example, learning the types of diseases that can be treated with wearables (ACGME milestone levels 1-2); developing a plan to review, communicate, and deliberate on data (ACGME milestone levels 3-4); and researching new ways to improve care using DHTs such as AI (ACGME milestone level 5). Standardized evaluation measures may help to determine the effectiveness of such frameworks.

Using AI Technologies Competently and Ethically

To train doctors to be competent in DHTs such as AI, professional bodies can offer courses and training programs to doctors through continuing medical education, as has been done by the Digital Medicine Society in partnership with Rocky Vista College of Medicine and the American College of Osteopathic

Family Medicine in the United States [65]. Such programs can help educate and encourage health care professionals to embrace digital medicine and train them in the benefits, risks, and pitfalls of AI. Another way to encourage the adoption of DHTs among health care professionals is to share published data on studies that involve large patient cohorts and that report on the accuracy of well-documented DHTs.

To address the concerns about possible intrusions of personal data, a regulatory framework that understands the workings of technological innovations and their potential lapses needs to be introduced in order to prevent the leakage of sensitive information. In addition, tighter laws on data breaches need to be legislated to improve public trust. In the United States, laws such as Genetic Non-Discrimination Act serve to defend patients from unauthorized third-party access to data [59]. More such laws need to be devised and implemented to increase public trust in DHTs. Doctors and medical trainees also need to be trained in handling medical data ethically in order to safeguard patients' confidential information. The proliferation of medical data breaches in recent years caused by cyberattacks and ransomware attacks in Singapore and around the world necessitates tighter laws to protect patients' medical data.

Strengths and Limitations

This qualitative study informs us about the expectations and concerns of patients with DHTs. By interviewing participants from different social and economic backgrounds, as well as medical conditions, the sample achieved diversity in narratives, and the study benefited from the rich data. Seeking the opinions of patients from outpatient clinics, most of whom had been hospitalized for the same conditions, also allows us to uncover their experiences in both the inpatient and outpatient settings. In addition, conducting qualitative interviews enables us to gain in-depth insights into patients' experiences and expectations and place their narratives at the forefront of our research.

A perceived limitation of this study is its small sample size. This may limit the generalizability, validity, and reliability of the study. With a small sample size, it is challenging to generalize the findings to a larger population. The findings may only be applicable to the individuals included in the study and may not represent broader groups [21]. Furthermore, a small sample size may not adequately capture the diversity within the population of interest [21]. Consequently, the findings may lack depth and breadth, leading to a limited understanding of the phenomenon under investigation. In addition, small sample sizes increase the risk of selection bias in the recruitment strategy. Researchers may inadvertently select participants who are more accessible or willing to participate, thus leading to a biased sample that does not accurately represent the population.

Nonetheless, as with other qualitative studies that adopt interviewing techniques, an in-depth analysis of participants' narratives offers a contextualized understanding of their expectations and concerns. Furthermore, although not entirely generalizable, the findings from this study would bear important implications for digital health training programs, initiatives, and frameworks in other developed countries. As a scoping review on digital health competency frameworks for health care professionals has shown, frameworks for training doctors and

medical trainees in relevant digital competencies are still lacking [66].

Another limitation lies in the lack of language diversity among participants, all of whom happened to be English-speaking. Their English language proficiency is likely attributed to the widespread use of English as the official language of communication in Singapore. Having research participants come from a homogenous linguistic background may restrict the ability to apply the findings to diverse communities where other languages are spoken. Since language is intricately linked to culture and educational background [8], this may also exclude the influence of cultural and class factors on patient expectations. Despite the language limitation, participants came from diverse ethnic, educational, and socioeconomic backgrounds.

In addition, we acknowledge that there are other digital technologies that are not discussed in this study, given its focus on the type of technologies that have been introduced for clinical practice in Singapore. Therefore, future research should also examine how more recent AI technologies such as ChatGPT could potentially transform health care from the perspectives of different stakeholders including patients and health care professionals. ChatGPT is an AI-powered conversational agent developed by OpenAI. It is based on the GPT architecture. Designed to understand and generate humanlike text based on the input it receives, it has the potential to revolutionize health care delivery and services in several ways. These include promoting healthier lifestyle habits through personalized health coaching and interventions and serving as a clinical decision support tool for health care providers. The latter may include offering real-time access to evidence-based guidelines, medical literature, and treatment protocols. Such technologies raise the question of how medical diagnosis, treatment plans, and patient management may evolve in the future.

Conclusions

This study has explored the clinical encounters of patients with chronic illnesses amid the increasing digitalization of health care. Evaluating their perspectives proves crucial, as they can be considered a key facilitator for technology implementation and enhancement in health care settings. By identifying their expectations of doctors' clinical competencies, this study has shown that traditional and basic clinical skills such as effective communication, clinical reasoning, history taking, physical examination, and procedural skills should neither be neglected nor compromised in the digital age. Nonetheless, the role of clinicians needs to evolve with the introduction of DHTs. For example, the way in which DHTs are transforming the traditionally paternalistic rapport between the doctor and patient needs to be considered. With patients now holding the power to assess the standard of health care received and being more involved in the decision-making processes of their own health [59], an expansion of doctors' clinical competencies is needed in order to consider these shifts.

In addition, the findings of this study might inform the health care practices and policies in other high-income countries. These include prioritizing the integration of digital health care education into medical training programs to equip doctors with

the necessary competencies. Examples of initiatives may include updating the curricula of medical schools, offering continuing professional development opportunities, and fostering a culture of lifelong learning among health care professionals. In addition, governments and health care systems should allocate resources toward implementing DHTs that align with patient expectations and preferences. They could also implement patient engagement and education initiatives to increase the awareness and

acceptance of DHTs among the population. Moreover, policy makers should develop regulations and guidelines to govern the use of DHTs in health care delivery including ensuring data privacy and security and addressing issues related to liability. Overall, the findings from this research could serve as a road map for other high-income countries to leverage the potential of DHTs in enhancing health care delivery in the digital age.

Acknowledgments

This study was funded by SingHealth Duke-NUS Medicine Academic Clinical Programme under Seah Cheng Siang Distinguished Professorship in Medicine. The authors would like to thank the participants of this study for their invaluable insights and the reviewers of this journal for their helpful comments. They are also grateful to the following individuals for their assistance in some of the recruitment efforts: Woon Ting Hui from Singapore General Hospital; Gordon Ho from Society for the Physically Disabled, a local charity set up to help people with disabilities; Zarina Yusof from National Kidney Foundation; and Syawal Yusoff from BERITAMediacorp.

Abstract

Background: Knowledge sharing is a crucial part of any knowledge management implementation. It refers to sharing skills and experience among team members in an organization. In a health care setting, sharing knowledge, whether tacit or explicit, is important and can lead to better health care services. In medical imaging departments, knowledge sharing can be of particular importance. There are several factors that affect knowledge-sharing practices in medical imaging departments: individual, departmental, and technological. Evaluating the importance of these factors and understanding their use can help with improving knowledge-sharing practices in medical imaging departments.

Objective: We aimed to assess the level of motivation, identify current knowledge-sharing tools, and evaluate factors affecting knowledge sharing in the medical imaging departments of 2 cancer centers, The Christie, United Kingdom, and the Kuwait Cancer Control Center (KCCC).

Methods: A concurrent mixed methods study was conducted through nonprobability sampling techniques between February 1, 2023, and July 30, 2023. Semistructured interviews were used to validate the results of the quantitative analysis. Data were collected using an electronic questionnaire that was distributed among health care professionals in both cancer centers using Qualtrics. Semistructured interviews were conducted online using Microsoft Teams. The quantitative data were analyzed using the Qualtrics MX software to report the results for each question, whereas the qualitative data were analyzed using a thematic approach with codes classified through NVivo.

Results: In total, 56 respondents from the KCCC and 29 from The Christie participated, with a 100% response rate (56/56, 100% and 29/29, 100%, respectively) based on the Qualtrics survey tool. A total of 59% (17/29) of health care professionals from The Christie shared their knowledge using emails and face-to-face communication as their main tools on a daily basis, and 57% (32/56) of health care professionals from the KCCC used face-to-face communication for knowledge sharing. The mean Likert-scale score of all the components that assessed the factors that affected knowledge-sharing behaviors fell between “somewhat agree” and “strongly agree” in both centers, excepting extrinsic motivation, which was rated as “neither agree nor disagree.” This was similar to the results related to incentives. It was shown that 52% (15/29) of health care professionals at The Christie had no incentives to encourage knowledge-sharing practices. Therefore, establishing clear policies to manage incentives is important to increase knowledge-sharing practices.

Conclusions: This study offered an evaluation of factors that affect knowledge sharing in 2 cancer centers. Most health care professionals were aware of the importance of knowledge-sharing practices in enhancing health care services. Several challenges were identified, such as time constraints, a lack of staff, and the language barrier, which limit knowledge-sharing practices.

Therefore, establishing a clear policy for knowledge sharing is vital to practicing knowledge-sharing behaviors and facing any challenges that limit this practice.

Introduction

Background

Knowledge consists of a combination of facts, ideas, experiences, and information that is gained through experience and practice [1]. Knowledge management is the organizational capability to identify, transfer, convert, and share knowledge to attain institutional success. In health care, knowledge is an important asset in following the best medical practices. In recent years, health care intuitions have had a clear mission to establish a strong knowledge management system to use their knowledge in a good way by sharing health care professionals' knowledge with others [2]. Knowledge management is directly related to good performance [3]. The primary aim of knowledge management in a health care setting is to create a culture of knowledge sharing among health care professionals, allowing them to carry out hospital tasks in an efficient way, leading to an increase in successful patient outcomes and a reduction in repetitive medical errors [4,5]. Knowledge management consists of 4 processing steps: knowledge creation, knowledge capture, knowledge sharing, and knowledge application [6]. According to a 2016 report by the World Health Organization, there are many challenges that health care institutions face, such as long wait times for patient services, a lack of health care professionals, and inadequate information and communications technology (ICT) infrastructures in health care centers [1,7]. Good knowledge management practice starts with understanding each processing step and trying to identify the challenges and solutions for each of them [5,6].

Knowledge sharing in health care institutions has a positive impact on institutional performance [8]. Effective knowledge sharing has several benefits related to increasing successful patient outcomes, such as innovation, critical thinking, problem-solving, reducing medical errors, avoiding repetitive medical errors, increasing performance, and gaining competitive advantages [6,9-11]. Furthermore, improving knowledge-sharing practices among health care professionals allows them to learn and use resources efficiently [7]. Health care institutions have complex organizational structures [5]. They employ a variety of multidisciplinary professionals who communicate and share knowledge among each other as a part of day-to-day medical practice. Effective knowledge-sharing practices among health care professionals contribute to a positive overall knowledge-sharing culture [5]. Ipe [12] defined knowledge sharing as “the act of making knowledge available to others within the organizations.” Knowledge sharing is the way in

which health care professionals share their tacit and explicit knowledge [13]. Tacit knowledge is defined as any thoughts and ideas that exist in the human mind [14]. It is difficult to capture and can be shared through interaction with others [15]. Explicit knowledge, in contrast, exists in the documents, policies, and manuals that departments have, and it is easy to capture [16].

Medical imaging departments consist of several divisions: radiology, nuclear medicine, radiotherapy, and physical radiation. The names of the divisions and their number differ from one hospital to another. Medical imaging departments can be considered the backbone of a hospital due to the importance of the tasks that are performed there by specialized health care professionals [17,18]. The number of health care professionals working in medical imaging departments has increased in recent years due to the expansion of the duties carried out in these departments [19].

Factors Affecting Knowledge Sharing

There are several factors that affect knowledge-sharing practices [20-31]. These factors can differ from one institution to another depending on the nature of each environment [20-31]. Technological factors often differ between institutions due to the use of specialized technologies (eg, the use of a picture archiving and communication system [PACS] in medical imaging departments), whereas individual factors are often the same across institutions as they relate to human nature [32-34]. Departmental factors often have commonalities across institutions related to their dependence on the use of resources for enhancing knowledge sharing among workers [35,36]. Evaluating knowledge-sharing behaviors among employees in medical imaging departments at cancer centers depends on identifying the level of awareness of the importance of knowledge sharing and the factors that affect knowledge-sharing practices [37]. These factors are divided into facilitators and barriers. On the basis of a previous study by Almashmoum et al [38], we can divide the facilitators of knowledge sharing in medical imaging departments in cancer centers into 3 categories—individual, departmental, and technological facilitators—and the barriers that affect knowledge sharing into 4 categories—individual, departmental, technological, and geographical. Table 1 shows these factors and their components [38]. On the basis of these factors, we sought to identify awareness of knowledge-sharing behaviors, evaluate the factors affecting knowledge sharing in the medical imaging departments of 2 cancer centers (The Christie and the Kuwait Cancer Control Center [KCCC]), and compare results across these 2 centers.

Table 1. Factors that affect knowledge-sharing practices in medical imaging departments [38].

	Factors
Facilitators

An Overview of The Christie and KCCC

Cancer centers are tertiary care units performing diagnostic scans and therapeutic treatments, blood testing, histology, stem cell laboratory tests, and palliative care related to cancer. The Christie is the largest single cancer center in Europe. It is located in Manchester, United Kingdom; serves 3.2 million people across the Greater Manchester region; and provides treatment for >60,000 patients with cancer per year [39].

The KCCC was established in 1968 and is one of the largest centers in Kuwait that provides comprehensive care for patients with cancer. Its main mission is to focus on improving physician and nursing education. More than 2000 patients with cancer are treated annually at the KCCC [40].

Objectives

This study had several objectives. The purpose of this study was to evaluate knowledge-sharing practices among health care professionals at The Christie and KCCC, as well as identifying the current knowledge-sharing mechanisms and the facilitators

and barriers that affect knowledge sharing among health care professionals in the medical imaging departments of the aforementioned 2 cancer centers. From this, we aimed to construct a new definition of knowledge sharing as it relates to medical imaging departments. Finally, we aimed to draw conclusions on how to improve knowledge-sharing practices and their effects on the quality of patient services.

Research Questions

There are several challenges in communication among health care professionals, such as lack of awareness of the importance of knowledge-sharing behaviors and factors that affect knowledge-sharing practices. This affects knowledge-sharing behaviors and, therefore, knowledge management implementation, which is considered important in any health care institution to perform tasks for patients. There are several questions raised based on that observation:

1. What is the level of motivation for knowledge sharing among employees in health care institutions?

2. What current knowledge-sharing tools exist in health care institutions?
3. What are the challenges faced by health care professionals related to knowledge sharing?
4. How can knowledge-sharing practices in medical imaging departments be improved?
5. What are the factors that affect knowledge sharing among health care professionals?
6. What is the definition of knowledge sharing in medical imaging departments?

Methods

Research Design and Sampling Techniques

This study was performed using a concurrent cross-sectional triangulation mixed methods design, which combined online semistructured interviews with health care professionals who worked in medical imaging departments and an electronic survey that was distributed among health care professionals who worked at The Christie and KCCC to evaluate knowledge-sharing practices and identify factors that affect knowledge-sharing behaviors. This study was conducted between February 2023 and July 2023. The sampling techniques that were used for the selection of health care professionals for the questionnaire and semistructured interviews were self-selection sampling and snowball sampling, respectively. A self-selection approach was applied to select participants who indicated a desire to take part in the research [41]. Self-selection sampling was used for the questionnaires and snowball sampling was used for the semistructured interview because this study evaluated knowledge-sharing practices in medical imaging departments. The questionnaire was distributed among professionals using a WhatsApp group (Meta Platforms) at the KCCC and on the internal page of The Christie. Snowball sampling focused on a group of people who had the same specialties to participate in the interviews. There were several specialties in this department, such as physicians, technologists, senior managers, the head of the department, nurses, and radiotherapists.

Textbox 1. The sections of the questionnaire.

- Section 1: an overview of knowledge sharing
- Section 2: the consent form (5 statements)
- Section 3: demographic profile of the health care professionals (7 multiple-choice questions)
- Section 4: questions about knowledge-sharing practices and background (4 multiple-choice questions)
- Section 5: questions that examined knowledge-sharing factors (55 questions on a 7-point Likert scale from “strongly disagree” to “strongly agree”)
- Section 6: 1 open-ended question

Qualitative Methods and Data Analysis

The semistructured interviews were conducted on the web using Microsoft Teams at the same time as the distribution of the questionnaires. The interviews started with brief introductory remarks about knowledge sharing followed by questions that

Ethical Considerations

This study followed the University of Manchester’s ethical guidelines. The ethics committee of The Christie determined that the study did not require ethical approval based on the official decision tool of the University of Manchester because the study was conducted with professionals and did not require sensitive questions, vulnerable groups, or risk of disclosures of anonymized information. Whereas the KCCC did require ethical approval especially for them, which it provided (3797). All respondents were health care professionals who signed a consent form to participate in the questionnaires and audio-recorded semistructured interviews. The consent form explained the purpose of the study as well as any other information that the participants might require. In addition, the health care professionals’ personal information was kept anonymous and confidential.

Quantitative Methods and Data Analysis

The purpose of this questionnaire was to evaluate the level of awareness of the importance of knowledge-sharing practices in medical imaging departments and the factors that affect knowledge-sharing behaviors. The questions were derived from previous related studies on knowledge sharing and modified to fit the overall research aim and answer the research questions [42-44]. The questionnaire items were written in English. They consisted of both nominal and ordinal scales. The entire questionnaire that was used in this study can be found in [Multimedia Appendix 1](#). It was divided into 6 sections, as shown in [Textbox 1](#). It consisted of 66 questions, with an additional open-ended question at the end. A pretest study was conducted among 10 academic lecturers and PhD students at the University of Manchester. The purpose of the pretest study was to make sure that the questionnaire items could be understood in health care institutions. After that, the electronic questionnaires were distributed among health care professionals at the KCCC using WhatsApp and among health care professionals working at The Christie through a posting on the hospital’s intranet. After the collection of the quantitative data, an analysis was performed using the Qualtrics XM software package (Qualtrics International Inc).

related to the health professionals’ experiences and definitions of knowledge sharing. After that, the questions were designed to assess factors and practices related to knowledge sharing. [Multimedia Appendix 1](#) presents the consent form and the interview questions. The semistructured interviews were conducted with health care professionals who were working in

the medical imaging departments of both cancer centers. Each interview took approximately 25 to 45 minutes. Invitations were sent electronically via WhatsApp for KCCC participants and posted on the internal page of The Christie. All the participants signed a consent form related to the interviews and audio recording. Thematic analysis was used to analyze the semistructured interview transcripts. The coding and creation of themes was conducted using the NVivo software (Lumivero).

Results

Quantitative Analysis

Demographic Characteristics and Response Rate

A total of 77 health care professionals from The Christie participated in this study with a 100% (77/77) response rate

based on the statistical analysis using the Qualtrics XM software. In total, 38% (29/77) of the respondents answered all the survey questions. In addition, all of them worked in the medical imaging department. The response rate from the KCCC was 100% (145/145), of whom 48% (70/145) from all departments completed all survey questions. A total of 80% (56/70) of the health care professionals who participated were from the medical imaging department at the KCCC. The demographic characteristics for both centers are shown in [Table 2](#).

Table 2. Demographic characteristics.

^aKCCC: Kuwait Cancer Control Center.

Knowledge-Sharing Practices

Knowledge sharing is defined as sharing ideas, thoughts, and experiences among health care professionals to create new knowledge. Sharing knowledge requires several facilitators to accelerate knowledge-sharing behaviors, for example, in morning meeting sessions, multidisciplinary team meetings, and conferences. These practices can improve patient outcomes

and minimize medical errors. In addition, they can help make such shared knowledge reusable for all health care professionals. The results at The Christie revealed that 59% (17/29) of health care professionals participated in knowledge-sharing activities available in their department on a daily basis and only 14% (4/29) of health care professionals did not participate in any of those activities. At the KCCC, the results showed that 57% (32/56) of health care professionals participated on a daily basis

in the knowledge-sharing activities that were available in their department. On the other hand, only 4% (2/56) of health care professionals never participated in those activities.

The Mechanisms of Knowledge-Sharing Practices

Sharing knowledge among health care professionals requires different mechanisms. Those mechanisms were classified into either physical or online tools, for example, face-to-face communication, phone calls, social media, emails, and Microsoft Teams. The results showed that 83% (24/29) of the health care professionals at The Christie used email and face-to-face communication to share their knowledge, whereas 86% (48/56) of the health care professionals at the KCCC used face-to-face communication as the main tool to share their knowledge. In total, 59% (17/29) of the health care professionals at The Christie used Microsoft Teams as a tool to share knowledge. At the KCCC, the results showed that 48% (27/56) of the health care professionals also used phone calls and social media to share their knowledge.

Level of Motivation

We examined the motivational level by exploring the level of willingness to share knowledge among health care professionals. Most of the health care professionals in both cancer centers had a high motivational level to practice knowledge-sharing behaviors with their peers at the workplace. The findings showed that 38% (21/56) of the health care professionals at the KCCC were highly motivated compared with 48% (14/29) of the health care professionals at The Christie, as shown in [Table 3](#). This percentage indicated that the level of motivation in both centers among health care professionals was high. Regarding incentives and policies, [Table 4](#) shows that 79% (44/56) of the health care professionals who worked at the KCCC indicated that there were incentives to encourage knowledge-sharing practices, whereas half (15/29, 52%) of the health care professionals who worked at The Christie indicated that there were no incentives to encourage knowledge-sharing practices. This comparison showed that the health care professionals at The Christie had a high motivational level but their department did not have incentives and a clear policy to encourage knowledge-sharing practices, which could affect their engagement in these practices.

Table 3. Motivational level of the health care professionals at The Christie and Kuwait Cancer Control Center (KCCC).

	Very low, n (%)	Low, n (%)	Medium, n (%)	High, n (%)	Very high, n (%)
The Christie (n=29)	2 (7)	0 (0)	6 (21)	14 (48)	7 (24)
KCCC (n=56)	0 (0)	5 (9)	14 (25)	21 (38)	16 (29)

Table 4. Comparison of incentives or policies in place to encourage knowledge sharing between The Christie and the Kuwait Cancer Control Center (KCCC).

	Yes, n (%)	No, n (%)
The Christie (n=29)	15 (52)	14 (48)
KCCC (n=56)	44 (79)	12 (21)

Factors Affecting Knowledge-Sharing Practices

The questionnaire evaluated the factors that affect knowledge sharing in medical imaging departments. On the basis of prior work, we identified 19 factors that affect knowledge-sharing behaviors among health care professionals working in medical imaging departments [38]. These factors are divided into 3 categories: individual, departmental, and technological. Individual factors comprise 8 components (trust, positive attitudes, awareness, experience, personality, intrinsic motivation, self-esteem, and self-efficacy). Departmental factors comprise 8 components (community of practice, leadership, culture, teamwork, extrinsic motivation, learning and training, physician rounds, and departmental arrangements). Technological factors comprise 3 components (ICT, network, and digital technology). These factors were measured on a 7-point Likert scale using an equivalent interval of $6/7=0.86$. [Multimedia Appendix 2](#) shows the mean score for each component. The mean score was classified as follows: “strongly disagree” for values within the range of 1.00 to 1.86, “disagree” for values within the range of 1.86 to 2.72, “somewhat disagree” for values within the range of 2.72 to 3.58, “neither agree or disagree” for values within the range of 3.58 to 4.44, “somewhat agree” for values within the range of 4.44 to 5.3, “agree” for

values within the range of 5.30 to 6.16, and “strongly agree” for values within the range of 6.16 to 7 [28]. All the Likert scale results can be found in [Multimedia Appendices 3 and 4](#) for The Christie and KCCC, respectively.

At the KCCC, the values for all the components of the factors that affect knowledge-sharing behaviors fell between “agree” and “strongly agree.” At The Christie, the values fell between “somewhat agree” and “strongly agree.”

Individual factors are important for enhancing knowledge-sharing practices among health care professionals. Trust plays a vital role in knowledge-sharing practices. It creates a strong relationship among health care professionals. In medical imaging departments, trust between the senior manager and health care professionals and among health care professionals is vital to share knowledge smoothly and provide high-quality health care services. The mean scores for trust were 5.7 and 5.51 in both centers, which corresponds to “agree.” Thus, more than half of the health care professionals had a level of trust that could improve knowledge-sharing behavior by building trust relationships among each other. Awareness of the importance of knowledge sharing helps increase knowledge-sharing behaviors in daily work. In addition, knowledge sharing helps

health care professionals gain new knowledge, fosters learning, and prevents repetitive mistakes. The results showed that the mean score for awareness was 6.42 at the KCCC, which corresponds to “strongly agree,” versus 5.48 at The Christie, which corresponds to “agree.” Therefore, health care professionals in both centers had a clear awareness of the importance of knowledge sharing in improving their skills and health services. Health care professionals in both cancer centers believed that positive attitudes help enhance knowledge-sharing behaviors. The results showed that the mean scores for positive attitudes in both cancer centers were 6.4 and 6.16, which correspond to “strongly agree.” Health care professionals having good experience increases knowledge-sharing behaviors. The mean scores for experience were 6.2 at the KCCC and 5.77 at The Christie, which correspond to “strongly agree” and “agree,” respectively. Therefore, health care professionals in both centers believed in the importance of experience in enhancing knowledge sharing. In addition, they had enough experience that could help them share it with others. Health care professionals in both centers had an extroverted personality, which opens to others and allows them to share knowledge with others. As shown in [Multimedia Appendix 2](#), the mean scores for personality were 6.15 for KCCC and 6.18 for The Christie, which correspond to “agree” at the KCCC and “strongly agree” at The Christie. Hence, the results showed that most of them have self-confidence and felt open to new ideas when they practiced knowledge sharing. Self-esteem and self-efficacy are the main components of the individual factors. The mean scores for these components in both cancer centers were close to “agree,” which means that health care professionals have self-efficacy and self-esteem regarding their ability to successfully share knowledge with their peers. Finally, regarding intrinsic motivation, the mean scores were 5.96 at the KCCC and 5.89 at The Christie, which means that most of the health care professionals had intrinsic motivation that allowed them to share their knowledge.

Health care institutions are considered knowledge-based environments due to the large amount of knowledge, either tacit or explicit, that needs to be managed. To maximize the benefit of that knowledge, each department in a health care institution has a responsibility to share knowledge among their professionals. Extrinsic motivation is important to enhance knowledge-sharing practices through providing acknowledgment, appreciation, incentives, and bonuses to health care professionals. The results showed that the mean score for extrinsic motivation was 5.66, which corresponds to “agree,” at the KCCC. Thus, health care professionals who worked at the KCCC received motivation from their senior managers. In contrast, the mean score was 4.37 at The Christie, which corresponds to “neither agree nor disagree.” This implies an absence of departmental encouragement of knowledge-sharing behaviors, as the respondents believed in the importance of extrinsic motivation in enhancing knowledge sharing. Health care professionals in both cancer centers believed that the leadership plays a significant role in providing encouragement, improving knowledge-sharing activities, and minimizing conflict. The mean scores for leadership in both cancer centers were close to “agree,” which means that the leadership in both cancer centers had a positive impact in enhancing knowledge

sharing. Working and learning as a team is important to enhance knowledge-sharing practices. Health care professionals in both centers believed in the importance of teamwork for increasing knowledge-sharing practices. The mean scores for teamwork in both cancer centers were close to “strongly agree,” which means that they worked as a team to increase productivity. Both cancer centers had a culture of communication to enhance knowledge sharing, with mean scores close to “strongly agree.” The community of practice consists of several communities that specialize in making decisions in specific cancer centers. In addition, multidisciplinary team meetings are one of the most prominent types of meetings in cancer centers. The mean scores for community of practice in both cancer centers corresponded to “agree,” which means that, in both centers, there are several specialized meetings that play important roles in making decisions by enhancing knowledge-sharing behaviors. Learning and training activities, such as workshops, lectures, and conferences, play a vital role in enhancing knowledge sharing. At the KCCC, the mean score for this component was 5.79, which corresponds to “agree.” Thus, health care professionals participated widely in several learning and training activities to enhance their skills. In contrast, at The Christie, the mean score for this component was 5.25, which corresponds to “somewhat agree.” Thus, health care professionals received limited learning and training support to increase their skills. At the KCCC, there were enough empty rooms and open space to enhance knowledge sharing, with a mean score of 6.1 for departmental arrangements, which corresponds to “agree,” compared with not enough space at The Christie, with a mean score of 5.29 for departmental arrangements, which corresponds to “somewhat agree.” Daily physician rounds play a vital role in developing health care professionals’ skills. The mean score for this component was 5.64 at the KCCC, which corresponds to “agree,” and 4.82 at The Christie, which corresponds to “somewhat agree.” Therefore, health care professionals at the KCCC believed in the importance of physician rounds in enhancing knowledge sharing more than professionals at The Christie.

Technological factors are considered a dynamo of knowledge-sharing practices. High-speed networks play a significant role in enhancing knowledge-sharing practices. Both cancer centers had a high-speed network and believed in its importance, with mean scores of 5.33 at the KCCC and 5.56 at The Christie, which correspond to “agree.” ICT is crucial to support sharing information. Intranet, extranet, PACS, and social media are considered types of ICT. In addition, ICT requires skills to use it and maintenance to address and report any related problems. At the KCCC, the mean score for ICT was 5.62, which corresponds to “agree.” Thus, in the medical imaging departments, there were enough ICT infrastructures that they used to share their knowledge, and health care professionals were trained well to use those technologies and report any problems they faced. At The Christie, the mean score for ICT was 5.20, which corresponds to “somewhat agree.” Thus, in the medical imaging departments, health care professionals used ICT to share their knowledge, and they had enough skills to use it. However, they did not frequently use social media to share their knowledge compared to health care professionals at the KCCC. To access to updated articles and resources, digital

libraries were a valuable tool that allowed health care professionals to gain new information to share their knowledge with each other. The mean scores for this component were 5.91 at the KCCC and 5.62 at The Christie, which correspond to “agree.” Thus, health care professionals in both cancer centers believed in the importance of digital libraries in enhancing knowledge sharing.

Qualitative Analysis

Overview of Analysis

Semistructured interviews were used to gather the background experience of health care professionals who worked in the medical imaging department (heads of department, technologists, nurses, physicians, and radiotherapists). The data were used to validate the quantitative data. A total of 13 health care professionals participated in this part of the study. Of the 13 participants, 11 (85%) were from the KCCC, and only 2 (15%) were from The Christie. The outcomes of the online semistructured interviews shed light on 3 themes that related to knowledge-sharing practices, such as definitions of knowledge sharing, factors, and challenges to knowledge-sharing behaviors.

Theme 1: Definition of Knowledge Sharing in Medical Imaging Departments

Despite the fact that the term *knowledge sharing* is not new, most of the health care professionals asked for clarification of the term before giving their definition based on their experience in the department. In general, most of them gave the proper definition of knowledge sharing in the medical imaging department; [Multimedia Appendix 5](#) shows their definitions. On the basis of their views, the general key points to structure the definition of knowledge sharing are as follows:

1. All health care professionals have a specific amount of knowledge derived from their studies and experience.
2. Knowledge sharing involves sharing information and updated protocols and circulars among health care professionals.
3. Knowledge sharing takes places between colleagues or among a wider team in one department or with professionals from another hospital.
4. Knowledge sharing occurs through various activities, such as lectures, workshops, meetings, and conferences.
5. There is no benefit from keeping knowledge to oneself. It remains inactive until it is shared.
6. Knowledge sharing among health care professionals helps patients obtain a more accurate diagnosis.

Theme 2: Factors Affecting Knowledge Sharing

The findings of a deep analysis of the qualitative data were consistently validated by the quantitative data. The factors that affect knowledge sharing could be classified as facilitators that enhance knowledge sharing and as barriers when those factors have a negative impact on knowledge-sharing behavior. Facilitators are classified into 3 categories: individual factors, departmental factors, and technological factors.

Subtheme 2.1: Individual Factors

Participants stated that they were aware of the importance of knowledge-sharing practices in maximizing health services in various specialties. In addition, they were aware of the importance of sharing knowledge with other peers to apply it in various situations. Participant C indicated the following:

Knowledge sharing is very important amongst clinicians of various specialities and various field.

Most health care professionals had a variety of skills and experience that they had gained throughout their careers. Their skills and experience allowed them to share their knowledge with other peers who had less experience. However, some of them felt shy about sharing their knowledge with others in a large group. In addition, sharing knowledge among health care professionals depends on the personality of those doing the sharing. Participant B said the following:

And lots of knowledge, but those kinds of people also they do not want to share it in public among larger group of audience or larger group of attendees. Things can be accomplished by dealing with getting the information from a group in a way that they do not feel uncomfortable in sharing their ideas.

Subtheme 2.2: Departmental Factors

According to the findings of this data analysis, there are several factors related to departmental factors. Knowledge-sharing practices increased with the ability of the department to foster a culture of communication that allowed health care professionals to share their knowledge. Participant C indicated the importance of creating a culture to support sharing knowledge:

So definitely there is a good positive environment of knowledge sharing and knowledge building also...sharing information maybe I think it changes the culture of the team if we can inspire people to learn and share more.

In addition, working as a team helps enhance knowledge-sharing practices because health care professionals work in groups to perform specific tasks and procedures. The leadership plays an important role in enhancing knowledge sharing by establishing clear policies for sharing knowledge and allowing health care professionals to participate in several activities. Those activities fall under the component of learning and training. Most respondents indicated that there were several activities available, such as presenting and attending lectures, attending conferences locally and internationally, participating in training sessions and workshops, creating posters, attending seminars, and engaging in continuing education. In addition, respondent C suggested participating in journaling sessions to keep up to date on information and maximize their knowledge, allowing knowledge-sharing with others to improve treatment plans. Extrinsic motivation is divided into 2 categories: physical and emotional incentives. In this regard, participants B and F indicated that excellent evaluations and other signs of appreciation, such as receiving certificates or having their names added to papers, posters, or lectures prepared by professionals, were an effective means of encouragement. A community of

practice involves specialized meetings among health care professionals, including multidisciplinary team meetings. These high-level knowledge-sharing meetings can involve decisions on treatment plans for patients with cancer. All health care professionals in different disciplines play a certain role in interpreting the final treatment plan. Therefore, attending these meetings helps them develop their skills by gaining new knowledge. However, a few of the respondents from KCCC indicated that they did not have any idea about those meetings and they were not involved in them at all.

Subtheme 2.3: Technological Factors

Technological factors are considered a dynamo of knowledge-sharing practices. The results revealed that there were several types of ICT infrastructure in both departments, such as PACS, the bleep system, hospital information system, registration information system, and social media apps, in addition to online communication tools such as Zoom and Microsoft Teams. The use of online tools became prevalent after the COVID-19 pandemic to maintain communication among health care professionals by setting online meetings, videoconferences, and online circular discussions for better patient services and to protect their lives. As a consequence, most of the respondents preferred online tools over face-to-face communication for several reasons, such as availability, time saving, and removing geographical barriers. On the other hand, most of the participants indicated that using online tools requires positive attitudes toward technology, maintenance, and a high-speed network to keep the tools active for sharing knowledge. Participants C and K indicated the following:

I would say sometimes because of some Internet issues or some Internet connection, yes. So it becomes difficult. Sometimes it takes time for the reports to be automatically uploaded into HIS.

Theme 3: The Challenges to Knowledge-Sharing Behaviors

The in-depth analysis of the participants' views brought about some of the challenges that health care professionals face in practicing knowledge sharing. They mentioned that a lack of staff is one of the challenges that managers face, which results in a lot of duties in daily work, influencing knowledge sharing. This prevents them from practicing knowledge-sharing activities. Participant B indicated the following:

I think this is actually one of the problem in the cancer Control Center is that you don't have we don't have enough stuff for the number of the service that we are doing so it it's you know one can imagine that three or five physician do a delivery of probably 50 or 60 clinical service a day for the whole 365 days a year and we are expected to give our time to knowledge share as reserving one or two hours per week knowledge sharing when we are expected to finalize the clinical service, this is the problem.

In addition, time constraints were a main challenge to knowledge sharing that participant C mentioned:

We wish we had more time for knowledge sharing because definitely it is very useful, but maybe we're

not able to do it as often or as for a longer period of time because of the time constraint. Yeah. Our challenge I would say one is the time that we would want, definitely we don't have. I feel that we don't have enough time to sort of have more of discussing of cases. Interacting with more with each other because many times when I have faced that that I want an opinion but there's just no time for me or for the other person to actually look at the case and go into details and try to get some information and then. So, we tend to sort of maybe cut down on the sessions and use that time to report our cases. So, I feel that we should have more dedicated time. can make sure that the message delivered to him that he will ask his colleague or there is a minute. Of course, we can share it with him.

In addition to these challenges, there were challenges related to a person's attitudes. For instance, some were less interested in sharing their knowledge because of a lack of awareness of the importance of knowledge sharing. Some lacked awareness regarding who was responsible for sharing knowledge and were not aware of the benefits of sharing their knowledge. In addition, according to participant L, "It's a cooperation. I said yes, this is one challenge and then also communication with the patient."

Discussion

Principal Findings

Health care institutions are knowledge-based environments where knowledge-sharing practices are an important step to achieve good knowledge management. This can help these departments reach their intended goals, mission, vision, and objectives for the delivery of high-quality health services. The objectives of this study were to evaluate the factors that affect knowledge sharing in the medical imaging departments of 2 cancer centers, identify the current tools for knowledge-sharing practices, structure a new definition of knowledge sharing, assess the challenges, and identify the areas for improvement in knowledge-sharing behaviors. On the basis of the respondents' views and thoughts on knowledge sharing during the semistructured interviews, we can define knowledge sharing as follows: "All health care professionals have a certain amount of knowledge built up through their work in a specific field. That knowledge (either tacit or explicit) will remain inactive until they share it with their peers or the wider team through meetings, lectures, and workshops and confirm that knowledge, or recreate new knowledge to better help patients."

The results showed that the level of motivation of the health care professionals to share their knowledge in their daily work was high in both cancer centers. There are several studies that suggest the same results regarding the high level of motivation toward knowledge sharing [20,37]. There were several mechanisms for sharing knowledge among health care professionals. The findings illustrated that the current mechanisms of knowledge sharing at The Christie were face-to-face communication and email, each with an equal percentage of participants (24/29, 83%), compared with the use of face-to-face communication as a main tool to share

knowledge at the KCCC (48/56, 86%). This agrees with research showing that radiologists prefer face-to-face communication to share their thoughts and interests [45]. In addition, using social media as a tool for sharing knowledge among health care professionals was a common practice at the KCCC, for instance, using WhatsApp as a main tool for internal circulation of information, announcements, and updates regarding protocol. Most respondents expressed that using social media as an online tool is faster than using traditional tools. In terms of availability, the information will remain in an app that can be accessed at any time because most health care professionals are busy with cases and do not have enough time to attend meetings face-to-face. Informing other people about key points of the meetings using those apps helps enhance knowledge-sharing practices among health care professionals. However, the use of social media apps in health care institutions still appears to be more prevalent in the West compared to the East [37,46-48]. During the COVID-19 pandemic, the use of online tools for sharing knowledge came to play a vital role in keeping knowledge circulating among health care professionals and making communication with others safe [49]. There is evidence to suggest that these practices led to an increase in positive patient outcomes and health services during the crisis [49,50]. Using hybrid tools contributes to the ability to share knowledge in a way that suits health care professionals [50].

The health care professionals in this study responded “strongly agree” or “somewhat agree” to questions on the importance of the examined knowledge-sharing practices. Therefore, this study found that health care professionals in both cancer centers believed in the importance of factors that affect knowledge sharing in enhancing knowledge-sharing practices in their daily work. Several studies support this finding [20-31]. However, the mean score for extrinsic motivation at The Christie was 4.37, which corresponds to “neither agree or disagree,” suggesting that the department may not have given enough encouragement for knowledge-sharing practices. This is reflected in the answers to the questions on encouragement and incentives at The Christie. More than half (15/29, 52%) of the respondents at The Christie indicated that there were no incentives to encourage knowledge-sharing practices. Therefore, health care professionals might intend to avoid participating in knowledge-sharing practices, which has a negative impact on practicing knowledge sharing in general.

In addition to those factors, there were several challenges that affected knowledge-sharing practices addressed by respondents in the semistructured interviews at both cancer centers, such as time constraints and attitudes toward knowledge sharing. In addition, at the KCCC, the respondents addressed language as the main challenge in sharing knowledge because the environment consists of international workers, which means that they communicate with their colleagues using their second language. Previous studies have shown that language is the main barrier that limits knowledge-sharing practices [33,34,37,51]. Fatahi et al [52] have illustrated that language is the first route for communication. Therefore, using a universal language that allows all health care professionals to communicate with their peers is important to enhance knowledge-sharing practices.

To improve knowledge-sharing practices, senior managers suggested in the semistructured interviews that creating a clear policy to share knowledge in the department is important in enhancing knowledge-sharing practices, starting with increasing awareness of the importance of knowledge sharing, followed by encouraging participation in various learning and training activities; improving attitudes to using technology; and, finally, providing encouragement via physical incentives (eg, bonuses and promotions) and emotional incentives (eg, excellent evaluations, certificates of appreciation, or adding an individual's name to a research paper or lecture). Moreover, hiring more staff helps enhance knowledge sharing by reducing the workload and giving staff members time to share their knowledge and participate in several activities.

Limitations

There were several limitations to this study that need to be addressed. The sample from The Christie was small in both parts of the study compared to the sample from the KCCC. There was a lack of staff, which limited their participation in the questionnaires and interviews due to work pressures. This study focused only on medical imaging departments and was limited to only those who worked in those departments. Therefore, this study could not evaluate the level of motivation and factors that affect knowledge sharing in all departments in both centers. Future work needs to assess the level of knowledge-sharing practices. A better approach may be to create a maturity model for knowledge sharing to assess the level of maturity and help managers put a clear plan and policy in place to manage knowledge-sharing practices.

Conclusions

This concurrent mixed methods study provides an evaluation of the factors that affect knowledge sharing in medical imaging departments. In addition, it structured a definition of knowledge sharing in medical imaging departments. On the basis of the questionnaires, health care professionals used face-to-face communication as a main mechanism to share knowledge within these departments at The Christie and KCCC (24/29, 83% and 48/56, 86%, respectively). Therefore, using knowledge-sharing mechanisms within departments for the purpose of enhancing knowledge-sharing practices is vital to speed up the knowledge-sharing process. In addition, health care professionals in the medical imaging departments in both centers had a good personality, positive attitudes, trust, a high self-esteem, and self-efficacy. Therefore, the intention to share knowledge was high in both cancer centers based on the individual factors. In the medical imaging departments, there were health care professionals that led the process of knowledge sharing by creating a culture of communication, setting several meetings, and giving everyone an equal opportunity to participate in learning and training activities. However, regarding extrinsic motivation, half (15/29, 52%) of the respondents at The Christie indicated that there was a lack of incentives, which was reflected in the low mean score for this component. Therefore, establishing a clear plan and providing incentives has a positive impact on knowledge-sharing practices. ICT infrastructures were available in both cancer centers, with a high-speed network to run those technologies. Most of the

respondents in the semistructured interviews addressed several challenges of knowledge sharing, such as language barriers and a lack of time, staff, and a clear plan for knowledge sharing.

Finally, this study provides managers with an evaluation of the factors that affect knowledge sharing in both cancer centers and allows them to address the challenges and improve them.

Acknowledgments

This study was completed as part of doctoral studies funded by the Ministry of Health, Kuwait, and the University of Manchester, United Kingdom.

Abstract

Background: Telemedicine and mobile health (mHealth) apps have emerged as powerful tools in health care, offering convenient access to services and empowering participants in managing their health. Among populations with chronic and progressive disease such as multiple sclerosis (MS), mHealth apps hold promise for enhancing self-management and care. To be used in clinical practice, the validity and usability of mHealth tools should be tested. The most commonly used method for assessing the usability of electronic technologies are questionnaires.

Objective: This study aimed to translate and validate the English version of the mHealth App Usability Questionnaire into Italian (ita-MAUQ) in a sample of people with MS.

Methods: The 18-item mHealth App Usability Questionnaire was forward- and back-translated from English into Italian by an expert panel, following scientific guidelines for translation and cross-cultural adaptation. The ita-MAUQ (patient version for stand-alone apps) comprises 3 subscales, which are ease of use, interface and satisfaction, and usefulness. After interacting with DIGICOG-MS (Digital Assessment of Cognitive Impairment in Multiple Sclerosis), a novel mHealth app for cognitive self-assessment in MS, people completed the ita-MAUQ and the System Usability Scale, included to test construct validity of the translated questionnaire. Confirmatory factor analysis, internal consistency, test-retest reliability, and construct validity were assessed. Known-groups validity was examined based on disability levels as indicated by the Expanded Disability Status Scale (EDSS) score and gender.

Results: In total, 116 people with MS (female n=74; mean age 47.2, SD 14 years; mean EDSS 3.32, SD 1.72) were enrolled. The ita-MAUQ demonstrated acceptable model fit, good internal consistency (Cronbach $\alpha=0.92$), and moderate test-retest reliability (intraclass coefficient correlation 0.84). Spearman coefficients revealed significant correlations between the ita-MAUQ total score; the ease of use (5 items), interface and satisfaction (7 items), and usefulness subscales; and the System Usability Scale (all P values $<.05$). Known-group analysis found no difference between people with MS with mild and moderate EDSS (all P values $>.05$), suggesting that ambulation ability, mainly detected by the EDSS, did not affect the ita-MAUQ scores. Interestingly, a statistical difference between female and male participants concerning the ease of use ita-MAUQ subscale was found ($P=.02$).

Conclusions: The ita-MAUQ demonstrated high reliability and validity and it might be used to evaluate the usability, utility, and acceptability of mHealth apps in people with MS.

Introduction

Telemedicine has enabled convenient and effective visits; reduced unnecessary testing and referrals; maintained good perception of care; reduced travel costs and caregiver burden; and, not least, helped health care providers to manage an

ever-increasing volume of information and relationships [1,2]. Growing use of smartphones and tablets has made mobile health (mHealth) apps promising tools for empowering and engaging people in the self-management of their own health [3]. mHealth tools create opportunities to deliver new forms of health care and to expand services without the need to increase the existing workforce. For example, medical apps can be used within

various domains such as wellness management, behavior change, health data collection, disease management, self-diagnosis, and rehabilitation as well as act as an electronic patient portal and medication reminder [4,5], leading to greater time spent at home and fewer medical visits at the center [6]. Furthermore, they represent useful solutions for participants with chronic and progressive diseases, such as multiple sclerosis (MS), that require continuous assistance and care.

mHealth apps promise to offer alternative methods for enhanced real-time data capture to screen for, monitor, and treat the heterogeneous symptoms in MS, thus favoring a substantial transformation in traditional paradigms of medicine [7-13]. However, as the number of mHealth apps increases, the demand for scientific evaluation of these solutions is strongly recommended as well [14]. Despite the growing popularity of mHealth apps, the amount of usability reports does not correlate with the number of published digital health implementation studies [15]. For instance, while Salimzadeh and colleagues [3] found 104 MS-related apps in iTunes (Apple Inc) and Google Play (Google LLC), they noted that there was no corresponding evidence regarding the usability and utility of these solutions in people with MS. To be used in clinical practice, the validity and usability of mHealth tools should be tested. mHealth apps must be designed to ensure good usability, and they must be easy to use and able to reach their goals efficiently. As indicated by Wilson and Lankton [16], perceived ease of use and usefulness affect people's intention to adopt mHealth devices. Generally, a mobile app is considered to have good usability when (1) it is efficient, (2) users have a positive opinion about the app, (3) it is easy to learn, (4) it is easy to remember even after users have not used it for a while, and (5) it has a low error rate [17].

The mHealth apps can be grouped according to the nature of the interaction between patients and health care providers in the app: interactive and stand-alone mHealth apps. In interactive mHealth apps, users can send and receive information from their health care providers or patients via the app in a synchronous or asynchronous modality. In stand-alone mHealth apps, users enter, collect, or store health information about themselves or other people, which are not directly sent to the user's health care providers [18].

The most commonly used method for assessing the usability of electronic technologies are questionnaires. General and technology-independent questionnaires such as the System Usability Scale (SUS) [19] and the Post-Study System Usability Questionnaire [20] are usually used in usability studies of mHealth apps [15]. However, these questionnaires were created for general software systems and cannot reliably identify mHealth specific problems that may arise, for example, in health self-management or accessing health care services.

In this context, a new specific usability scale for evaluating the validity of mHealth apps was developed, the mHealth App Usability Questionnaire (MAUQ) [18]. The English version of MAUQ has been translated to various languages such as Malay [21], Chinese [22], Spanish [23], German [24] and French [25]. However, no literature was found reporting a translated version of the questionnaire in Italian, although it was used in 1 study

on app usability [26]. Thus, this study aimed to translate and validate the English version of the mHealth App Usability Questionnaire into Italian (ita-MAUQ) in a sample of people with MS.

We specifically hypothesized that the ita-MAUQ would retain acceptable model fit in confirmatory factor analysis, acceptable levels of internal consistency, and test-retest reliability. We also hypothesized an acceptable construct validity, defined based on relations between the ita-MAUQ and another standardized usability scale, and differences in known-groups.

Methods

mHealth App Usability Questionnaire

The MAUQ was first developed by Zhou and colleagues [18]. MAUQ is designed for different users (patients or health care providers) and different interaction modes (interactive or stand-alone). For study purposes, the patient version for stand-alone mHealth apps was used. It consists of 18 items divided into 3 subscales: ease of use (5 items; MAUQ_E), interface and satisfaction (7 items; MAUQ_I), and usefulness (6 items; MAUQ_U). The overall Cronbach α coefficients of the original questionnaire were 0.85 for MAUQ_E, 0.90 for MAUQ_I, and 0.72 for MAUQ_U, which indicated strong internal consistency of the questionnaire [18]. The questionnaire uses a 7-point Likert scoring system: 1 (strongly disagree), 2 (disagree), 3 (somewhat disagree), 4 (neither agree nor disagree), 5 (somewhat agree), 6 (agree), and 7 (strongly agree). The authors point out that there are no licensing fees for using the questionnaire, and it is not necessary to request permission before using it. The questionnaire is freely accessible on the website.

MAUQ Translation and Cross-Cultural Adaptation

The original MAUQ questionnaire for stand-alone mHealth apps (patient version) was translated into the Italian language using a guideline for the translation, adaptation, and validation of instruments or scales for cross-cultural health care research [27]. The questionnaire was first translated by native Italian speakers proficient in English. The forward-translated versions of the instrument were initially compared by a third independent translator regarding ambiguities and discrepancies of words, sentences, and meanings to generate a preliminary initial translated version of the questionnaire. The back translation was verified by translating the Italian version to English by 2 native English speaker translators with a high Italian proficiency. A multidisciplinary panel with 3 health care professionals with expertise in MS (an occupational therapist, a physiotherapist, and a psychologist), 2 researchers with expertise in scale validation, and 1 expert in app development compared the translated versions with the original questionnaire and made modifications to make the questionnaire more understandable to Italian people with MS. The final ita-MAUQ questionnaire can be viewed in [Multimedia Appendix 1](#).

mHealth App Used for Validation of the Ita-MAUQ

In addition to motor and sensory difficulties, cognitive impairment, known as an invisible symptom, affects up to 65% of people with MS. Documented in all MS courses, with more

severe deficits in progressive forms, both secondary progressive and primary progressive, compared to relapsing-remitting MS [28], cognitive impairment is recognized as one of the most disturbing disorders in MS, negatively affecting the quality of life and independence of people with MS. Attention, information processing speed, learning and memory, and executive functions seem to be the most commonly affected cognitive domains [29]. Consistent evidence indicates that cognitive functions in people with MS can be grouped into cognitive phenotypes, that is, subgroups of people with MS with a similar pattern of cognitive functioning [30-32]. The validation of the ita-MAUQ was conducted using DIGICOG-MS (Digital Assessment of Cognitive Impairment in Multiple Sclerosis), a smartphone- and tablet-based app for self-assessment of cognitive impairment in people with MS [33] (please see Figure 1 for an overview of the mHealth app). DIGICOG-MS (intellectual property of Italian Multiple Sclerosis Foundation; Italian Society of Authors and Publishers Registration ID: D000018162, 27-12-2022) includes 4 digital tests designed to evaluate the most affected cognitive domains in MS as visuospatial memory, verbal memory, semantic fluency, and information processing speed [34,35]:

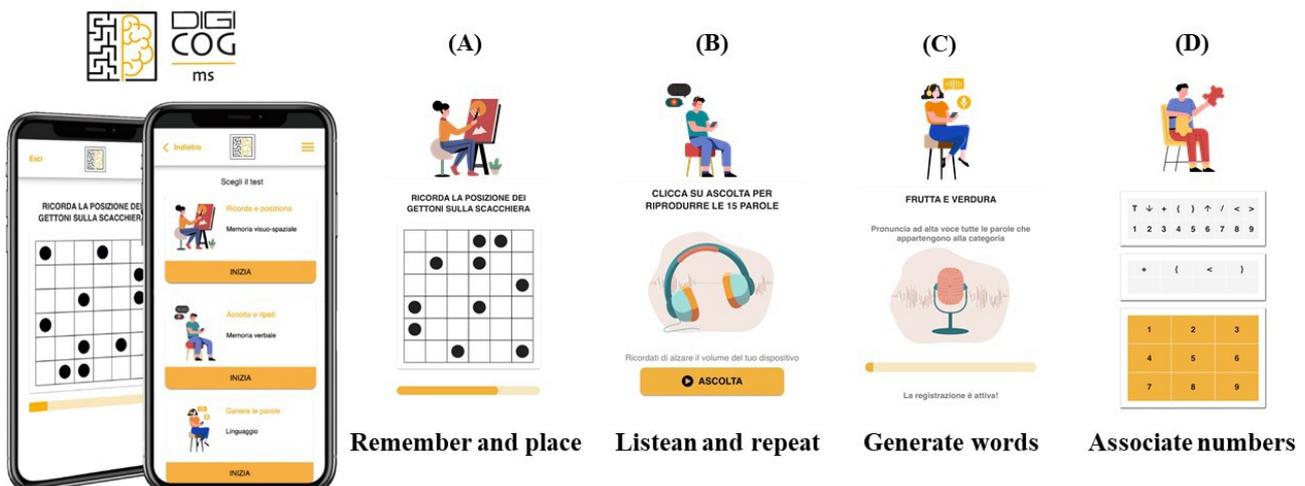

- *Remember and place* assesses visuospatial episodic memory. A 36-square grid with 10 black checkers is displayed on the screen for 10 seconds. After the time elapses, the pattern disappears, and participants must reproduce it on a blank checkerboard. This replicates the 10/36 Spatial Recall Test [35], in which a 6 × 6 checkerboard with 10 pieces arranged in a particular pattern is shown to the participant for 10 seconds. Both tests (digital and traditional) include 3 consecutive trials, and the score consists of the total number of correct responses for the 3 trials.
- *Listen and repeat* was developed as an electronic version of the Rey Verbal Learning Test [36] that evaluates verbal

memory. Participants listen to a prerecorded list of 15 common nouns and are asked to recall as many words as possible 5 times. Responses are recorded and then scored by the neuropsychologist. In the traditional test, words are read aloud to the participant who is asked to repeat as many words as possible in any order. All pronounced nouns in each of the 5 learning trials are transcribed by the neuropsychologist. For both versions of the test, the total score consists of the number of words recalled across the 5 trials.

- *Generate words* is a digital adaptation of the Word List Generation [35,37] and measures semantic verbal fluency. Participants generate a list of words, typically constrained by a specific semantic category, in 90 seconds. Recordings of pronounced words are processed by the neuropsychologist for scoring. In the traditional test, all words generated within the given semantic category are transcribed by the neuropsychologist. The total score is based on the number of correct words produced.

In a study by Podda and colleagues [33], correlation analysis was performed to determine the strength of the association between digital (ie, remember and place, listen and repeat, generate words, and associate numbers) and traditional (ie, 10/36 Spatial Recall Test, Rey Verbal Learning Test, Word List Generation, and Symbol Digit Modalities Test) tests. Overall, the findings revealed strong correlations between digital and traditional paper-based tests across all cognitive domains, with correlation coefficients (*r*) ranging from 0.58 to 0.78. Test-retest reliability was excellent for verbal memory and information processing speed (intraclass correlation coefficients [ICCs] ≥0.95) and good for visuospatial memory and semantic fluency (ICCs≥0.83).

Figure 1. Overview of DIGICOG-MS, the mobile health for cognitive assessment of people with multiple sclerosis. The 4 digital tests implemented in DIGICOG-MS that measure visuospatial memory (A), verbal memory (B), semantic fluency (C), and information processing speed (D). DIGICOG-MS: Digital Assessment of Cognitive Impairment in Multiple Sclerosis.

Study Participants

This study’s participants were people with MS enrolled by the Italian MS Foundation and followed as outpatients at the Italian Multiple Sclerosis Society Rehabilitation Service in Genoa

(Italy). Eligibility criteria were to be aged 18 years or older; have a confirmed MS diagnosis following the McDonald criteria [38]; have any disease course (relapsing-remitting MS, secondary progressive MS, and primary progressive MS); have not relapsed in the last 3 months; have an Expanded Disability

Status Scale (EDSS) score [39] ≤ 7.5 ; and have adequate visual, hearing, and motor capabilities to work on a tablet. Exclusion criteria were a Montreal Cognitive Assessment score < 18 , neurological and major psychiatric illness, past serious head trauma, and alcohol or drug abuse. Data were collected from January 2023 to November 2023.

Study Procedure

Participants received a brief explanation of this study's process and goal at the Rehabilitation Service of the Italian Multiple Sclerosis Society in Genoa (Italy). People with MS were invited to use DIGICOG-MS. Particularly, they were required first to perform the 4 digital cognitive tests and then to explore other functionalities of the app (ie, how to log in, insert, and modify personal information; check for historical results of a specific test; consult the app tutorial; and ask for support). While the digital cognitive assessment was supervised by a neuropsychologist, people with MS were invited to navigate through DIGICOG-MS autonomously, and no specific instructions on how to use other functionalities of the app were given. After finishing the tasks, people with MS completed the ita-MAUQ and SUS [19,40]. SUS was included to test construct validity of the translated questionnaire. The 10-item SUS evaluates users' personal perceptions about how to use a given system or device, ranging from "strongly disagree" (1 point) to "strongly agree" (5 points). The SUS score is calculated by adding the individual scores and then multiplying that sum by 2.5. Thus, the SUS score ranges from zero (lowest usability) to 100 (highest usability), with a value of 68 considered above average. Although the SUS has already been translated and validated in many languages [41], individual problems that people may have when using mHealth apps are not specifically identified by the SUS.

Statistical Analysis

Categorical data were summarized by numbers and percentages, while numerical data were indicated by the mean and SD. Degree of education was coded as less than or equal to 12 years (primary school), between 13 and 15 years (high school), and equal to or more than 16 years (university).

Since confirmatory factor analysis (CFA) has emerged as a pivotal technique in such contexts, offering a comprehensive method for comparing the hypothesized measurement model structure with the observed one [42], it was conducted on the 18-item ita-MAUQ using the original 3 higher-order factors structure (ie, MAUQ_E, MAUQ_I, and MAUQ_U) [18]. CFA was used instead of "discovering" or exploring potential relationships between variables, as in exploratory factor analysis, because it is designed to test a predefined model based on consistent theoretical expectations [43]. Goodness-of-fit was tested with the ratio between chi-square (χ^2) and df (χ^2/df ; good if ≤ 3), root mean square error of approximation (good if ≤ 0.08) and comparative fit index > 0.9 [44]. We reported these statistics using the Satorra-Bentler adjustment because the scale item distribution was nonnormal [45]; the covariance of error terms was considered to improve the model fit. In the data analysis, missing data were replaced with a value of 4.

The internal consistency of the ita-MAUQ was assessed by calculating Cronbach α coefficient and average interitem correlation. The statistically acceptable Cronbach α coefficient should be > 0.7 [46], and average interitem correlations should be between 0.30 and 0.70 [47].

The ICC (2-way analysis of variance random effect model for agreement) was calculated to assess the test-retest reliability. A very small sample size is required for estimating the desired value of ICC (especially when a researcher aims to estimate a very high value of ICC). Using power analysis calculations to test reliability between 2 different observations as described by Bujang and Baharum [48], a minimum of 22 participants is needed to have an acceptable ICC value ≥ 0.5 ($\alpha = .05$, power = 80%, $n = 2$). The ICC was calculated on subscales and total scores, which are expected to remain stable. An ICC value of 0.70 was recommended as a minimum standard for reliability [49].

Ceiling and floor effects were calculated for the overall ita-MAUQ and its subscales. The floor and ceiling effects were defined as the percentages of respondents who reported the lowest score and the highest score, respectively. Floor and ceiling effects were considered present if $> 15\%$ of participants achieved either the lowest or highest scores in ita-MAUQ and its subscales [50].

To examine the construct validity, Spearman correlations coefficients (ρ), used for nonnormally distributed data, were calculated between the ita-MAUQ overall score and subscale scores, and the SUS. Spearman coefficients were considered low for $\rho < 0.30$, moderate for $\rho 0.30-0.59$, and high for $\rho \geq 0.60$ [51].

Known-groups validity evaluates whether an instrument can discriminate between known groups of people with MS that are expected to score differently on the measure of interest (ie, EDSS and gender). Here, it was assessed by comparing, with the Mann-Whitney U test, the total score and subscale scores of participants' groups with different levels of disability. Groups were defined using an EDSS cutoff value of 3.5, discriminating between people with MS with a mild and moderate disability: able (EDSS ≤ 3.5) or unable (EDSS > 3.5) to walk without aid or rest for more than 500 m. Furthermore, since previous research investigating gender differences in users' acceptance for website usability highlights gender as a key variable in understanding usage behavior in information and communication technology [5,52,53], ita-MAUQ total score and subscale scores were also compared with groups divided by participants' gender.

The P values $< .05$ were considered statistically significant. Data were analyzed using Stata (version 17; StataCorp).

Ethical Considerations

This study was approved by Regional Ethics Committee of Azienda Ospedaliera "San Martino" of Genoa (Italy N. 240/2022DB id 12354) and conducted according to the Declaration of Helsinki [54]. Before entering this study, participants had to read, complete, and sign an informed consent. Data collected were stored in an anonymized format to properly protect the privacy and confidentiality of participants, ensuring that no participant can be identified from the data provided.

Participants have been informed that data collection could be used only for research purposes. They did not receive any compensation for taking part in the study

Results from CFA of the 18 items-MAUQ order structure, defined by Zhou and colleagues [18], indicated acceptable fit for a 3D scale: $\chi^2/df=2.1$, root mean square error of approximation 0.068, and comparative fit index 0.92.

Results

In total, 116 people with MS (female: n=74; mean age 47.2, SD 14 years mean EDSS 3.32, SD 1.72) were enrolled (see Table 1).

Table 1. Demographic and clinical sample characteristics (N=116).

Characteristics	Value
Gender, n (%)	
Male	42 (36.2)
Female	74 (63.8)
Age (years)	
Mean (SD)	47.2 (14)
Range	19 - 70
Years of education, mean (SD)	13.3 (2.6)
Education, n (%)	
Primary school	16 (13.8)
High school	80 (69)
University	20 (17.2)
MS^a duration (years)	
Mean (SD)	11.2 (9.6)
Range	0 - 32
MS course, n (%)	
RR ^b	91 (78.5)
SP ^c	15 (12.9)
PP ^d	10 (8.6)
EDSS^e	
Mean (SD)	3.32 (1.72)
Range	1 - 7.5
EDSS, n (%)	
Mild disability, score ≤ 3.5	67 (57.8)
Moderate disability, score > 3.5	49 (42.2)

^aMS: multiple sclerosis.

^bRR: relapsing-remitting multiple sclerosis.

^cSP: secondary progressive multiple sclerosis.

^dPP: primary progressive multiple sclerosis.

^eEDSS: Expanded Disability Status Scale.

The internal consistency of the overall ita-MAUQ and each subscale was good. The Cronbach α for the ita-MAUQ was 0.92, and those for the 3 subscales were 0.78 (ita-MAUQ_E), 0.89 (ita-MAUQ_I), and 0.87 (ita-MAUQ_U). Similarly, the average interitem correlation was between 0.41 and 0.53. These results align with published satisfactory thresholds for scale reliability [23,24].

To assess the test-retest reliability, 25 participants were required to complete the ita-MAUQ, 2 weeks apart. ICC was 0.84 (95% CI 0.66 - 0.92) for ita-MAUQ total score, 0.66 (95% CI 0.36 - 0.84) for ita-MAUQ_E, 0.88 (95% CI 0.75 - 0.94) for ita-MAUQ_I, and 0.67 (95% CI 0.38 - 0.84) for ita-MAUQ_U, showing good or moderate temporal stability.

There were no floor or ceiling effects for the ita-MAUQ total score (0% scored 18 and 6.9% scored 126). The floor effect for ita-MAUQ_E and ita-MAUQ_I subscales was again null, while for ita-MAUQ_U, only 1 participant had the worst possible score of 6 (0.9%). The ceiling effect for ita-MAUQ subscales was 38.8%, 36.2%, and 9.5%, respectively. No other previous study reported the measure of ceiling and floor effects of this instrument [22-24], and therefore a comparison cannot be established.

Spearman coefficients revealed significant correlations between ita-MAUQ total score; ita-MAUQ_E, ita-MAUQ_I,

ita-MAUQ_U subscales; and SUS (85.43, SD 14.3; all *P* values <.05). Table 2 shows the results of the construct validity analysis.

Known-group analysis found no difference between people with MS with mild and moderate EDSS (all *P* values >.05), suggesting that ambulation ability, mainly detected by the EDSS, did not impact the ita-MAUQ scores (Table 3). Interestingly, statistical differences between female and male participants concerning the ita-MAUQ_E was found (*P*=.02; Table 4).

Table . Spearman correlation (ρ) between the ita-MAUQ total^a score; ita-MAUQ_E^b, ita-MAUQ_I^c, and ita-MAUQ_U^d subscales; and SUS^e total score.

Discussion

Digital solutions as mHealth apps promise to offer alternative methods for enhanced real-time data capture to screen for, monitor, and treat symptoms in MS. These solutions may fundamentally shift traditional paradigms of medicine [7-12]. To be used in clinical practice, the validity and usability of mHealth tools should be tested. Questionnaires are the well-known methods for usability testing, but developing a new one might require concerted effort by the members of a research team, extra cost, and a lot of time [55]. Thus, adaptation of established, appropriate, and available questionnaires with documented validity in other languages is recommended [55].

Thus, the aim of this study was to translate and validate the English version of the ita-MAUQ in a sample of people with MS. Overall, findings demonstrated that the novel translated questionnaire ita-MAUQ is a reliable and valid measurement tool to assess the usability of mHealth apps for people with MS. In this context, people with MS self-administered the ita-MAUQ after interacting with DIGICOG-MS, a novel mHealth app for cognitive self-assessment in MS.

Results indicated that the ita-MAUQ had good internal consistency and stability, as indicated by the Cronbach α coefficient of 0.92. This is in line with the original version of the MAUQ [18] and with other translations of the same questionnaire [23,24,56].

Worldwide, Spearman coefficients between ita-MAUQ total score, subscales, and SUS were statistically significant, proving good criterion and construct validity. However, correlation between the SUS and ita-MAUQ_U was found to be low (0.26). This was in line with the study by Zhou et al [18], in which correlation between MAUQ_U and the SUS was 0.383, reflecting that MAUQ_U is mainly about the usefulness of apps for health care, which is an aspect not covered by the SUS.

Compared to another previous study on MAUQ that did not perform test-retest [24], results revealed good or moderate temporal stability. Given that mHealth apps may allow continuous health care services over time, identifying valid methods to test whether a digital tool is reliable in different measurements is crucial.

The ceiling effect of the ita-MAUQ subscores could indicate that the proposed mHealth app was indeed easy to use for many people with MS. Even though the interaction with DIGICOG-MS was supervised by a neuropsychologist to

provide adequate responses to any questions from participants, they were invited to navigate through the mHealth app autonomously, since no specific instructions on how to use other app functionalities were given. In this way, we interpreted this ceiling effect positively as a successful interaction.

In general, the known-groups validity of the instrument was shown by the comparison of ita-MAUQ total and subscale scores between people with MS with different disability levels. The results indicate no significant difference in people with MS with mild and moderate EDSS. Since EDSS mainly measured ambulation capacity, this suggests that such mHealth apps could be found usable for both people that need assistance during ambulation and those who are able to walk without any aid or support.

Concerning gender, earlier studies found that perceived ease of use and usefulness technology may differ by gender [5,52]. Our results are in line with a previous study that demonstrated that gender was associated with higher usability scores in female than male participants [57]. Interestingly, male and female people with MS had different scores in ita-MAUQ_E, suggesting that women are more likely than men to be influenced by effort expectancy and facilitating conditions [53]. These results can help developers to enhance the usability of their services for all users with different personal and clinical characteristics, since men and women still have different traits and societal roles, which may affect their perceptions and usage of technologies.

Our study has several limitations. First, as a single-center study, participants' characteristics may limit the interpretation of our results. The study sample may be considered representative of those clinic-attending people with MS followed as outpatients in rehabilitation centers (ie, middle-age or older adults and with a longer disease duration) [58]. Thus, results may not generalize to other populations of participants with MS (eg, young and neo-diagnosed people). Second, in this validation study, we used DIGICOG-MS that was designed and developed to assess a specific symptom in MS, that is cognitive impairment. Given the high frequency of cognitive impairment in people with MS, it is reasonable to conclude that study participants who have experienced such a disturbing symptom tended to appreciate the mHealth app more compared to people with other neurological diseases. People with MS with cognitive impairment might find such digital tools particularly beneficial due to their potential to offer structured cognitive training and monitoring, which can enhance their daily functioning and quality of life [59]. Thus, it cannot be ruled out that the results

of the ita-MAUQ validation would have been different with a clinical population with dissimilar characteristics.

Third, this study was conducted in a controlled clinical setting, allowing participants to familiarize themselves with both the novel technology and usability questionnaires' items. While this approach may have some limitations in terms of generalizability to real-life scenarios and may influence participants' engagement and perceived usability, having a facilitator available to assist, if needed, people with MS that could have problems with reading and interpreting the questionnaire items ensured they understand each question before responding. Furthermore, in this study we overlooked other key factors that may influence usability, such as assessing the importance of providing adequate training and continuous support to users or the role of previous experience with a similar technology; investigating how interface design that considering layout, navigation, and accessibility features makes the app user-friendly for participants with cognitive impairments; evaluating the concerns and preferences of users regarding data

security and privacy, which are crucial for building trust and ensuring compliance with health regulations data security and privacy. Here, we did not collect additional feedback after the completion of both digital assessment and usability questionnaires from people with MS. Further study should include feedback sections where participants can indicate if they found any items difficult to understand, allowing for continuous improvement of the novel tools. Worldwide, incorporating these factors into future research can lead to the development of more effective, user-friendly, and impactful mHealth apps for people with MS.

In conclusion, the ita-MAUQ demonstrated high reliability and validity, and it might be used to evaluate the usability, utility, and acceptability of mHealth apps in people with MS. This finding is in line with previous validation of the MAUQ in different languages as Malay [21], Chinese [22], Spanish [23], German [24], and French [25], further confirming the cross-cultural validity, reliability, and adaptability of the MAUQ.

Acknowledgments

We would like to thank Maria Madera and Giulia Bignone for their help in participants' enrollment and all the people with MS that took part in our study. This work has been funded as Progetto Ricerca Speciale by Italian Multiple Sclerosis Foundation (2021/Special/005).

Data Availability

All data produced in this study are available upon reasonable request to the corresponding author.

The questionnaire can be used in clinical trials and is available free of charge for non-commercial parties, provided the authors are cited, or by contacting the corresponding author.

Authors' Contributions

JP conceived this study, interpreted results, and drafted this paper. MP performed statistical analysis, created tables, and contributed to the initial draft of this paper. AS performed data collection. FDA, AT, LP, and EG revised this paper. All authors read and approved the final paper. This paper was written entirely by humans. All authors are responsible and accountable for the originality, accuracy, and integrity of the work.

Conflicts of Interest

None declared.

Abstract

Background: New digital technology presents new challenges to health care on multiple levels. There are calls for further research that considers the complex factors related to digital innovations in complex health care settings to bridge the gap when moving from linear, logistic research to embracing and testing the concept of complexity. The nonadoption, abandonment, scale-up, spread, and sustainability (NASSS) framework was developed to help study complexity in digital innovations.

Objective: This study aims to investigate the role of complexity in the development and deployment of innovations by retrospectively assessing challenges to 4 digital health care innovations initiated from the bottom up.

Methods: A multicase retrospective, deductive, and explorative analysis using the NASSS complexity assessment tool LONG was conducted. In total, 4 bottom-up innovations developed in Region Västra Götaland in Sweden were explored and compared to identify unique and shared complexity-related challenges.

Results: The analysis resulted in joint insights and individual learning. Overall, the complexity was mostly found outside the actual innovation; more specifically, it related to the organization's readiness to integrate new innovations, how to manage and maintain innovations, and how to finance them. The NASSS framework sheds light on various perspectives that can either facilitate or hinder the adoption, scale-up, and spread of technological innovations. In the domain of condition or diagnosis, a well-informed understanding of the complexity related to the condition or illness (diabetes, cancer, bipolar disorders, and schizophrenia disorders) is of great importance for the innovation. The value proposition needs to be clearly described early to enable an understanding of costs and outcomes. The questions in the NASSS complexity assessment tool LONG were sometimes difficult to comprehend, not only from a language perspective but also due to a lack of understanding of the surrounding organization's system and its setting.

Conclusions: Even when bottom-up innovations arise within the same support organization, the complexity can vary based on the developmental phase and the unique characteristics of each project. Identifying, defining, and understanding complexity may not solve the issues but substantially improves the prospects for successful deployment. Successful innovation within complex organizations necessitates an adaptive leadership and structures to surmount cultural resistance and organizational impediments.

A rigid, linear, and stepwise approach risks disregarding interconnected variables and dependencies, leading to suboptimal outcomes. Success lies in embracing the complexity with its uncertainty, nurturing creativity, and adopting a nonlinear methodology that accommodates the iterative nature of innovation processes within complex organizations.

Introduction

Why Is it so Difficult to Develop and Spread New Innovative Technologies in Health Care?

There has been an increasing focus on innovation and the role of new technologies (eg, electronic health records, smartphones, and health applications) in health care. However, developing new technologies comes with significant challenges. Studies show that technology projects in health care, particularly large and complex projects, have a high rate of failure and seldom produce the anticipated results [1-5]. Bottom-up innovations in health care are innovations for service delivery that have been developed “from the ground up,” often focusing on preventive patient-centered care, typically driven forward by small interdisciplinary groups of professionals and patients [6-9]. As a result, they may not be captured by existing metrics, thus being “invisible” to senior management and policy makers [10].

The challenges when it comes to developing and making use of innovations, such as spreading or implementing new ways of working [11], have been described by many, often as a “knowledge translation or production problem” [12]. Braithwaite et al [13] compared the traditionally dominant linear and causal thinking that characterizes early implementation science and the evidence-based medicine paradigm with features such as those in systems thinking. The linear approach applies simple, orderly processes with cumulative sequences of stages to produce results building on a knowledge of the way things work, making use of predictable relationships between causes and effects. This has helped generate many successes in the past, not least in health care, but it tends to increase rigidity and fail when applied in more complex and messy systems where things change dynamically and are therefore unpredictable [13]. Instead, systems thinking and the related complexity science recognize system characteristics in building an understanding of how best to move forward.

To drive change in a predictable “simple” system where causes and effects are known, a linear, stepwise approach has a greater chance of success. However, complex systems are not only dynamic but also are often described as adaptive (as in complex adaptive systems) in that they are constituted of agents and artifacts that communicate and learn from each other and the surrounding environment, creating opportunities to learn from experience, self-organize, and evolve, making them less predictable systems [14].

Even though the linear approach has previously dominated implementation and development initiatives in health care, many researchers point to the necessity to apply systems thinking and

complexity science when developing health care through the innovative use of new technologies, as exemplified in the study by Greenhalgh and Papoutsi [2]. As the concept of stepwise, linear cause and effect is not sufficient when studying complex systems that evolve in ways that are impossible to predict, it is relevant to use the knowledge of complex systems when understanding and studying health services [15]. Complex systems are defined by (1) intricate intertwined processes, (2) interconnectivity between systems, (3) interconnectivity between levels within systems, and (4) interconnectivity between actors and elements, giving complex systems different properties from those of less complex systems [1]. In short, a complex system does not work linearly but dynamically, with fundamentally different logics [16], and needs to be addressed and understood accordingly during innovation and implementation. If not, there is a risk that new technology and innovations will further increase the complexity rather than actually supporting the needs and demands for an improved health care system [17].

The Challenges

A total of 4 bottom-up innovators found that there was a need to gain insights into the complexity involved in developing and executing bottom-up innovations in a complex health care organization. All 4 innovators had met with hindrances preventing them from moving forward with their innovations. It was necessary to pause and retrospectively try to comprehend the underlying reasons for the stagnation in the 4 cases in question.

Project representatives, all health care professionals, joined forces to identify challenges by assessing project complexity to increase an understanding of the role of complexity and find ways to explore and assess it. As they all worked within the same regional system, it was crucial to involve regional stakeholders (support functions) during the learning process.

The aim of this study was to investigate the role of complexity in the development and deployment of innovations by retrospectively assessing the challenges to 4 digital health care innovations initiated from the bottom up.

Methods

This section describes the theoretical framework that underlies our methodological approach, the settings, and the 4 cases under study, as well as the procedure.

Theoretical Framework

An impressive amount of knowledge related to the diffusion of innovations and their implementation in health care by the start of the new millennium is summarized in the extensive review

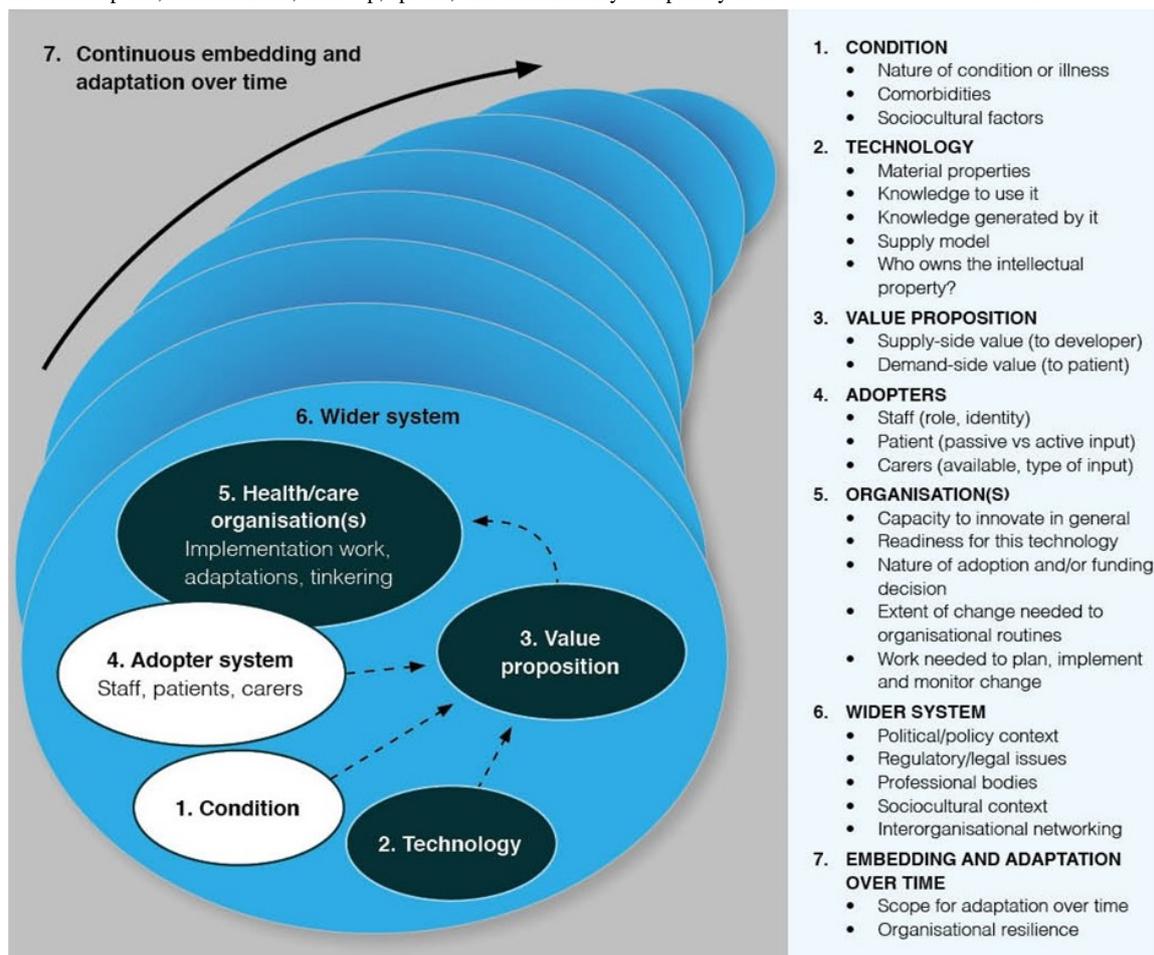

by Greenhalgh et al [11] from 2004. It builds partly on the ideas by Rogers [18] that innovations have characteristics that will affect their diffusion, as well as affect other domains (eg, the readiness of the system for change, the implementation process, the adopter, and the external wider [sociopolitical] context). As innovations in health care were increasingly associated with new technologies, a new review was conducted by Robert et al [19] in 2010, adding more recent data and focusing on the adoption and assimilation of new technologies into health care.

This, along with the high failure rate of health care technology innovation projects, inspired Greenhalgh and colleagues to deepen their knowledge of the diffusion of innovations, with

an emphasis on health technology projects. Building on previous work, reviewing the literature, and using empirical studies of technology implementation, they elaborated on and explained domains of importance. This resulted in the nonadoption, abandonment, scale-up, spread, and sustainability (NASSS) framework (Figure 1 [20], published under Creative Commons Attribution 4.0 International License, CC BY).

The NASSS framework was developed into a complexity assessment tool (NASSS-complexity assessment tool [NASSS-CAT]) [20] to help assess the complexity of health technology projects before, during, or after they were finished.

Figure 1. The nonadoption, abandonment, scale-up, spread, and sustainability complexity assessment tool with its 7 domains.

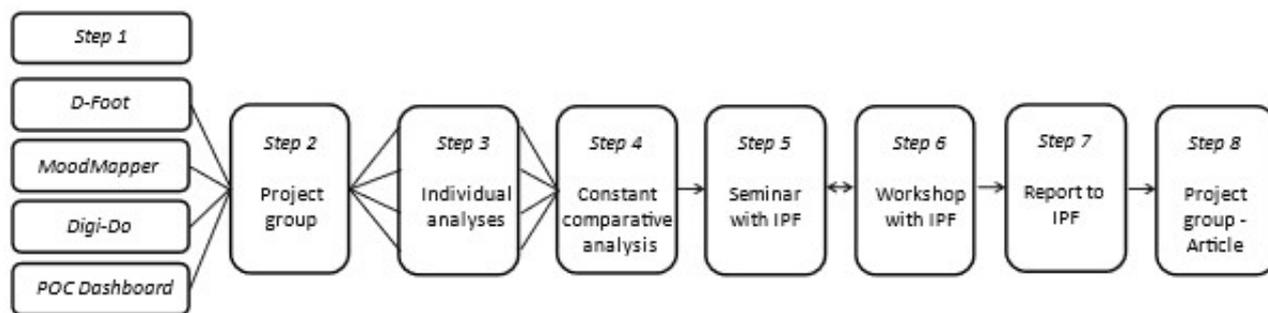

Design and Methodological Approach

A multicase retrospective, deductive, and explorative analysis using the NASSS-CAT LONG was conducted [15,21]. The process of analysis is shown in Figure 2 and is described at the end of the *Methods* section. The complexities of 4 bottom-up innovations developed in Region Västra Götaland (VGR) in Sweden were explored. The NASSS-CAT LONG consists of 2 parts divided into 7 domains (Figure 1). First, one is asked to describe the project and its potential messiness in their own words. Writing this narrative can help surface interdependencies and tricky issues of the project, hence revealing complexity.

Second, one answers the questions related to the domain to help them estimate key areas of complexity. One can define whether the question is complex or not complex, whether they do not know, or whether it is not applicable. The total score of orange boxes ticked tells one how complex a certain domain is for their project. In part 2, one is guided through prompts to help them plan for and manage complexity by *reducing* it where possible and *responding* to it if or where it cannot be reduced. The questions can be answered by different people who will provide the needed insights into the domain and the project under evaluation.

Figure 2. Flowchart illustrating the study process when exploring the role of complexity in health care technology projects. This figure presents the different steps (1-8) in the study. Details can be found in the main text. IPF: Innovation Platform.

Setting

The 4 bottom-up innovators were from different parts of the organization in the VGR [22]. All of them had unique experiences of their own departments of the VGR and the surrounding supporting systems, such as the IT departments, purchasing departments, and legal offices. Although all 4 worked in specialized care, the care flow for each of the relevant diagnoses spanned specialized care, primary care, and municipal care.

The VGR is a region on the western coast of Sweden with a total population of 1.8 million. For several years, there has been a push for increasing the development of innovative solutions to the challenges faced by, for example, the public health care system. This has been implemented through the formation of an Innovation Platform (IPF) that develops processes and supportive structures as well as approving funds to help innovative ideas thrive. The mission of the IPF is to contribute to a sustainable innovation system that promotes innovation in health care and ensures that collaboration between academia and business fulfills the needs of patients within the health care system.

In total, 4 bottom-up innovators in the VGR pioneering eHealth and clinical research united in 2019 after realizing that there were barriers to their separate innovations due to an organizational lack of an innovation framework and to inexperience in developing, testing, implementing, and maintaining digital innovations. One author, familiar with the NASSS framework, encouraged the others to explore complexity in innovation. Together, they adapted the NASSS-CAT to identify unique and shared complexities in their innovations. Concurrently, at the same network meeting, representatives from the IPF wanted to be a part of the study, exchanging insights on how to identify and manage complexities in the innovation process.

Ethical Considerations

Because no personal data were collected, no ethics approval was needed. All participants agreed, orally, to take part. No sensitive personal information was collected, and no patients participated in the workshops. The IPF, the regional support resource for innovations in health care, read and commented on the Swedish report before publication.

The 4 Bottom-Up Innovations

Overview

Each innovation is presented in the following sections and in [Multimedia Appendix 1](#) [15,20,23-38]. The cases are heterogeneous with regard to intended user, phase in the innovation process, and place of implementation (locally, regionally, and nationally). Despite their differences, they all existed in the same environment, framed by the regulations of the VGR and its support system for innovation.

Case 1: The D-Foot

The lifetime risk of developing diabetic foot ulcers (DFUs) is as high as 34% for patients with diabetes [23]. It is a burden for the patient and for health care with regard to costs. With prompt prevention, the prevalence of DFUs can be halved [24].

The D-Foot is a digital decision support system designed for preventing DFUs. It conducts early screening and provides treatment recommendations based on a risk grade (ranging from 1=no risk to 4=ongoing foot ulcers) [25,26]. The risk grade is automatically generated through a series of structured foot assessments and patient surveys [27]. A printable report of foot assessments, risk grade, and recommendations is generated. The innovation's reliability and usability have previously been reported and assessed as good [27,28]. The innovator's intention was that the D-Foot would serve as a tool in the national effort to implement a person-centered and seamless care chain for preventing foot ulcers in people living with diabetes [25,26].

The seamless care chain consists of (1) an annual foot examination, (2) a podiatry intervention, (3) the provision of appropriate footwear for at-risk patients, and (4) treatment in a multidisciplinary team for patients with active DFUs [25,39]. The D-Foot was developed as an easy-to-use digital tool to support foot examinations for individuals diagnosed with diabetes, primarily targeting prosthetic and orthotic specialist care [27,28,40]. The goal was to implement the D-Foot nationally, expecting early prevention of DFUs, improved quality of life for affected individuals [29,41], and reduced health care costs [42].

Version 1.0 of the D-Foot software was developed from 2011 to 2016 by an expert group comprising certified prosthetists and orthotists, patient representatives, and orthopedic surgeons in the VGR [27]. Initially, it underwent regional testing with positive results. Thereafter, continuous improvements have been made based on users' comments [28]. Not yet executed is the

request from users for integration between the D-Foot and the major medical record system [28].

Case 2: The MoodMapper

Bipolar disorder, often diagnosed in early adulthood, typically necessitates lifelong treatment. It leads to undesirable mood swings affecting daily functioning. Mood episodes vary from extreme “highs” (manic episodes) to severe “lows” (depressive episodes) lasting for days or weeks. Even with proper treatment, mood fluctuations can occur. Collaborative communication between patients and health care providers enhances treatment effectiveness. Moreover, the early detection of behavior changes is of the utmost importance in the successful treatment of bipolar disorder.

The aim of this innovation was to determine whether smartphone use data are a reliable source for studying changes in the digital behavioral patterns of individuals with bipolar disorder by exploring correlations between different parameters of smartphone use data.

The MoodMapper is a mobile app that, through real-time data collection, can provide valuable insights into a patient’s smartphone use. The ambition was, after pilot-testing, to study and evaluate the connection between mobile-generated passive data and documented changes in the patient’s mental well-being, with the goal of making it easier for both patients and health care professionals to monitor the progression of the patient’s condition and make decisions regarding prevention and care.

Case 3: The Digi-Do

Radiation therapy (RT) is a common treatment after breast cancer surgery. The high-technology environment and unfamiliar nature of RT can affect the patient’s experience of the treatment. Misconceptions or a lack of knowledge related to RT processes can increase levels of anxiety and enhance feelings of being unprepared at the beginning of the treatment. Moreover, the waiting time is often fairly long. Cancer care involves several, often independent clinics. Even if the clinical pathway is clearly described, transitions and information exchange can be problematic. RT is only provided at the university hospital in the region, with long distances and long waiting times for many patients.

The Digi-Do tool consists of two separate mobile apps: (1) an app providing a guided digital tour of the RT department, where the patient can familiarize themselves with the department by using virtual reality glasses; and (2) an app with additional information, including questions and answers, practical information, and short animated films about the RT process. The design of both apps was developed in a co-design process with patients and staff [43]. The primary aim of the researcher or innovator was to evaluate whether a digital information tool with virtual reality technology and preparatory information was able to reduce distress and enhance the self-efficacy and health literacy of patients with breast cancer before, during, and after RT. A secondary aim was to explore whether the digital information tool increased patient flow while maintaining or improving the quality of care [44].

Case 4: A Point-of-Care Dashboard for Schizophrenia Care (the PoC Dashboard)

The Department of Schizophrenia Spectrum Disorders at Sahlgrenska University Hospital delivers specialized care for people with psychotic disorders in the metropolitan Gothenburg area (with a population of approximately 600,000 people) in Sweden. Schizophrenia is the most common diagnosis among the approximately 3000 patients who receive care at the department’s 7 outpatient units. Approximately 20% of these patients also need acute inpatient care at 1 of the department’s 4 wards each year.

With the aim of supporting patient coproduction of health, a digital dashboard was developed to be jointly reviewed at the point of care by patients and case managers and psychiatrists to support evaluation and planning, outcome questionnaires, and patients’ care plans [45]. The dashboard was developed between 2016 and 2018 and was piloted at 2 outpatient units with approximately 400 patients for 18 months. The dashboard is one of several connected applications and displays for visualizing data fed by multiple systems to support, for example, planning, management, and triage and includes a unit-level overview of quality indicators to identify patients at risk. The dashboard project also served as a case in the development of the NASSS-CAT [20].

Study Procedure

This study followed an iterative process, including analyses, discussions, and seminars (Figure 2).

As we used the NASSS-CAT, the analysis was deemed to be of an exploratory, deductive nature. First, an individual assessment of each case was made, and then the 4 cases were compared to find similarities. However, while using the NASSS-CAT in each of the 4 cases, the innovators had discussions about how to interpret the questions in the 7 domains. An additional method, namely, constant comparative analysis (CCA), was chosen as it is appropriate in collaborative projects to facilitate and identify agreements and disagreements [46,47] (Multimedia Appendix 2). After agreeing on how to interpret the questions, members of the IPF were invited to complete the analysis in a workshop.

In total, 4 bottom-up innovators had individually experienced complexities during their respective innovation processes from 2010 to 2019.

1. The 4 innovators got together and started the study in January 2020 by learning how to use the NASSS framework based on the work by Greenhalgh et al [15]. Support was available as one of the authors had been involved in the development of the NASSS-CAT [20].
2. The innovators identified complexities in their individual projects using the NASSS-CAT [20] in 2020.
3. During >30 one-hour meetings using the NASSS-CAT and taking minutes, the innovators identified, compared, and discussed similarities and differences regarding complexities in their respective innovations. A CCA was included in the process and is described in Multimedia Appendix 2.

4. A seminar was held in April 2020 with one of the bottom-up innovators and the IPF presenting the concept of complexity and the NASSS framework.
5. In October 2020, another seminar was held with the 4 innovators and staff members from the IPF to discuss the domains of the NASSS-CAT, illustrated by examples and findings from the assessment of the 4 bottom-up innovations. The participants from the IPF discussed and reflected on experiences of complexities. The seminar was recorded and summarized in a report in collaboration with a representative from the IPF [48].
6. The authors were commissioned to write a report (in Swedish) for the IPF exploring and summarizing the NASSS framework and complexity with examples from the bottom-up innovations [48].
7. The insights gained into the role of complexities from the entire aforementioned process were discussed and summarized and are presented in this paper.

Results

In this retrospective exploration of the role of complexity in 4 bottom-up health care innovations in a Swedish region, both similarities and differences emerged among the 4 cases when using the NASSS-CAT ([Multimedia Appendix 3](#)). The findings for each domain are described in the following sections.

Complexity Domain 1: The Illness or Condition

This domain has no or low complexity when the illness is well known and an assessment can result in a well-defined diagnosis and when there is, furthermore, knowledge and know-how regarding how to treat the condition successfully. Complexity can be related to conditions with less known causes, a high prevalence of multimorbidity, and challenging sociocultural factors (eg, language barriers). In our study, the cases that addressed mental illness (PoC Dashboard and MoodMapper) and diabetes (D-Foot) had more complexity related to the actual illnesses than the case aiming to prepare women before RT for breast cancer (Digi-Do) [49,50]. Both bipolar disorder and schizophrenia are strongly connected with comorbidity and lifestyle-related conditions, and even though national guidelines exist, there is no simple pathway to treat those conditions. The third case (D-Foot) involved diabetes, also an illness defined as complex due to the patient being treated in various institutions and with several lifestyle factors influencing the outcome of the treatment [39].

Complexity Domain 2: The Technology (or Other Innovations)

An innovation is less complex if it is well known, ready, and easy to use and has a clear supply model, well-defined ownership regarding its intellectual properties, and low or no dependency on other systems. For the actual technologies under study, similarities regarding complexities revolved around interdependencies with other IT systems, ranging from local to regional and even national systems. Even if the technology already existed (D-Foot) or if new software was developed to create a better overview of data in several existing systems (PoC Dashboard), it was difficult to develop the innovation so that it

enabled adoption beyond the local settings. Regulations regarding software used as a medical device [30] sometimes prevailed over the simple adaptations for different target groups. “Fireproof” walls exist between organizations (eg, municipal care, primary care, and specialist care), and different versions of the regional information systems, being related to ownership, budget, and management, make it less clear whether and how new technologies can be bought, adapted, and used in a local setting. In contrast, the Digi-Do app does not require any interaction with existing IT systems and was not deemed to be a medical technical device. The MoodMapper app, on the other hand, is complex as it aims to interact with both patients and health care staff, requiring interaction with medical electronic health records as well as ensuring a very high level of security to safeguard the patients’ integrity [51]. The need for supply chains included both purchasing and procurement and clinical implementation, the latter involving questions regarding intellectual properties (is the owner the bottom-up innovator or is it the region?), ownership management (which regulation steers the region when managing a medical device owned by the region?), and updates and maintenance of the eHealth tools (which department in the VGR is responsible for updates and maintenance of the innovations?). All the cases had run into or expected to run into severe complexity when planning to launch their innovations. It was clear that complexity regarding supply chains had not been considered by either the innovator or the VGR when intending to expand from a local level to a regional or national one. An example of the complex challenges related to the spread and maintenance of one of the eHealth tools, the D-Foot, is presented in the following paragraphs.

Regulations regarding funding and ownership made it difficult to implement a supply chain outside the local region as each of Sweden’s 21 regions has its own procurement processes. Since the start, the D-Foot project had been aiming for national spread. In 2017, the IPF approved funding with the aim of testing, Conformité Européenne (CE) marking, and thereafter implementing the D-Foot first in the VGR at the department of prosthetics and orthotics and then nationally. At the same time, several departments of prosthetics and orthotics in other regions were interested in using the D-Foot as soon as the CE marking was finalized. However, in June 2017, an official at the VGR decided that the region was only able to allow the D-Foot to be used within the region (Article 5.5 in the Regulation [European Union] 2017/745) [30]. Following this decision, national spread was impossible. The bottom-up innovator continued to have a dialogue with the IPF seeking a solution for national spread. In 2020, an opportunity for national spread arose by registering the D-Foot as a national medical information system (NMI) at the Medical Products Agency. An NMI is an information system developed for joint use at nationwide, regional, or municipal level in Sweden.

Thus, the D-Foot transitioned from being a “self-manufactured medical device” to becoming an NMI registered with the Swedish Medical Products Agency in 2020. However, the NMI registration was withdrawn by the VGR in 2021 due to new regulations from the Swedish Medical Products Agency [52]. The D-Foot remains a separate software program not integrated into the standard medical record system in the VGR. As a result,

one option remained for national spread, namely, to CE mark the D-Foot, a procedure that was not as yet allowed or tested in the region.

Complexity Domain 3: The Value Proposition (Costs and Benefits of the Technology)

Complexity in this domain arises when determining the value provided by the innovation to developers, users (patients, staff, and health care systems), and the broader health care ecosystem. Despite their origin as bottom-up innovations aimed at improving care, the complexities of demonstrating supply-side value in terms of business models and monetary benefits were challenging. Key questions included defining improved value, decision-making processes, the inclusion of nonmonetary values, and the extent of evaluation required: what is regarded as improved value? Who decides? Is it only monetary or other types of value as well? How much does the innovation need to be evaluated and how?

The Digi-Do has a defined regional vision and has faced challenges in quantifying value, especially regarding soft values such as reduced distress and increased health literacy and self-efficacy. The Digi-Do aims to optimize the use of waiting time before RT, adding value by reducing waiting times and queues. Furthermore, the innovation aims to create value for patients by delivering information in a novel, accessible format, potentially improving health literacy even for those with language difficulties or cognitive impairments. It also extends benefits to the patient's social network, enhancing support and knowledge and reducing distress among family and friends affected by the patient's cancer diagnosis. By using the often idle waiting time for meaningful preparation, the innovation may foster a sense of control and inclusion, diminishing distress and worry. Well-prepared patients may navigate the system more efficiently, potentially reducing waiting times for information dissemination.

The evaluation of the outcomes in this specific project is still ongoing through an unpublished randomized controlled trial [44], but so far, the qualitative results show a high level of acceptance of and positivity toward the tool. Nevertheless, there needs to be a discussion about how to endorse a more pragmatic evaluation of both effectiveness and process outcomes [53].

If successful, this approach could be adapted for other health care domains, although commercialization is not the project's primary goal. Measuring soft values has proved challenging as they might not directly impact traditional health care outcomes. The other cases faced similar difficulties in pinpointing the exact stages in which costs and values could be calculated.

Enhancing foot health can improve the quality of life of patients and reduce health care costs associated with treating DFUs and amputations. Objective risk assessment by using the D-Foot precedes interventions, aligning with the vision of providing equal, high-quality care to citizens. Early interventions in the prevention process (D-Foot) might require more resources within primary care but were expected to be cost-effective in the long term due to a reduction in specialist care following fewer ulcer treatments and amputations [31,42]. In terms of quality of life and cost reduction, the value proposition needs further

evaluation over a longer period relying on data related to care costs for at-risk patient groups. The D-Foot database contains valuable information on risk groups and foot status, serving as a data source for audits and evaluations to optimize foot care. It could also function as a quality registry, potentially becoming the new diabetic foot register in Sweden.

The MoodMapper aims to provide a more objective risk analysis and early interventions, potentially preventing hospitalization. In the examples of innovations (MoodMapper and PoC Dashboard) designed to prevent relapses in severe mental illness by coordinating data or even by asking patients to send and react to data, the need for hospital care could be reduced. However, this area is as yet unexplored.

The value proposition of the PoC Dashboard remains uncertain. Case managers and patients find the technology useful based on preliminary data. Local testing and piloting suggest perceived effectiveness, although the degree of cost-effectiveness is still unknown. The dashboard streamlines administrative tasks for staff, offering an overview of patients' progress and risks while facilitating collaborative care planning. However, the technology's potential as a commercial product is uncertain, mainly because it is integrated with older systems. Additional uncertainties involve the IT department's role in dashboard maintenance and associated costs.

Complexity Domain 4: The Intended Adopters of the Innovation and Technology

Complexity in this domain is higher when adopting the innovation, necessitating changes in routines, roles, and identities. Innovations that support existing routines with minimal disruption are associated with lower complexity, and all 4 cases required either behavior changes by patients or modifications to work routines for health care staff. For example, the PoC Dashboard simplified patient overview and reduced administrative work for staff, thus positively impacting daily tasks [54].

However, transferring the D-Foot to primary care posed challenges as different health care professionals (podiatrists, nurses, and physicians) with varying roles and routines questioned its added value. The MoodMapper required patients to trust the handling of their behavioral data, which could be challenging for those with symptoms of paranoia.

Complexity Domain 5: The Organization Implementing the Technology

Complexity in this domain pertains to the efforts required to plan, implement, and monitor the innovation's adoption, as well as to the organization's overall capacity for innovation. Challenges included a lack of clear pathways for support, making it necessary to find the right individuals at the right levels for consultations. Different organizational levels faced varying complexities, and despite a desire for innovation, built-in regulations sometimes hindered dissemination. For instance, regulatory obstacles prevented the national spread of the D-Foot.

Complexity Domain 6: The External Context for Innovation

Complexity in this domain is influenced by the political, sociotechnical, and regulatory context, as well as by stakeholder groups and interorganizational networking. In Sweden, despite a national Vision for eHealth by 2025 [55], the existence of 21 independent regions creates complexity in decision-making for local, regional, and national development and for the implementation of digital health care innovations. For instance, there is a national initiative from the government to improve cancer care, but the regions are self-governed in terms of budget and implementation. This means that, even if the regional cancer center had a national assignment to improve cancer care generally and the RT process in the local region specifically, it has no mandate to implement the Digi-Do without the approval of the RT department at each separate regional hospital.

Furthermore, if an innovation needs to be integrated with the IT systems, such as in the other 3 cases, national initiatives can be ruled out by regional procurement, management supply chains, and European regulations regarding medical devices [30]. If regional support and the management of supply chains only permit regional use, there will be no dissemination, and thus, bottom-up innovations risk becoming only local or, at worst, experiencing the “death of innovations” after the initial project phase.

Complexity Domain 7: Emergence Over Time

Complexities were identified in all 4 cases (Multimedia Appendix 3). When summarizing the complexities from domains 1 to 6, all the authors concluded that the complexities were likely to increase in the coming 3 to 5 years, probably due to advances in technology, unexpected events such as pandemics, international conflicts, and new regulations and standards. In the coming years, a new regional medical record system, Millennium, is planned to be implemented. For small bottom-up innovators, it is not yet clear how the implementation of Millennium will affect their innovations [37].

Discussion

Principal Findings

Overview

In this study, we conducted a retrospective, deductive, and exploratory analysis of 4 cases using the NASSS-CAT LONG. We intended to explore whether there were shared or individual challenges related to bottom-up innovation projects in the same health care region. The analysis itself was complex, but it resulted in both common and individual learning, and all but one case have moved forward, partly due to new insights gained that have made progress possible. By applying the NASSS-CAT in various projects, the authors learned several lessons, the most important of which are described in the following sections. After that, we discuss and reflect on the methodology and the need or suggestions for further research. Finally, we briefly present how the cases have developed since the analysis.

The Innovation Versus the System

As proposed by Rogers [18], the properties of the innovation affect its probability of diffusion within and beyond the organization. Through this study, we have become aware of the need to understand the “system” in which we are working to develop and adopt innovations and make effective use of those innovations. The NASSS framework sheds light on various perspectives that can either facilitate or hinder the adoption, scale-up, and spread of technological innovations. Before our projects, none of us had fully considered all these perspectives. During this study, complexity was found and highlighted, involving many issues related to the organization or system rather than the specific innovation itself. Multiple regulations must be considered, and regional procurement [56], management of supply chains, and European regulations regarding medical devices [30] can hinder the spread of innovation. A lack of necessary interorganizational networking further complicates matters.

Linear Logic Versus Dynamic Complex Processes

By applying the NASSS framework, we discovered how the innovation process and the training we had all had in evidence-based medicine and the research process were geared toward a linear process rather than embracing complexity. We also discovered that the complexity was mostly found outside the actual innovation and related more to the system that the innovation was supposed to live in and to regulations and legislation. More specifically, it related to the organization’s willingness to integrate new innovations and to questions regarding how to manage, maintain, and finance innovations.

Developing and deploying new bottom-up innovations in health care involves multiple logics [57]. Initially, we attempted to approach this in a traditional linear fashion with sequential steps from idea to widespread adoption. However, we quickly realized that this linear approach did not align with the reality of navigating the complexities of health care innovation. Instead of a straightforward innovation journey, it often felt like traversing a dense jungle, making it challenging, if not impossible, to gain a comprehensive overview of the landscape, identify opportunities, and predict the appropriate course of action.

Complex environments often require creative and dynamic thinking; in contrast, a linear approach may stifle the ability to respond to unexpected challenges or opportunities. Innovation is inherently uncertain and unpredictable [58]. It often involves trial and error, experimentation, and the willingness to explore unconventional ideas. A rigid stepwise approach may not accommodate the iterative and nonlinear nature of the innovation process. Complex organizations involve numerous interconnected variables and dependencies. A linear approach may overlook these interconnections, leading to suboptimal solutions or unintended consequences. Innovation often requires a holistic understanding of the organization’s ecosystem. This understanding is hindered if established cultures in the complex organizations are resistant to change [57]. A nonlinear approach may face resistance from employees or departments unwilling to deviate from established norms.

Successful innovation requires addressing cultural and organizational barriers, which may not fit neatly into a linear plan. Finally, complex organizations require adaptive leadership that can navigate ambiguity and inspire a culture of continuous improvement [59]. These are important findings as innovation, particularly in the realm of new technologies, is often seen as a potential solution to address the challenges facing health care. Calls for innovation and new ways of working have come from various sources, including governments, health care organizations, and life sciences clusters. However, the high failure rate of health care technology projects suggests that there may be deficiencies in the structure, resources, and knowledge needed for success [60]. Furthermore, there is a risk of simplifying the complex innovation process by building a support system that is linear. The linear and stepwise approach (first do this, then do that) is counterproductive. While a linear approach may work in certain situations, the nature of innovation in complex organizations demands a more flexible, adaptive, and nonlinear methodology. Embracing uncertainty, fostering creativity, and adapting to change are critical elements that a rigid stepwise approach may not adequately address in the context of complex organizational innovation [58].

Value

For all 4 cases, questions arose related to value and costs. Will there be an initial or a recurrent cost for the product, or will the cost be related to a new service that entails new tasks for staff? There is an advantage in specifying both costs and values, as well as the effect of the innovation on other resources, early in the innovation process. Therefore, health-economy analyses are needed, but they are difficult to design and perform as some innovations focus on increasing soft values that are difficult to translate into monetary variables.

Indeed, evaluating the values—different kinds of values and on different levels—of health care innovation is complex. While clinical testing can demonstrate its usefulness to end users, it is often difficult to determine whether the outcomes involve soft values (eg, reduced distress and improved health literacy and self-efficacy) or hard, monetary values [14]. Furthermore, the distribution of costs and value resulting from an innovation can be intricate, making it hard to assess. Questions arise about the initial and recurrent costs and whether they relate to the product or to new services that require additional staff tasks. Early in the innovation process, there is a need to specify both costs and values, be they monetary or qualitative. Clearly describing and anchoring a value proposition, whether it involves soft or hard values, with stakeholders early in the process is crucial for understanding costs and outcomes. However, finding effective ways to evaluate an innovation before it is ready for large-scale testing can be challenging. Similarly, value and costs stemming from an innovation can be distributed across the organization or organizations in ways that are difficult to assess. Calculating the health costs of improving care processes that involve many actors in a complex organization such as the VGR is complicated [61]. More pragmatic evaluations of both effectiveness and process outcomes are needed and can help show the effect from different angles [53].

For all cases dealt with in this study, the value proposition in terms of quality of life and cost reduction needs further evaluation over a longer period relying on data related to care costs for at-risk patient groups. The D-Foot database contains valuable information on risk groups and foot status, serving as a data source for audits and evaluations to optimize foot care. It could also function as a quality registry, a new diabetic foot register in Sweden. In the MoodMapper, the users comprise patients; their clinical teams; and, occasionally, relatives or caregivers. A published study highlights the value of implementing and receiving psychological relapse prevention for these groups, leading to improved understanding of bipolar disorder [62] that might, in turn, lead to enhanced working relationships and better condition management. However, the evidence is not consistent, and further studies are needed [61]. Moreover, for patients with bipolar disorders, having some of their behavioral patterns (such as step count and estimated sleep) automatically monitored meant that there needed to be a great deal of trust in how data are handled, something that might be difficult for patients experiencing symptoms of paranoia.

Co-Design and Coproduction

Involving users both directly and indirectly at an early stage of the development process is highly beneficial, particularly because what benefits one person may pose challenges for another, thereby creating complexity. Although there are several examples of how coproduction is useful in the innovation process, the existence of complexity must not be neglected in the co-design.

Bottom-up innovations in care encompass a wide spectrum of patient-centric approaches, empowering individuals and communities to actively participate in projects aiming to support well-being. These innovations, driven by the challenges that health care faces, range from self-management tools [62-64] and patient support networks to community-driven health programs [6-8,10,59-61,65-67]. They appear with different approaches, such as lean production [9] and Six Sigma [68]. Coproduction can enhance the 3 Rs in research—reach, rigor, and relevance [69]—by ensuring that the right needs are addressed and that the innovation is practical for both patients and staff.

Enthusiastic innovators and staff should be engaged early in the process, along with representatives from patient organizations or individuals with relevant experience. There is a strong movement toward involving patients in health care improvement, and genuine engagement is necessary for truly bottom-up innovation involvement [70] as it can lead to more radical solutions or suggestions when used correctly [71]. If a technological innovation is too demanding or unfamiliar for users, it is unlikely to be accepted. Piloting with stakeholders is crucial for assessing practicality [59], and using input from stakeholders in the right phase can increase the possibility of finding radical suggestions, as well as saving time for both parties (developers and patients) [71]. We support the idea that coproduction incorporating the multifaceted aspects of complexity is necessary in the evaluation of success in the implementation of bottom-up innovations [4].

Methodological Considerations

Performing a retrospective, deductive analysis as a case study [21] with 4 cases with differences regarding where they were in the innovation process and with different technical solutions was challenging, but it provided multiple valuable insights. The authors found that, before using the NASSS-CAT, users need to be familiar with the NASSS framework [15]. The NASSS-CAT appeared deceptively easy at first, but it was more difficult to use and more time-consuming than expected. A need for a way to track how we could jointly understand and agree on the meaning of the NASSS-CAT by using CCA became apparent during the work, leading to a common language being agreed upon and a consensus being reached on how to interpret the terminology used in the NASSS-CAT. During the CCA, discussions about how to interpret the questions in the 7 domains of the NASSS-CAT took place in cycles, and thus, it was a continuous learning process. As intended by the method [46,47], finding disagreements and negotiating led to a higher degree of understanding not just of the instrument but also of the concept of complexity. The 4 innovators contributed multiple perspectives based on their own cases and discussed their different understandings of the narratives, the domain questions, and the subquestions. As the authors used a nontranslated version of the NASSS-CAT and are native speakers of Swedish and not English, the CCA helped them understand the questions in the NASSS-CAT. Therefore, the use of CCA statements and negotiations on how to interpret the questions in the NASSS-CAT facilitated the analysis and helped create a common language within the group.

The NASSS framework was developed through a detailed review of the existing literature and clinical cases [15,20], but to our knowledge, the tools (NASSS-CAT) have so far been sparsely tested for their ability to unveil complexity in bottom-up projects in public health care. Going from commonly used methods for quality improvement (eg, using the Plan-Do-Study-Act method [72] to incorporate complexity assessment) shows promising results. A recent study used the framework and tool combined with the Plan-Do-Study-Act cycles of improvement to plan and evaluate digital services for patients in Sweden [73]. Similar to our retrospective analysis, that study identified several elements of complexity, explaining a gap among the capacity of adopters, the organization, the wider system, and how intended users valued the service. This gap hindered the innovations from integrating new services into routine care effectively [73]. Similarly to us, these authors found the tool and framework helpful in that they allowed for deeper insights into the project compared to only following method, approach, or cycles or other tools or models for innovation. It seems that, even if complexity is revealed early in the process, this still does not solve the problems. However, if people working with innovation or in supporting innovation become more aware of complex elements, issues might be easier to anticipate or even deal with earlier. Such awareness can thereby help explain obstacles and prevent failure, hence enabling more successful innovation projects in health care, as presented by Greenhalgh et al [15].

Strengths and Limitations

The strength of this study lies in the 4 different cases representing both somatic and psychiatric care and the innovators' long experience in both health care and eHealth. The diversity of innovations presented and the different departments that each of the innovators worked in contribute to a broad overview of shared experiences. None of the innovators had worked together before this study. The fact that all cases came from the same region with the same support function strengthens our results by showing that (1) knowledge of complexity needs to be improved in such systems and (2) the project itself contains complexity in different domains even if we found several common problems. Therefore, the study increased the understanding of the role of complexity, not only in the studied bottom-up innovations but also in the system in which the innovations took place, through prolonged engagement [50]. This study was strengthened by the support of one of the authors, who was involved in the development of the NASSS-CAT [20], but despite this, it appears that adaptation to the setting (geographic and cultural) is crucial.

The retrospective NASSS-CAT analysis of 3 of the 4 cases was mainly performed by the respective innovators without direct input from stakeholders involved in each of the cases. This meant that only 1 perspective from the many actors involved in each of the projects was put forward. The rationale for this was that each innovator had already faced and, therefore, was acquainted with the diverse complexities addressed in all 7 domains. However, other perspectives might have further improved the analysis. The PoC Dashboard project was assessed regarding complexity in a workshop with stakeholders and discussed with management [54].

Even though the NASSS-CAT tools have been used previously [74], more testing in clinical bottom-up innovation cases is needed to scrutinize their utility in a Swedish setting and to learn from the experiences originating from 4 different cases that used the tools.

Use and Usefulness of the NASSS-CAT

In this section, experiences of the use and utility of the NASSS-CAT are presented. At the start, the 4 bottom-up innovators were naïve and expected the NASSS-CAT [20] to be easy to comprehend and use as they identified complexities in their own innovations. As mentioned previously, by using the CCA interpretations from multiple perspectives (the 4 cases), a shared understanding and language regarding how to interpret the questions in the NASSS-CAT was established. The results from the CCA revealed that each of the 4 innovators needed to clarify or consider a number of points in their own NASSS-CAT analysis while assessing complexities in each of the domains. The most important issues were as follows:

1. To define the time frame and the scope that the innovator is assessing.
2. To define the intended users and adopters at the time of the studied project.
3. To rethink the way in which the value proposition can be measured.

- To consider that questions in the NASSS-CAT regarding ownership; supply chains; and use and spread at the local, regional, national, and international level belong to both “Domain 5: organization” and “Domain 2: technology.”

Moving Forward in Supporting Bottom-Up Innovation

This study explored insights from the NASSS framework, revealing that the adoption and dissemination of technological innovations are influenced by organizational and systemic factors rather than by the innovations themselves. The success of bottom-up innovators in navigating complexities emphasizes common challenges across innovations. The NASSS framework has illuminated various perspectives that can either facilitate or impede the adoption, scale-up, and dissemination of technological innovations.

The 4 bottom-up innovators managed to navigate through the complexities within the innovative system, uncovering overarching challenges that unified their respective innovations. However, it is essential to recognize that the NASSS-CAT cannot be used as a linear checklist. Existing support systems, while aiming to foster innovation, may unintentionally follow a linear approach rather than embracing frameworks suitable for complex interventions, such as the Medical Research Council guidance [75]. To better support health care innovators, a “midway filter system” is needed, which offers profound insights into innovation within complex systems. Implementing such a filter between top-down and bottom-up approaches would facilitate bidirectional knowledge transfer. It would enable clinical insights, ideas, and innovations to be discussed in harmony with the regulatory framework, ultimately leading to improved and equitable health care as envisioned by Tierney et al [10], who found that localized, regional, and flexible innovations can shape care in the future [10]. Incentives to connect bottom-up initiatives with a top-down vision at a national level in building systems for digital innovation and health IT are presented by Sheik et al [67] from the United Kingdom. We share their vision to improve usability and interoperability and integrate bottom-up with top-down resources.

Our study, similarly to the research by Batalden and Davidoff [76], discusses the complexities of integrating grassroots idea innovations into established health care systems. Batalden and Davidoff [76] highlight the need for organizational changes and a shift in culture to recognize the value of patient-driven innovations and effectively incorporate them into clinical practice.

Future studies should consider a translation project of the NASSS framework from English into Swedish. This would facilitate the framework’s use in a Swedish context, similar to the translations of health-related quality of life questionnaires, which follow guidelines to ensure validity in terms of language and culture [53]. In addition, an evaluation is recommended alongside updates to the NASSS-CAT. Some subquestions may benefit from further splitting, such as assessing the likelihood of technology obsolescence or the measurement of alternative ways to evaluate innovation. It is crucial to involve relevant stakeholders in these changes. Cultural adaptation should receive significant emphasis to provide a language that is relevant to

the Swedish context. We also suggest that future studies explore similarities and differences regarding the existence of complexities when bottom-up innovations are developed and implemented in other regions. Finally, we consider making a follow-up prospective evaluation of our 4 innovations. By doing this, we can possibly review the impact of this study on the long-term outcomes of each innovation using the NASSS-CAT LONG.

The Progress of the 4 Cases

The insights gained from our exploration of the existence of complexities in innovation processes led to some of the presented innovations being appreciated in the VGR. The Digi-Do and the D-Foot have gradually, during the study, been acknowledged as important in building future care with digital tools. The VGR has granted the innovator of the D-Foot the legal rights to be spread nationally and internationally and to be implemented and scaled up to prevent DFUs through early screening.

The Digi-Do has been evaluated, and the results show a positive effect on the users, indicating reduced levels of distress and an improved sense of preparedness [43,77]. Hence, the difficulties in evaluating soft values have been successfully dealt with. Since the analysis presented in this paper, the intellectual properties have been transferred to the VGR together with the RT department, and updated versions of the Digi-Do are underway.

Learnings from the complexity assessment of the PoC Dashboard [54] helped address the challenges differently by going for a simpler technical solution with less dependencies on other information systems and focusing on core features such as supporting patients and health care professionals in the planning and evaluation of care. This was done by adapting Dialog+, which is both a tool to measure and monitor patient-reported outcome measures and patient-reported experience measures and a solutions-focused methodology, to fit Swedish psychiatric care [78]. It has since then been piloted and tested for >4 different patient groups in mental health care settings and is being implemented as part of routine psychosis care. The MoodMapper is not an active innovation project in Sweden. However, it is used internationally in research to map behavior changes in mental disorders [79,80].

Conclusions

The NASSS framework increased the bottom-up innovators’ understanding of the role of complexity in their innovations. The analysis provided valuable insights by identifying and bringing attention to complexities, particularly within the broader system, albeit requiring a deep understanding. This study enriched our comprehension of the pervasive role of complexity in bottom-up innovations within public health care and shed light on the practical utility of the NASSS-CAT. Early use of a validated tool aids in identifying complexities and pinpointing the domains in which these complexities exist. Importantly, even when bottom-up innovations arise within the same support organization, the complexity can vary based on the developmental phase and the unique characteristics of each project. Identifying, defining, and understanding complexity

may not solve the issues but substantially improves the prospects for successful innovation implementation provided the right expertise is available to support the process.

Successful innovation within complex organizational structures necessitates a comprehensive understanding and an adaptive leadership to surmount cultural resistance and organizational

impediments. A rigid, linear, and stepwise approach risks disregarding interconnected variables and dependencies, leading to suboptimal outcomes. Success lies in embracing the complexity with its uncertainty, nurturing creativity, and adopting a nonlinear methodology that accommodates the iterative nature of innovation processes within complex organizations.

Acknowledgments

The authors are most grateful for the collaboration with the Innovation Platform in Region Västra Götaland. They would also like to acknowledge the Regional Cancer Centre West, the Department of Prosthetics and Orthotics at Sahlgrenska University Hospital, and the Department of Schizophrenia Spectrum Disorders at Sahlgrenska University Hospital for their support.

Abstract

Background: Physicians and patient-facing caregivers have increasingly used mobile health (mHealth) technologies in the past several years, accelerating during the COVID-19 pandemic. However, barriers and feedback surrounding adoption remain relatively understudied and varied across health systems, particularly in rural areas.

Objective: This study aims to identify provider adoption, attitudes, and barriers toward mHealth in a large, multisite, rural US health care system. We investigated (1) mHealth apps that providers use for their own benefit and (2) mHealth apps that a provider uses in conjunction with a patient.

Methods: We surveyed all patient-seeing providers within the Marshfield Clinic Health System with a brief, 16-item, web-based survey assessing attitudes toward mHealth, adoption of these technologies, and perceived barriers faced by providers, their peers, and the institution. Survey results were summarized via descriptive statistics, with log-binomial regression and accompanying pairwise analyses, using Kruskal-Wallis and Jonckheere-Terpstra tests for significance, respectively. Respondents were grouped by reported clinical role and specialty.

Results: We received a 38% (n/N=916/2410) response rate, with 60.7% (n=556) of those sufficiently complete for analyses. Roughly 54.1% (n=301) of respondents reported mHealth use, primarily around decision-making and supplemental information, with use differing based on provider role and years of experience. Self-reported barriers to using mHealth included a lack of knowledge and time to study mHealth technologies. Providers also reported concerns about patients' internet access and the complexity of mHealth apps to adequately use mHealth technologies. Providers believed the health system's barriers were largely privacy, confidentiality, and legal review concerns.

Conclusions: These findings echo similar studies in other health systems, surrounding providers' lack of time and concerns over privacy and confidentiality of patient data. Providers emphasized concerns over the complexity of these technologies for their patients and concerns over patients' internet access to fully use mHealth in their delivery of care.

Introduction

Increased technological and medical advancements have naturally led to the intersection of these 2 fields of study, commonly known as mobile health (mHealth) [1]. mHealth has been defined as “mobile computing, medical sensor, and communication technologies for healthcare” and has seen increasing adoption in recent years, particularly following the shift to virtual health delivery during the COVID-19 pandemic [1-3]. However, given privacy concerns, institutional hesitancy, and the wide array of programs and devices available, adoption and use of mHealth have been mixed [4].

The 2 prevailing mobile platforms include Android and iOS, which collectively comprise more than 99% of mobile use today on phones, tablets, and wearable devices [5]. Traditionally, the development of mobile apps required maintaining separate codebases and expertise per platform. Advances in web technologies, coupled with the establishment of these 2 universal operating systems, have ushered in new and dynamically evolving cross-platform solutions. Vastly expanded broadband cellular networks have simultaneously led to a surge in mobile accessibility, with 95% of the globe reaching 3G coverage as of 2022 and 80% obtaining 4G or faster speeds, including throughout rural regions [6].

To streamline development resources while maximizing user reach, cross-platform frameworks have become dominant across all sectors of mobile apps, including mHealth [7]. These libraries leverage existing technologies, often derivatives of web languages such as HTML, cascading style sheets, and JavaScript, while seamlessly interfacing with the native capabilities of each platform. Two of the most popular architectures for modern cross-platform apps include React Native (Meta Platforms) and Flutter (Google) [8]. Similarly, 2 popular hybrid solutions include Cordova and Capacitor, which can efficiently embed existing websites into native web views to achieve familiar native app behavior.

Emerging app-connected wearables—smartwatches, eyewear, earwear, and clothing—synergize with cross-platform apps to offer new ways of interacting with consumers and patients. Adaptation of wearable technologies has boomed in recent years, with a projected 1 billion circulated wearables in 2022 compared with 325 million in 2016 [9]. Android and iOS smartwatches offer core health initiatives, with sensors and apps that can automatically analyze heart health, blood oxygen, sleep cycles, and fitness. This innovation is rapidly superseding traditional life alert functionality with recent developments including fall detection, automatic location-aware emergency dialing, predictive warnings of heart arrhythmia, and reported seamless syncing of medical records [10].

Many promising new use cases of wearable tech in the mHealth industry are emerging after years of research and pilot studies. For example, after 12 years of testing, Apple has proofed a noninvasive continuous blood glucose monitor system that uses silicon photonics and optical spectroscopy, which is expected to be miniaturized into a common watch-sized wearable within 3 years for consumer use [11]. Manufacturers have also continued exploring augmented reality medical applications for

eyewear and are working on adaptive lens adjustment technologies, which would dynamically adjust to one’s eyesight with no prescription lens required. Other types of wearable devices are continuously being tested, including ones that can monitor saliva or tear gland fluids to detect eye or oral diseases, among other medical conditions [12].

These advances in technologies and applications have moved at incredible speeds, most often ahead of health systems’ and providers’ organizational abilities or individual preparedness to adopt, test, and implement for their own use or use with patients. Nonetheless, health care providers can and do leverage available advances in medical technologies for the benefit of the patient, and we would fully expect that mHealth apps and wearable technologies are no exception.

To better understand the current environment of mHealth adoption and barriers among rural providers and patients, we sought to further explore two key topics in this study: (1) apps that providers use for their own benefit and (2) apps that a provider uses in conjunction with a patient.

Khatun et al originally described a conceptual model for mhealth readiness through the lens of a health workforce in rural Bangladesh [13]. The model was later advanced and refined by Weichelt et al in 2019, furthering discussions of the interplay of rural patients, clinicians, and their organizations in mHealth adoption [14,15]. This prior research found that the organization plays a role in impacting providers’ and patients’ adoption of mHealth; however, we need to first gain a deeper understanding of providers’ current levels of adoption and familiarity and awareness with these new technologies.

This line of research, beginning with an assessment and inventory of mHealth adoption, is essential for the future of health care delivery. Marshfield Clinic Health System (MCHS) is a predominantly rural health system with patients scattered across northern Wisconsin, the Upper Peninsula of Michigan, and beyond [16]. While well positioned to test and deploy new and innovative technologies in the broad field of mHealth, leadership first needs to gain a deeper understanding of the system’s provider and patient needs, desires, and current use. Therefore, we conducted a survey of all patient-seeing providers within MCHS to identify mHealth adoption, attitudes, and perceived barriers to use.

Methods

Data Collection

In July of 2020, we emailed a survey to 2410 MCHS providers via an information systems–supplied “MCHS Providers” email list. The survey was designed to assess providers’ motivators and barriers to the adoption of mHealth technologies in patient care. The survey was open and available from July 21 to August 31 (6 weeks), with 2 reminders sent every 2 weeks.

Instrument design and line of inquiry leveraged previous work by this research team, including the previously published conceptual model for assessing necessary conditions for rural health care’s mHealth readiness, with an emphasis on clinician-perceived barriers. Providers were asked about

mHealth use, both personal and with patients, as well as personal, perceived colleague, patient, and institutional barriers to mHealth adoption. Providers were also asked about the perceived COVID-19 impact on mHealth use and anticipated future mHealth use after the pandemic subsided.

Incentives

Participants were presented with the option of selecting one of five local nonprofits to receive a US \$10 donation for their voluntary participation in the survey. We distributed our full budgeted allotment of US \$2800 as chosen by the research participants. No other incentives were offered during the study.

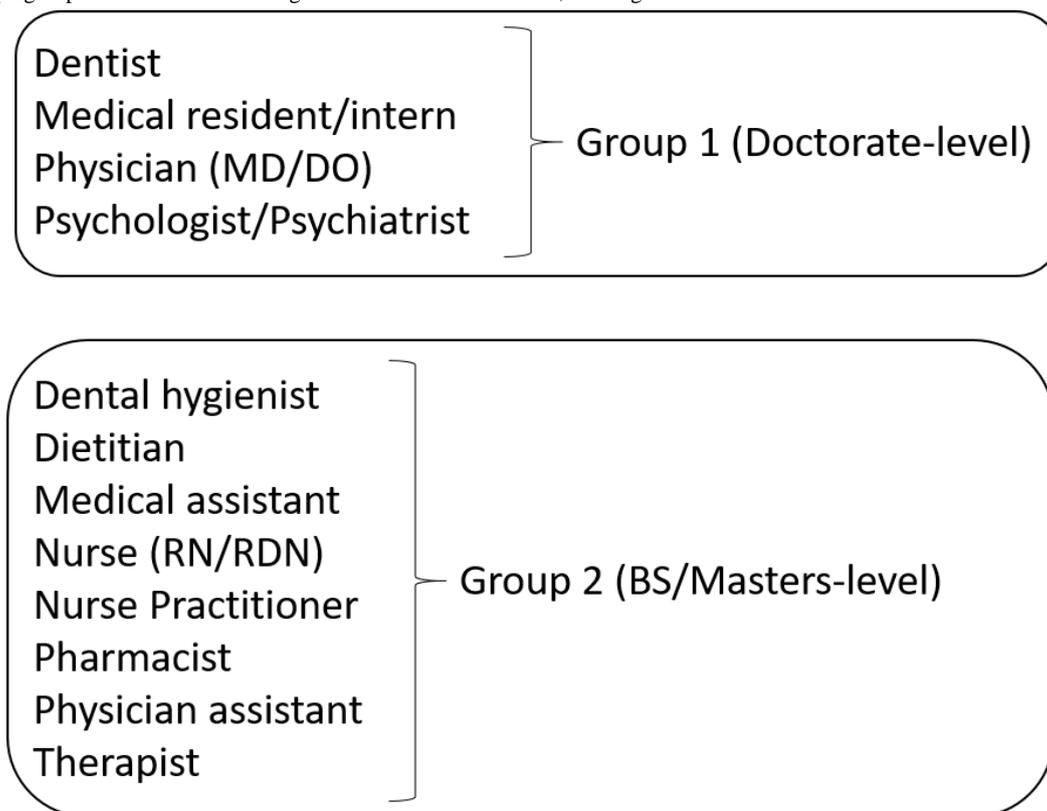

Ethical Considerations

The project submission was evaluated by the Marshfield Clinic institutional review board. It was determined that the activity as described does not meet the definition of human participant research, and no further institutional review board action was needed.

Analyses

Due to the small number of responses in some niche roles and specialties, participants' roles were grouped into 2 categories based on education and degree level (Figure 1). Provider specialty was also compartmentalized into 9 categories, mirroring the distribution of specialties across MCHS.

Figure 1. Grouping of provider roles. RDN: Registered Dietitian Nutritionist; RN: registered nurse.

We used log-binomial regression to analyze survey questions with dichotomous (yes or no) responses [17]. Specifically, we fit univariable models where the dependent variable was the dichotomous response and the independent variable was either provider role, provider specialty, or number of years in practice (7 categories: 0-5, 6-10, 11-15, 16-20, 21-25, 26-30, and >30 years). We assessed the overall statistical significance of the independent variable and proceeded with pairwise comparisons versus a referent category when warranted (ie, when the *P* value for the overall effect was $\leq .05$). BS and MS-level providers, family medicine, and 16-20 years in practice were the referent categories in the calculations. Since provider roles had 2 categories, corresponding pairwise comparisons were unnecessary (redundant).

A similar general strategy was used for Likert-scaled survey questions (ie, assessment of the overall statistical significance of the independent variable followed by pairwise comparisons vs a referent category when warranted). The Kruskal-Wallis

test was used to evaluate overall significance and the Jonckheere-Terpstra test for pairwise comparisons [18,19]. The same independent variables were examined.

Results

Overview

We received a total of 916 responses (38% response rate), of which 556 (60.7%) responses were sufficiently complete to be included in the statistical analyses. Of these responses, 301 (54.1%) participants reported using health-related apps on their phone or tablet. The most common purposes for these apps were use as informational resources (234/301, 77.7%) and for decision-making (180/301, 59.8%). Providers who used mHealth with patients (202/556, 36.3%) reported doing so primarily for exercise and activity monitoring (105/202, 52%), and enhancing patients' experiences via the My Marshfield Clinic app (105/202, 52%), an in-house app that allows patients to schedule

appointments, view lab results, message providers, etc. Those who do not use health-related apps (255/556, 45.9%) stated their primary reasons as inadequate information available on the use of such apps (59/255, 23.1%), not having enough time to use the apps (55/255, 21.6%), or being unsure of the organization's attitudes toward mHealth (59/255, 23.1%). The most common barriers to mHealth adoption cited by providers were a lack of both knowledge about mHealth technologies (293/556, 52.7%) and time (201/556, 36.2%), as well as being unsure of their patients' access to reliable internet services (171/556, 30.8%). These same concerns arose when we asked respondents which barriers they thought other providers had surrounding mHealth (319/556, 57.4%; 283/556, 50.9%; and 163/556, 29.3%). Perceived organizational barriers to clinicians using mHealth in their practices were primarily concerns related to confidentiality (313/556, 56.3%) and mHealth technologies being too complicated for patients (288/556, 51.8%). Overall, however, providers had a favorable view of mHealth, with a majority stating they either intend to continue using mHealth following the COVID-19 pandemic or would look further into mHealth technologies.

Provider Demographics

We had a broad representation of specialties and experience levels in our responses. The most common specialties were family medicine, surgery, pediatrics, and physical and occupational therapy. The survey respondents averaged 19 years of experience practicing medicine.

Clinician Adoption

Clinician adoption of mHealth varied by role and specialty. Doctoral-level providers reported higher mHealth use on their own devices compared with other providers, with 65% (n/N=154/237) and 46% (n/N=138/300) adoption ($P<.001$), respectively. Among mHealth users, doctoral-level providers used these apps as an informational resource at a higher rate (131/154, 85.1% vs 98/138, 71%; $P=.005$). Compared with midtenure providers (16-20 years of experience, 51/81, 63% mHealth adoption), mHealth adoption levels were reported to be lower among more experienced providers (34/72, 47.2% for 21-25 years of experience; 29/64, 45.3% for 26-30 years; and 43/84, 51.2% for >30 years), and similar among less experienced providers (52/95, 54.7% for 0-5 years of experience; 43/73, 58.9% for 6-10 years; and 39/64, 60.9% for 11-15 years). mHealth use with patients was similar between doctoral-level and other providers (84/237, 35.4% vs 110/300, 36.7%; $P=.77$) and across the range of years of experience (33/95, 34.7% for 0-5 years of experience; 27/73, 37% for 6-10 years; 22/64, 34.4% for 11-15 years; 29/81, 35.8% for 16-20 years; 34/72, 47.2% for 21-25 years; 24/64, 37.5% for 26-30 years; and 29/84, 34.5% for >30 years; $P=.63$). Notably, compared with family medicine with 48.4% (n/N=31/64) mHealth use with patients, 3 specialties reported use of $\leq 30\%$ (Cancer Care and Research, 6/27, 22.2%, $P=.04$ vs family medicine; Cardiology, 7/29, 24.1%, $P=.05$; Surgery, 14/60, 23.3%, $P=.007$), while psychiatry and psychology reported 78.3% (n/N=18/23) adoption, significantly higher than family medicine ($P=.005$). No important differences in reported mHealth use with patients were observed regarding diet and nutrition tracking, weight

management, dental reminders, direct communication with the patient's care team, and medication reminders. Not surprisingly, psychiatry and psychology reported use of mHealth more frequently for mood and depressive symptom monitoring (12/18, 66.7% vs $\leq 7\%$ for all other specialties that responded to this question [no responses in Cancer Care and Research, Cardiology, OB/GYN, Physical and Occupational Therapy, and Surgery; 1/24, 4.2% in Pediatrics; and 4/65, 6.2% in other specialties], $P=.001$ vs family medicine, 2/31, 6.4%) and sleep tracking (7/18, 38.9% vs $\leq 16.7\%$ for all other specialties that responded to this question [no responses in Cardiology, OB/GYN and Physical and Occupational Therapy; 1/6, 16.7% in Cancer Care and Research; 2/24, 8.3% in Pediatrics; 1/14, 7.1% in Surgery; and 4/65, 6.2% in other specialties], $P=.02$ vs family medicine, 2/31, 6.4%). Physical and occupational therapy, cardiology, and psychiatry and psychology reported substantially higher mHealth use with patients for informational and educational purposes (12/17, 70.6%; 4/7, 57.1%; and 10/18, 55.6%, with $P=.002$, .048, and .02 vs family medicine, 7/31, 22.6%).

Clinicians' Perceived Barriers Category 1—Personal (Clinician)

Overall, providers reported lack of knowledge about mHealth technologies (293/556, 52.7% for themselves; 319/556, 57.4% in their perceptions regarding other clinicians) and lack of time (201/556, 36.2% and 283/556, 50.9%) as the primary personal barriers. Insufficient levels of patient internet access were also a commonly cited concern (171/556, 30.8% and 163/556, 29.3%). We found relatively few differences between provider roles and specialties regarding personal barriers to mHealth adoption. Doctoral-level providers cited a greater number of financial barriers surrounding a lack of value in mHealth technologies (29/237, 12.2% vs 12/300, 4%, $P<.001$ for themselves; 44/237, 18.6% vs 26/300, 8.7%, $P=.001$ in their perceptions regarding other clinicians), insufficient reimbursement options (27/237, 11.4% vs 14/300, 4.7%; $P=.005$ for themselves), and mHealth technologies not being worth the cost of adoption (22/237, 9.3% vs 7/300, 2.3%; $P=.001$ for themselves). With respect to their perceptions regarding other clinicians, cancer care and research providers reported a lack of communication between providers at a substantially higher rate than all other specialties (12/27, 44.4% vs 11.7%-33.3% [5/29, 17.2% in Cardiology; 9/27, 33.3% in OB/GYN; 9/47, 19.1% in Pediatrics; 6/42, 14.3% in Physical and Occupational Therapy; 5/23, 21.7% in Psychiatry and Psychology; 7/60, 11.7% in Surgery; and 45/214, 21% in other specialties] $P=.02$ vs family medicine [13/64, 20.3%]). Furthermore, regarding their perceptions of other clinicians, OB and GYN and pediatrics providers reported a lack of knowledge about mHealth technologies at rates that exceeded all other specialties (21/27, 77.8% and 37/47, 78.7% vs 45%-71.4% [13/27, 48.1% in Cancer Care and Research; 20/29, 69% in Cardiology; 30/42, 71.4% in Physical and Occupational Therapy; 13/23, 56.5% in Psychiatry and Psychology; 27/60, 45% in Surgery; and 110/214, 51.4% in other specialties], $P=.03$ and .01 vs family medicine [36/64, 56.3%]). Interestingly, the only self-perceived barrier that was modified by years of experience was the lack of reliable internet access ($P=.02$ for the overall effect). With

the exception of relatively new providers (0-5 years of experience; 22/95, 23.2% of these providers reported this concern), providers in age groups with ≤ 20 years of experience (31/73, 42.5% with 6-10 years of experience; 24/64, 37.5% with 11-15 years; and 33/81, 40.7% with 16-20 years) reported higher rates of this concern than those in age groups with >20 years of experience (15/72, 20.8% with 21-25 years of experience; 18/64, 28.1% with 26-30 years; and 23/84, 27.4% with >30 years).

Clinicians’ Perceived Barriers Category 2—Patient

Survey respondents reported substantial perceived patient concerns relating to mHealth technologies being too complicated (371/556, 66.7%), lack of access to mHealth technologies (327/556, 58.8%), poor delivery mechanisms (eg, cell service or internet coverage, 252/556, 45.3%), and privacy concerns (207/556, 37.2%). These perceptions did not differ meaningfully by provider type, specialty, or years of experience, with the exception that privacy concerns were more prevalent in doctoral-level providers (105/237, 44.3% vs 93/300, 31%; $P=.002$).

Clinicians’ Perceived Barriers Category 3—Organizational

The most prevalent organizational barriers perceived by providers were concerns related to confidentiality (313/556,

56.3%) and that mHealth technologies were too complicated for patients (288/556, 51.8%). Confidentiality concerns differed meaningfully by provider type (149/237, 62.9% and 154/300, 51.3% for doctoral-level vs other providers, $P=.007$), specialty ($P<.001$ for the overall specialty effect; 37/47, 78.7% vs 36/64, 56.3% for pediatrics vs family medicine, $P=.01$), and years of experience ($P=.03$ for the overall effect; no specific trend across age groups). Privacy concerns (168/556, 30.2% prevalence) varied only by years of experience ($P=.006$ for the overall effect; no specific trend across age groups).

COVID-19 and Anticipated mHealth Adoption

When providers were asked to what degree (1) the COVID-19 pandemic impacted their mHealth adoption and (2) they intend to look further into mHealth following the resumption of normal MCHS activities, meaningful differences were detected only between provider specialties ($P=.02$ and $.001$ for the overall specialty effects, respectively). These differences were driven by psychiatry and psychology providers, who reported higher scores (10-point Likert scale, where 1=not at all and 10=a great deal) on both survey questions ($P=.002$ and $.002$ vs family medicine; Figures 2 and 3).

Figure 2. Response distributions for psychiatry and psychology and family medicine for the question “To what degree has the COVID-19 pandemic impacted your mHealth adoption?”. mHealth: mobile health.

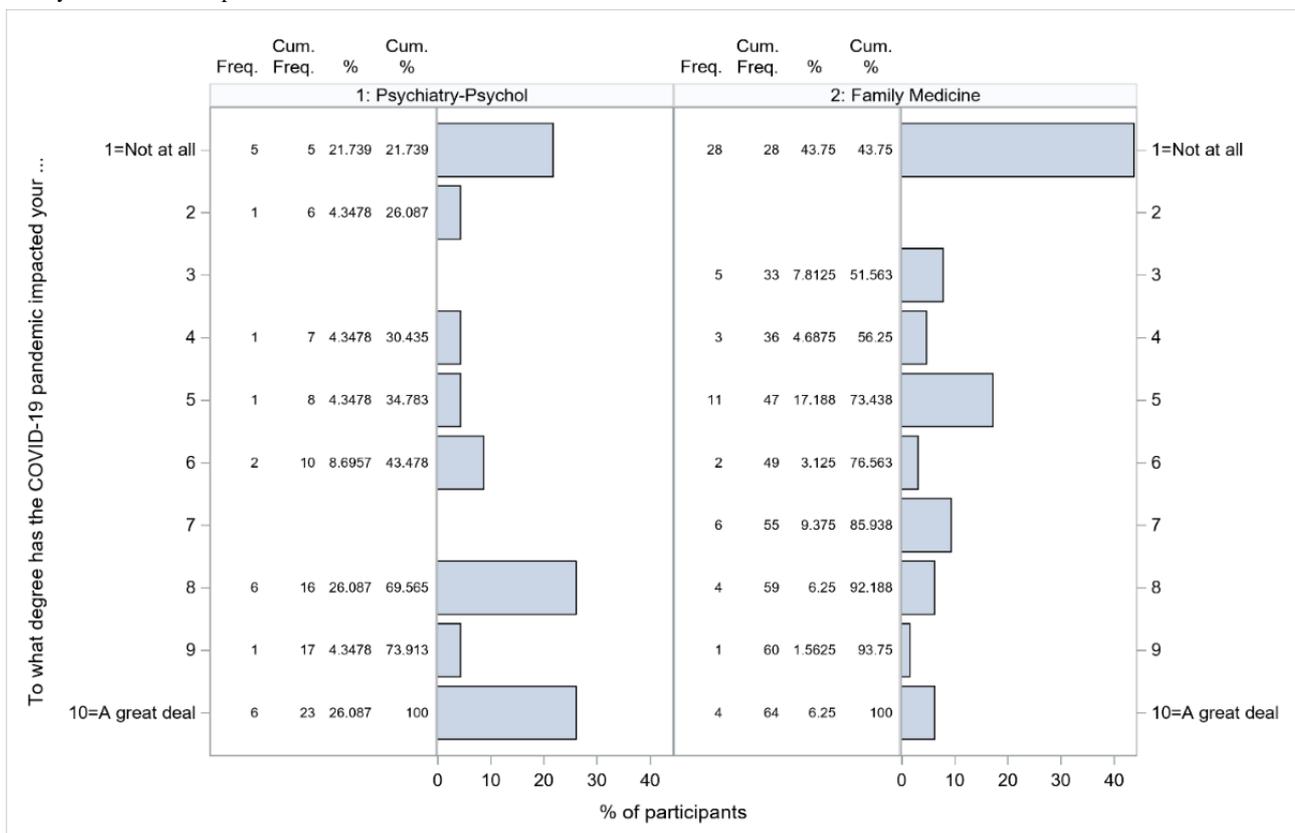

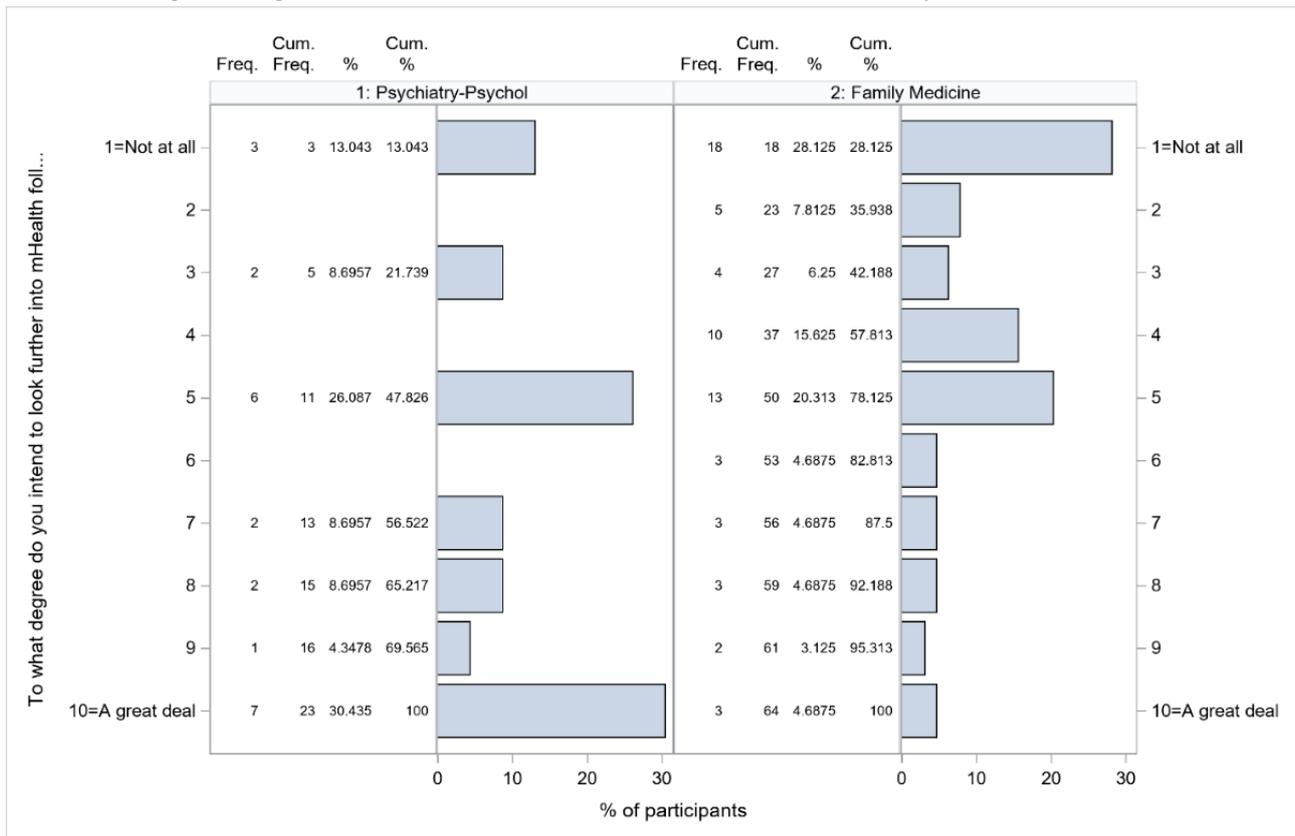

Figure 3. Response distributions for psychiatry and psychology and family medicine for the question “To what degree do you intend to look further into mHealth following the resumption of normal MCHS activities?” MCHS: Marshfield Clinic Health System; mHealth: mobile health.

Discussion

Principal Findings

The varied responses and rate of mHealth use across provider roles and specialties emphasize the variety and task-specific role mHealth can have in a health system. Some specialties, such as psychology and psychiatry, showed high rates of adoption for specific tasks such as mood and sleep tracking; however, no other specialties reported substantially greater mHealth adoption compared with the reference to family medicine. If looking to increase mHealth use across a health system, leadership should consider identifying specific tasks or poorly performing metrics that mHealth could potentially improve upon.

Our survey grouped potential barriers into 3 levels (provider, patient, and organizational) in line with past qualitative findings [13]. Providers’ self-barriers encompassed themes of lack of knowledge about mHealth technologies, lack of time, and lack of patients’ access to the internet. Commonly reported barriers relating to both patients and the organization were mHealth technologies being too complicated and concerns related to privacy. The predominant organizational barrier was confidentiality concerns, whereas lack of access (cell phone coverage, internet, and mHealth technology in general) was a frequently perceived barrier for patients.

It is understandable that health care providers feel overwhelmed, with the top barrier to mHealth use being a lack of time and information. These technologies evolve at incredible speeds. How might one stay abreast of the scientific and technological

advances of mHealth technologies? Even in the peer-reviewed literature, which can take months or years to publish, we witness an overwhelming ocean of information. At the time of this writing, a Google Scholar search of “mHealth” papers since 2020 (January 1, 2020, to April 5, 2024) yielded nearly 25,000 results and nearly 8000 results since January 1, 2024.

The pace of emerging and simultaneously retiring technologies remains a substantial barrier across many mHealth studies. A typical full-scale trial to evaluate a mHealth initiative lasts more than 5 years from recruitment, during which time many changes within the pertinent technologies will occur or be superseded entirely [20]. Consequentially, many trials are reduced in scope, hindering true evaluation and understanding of the prospect’s long-term value.

Years of technological ambition surrounding deep machine learning and voluminous data sets reached fruition in the 2020s with the advent of widely accessible artificial intelligence (AI) apps. These AI-powered breakthroughs have impacted nearly every industry, including medicine, in ways that are still in the infancy of exploration. By digitally processing millions of training samples, including imagery, transcripts, audio recordings, and academic papers, sophisticated computer algorithms have reached new potential in data analysis and user reactivity [21]. What once required thousands of hours and access to prohibitively expensive data centers to compute is now within a finger’s reach from any consumer phone or computer.

Leveraging computer-assisted workflows to automate tasks is not a new concept in the medical world. Health care

organizations have spent decades exploring increasingly advanced forms of speech recognition software to facilitate medical transcriptions, among other areas of automation [22]. The latest groundbreaking strides in these efforts come in the form of OpenAI's ChatGPT and associated tool sets [23]. A recent study hypothesized more than 130 different ways ChatGPT could positively benefit both patients and doctors in the foreseeable future, including education, prediction support, prevention of medical errors, record-keeping, and continual clinical assistance [24].

However, many analysts warn that such tool sets—when used in isolation without a human consultant—can yield bad data or other repercussions not yet realized. The most prevalent example of these dangers is how AI modeling is prone to hallucinations, in which the chatbot may return seemingly factual and confident responses but uses nonexistent citations or made-up passages due to anomalies in its training data and other limitations [25,26].

Limitations

The response rate to our mHealth survey was 38% (n/N=916/2410), with a further completion rate of 60.7% (n/N=556/916). It is possible that response bias was present, potentially skewing toward clinicians who have an interest in mHealth technologies. While this response rate is moderately high compared with other surveys of providers, the topic of mHealth being mentioned foremost in the survey invitation may have resulted in an overestimation of mHealth use and intentions.

Notably, MCHS, along with many other health care organizations at the time, was struggling due to the COVID-19 pandemic during our survey timeframe, with rolling temporary

furloughs throughout the health system. This limited our possible response rate and created uncertainty in the accuracy and complete capture of our sample. However, our survey was open for 6 weeks with multiple reminder emails sent out, theoretically limiting this effect. Nevertheless, biases in responses may remain due to the work environment and shifting priorities surrounding the COVID-19 pandemic. A future resurveying of providers would help characterize these possible impacts.

Conclusions

Health systems should continue to evaluate mHealth adoption, and more formally and proactively investigate innovative solutions. Consulting with patient safety and legal departments regarding the use of mHealth apps is crucial, as quality clinical outcomes are not often in correlation with popularity ratings on app stores [27]. If a mHealth tool is deemed to be a valuable tool for a hospital or health system, leadership should work toward identifying specific options and methods to address health outcomes and work toward simple and concise implementations to improve adoption and patient outcomes. The American Medical Association provides occasional reports and guidelines surrounding mHealth best practices, but does not have an official lobbying body, with more focus on telehealth [28-30]. The US Department of Health and Human Services provides resources for mHealth developers; however, these are primarily focused on privacy and confidentiality and are of little relevance to providers [31].

This study is arguably a foundational and necessary step in assessing a health system's status and potential for mHealth adoption. Further research and continued partnership with advisors and stakeholders will be needed if the health system hopes to more formally integrate mHealth technologies into rural health care.

Acknowledgments

The authors thank Marie Fleisner for her assistance with editing and formatting the manuscript. The authors also thank the clinicians who participated in this study and the stakeholders who helped and supported them throughout the early stages of this project, stating that their insight and guidance have been a tremendous help. Abstract

Background: Stroke may lead to various disabilities, and a structured follow-up visit is strongly recommended within a few months after an event. To facilitate this visit, the digital previsit tool “Strokehealth” was developed for patients to fill out in advance. The concept Strokehälsa (or Strokehealth) was initially developed in-house as a Windows application, later incorporated in 1177.se.

Objective: The study’s primary objective was to use a patient satisfaction survey to evaluate the digital previsit tool Strokehealth when used before a follow-up visit, with a focus on feasibility and relevance from the perspective of people with stroke. Our secondary objective was to explore the extent to which the previsit tool identified stroke-related health problems.

Methods: Between November 2020 and June 2021, a web-based survey was sent to patients who were scheduled for a follow-up visit after discharge from a stroke unit and had recently filled in the previsit tool. The survey covered demographic characteristics, internet habits, and satisfaction rated using 5 response options. Descriptive statistics were used to present data from both the previsit tool and the survey. We also compared the characteristics of those who completed the previsit tool and those who did not, using nonparametric statistics. Free-text responses were thematically analyzed.

Results: All patients filling out the previsit tool (80/171; age: median 67, range 32-91 years) were community-dwelling. Most had experienced a mild stroke and reported a median of 2 stroke-related health problems (range 0-8), and they were significantly younger than nonresponders ($P<.001$). The survey evaluating the previsit tool was completed by 73% (58/80; 39 men). The majority (48/58, 83%) reported using the internet daily. Most respondents (56/58, 97%) were either satisfied ($n=15$) or very satisfied ($n=41$) with how well the previsit tool captured their health problems. The highest level of dissatisfaction was related to the response options in Strokehealth ($n=5$). Based on the free-text answers to the survey, we developed 4 themes. First, Strokehealth was perceived to provide a structure that ensured that issues would be emphasized and considered. Second, user-friendliness and accessibility were viewed as acceptable, although respondents suggested improvements. Third, participants raised awareness about being approached digitally for communication and highlighted the importance of how to be approached. Fourth, their experiences with Strokehealth were influenced by their perceptions of the explanatory texts, the response options, and the possibility of elaborating on their answers in free text.

Conclusions: People with stroke considered the freely available previsit tool Strokehealth feasible for preparing in advance for a follow-up visit. Despite high satisfaction with how well the tool captured their health problems, participants indicated that

additional free-text responses and revised information could enhance usability. Improvements need to be considered in parallel with qualitative data to ensure that the tool meets patient needs.

e-health; stroke; Strokehälsa; follow-up; previsit; person-centred care; health literacy; digital tool; shared decision-making; survey; mobile phone

Introduction

Stroke affects more than 101 million people worldwide [1] and can lead to a range of physical, cognitive, and emotional disabilities [2]. In its newly launched “Package of interventions for rehabilitation for stroke” within its “Rehabilitation 2030 initiative,” the World Health Organization makes clear that people living with stroke need lifelong access to rehabilitation services because of continuing health problems [3]. Furthermore, there is a general trend toward shorter hospital stays after a stroke. Consequently, it is vital to identify individuals at risk of secondary health issues to provide them with prevention, treatment, and support in developing self-management strategies. Continuous health care interactions are required to achieve these outcomes [4].

Depending on the problem area, patients should be assessed accordingly to access targeted interventions including education, advice, and support for self-management [3]. Postdischarge stroke care, however, is often fragmented without standardized routines for long-term follow-up [4], and people frequently have difficulties accessing health care [5]. According to the Stroke Action Plan for Europe, structured follow-up visits should be offered to all patients within 6 months after a stroke to identify stroke-related health problems, address rehabilitation needs, and support adaptation to life after a stroke [4].

As part of the structures of care for people with long-term conditions, patients must be duly prepared and sufficiently informed before a visit to a proactive health care team [6]. In addition, a person-centered approach that involves patients in shared decision-making contributes to a positive impact on health outcomes and patient satisfaction [7]. A person-centered approach entails acknowledgment within health care services that individuals can collaborate with health care professionals and actively engage in the decision-making process, which nurtures the patient’s sense of empowerment [8].

To support better-structured follow-up visits after a stroke, the dialogue tool “Post-Stroke Checklist” was developed for health care professionals to use during outpatient visits [9]. The checklist comprises 11 questions that can aid in identifying common health problems (eg, mobility, cognition, and life after stroke) and guide health care professionals on appropriate actions, including recommendations for referrals [9]. Satisfaction with the dialogue tool has generally been high, but health care professionals have noted challenges in managing the checklist within the allotted timeframe [10,11], and patients have requested the ability to prepare in advance [11]. This can be achieved with previsit tools that can enhance patient experience,

patient engagement, and practice efficiency [12]. In response to this, the previsit tool Strokehälsa (“Strokehealth”) was developed based on the questions from the Post-Stroke Checklist [13]. The aim was to capture health problems and provide patients with information about common consequences after stroke and time to reflect [13]. Initially designed as a digital tool to enhance accessibility and usefulness, Strokehealth is now also available in a picture-supported version and in paper format, freely accessible in multiple languages. Other digital previsit tools usually concentrate solely on gathering self-reported data [12], or they may be more comprehensive, such as the stroke-related previsit tool “Rehabkompassen” [14]. Both Strokehealth and Rehabkompassen were initially developed in-house as a Windows application and later incorporated in the Swedish national patient portal.

Development and use of digital health service tools are crucial to involving patients in proactive management of their health [15]. Furthermore, as the use of diverse technologies increases within the health care domain, more patient engagement and participation will be required [16]. In general, digital tools yield positive impacts on patient empowerment, self-management, communication, and patient engagement [16-18]. In those with long-term conditions such as stroke, however, digital health solutions must be user-friendly in terms of eHealth literacy needs (ie, ability to comprehend health information and actively engage with eHealth services [19]), as these patients report related difficulties more than the general population [20]. The development of these tools thus must incorporate consideration of patient-related factors, including cognitive ability to process information, need for a sense of security and control, and intrinsic motivation to engage with digital health care services [19]. The patient perspective is a high priority in eHealth [17] because personal motivation for using digital health services is key to gaining eHealth literacy [19]. In keeping with these precepts, development of the previsit tool, Strokehealth, incorporated a comprehensive participatory approach, involving people with first-hand experience with stroke and health care professionals in the co-design process [13].

Initially, a prototype of Strokehealth was created, and subsequent iterations were tested on purposively selected patients with stroke and relevant health care professionals [13]. Based on user feedback, version 1.0 incorporated 11 features from the Post-Stroke Checklist and 3 additional questions pertaining to oral health, eating or swallowing problems, and other challenges after stroke. The final question offered a free-text option for users to add anything else they wished to share before the visit. In addition, explanatory texts were attached to all questions, and an advisory text was added.

Version 1.0 was launched at the Swedish national patient portal 1177.se. Personal accounts are created in the patient portal using a social security number and an electronic ID, enabling notifications for activities such as form submissions. We chose this secure platform because it provides a sustainable solution and enhances accessibility for patients [13].

The aim was to develop an easy-to-use previsit tool perceived as meaningful for users, with optimized conditions for implementation in keeping with service-design principles [21]. Strokehealth already has shown a potential to enable people with stroke to prepare for visits, to capture care needs, and to provide patients with valuable information related to stroke [13]. Its validity in a real-world setting, however, remains to be established. Real world feasibility testing is needed to evaluate the tool's usability and efficacy in capturing health problems and to facilitate its further development. The main study aim, thus, was to evaluate the previsit tool, Strokehealth, as used by people with stroke before a scheduled follow-up visit, with a focus on feasibility and relevance from the patient's perspective. A second aim was to explore the extent to which Strokehealth could identify stroke-related health problems.

Methods

Study Design

This study is part of a larger research project aimed at developing and evaluating the digital previsit tool Strokehealth in an article series with quantitative and qualitative methods, in line with the established framework for developing and evaluating complex interventions [22]. In total, 2 separate data collection procedures were used in this study (part 1)—one from the previsit tool and the other from a subsequently administered closed web-based patient satisfaction survey. The CHERRIES (Checklist for Reporting Results of Internet E-Surveys) checklist was followed in this study (Multimedia Appendix 1) [23]. Web-based surveys provide an efficient way to track user views and allow for the analysis of large volumes of information [24].

Ethical Considerations

The study was approved by the Swedish Ethical Review Authority (2017/556-17, 2020-03324, and 2021-06723-02). Patients received information about the research project after logging into the patient portal and were asked whether they agreed to participate in the study. Informed consent was obtained from patients as part of the process. It was not possible to continue filling out the survey if this question remained unanswered. The initial information clearly stated that completing the survey was voluntary, and that participation would not affect their medical care. No incentives were offered.

Study Context

Between November 2020 and June 2021, consecutive patients discharged from a stroke unit and scheduled for a follow-up visit with a stroke team member in primary health care received a digital message instructing them to log in to the patient portal and complete the previsit tool, Strokehealth, before their appointment (within 1-2 weeks). After submitting Strokehealth, patients received a second digital message prompting them to log in to the portal once again, where they were encouraged to fill out the patient satisfaction survey on the same platform (Multimedia Appendix 2). The log-in requirement prevented duplicate entries from the same user so that only unique visitors were registered.

Sampling and Participants

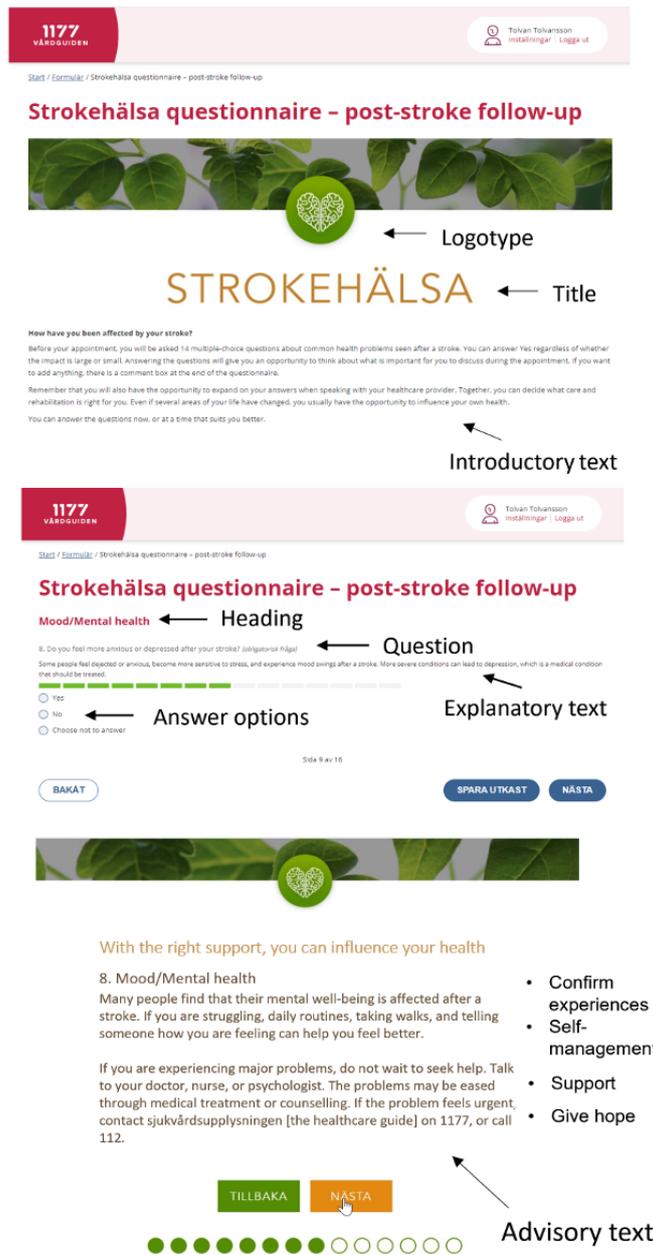

A convenience sampling was used with the aim of gathering data from a minimum of 50 patients [25]. Furthermore, 4 publicly-funded health care units were invited to participate (3 hospital-based stroke units and 1 primary health care unit). After inclusion in the study, the primary health care unit withdrew from participation because of reorganizations resulting from the COVID-19 pandemic, so ultimately only the 3 hospital units were included. One hospital (unit 1) was situated in an urban area, and 2 (unit 2 and unit 3) were situated in 2 middle-sized cities serving more rural areas. In addition, 1 stroke-specialized nurse at each unit was selected to participate. The follow-up visit was scheduled between 3 weeks and 3 months after the stroke event, depending on the standard routines within each unit.

Data Collection From the Previsit Tool Strokehealth

After receiving the digital message about Strokehealth, patients could choose to fill out the tool directly or to do so later. Help from next-of-kin was allowed but asked to be noted in the response. Each of the 3 nurses could monitor response status, and if no response was obtained, they could send a total of 2 reminders.

Strokehealth version 1.0 (Figure 1) began with a brief introductory text. Within this text, patients were encouraged to read additional information on stroke prevention and self-management strategies, with a clickable web link leading to advisory texts. Following the introductory text, patients answered 14 questions related to various health areas. These questions provided three response options, "yes," "no," and "choose not to answer," depending on whether respondents indicated a health problem or not. Finally, at the conclusion of Strokehealth, patients were given the opportunity to provide a free-text response to the question: "Is there anything else you want to add before your visit?"

Figure 1. A screenshot of the elements in the previsit tool Strokehälsa (English version; reproduced from Kjörok et al [13], which is published under Creative Commons Attribution 4.0 International License [26]).

Data Collection From the Patient Satisfaction Survey

The survey was constructed in accordance with the technology acceptance model, with a focus on ease of use and perceived usefulness and acceptability [27] regarding Strokehealth. Aspects of ease of use were explored, for example, related to the need for support from others when using Strokehealth, satisfaction with navigating in the tool, and access to the advisory text (web link). Perceived usefulness was explored, for example, related to whether their health problems were captured and their satisfaction with using Strokehealth before a visit. Acceptability was explored, for example, regarding their satisfaction with the layout, answer options, and if they would recommend its use. The usability and technical functionality of the survey were tested in collaboration with a co-designing partner patient before the survey was fielded.

The survey was visible as a 3-page survey containing 15 items with fixed response options and 4 items for free-text answers. The items were divided into different focus areas and each page included 3, 4, and 12 items, respectively, with the ability to scroll before viewing the next page. The items covered demographic data (age, sex, living conditions, education, and source of income), internet use habits, devices used to complete Strokehealth, perceptions about the usability of Strokehealth, and any stroke-related health problem that respondents felt was not addressed. For the last 2 questions, the 5 response options “very satisfied,” “satisfied,” “dissatisfied,” “very dissatisfied,” and “don’t know” were presented with no subsequent adaptive questioning. The 4 items for free-text answers were “Did you miss any health-related problems?”; “Name three advantages of Strokehealth”; “Name three disadvantages of Strokehealth”; and “Do you have any suggestions for improvement?” Before

a completed survey was submitted, respondents could view a summary of the responses and change any response if they wished. Once the survey was completed and submitted, respondents could not enter the survey interface again. Patients who filled out Strokehealth but did not complete the subsequent survey could receive a reminder.

Additional Data Collection

To describe the diagnoses and other characteristics correctly, clinical data were retrieved from the national stroke quality registry Riksstroke. Information included prestroke living conditions, stroke characteristics, and length of hospital stay. If data were missing, complementary information was collected from the medical records (although not all information could be retrieved due to missing data). Furthermore, on a few occasions, it became evident that some respondents did not fully understand one of the questions in the survey. Clarification was then obtained through personal interviews (conducted by EKK).

Data Analysis

Data were anonymized before all analyses to ensure patient privacy protection. Descriptive statistics were performed using IBM SPSS Statistics (version 24). Categorical values are presented by frequencies and proportion and quantitative variables as medians with ranges or IQRs. With respect to Strokehealth, the time interval from patient notification to registration of a response, as well as the responses themselves, were compiled based on the 3 units. We also conducted an analysis comparing data for those who did and did not respond to Strokehealth. For the nonresponse analysis, we used 2 statistical tests, which were the chi-square test of independence for comparison of 2 categorical variables and the Mann-Whitney *U* test for comparing a categorical with a continuous variable.

Free-text answers were analyzed using a qualitative thematic analysis as outlined by Braun and Clarke [28]. First, we (EKK and PP) analyzed the free-text answers from Strokehealth in an inductive manifest manner with a realist approach to create descriptive themes. In addition, we (KK and EKK) analyzed the free-text answers from the survey using an inductive and latent approach, and the underpinning philosophy was based on a constructionistic approach. The analysis started with the authors reading through the responses several times to become familiar with the data and then discussing underlying meanings and patterns, followed by manual coding. The data were then grouped based on potential themes. The authors reviewed themes several times after discussing them.

Results

Participant Characteristics and Responding Approaches

In total, 171 people with stroke were consecutively recruited and received the digital previsit tool, Strokehealth. Of these, 40% (68/171) were women, and 60% (103/171) were men. Finally, 47% (80/171) completed Strokehealth, with the largest proportions at unit 1 (34/80, 42%) and unit 2 (33/80, 41%). Patients from unit 1 were younger compared with the other 2 units (Figure 2 and Table 1). The subsequent survey was completed by 73% (58/80; Figure 2). One person started but did not complete the survey, and their responses were not included in the analyses. Most respondents to both Strokehealth (45/80, 56%) and the survey (39/80, 67%) were men. All completed the multiple-choice responses, but only about half responded to one or more of the free-text questions. The most common level of education among respondents was a university degree, and pension compensation was the most prevalent source of income (Table 1).

Figure 2. Flowchart of participants and dropouts divided based on the unit where they had their follow-up visit.

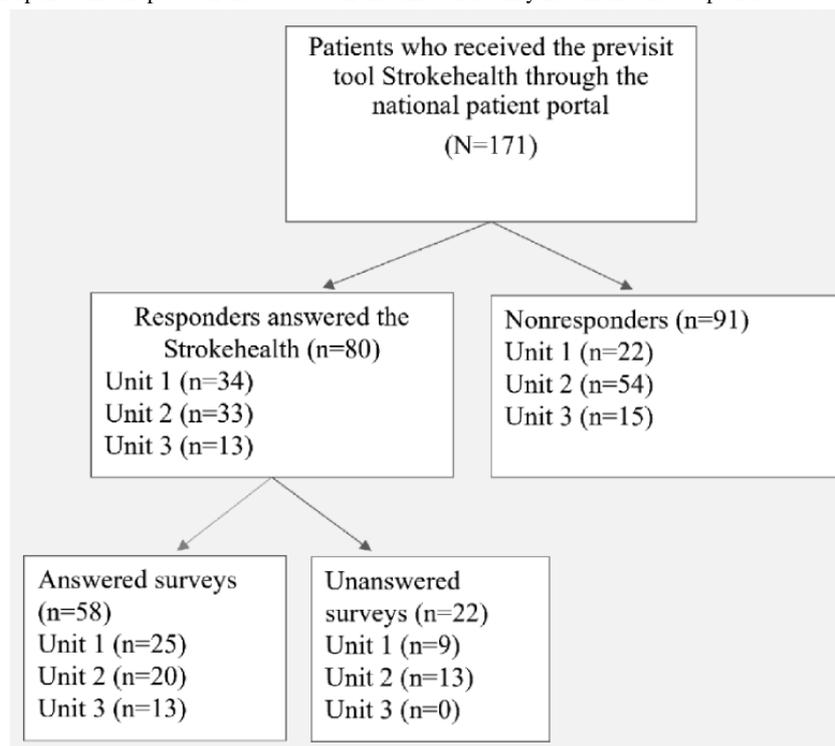

Table 1. Participant characteristics.

Characteristics	Patients answering the previsit tool (n=80)	Respondents of the subsequent survey (n=58)
Age in years, median (range^a)		
All patients	67 (32-91)	67 (43-91)
Unit 1	58 (32-85)	57 (43-85)
Unit 2	71 (44-91)	70 (53-91)
Unit 3	73 (51-87)	73 (51-87)
Sex, n (%)		
Male	45 (56)	39 (67)
Education (highest level), n (%)

^aRange: minimum-maximum.

^bNot applicable.

^cMissing data: Prestroke living conditions (n=5), stroke severity (n=7).

^dOther cerebrovascular events included transient ischemic attack (n= 3), subarachnoid bleeding (n=1), and sinus thrombosis (n=1).

^eNIHSS: National Institutes of Health Stroke Scale; measured ≤ 24 hours of admission, normal values 0-42. Values are presented as numbers and valid percentages unless stated otherwise.

The time interval from patient notification of Strokehealth to registration of a patient response varied greatly, with a median response time of 13 hours (range 9 minutes to 14 days). Internet use was high, with most respondents (48/58, 82%) reporting using the internet several times a day, and others (6/58, 10%)

using it a few times a week, a few (2/58, 3%) times each month, or a few times each year (2/58, 3%). The most commonly used device was a smartphone (29/58, 50%), followed by a computer (24/58, 41%) and a tablet such as an iPad (Apple Inc; 5/58, 9%).

Comparing Patients Responding to the Previsit Tool Strokehealth Versus Nonrespondents

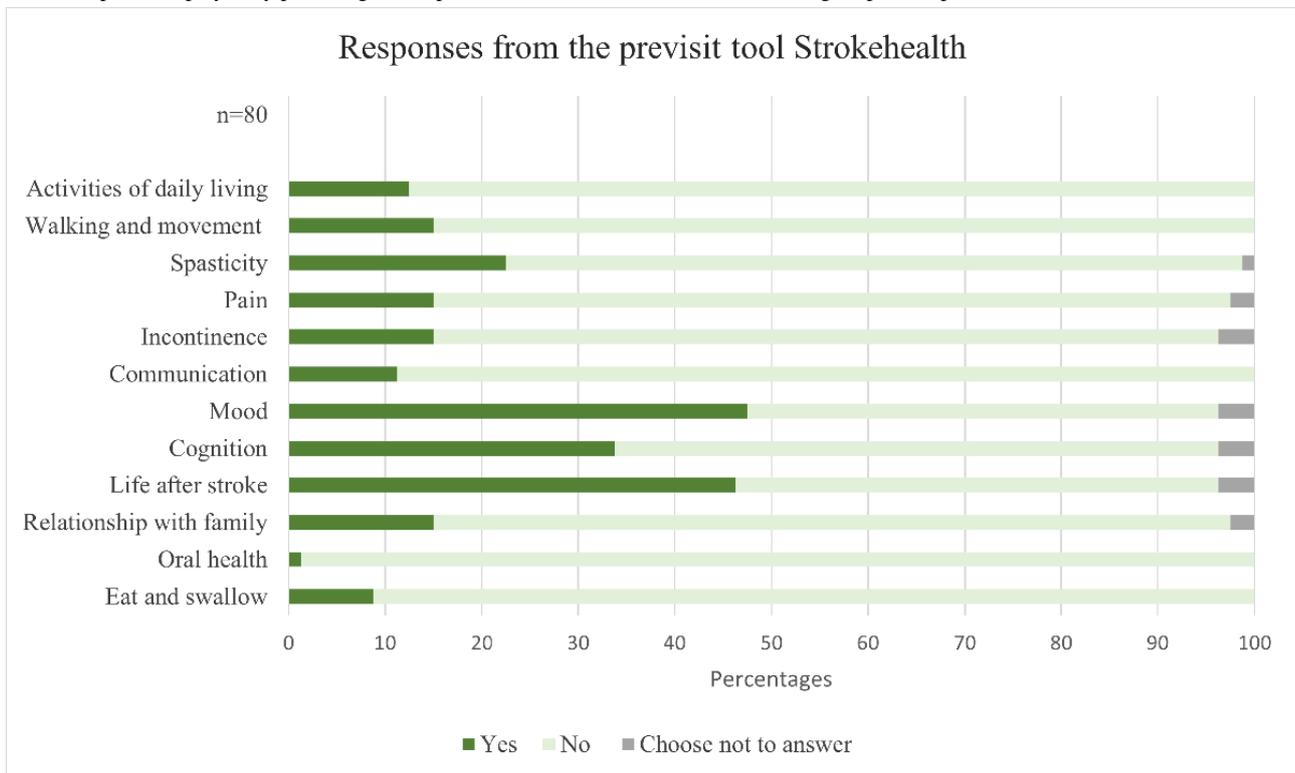

Respondents and nonrespondents differed significantly in age ($P < .001$), with a median age of 67 (IQR 56-75) years among respondents compared with 77 (IQR 69-83) years among nonrespondents. Gender proportions did not differ between the 2 groups ($P = .32$). In comparison with the included patients whose data are given in Table 1, nonrespondents (91/171, 53%) had a higher National Institutes of Health Stroke Scale score (stroke severity), with a median of 2 (IQR 1-6) versus 1 (IQR 0-3), and more often had a history of a previous stroke (17/87, 20%, vs 10/80, 12% for respondents). The proportion with cerebral infarct was 91% (82/90), compared with 81% (65/80) among respondents. Furthermore, 97% (84/87) were discharged

to their own home, whereas 100% (80/80) of respondents were discharged home.

Stroke-Related Health Problems Identified Within the Previsit Tool Strokehealth

Among those completing Strokehealth (80/171, the most reported health problems were as follows: mood, with 48% (38/80) experiencing feelings of anxiety or depression after their stroke; life after stroke, with 46% (37/80) noticing difficulties in carrying out tasks they deemed important; and cognition, with 34% (27/80) facing challenges in thinking, concentrating, and remembering. Conversely, oral health was the least frequently reported area, with only 1 respondent indicating a related issue (Figure 3).

Figure 3. Response displayed by percentage of respondents to the different health areas brought up in the previsit tool Strokehealth.

The initial question on Strokehealth, about the patient’s interest in receiving information on stroke prevention, received the highest proportion of affirmative responses (70/80, 88%). Patients reported an average of 2 health problems per person (median 2, IQR 0-3.8). When considering different care units, patients at unit 1 had a lower average number of problems

(median 1.5, IQR 0-3) compared with patients at unit 2 (median 2, IQR 1-5) and unit 3 (median 2, IQR 0-5.5).

The free-text option in the previsit tool (“Is there anything else you want to add before your visit?”) was used by 45% (36/80) of patients. The thematic qualitative analysis generated 3 categories (Textbox 1).

Textbox 1. Categories created by thematic qualitative analysis based on answers in free-text in the previsit tool Strokehealth.

Health- and risk-related worries:

- questions about medication side effects;
- medical records and requests for advice or practical support;
- concerns about health, including surgery risks; and
- specific questions centered on recommendations for returning to work, medical certificates, and use of a ladder.

Health problems and their daily impact:

- descriptions of health issues and perceived impact on daily life activities;
- health problems noted in relation to language, vision, taste, weakness, mobility, sensory perceptions, dizziness, balance, headaches, irritability, and sensitivity to sound and light; and
- impact on daily life related to isolation because of driving limitations and difficulties with house cleaning, baking, taking walks, shopping, and an inability to last the entire day.

Explanation of personal circumstances:

- factors that may have influenced their responses or general comments,
- additional diagnoses mentioned such as multiple sclerosis, and
- expressed a desire to provide more nuanced responses to certain questions during the visit.

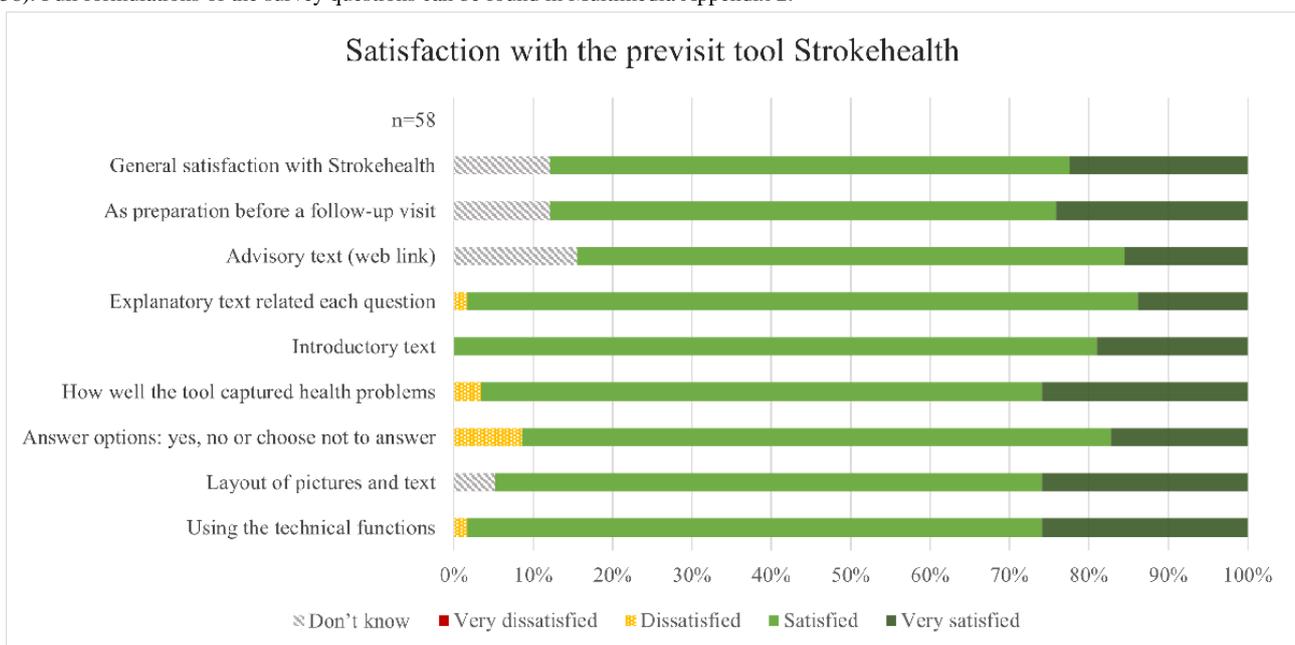

Satisfaction With the Previsit Tool

The majority of respondents (56/58, 97%) expressed satisfaction or high satisfaction with how well the previsit tool captured their health problems after stroke. In the free-text option, a few respondents identified some missing health areas in the previsit tool. These included vision (1/58), fatigue (2/58), mental health (1/58), and the location of pain, if present (1/58). The remaining

responses to this question (6/58) pertained to the design of the previsit tool rather than to a missing health area.

Overall, the feedback and satisfaction with Strokehealth were positive (Figure 4). None of the 58 individuals reported being very dissatisfied. Similarly, the number of respondents expressing dissatisfaction with any aspect of Strokehealth was minimal. The majority of respondents expressed either satisfaction or high satisfaction on the items addressing their experience with Strokehealth (Figure 4).

Figure 4. Satisfaction among respondents to the survey regarding different aspects of the previsit tool Strokehealth. Answers are displayed by percentage (n=58). Full formulations of the survey questions can be found in Multimedia Appendix 2.

A question that received the highest number of “Don’t know” responses (9/58) pertained to satisfaction with the advisory text about self-care and available support resources. This information

was provided through a separate link, which some respondents did not see (10/58). The highest level of dissatisfaction (5/58)

related to the layout of the response options in Strokehealth (“Yes,” “No,” or “Choose not to answer”).

Most respondents (43/58, 74%) expressed an intention to recommend Strokehealth to others who had experienced a stroke, but 26% (15/58) responded with “Don’t know.” The qualitative interviews (conducted by EKK) clarified that some respondents did not fully understand the question or found it challenging to respond on behalf of someone else. Of note, none of the 58 survey respondents stated that they would not recommend Strokehealth to others who had experienced a stroke.

Survey: Qualitative Text Analysis

In total, there were 20, 19, 17, and 10 written responses, respectively, to the 4 free-text questions on the survey. After analyzing these answers, the authors developed 4 themes that are described further with illustrative quotations.

Structure That Ensures That Issues Will Be Emphasized

Strokehealth was perceived as a valuable tool for structured follow-up care. Respondents expressed that it served as a supportive mechanism, capturing important aspects that might otherwise have gone unnoticed. In addition, respondents believed that Strokehealth facilitated increased involvement in their own care. The tool was reported to provide comprehensive and informative content, offering enhanced insights into their condition and available support. This sentiment is echoed in the following quotes: “Some things that had not been mentioned previously by health professionals were emphasized” and “good and clear debrief.” Furthermore, responses such as “good to prepare oneself in peace and quiet before the conversation” or “It [Strokehealth] helps me to reflect on my situation” indicated that Strokehealth was perceived as a structured tool for reflection and preparation.

Importance of User-Friendliness and Accessibility

Statements such as “Good that it is available on the web and easy to access the national patient portal” or “Easy to fill out” indicated that the previsit tool was perceived as user-friendly and readily accessible. However, 1 participant expressed the desire for “Better information than an email that it [Strokehealth] was available to fill out,” suggesting that some individuals may have been unaware of Strokehealth. To enhance usability, 1 participant suggested the ability to reopen and make alterations after completing the tool. In terms of usefulness, patient respondents thought that Strokehealth was a time-saving resource for health professionals. Nevertheless, suggestions for improvement included the desire for prompt feedback on completed responses. Furthermore, one participant’s comment, “Define more what ‘strokehälsa’ is,” may reflect either a lack of sufficient background information about Strokehealth or a misunderstanding of its identity as a digital tool.

A Digital Approach as a Means of Communication

Using a digital tool such as Strokehealth can contribute to patients’ feeling more acknowledged and heard. One of the patients stated that 1 advantage of Strokehealth was that “the questions are asked at all and [I] am given the opportunity to be answered.” Another expressed “It feels good to get to answer questions about the stroke.” One of the respondents remarked,

“This is the first contact I’ve had with medical care since I was discharged from the stroke unit. I wonder if this is the best contact?” Similarly, another respondent stated, “... Forms, either on paper or digital, create an impersonal impression in an often painful situation. I suppose the spectrum of how this is received by the patients is wide, depending on the consequences of the stroke.” Thus, attitudes toward the use of digital tools and the sense of inclusion or exclusion within the digital context played a significant role in shaping the perception of Strokehealth.

Experience of Answering Influenced by Response Options

Respondents frequently mentioned the answer options and a need to explain further and elaborate on their answers. They expressed dissatisfaction with the limited response options of “Yes,” “No,” and “Choose not to answer” for problem areas, as they felt that these options did not adequately capture the complexity of their individual situations. As 1 respondent noted, “The answers to the questions were a bit too much ‘all or nothing’, there weren’t enough alternatives in between.” Participants also highlighted the absence of opportunities to provide explanations or elaborate on their answers, stating that the single free-text question at the end of the tool was insufficient. One participant commented, “If the response was ‘No’, one wanted to be able to explain it in direct connection to that question.” Furthermore, patients complained about the limited word count allowed for the sole free-text response. This limitation also was visible in practice, in that several free-text replies ended abruptly in the middle of a sentence. In addition, respondents found some of the explanatory texts unclear or inconsistent with the questions, leading to confusion and the need to make assumptions about their intended meaning. Furthermore, respondents identified specific missing questions in the tool, such as inquiries about pain localization, while acknowledging the challenge of encompassing every individual’s unique problem within a standardized format.

Discussion

Principal Findings and Comparison With Previous Work

The digital previsit tool Strokehealth was designed for patients with stroke to complete before a follow-up visit to support a focused discussion with the stroke team member during the visit. The current findings from this real-world feasibility testing indicate that Strokehealth is a user-friendly and useful tool, essentially confirming previous findings [13]. Furthermore, Strokehealth effectively captured stroke-related health problems and prepared patients satisfactorily for the visit with the health care professional. However, data collected from Strokehealth and the subsequent survey also highlight important aspects to consider in the continuing co-design process to ensure that the tool meets patient needs.

Respondents considered that Strokehealth satisfactorily facilitated the process of identifying stroke-related health problems, even though the vast majority had experienced what was assessed to be a mild stroke. In addition, these findings support that subtle symptoms such as cognitive impairments

are common even after clinical recovery from stroke [29]. This study thus confirms the previously recognized potential benefits of a tool like Strokehealth [13]. All the health problems noted in Strokehealth had at least 1 response, demonstrating the relevance of the original Post-Stroke Checklist [9], as well as the 3 additional questions. However, patients also mentioned other health issues in Strokehealth and the survey. These issues are not specified as questions in Strokehealth but can be regarded as indirectly assessed (eg, fatigue, vision, or headache) in a manner analogous to the checklist [10,11]. Furthermore, the high proportion (36/80, 45%) using the free-text option at the end of Strokehealth illustrates that any perceived health issues can be identified in some way with this tool. The free-text option enables each patient's unique needs to be captured, in keeping with person-centered care [7,8]. Accordingly, the current findings indicate that the number of questions and response options in Strokehealth work satisfactorily in combination with free-text options to identify a patient's health problems. However, our qualitative findings indicate that the level of answer options, information, and free text needs to be considered (unpublished data) together with the results presented here.

Of note, digital tools such as Strokehealth should be considered an integrated part of the health service [16,21,30]. Our results indicate that Strokehealth has the potential to empower patients and increase their engagement in the follow-up process. In contrast to conventional health care practices in which patients are summoned for prescheduled visits, Strokehealth gives patients the chance to be informed about common consequences after stroke and to reflect on them in advance. The invitation to complete Strokehealth thus can be seen as a starting point for a shared decision-making process, enhancing patient-provider communication during the visit [30] by motivating patients to think about their life after stroke. However, the theme "digital approach as means of communication" raises awareness about patient expectations. Although Strokehealth provided additional support compared with traditional care, some people expected more from their first contact with health care. The principle of "digital first" has become an increasingly common strategy to facilitate proactive support or triage before a physical in-person visit [31], but it may not be consonant with current patient expectations. A patient's experience with health care relies to a large extent on a health care system's ability to meet patient expectations [32]. This reliance underscores that the development and use of Strokehealth need to be handled as an integrated part of overall follow-up [21,30] and adapted for the local context [22] (eg, provide information regarding follow-up routines before discharge) to better meet patient expectations.

The fact that 47% (80/171) of the patients filled in Strokehealth in advance is encouraging and shows that they perceive Strokehealth as acceptable. Also encouraging is that most respondents used a smartphone when filling in the form, which suggests that Strokehealth contributes to more accessible health care. The patient is no longer restricted to health care facilities or their own home to take part in health services; instead, they can prepare for a visit at the time and place of their choosing. However, the impact of contextual factors on effectiveness, acceptability [22], and eHealth literacy [19,33] is important to

consider. A patient's ability to engage with digital health services is influenced by how well the system meets patient needs and not only a patient's ability to understand and use health information [16,19]. Easy access prompts a design in which the patient is asked to fill in Strokehealth in a time and place that supports reflection. Since a few patients submitted Strokehealth very quickly (within 9 minutes), there may be a need to add clarification in the introductory information, for example, a sentence encouraging patients to choose an appropriate time to answer. Understanding the contextual factors influencing these response experiences can provide valuable insights into user's behavior and preferences, which in turn can inform continuous design and increase accessibility to health care services [21,22]. The initial attempt with Strokehealth [13] to maintain an easy-to-use tool guided by theoretical frameworks (eg, technology acceptance model) [27] with a person-centered focus [7] will also guide the ongoing co-design process.

Strokehealth was perceived to be feasible in a group of people who were almost all using the internet daily. In Sweden, 7 out of 10 people who were older than 75 years use the internet, and many retired people are as accustomed as younger people to doing so [34]. Although patients who completed Strokehealth were statistically significantly younger than those who did not, the number of elderly people using digital services is increasing [34,35]. With this in mind, Strokehealth was co-designed with stakeholders to meet future demands. Others have emphasized the importance of close collaboration with all stakeholders when developing effective digital health services [21]. However, several aspects still must be considered in enhancing user friendliness for the broad range of people with stroke. Among factors to consider in the design process are the ability to process information, the need to feel secure, and patients' motivations to be engaged in their own care [19]. Although next-of-kin were involved as support in some cases in this study, this involvement might not have been necessary if potential barriers were better addressed. Not all people are motivated or able to use digital health services, and for this reason, Strokehealth is available in multiple languages, in a picture-supported version, and in paper format [36]. Altogether, offering Strokehealth in different modalities is aimed at overcoming certain accessibility challenges to better meet the needs of the broad range of people with stroke.

Overall, this study contributes to the growing body of evidence supporting the effectiveness and implementation of digital tools in health care [21,37,38]. It is now recommended within the Swedish health care system that Strokehealth is administered before a planned follow-up visit and is thus expected to aid health care teams in adopting a previsit planning approach. Consequently, the preparatory opportunities that Strokehealth provides and the time during the actual visit can be used more effectively. Moreover, with increased knowledge, the hope is that patients can reduce their reliance on health care support and rely more on self-management strategies. User-friendly tools indeed have been shown to increase engagement and adherence to self-management strategies [17,39], which is also one of the main purposes of Strokehealth. By building on existing research, future studies can further explore and refine the role of digital tools, such as Strokehealth, in improving the

quality of stroke care. More in-depth qualitative investigation with patients as well as with health care professionals is needed to explore the experiences of using Strokehealth, including among diverse social groups and people with communication difficulties or complex needs.

Strengths and Limitations

A major strength of this feasibility testing is the evaluation of Strokehealth in a clinical context with real world patients before a scheduled follow-up visit. Furthermore, respondents represented people across a range of ages, sexes, education levels, and different health care settings in urban and rural areas. Consequently, the generalizability of the tool's usability is enhanced. However, there are some limitations. First, despite consecutive sampling, the follow-up routines at each site influenced the sample, leading to a lack of patients with more severe stroke or a higher level of dependency in daily life, and to a range of time intervals since the stroke. Nevertheless, this representation is in line with the stroke population in Sweden, where most patients are classified as having had a mild stroke [40]. Second, during inclusion, researchers did not verify the diagnosis, and some people invited to follow-up had a potential transient ischemic attack that was only recognized later through checks of the health registry or charts. In balance against this

limitation, another strength of the study is the comprehensive description of clinical and demographic data, which in turn provides knowledge about the potential target group for Strokehealth. Third, the influence of recall bias cannot be ruled out for the responses to Strokehealth or the survey. Given the number of free-text answers, though, it seems that most respondents had a clear opinion. A final strength is the high response rate of the survey. Since most strokes are mild in nature, as confirmed in our study, the current version of Strokehealth would be considered a user-friendly tool for most people with stroke.

Conclusions

This real-world feasibility study shows that the previsit tool, Strokehealth, is feasible when used before a follow-up visit after a stroke. Satisfaction with the tool's ability to capture health problems was high among patients, with a majority having experienced a mild stroke and being regular users of the internet. However, during subsequent co-design processes, features such as free-text options and information need to be considered in parallel with qualitative data. Further research is needed to explore the use and benefits for a broader range of users, including people with communication difficulties, and to gain health professionals' perspectives.

Acknowledgments

We thank people with stroke for their participation and their willingness to share their experiences. We also thank the health care professionals for handling the previsit tool besides their ordinary routines.

This study was funded in part by grants from the Swedish state under an agreement among the Swedish government and the county councils, the ALF agreement (ALFGBG-965653); the Local Research and Development Board for Gothenburg and Södra Bohuslän (VGFOUGSB-76712); Sahlgrenska Hospitals Foundation (SU-892141, SU-793481); the Swedish Stroke Association; an unconditional grant from Allergan; the Hjalmar Svenssons Foundation; Göteborg Foundation for Neurological Research; Rune and Ulla Amlövs Foundation; Per-Olof Ahls Foundation; John and Brit Wennerströms Foundation; the Innovation foundation at region Västra Götaland (VGRINN-968305); and the Greta and Einar Askers Foundation.

Abstract

Background: The exponential growth of telehealth is revolutionizing health care delivery, but its evaluation has not matched the pace of its uptake. Various forms of assessment, from single-item to more extensive questionnaires, have been used to assess telehealth and digital therapeutics and their usability. The most frequently used questionnaire is the “Telehealth Usability Questionnaire” (TUQ). The use of the TUQ is limited by its restricted availability in languages other than English and its feasibility.

Objective: The aims of this study were to create a translated German TUQ version and to derive a short questionnaire for patients—“Telehealth Usability and Perceived Usefulness Short Questionnaire for patients” (TUUSQ).

Methods: As a first step, the original 21-item TUQ was forward and back-translated twice. In the second step, 13 TUQ items were selected for their suitability for the general evaluation of telehealth on the basis of expert opinion. These 13 items were surveyed between July 2022 and September 2023 in 4 studies with patients and family members of palliative care, as well as patients with chronic autoimmune diseases, evaluating 13 health care apps, including digital therapeutics and a telehealth system (n1=128, n2=220, n3=30, and n4=12). Psychometric exploratory factor analysis was conducted.

Results: The analysis revealed that a parsimonious factor structure with 2 factors (“perceived usefulness in health care” and “usability”) is sufficient to describe the patient’s perception. Consequently, the questionnaire could be shortened to 6 items without compromising its informativeness.

Conclusions: We provide a linguistically precise German version of the TUQ for assessing the usability and perceived usefulness of telehealth. Beyond that, we supply a highly feasible shortened version that is versatile for general use in telehealth, mobile

health, and digital therapeutics, which distinguishes between the 2 factors “perceived usefulness in health care” and “usability” in patients.

Introduction

Telehealth, Mobile Health, and Digital Therapeutics

Telehealth is an umbrella term defined as “the provision of healthcare remotely by means of telecommunications technology,” whereas mobile health (mHealth) is an overlapping definition for “the use of mobile devices so that patients can solicit services electronically, use apps to verify information, and manage or monitor treatment or problems or other health-related issues” [1,2].

The exponential growth of telehealth and mHealth is revolutionizing health care delivery, because they have the potential to remove geographical barriers, increase access to medical services, and improve overall care quality [3]. Particularly, during the COVID-19 pandemic, there was a significant increase in the use of telehealth and mHealth, but the evaluation and its methodology have not matched the pace of its uptake [4,5]. Patients can thus receive support throughout the entire patient pathway, including app-supported diagnoses, therapy, and monitoring. Approved digital therapeutics (German: Digitale Gesundheitsanwendungen) are apps to improve treatment; their costs are covered by the statutory health insurance system in Germany. In the following discussion, we use “telehealth” to encompass the terms “mHealth” and “digital therapeutics.”

To achieve the greatest possible benefit from telehealth, usability is the key factor, especially with patients who have a cognitive limitation, are incapacitated by their disease, or are children [6-8]. This means that even evidence-based technology is not particularly effective for patient outcomes if it is difficult to use. This could be due to the technology itself or varying levels of eHealth literacy among users. According to Norman and Skinner [9], eHealth literacy is “the ability to seek, find, understand, and appraise health information from electronic sources and apply the knowledge gained to addressing or solving a health problem.”

Furthermore, measuring usability also protects patients from errors or experiencing harm. For example, if a certain telehealth system saves or displays medical data incorrectly and this leads to incorrect treatment, this inadequate usability can also disadvantage patients [10].

Definition of Usability

The International Organization for Standardization (ISO) norm 9241-11 defines usability as [11] “the extent to which a system, product or service can be used by specified users to achieve

specific goals with effectiveness, efficiency and satisfaction in a specified context of use.”

Yet, many researchers have used additional attributes to assess usability [12]. A systematic literature study by Weichbroth showed that in descending order of priority, learnability, memorability, cognitive load, errors, simplicity, and ease of use were additional attributes used to assess usability in mobile settings [13]. However, this literature study excluded publications from medical and health subject areas. Sousa et al [14] conducted a systematic review of usability questionnaires for eHealth and showed that many existing usability questionnaires share these attributes but generally lacked effectiveness, cognitive load, simplicity, and ease of use. Interestingly, Sousa and Lopez [14] reported that the majority of usability questionnaires not only assessed usability but also the perceived usefulness in health care. The questionnaires included questions aiming to assess whether telehealth was helpful in fulfilling health care needs, which is not part of the usability definitions listed. The usability attributes aim only to assess the app’s efficiency, for example, “duration spent on each screen” or the app’s effectiveness, for example, “number of steps required to complete a task” [13].

Usability Questionnaires

On the one hand, authors of various studies used the single-item “Net Promoter Scale” (NPS) and the derived Net Promoter Score to evaluate telehealth [15-18]. However, the psychometric correlates of the Net Promoter Score are not clear, and it is also thought to measure satisfaction and acceptance [15]. We believe that the NPS seems to be a valuable instrument because it offers a straightforward, quantifiable, and very short measure of the user experience and is easy for patients to understand and respond to accurately. Its numerical scale facilitates clear aggregation and analysis of data, allowing for effective comparison over time and across patient groups. The categorization into promoters, passives, and detractors appears to provide actionable insights for further improvements and its widespread use across industries, including health care [19].

On the other hand, up to 38-item questionnaires were used to measure usability [20]. We have, therefore, decided to include the NPS in our study to assess its association with known usability attributes.

A closer look at usability questionnaires reveals a need for development. First, different questionnaires exist side by side, sometimes measuring only different facets of usability or usability-related constructs [14]. Second, many questionnaires have little empirical evidence regarding their psychometric

properties or, third, they can only assess the usability of a specific or single technology [14]. Fourth, most of the questionnaires are only available in English. Accordingly, there are hardly any validated and appropriate questionnaires for usability studies in the German language [21]. As far as we know, only the German translation of the System Usability Scale—the origin of all usability questionnaires—seems to be available for wider use so far [22]. However, none of the 4 existing German versions is convincing [23]. The first 3 points also become clear when you look at the small number of questionnaires available in German.

Some questionnaires are available in German capture usability-related constructs, but do not focus directly on usability (eg, Mobile App Rating Scale-German [MARS-G] [24] and the User Experience Questionnaire [25]). The AttrakDiff questionnaire measures usability as merely 1 dimension among several others [26]. More specifically for the telehealth area, Altmann et al [27] published a German version and a short version of the “Telemedicine Perception Questionnaire” (TMPQ) in 2022. The original questionnaire includes 17 items designed to evaluate the patients’ impressions of home telecare, as well as to assess its potential risks and benefits. Thus, the TMPQ does not measure usability per se (see first point) and is limited to evaluating older patients receiving video consultations from a nurse (see third point). Moreover, the validation of the questionnaire is limited to only 32 and 10 participants in its validation study [28] (see second point). The German translation could be shortened after subgroup analysis to a short version with 5 items. The German version of the TMPQ showed sufficient reliability (Cronbach $\alpha=0.76$) in Altmann’s study with 32 participants compared to the original study (Cronbach $\alpha=0.8$). For the brief version, reliability was still acceptable with Cronbach α of 0.72.

There is another small number of questionnaires available in German whose area of application is very limited (eg, ISONORM 9241/110 on desktop apps [29]). Specific to the telehealth area, different authors in this field offered German translations of the mHealth App Usability Questionnaire (MAUQ) [30-32] (see third point). Moorthy et al [30] validated their translated MAUQ in a specific sample of 133 patients with cancer but, presumably due to the small sample size, the factor structure of the translated questionnaire was not further investigated. Kopka et al [31] provided a German version and a German short version in a sample of 148 patients using a symptom checker app in an emergency department in a randomized controlled trial. They showed that the original factor structure did not fit the data well, but no further investigation of the factor structure was conducted. In their validation study ($n=53$; see second point), Tacke et al [32] showed a strong positive correlation between their MAUQ translation and the System Usability Scale (SUS). However, the factor structure was not examined due to the sample size.

Considering these shortcomings, we still see a need for an appropriate questionnaire available in German. Our aim is to ensure that this German questionnaire is suitable for assessing the general usability of both telehealth and video consultations. In addition, the factor structure is to be evaluated on the basis of a sufficiently large dataset.

Telehealth Usability Questionnaire

The Telehealth Usability Questionnaire (TUQ) by Parmanto et al [33] in 2016 measures all usability attributes except memorability, allows the evaluation of video consultations, and is the most used usability questionnaire [34,35]. The TUQ uses preexisting items from other questionnaires and is freely available following the Creative Commons license 4.0. The TUQ is recommended by other authors and by frameworks for assessing telehealth [14,17,33-35]. We, therefore, translated and validated the TUQ in German (see Methods for further information on the TUQ).

Bibiloni et al [36] published an exploratory factor analysis (EFA; 150 questionnaires) of the TUQ [33] relating to video consultation. They found that 2 factors were sufficient to model the observed data. After the questionnaire was adapted to 12 items by an expert team, a confirmatory factor analysis (269 questionnaires) was performed. Both factors could be measured with good reliability, but they were highly positively correlated. Despite adapting the items and shortening the questionnaire to 12 items, the main problem with the questionnaire was that no good differentiation between usability and perceived usefulness in health care could be achieved. Although the high factor correlation raised the question of whether respondents differentiate between these 2 aspects, a 1-factor model showed a clearly worse fit than the 2-factor model. A limit to the application of the short questionnaire of Bibiloni et al [36] was that the inclusion criteria merely required a single instance of a video consultation and thus did not allow for the general evaluation of apps in telehealth. Besides, as the factor analysis of Bibiloni et al [36] confirmed, the TUQ measures usability, as well as perceived usefulness in health care, and the name “Telehealth Usability and Usefulness Questionnaire” would be more appropriate.

The primary objective of this study was to develop and validate a German language version of the TUQ and compare it to the NPS. This adaptation aims to make the TUQ readily accessible and broadly applicable for evaluating telehealth usability within German-speaking populations. The second aim was to reduce the number of items in order to optimize the feasibility for use in general field studies in telehealth.

Methods

Stages of the Study

Stage I (April 2022-January 2023) consists of translation, adaptation, and pilot-testing of face validity as a method of construct validity. Stage II (July 2022-September 2023) consists of the development of a short-scale—psychometric testing and final item selection. The reporting of this study has been structured according to the recommendations of Streiner and Kottner [37] for reporting the results of studies of instrument and scale development and testing.

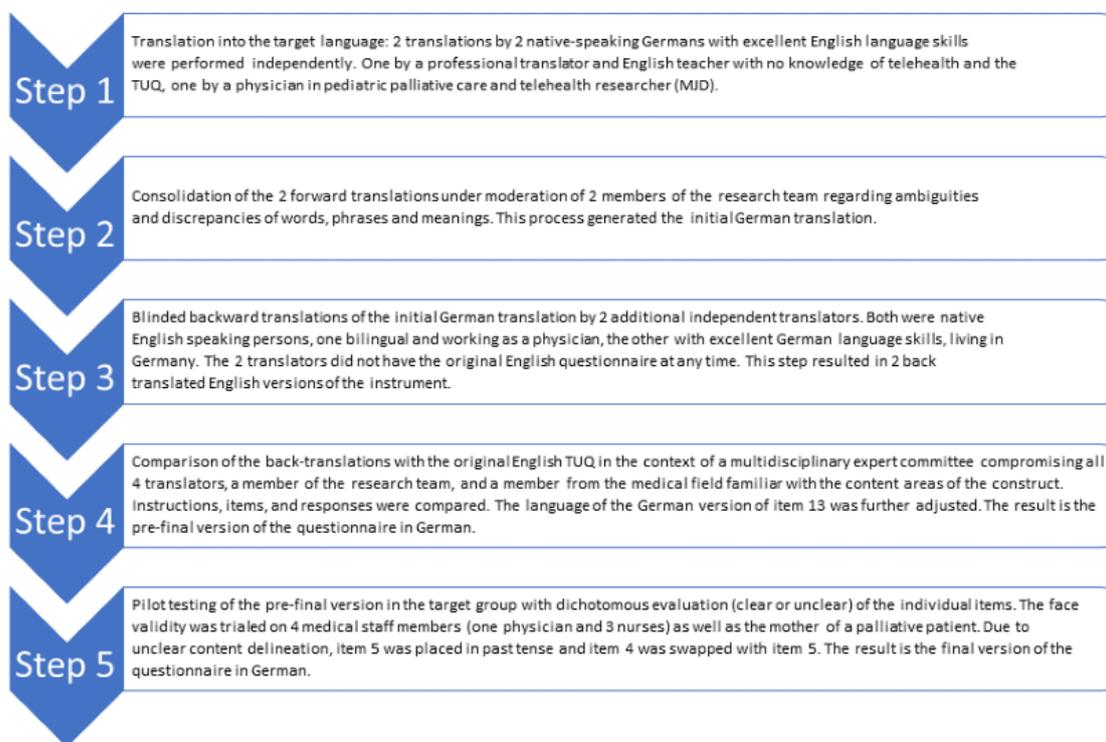

Stage I: Translation, Adaptation, and Pilot User Testing

High-quality translations can only be produced if measurement instruments are linguistically replicated and culturally adapted as rigorously as possible. Sousa and Rojjanasrirat [38] presented

a guideline on “Translation, adaptation and validation of instruments or scales for use in cross-cultural health care research.” In agreement with the lead author, Bambang Parmanto, we (MD and JZ) conducted translation and cross-cultural adaptation with a multidisciplinary expert committee. The members of the expert committee were selected on the basis of their knowledge and experience in the area of application of the questionnaire and their language skills, as reflected in their previous research activities and clinical experience. Translations were carried out by native speakers with proven expertise in the field of application and a high level of language skills in the target language of the translation. The recruitment took place within the authors and through the authors’ network.

To include users’ opinions and views on the German version of the TUQ, we conducted pilot-testing with medical staff, as well as a relative of palliative care children (Figure 1). Several staff members with a high level of clinical experience and patients in palliative care and their relatives were asked to participate in the pilot-testing. The aim of the test was to check whether the items were clear, understandable, and comprehensible. We recruited via the network of authors. The 3 nurses, 1 physician, and 1 relative who participated in the test were asked in an interview to indicate whether the item was clear or not (clear or unclear) and to briefly formulate how they understood the item (thinking aloud method). As a result, we made minor linguistic adjustments.

Figure 1. Stage I: the translation process and pilot user testing. TUQ: Telehealth Usability Questionnaire.

Stage II: Development of a Short Scale: Psychometric Testing in Different Target Populations and Final Item Selection

Design and Setting

A prospective observational cohort study was conducted on 2 sites—site 1 has an assessment of 13 digital therapeutics, some of which allow direct contact to the physicians of the gastroenterology and rheumatology outpatient clinic at the University Hospital Erlangen. Site 2 has an assessment of the video consultation and auscultation features of a telemedical system with patients and their parents receiving pediatric palliative home care (PPHC) in the German state of Hesse [39,40]. Both sites used modified versions of the TUQ. The survey period was between July 2022 and September 2023.

Participants and Patients

All patients who took part in the survey on site 1 were part of 1 of 3 studies conducted by the outpatient clinic at Erlangen

University Hospital and were prescribed 1 of the 13 digital therapeutics in the period from January to September 2023 (see Table S1 in Multimedia Appendix 1). All patients who took part in the survey on site 2 were patients with ongoing PPHC. All patients had to first sign the written informed consent. Inclusion criteria for site 1 were a minimum age of 18 years, diagnosis of a rheumatological disease or inflammatory bowel disease, and a prescribed digital therapeutic. The inclusion criteria for site 2 were ongoing PPHC. The exclusion criteria for site 2 were younger than 18 years of age for patients and family members and lack of mental incapacity. Baseline data on demographic characteristics, disease status, and type of digital therapeutics were collected.

Data Collection, Procedures, Measurement, and Scales

Baseline data on demographic characteristics, disease status, and usability measured were collected using questionnaires. We calculated the mean and SD for all results. Patients were asked to complete a shortened version of the TUQ before and

after the consultation in the ambulance (site 1) or after the use of the telemedical system (site 2). For these studies, 13 TUQ items were selected for their suitability for the general evaluation of telehealth on the basis of expert opinion (see [Multimedia Appendix 2](#) for Cronbach α and [Multimedia Appendix 3](#) for reasons of exclusion). In addition, the single-item NPS [41] was completed on site 1. The survey was completed partly on site or internet-based by email using the REDCap (Research Electronic Data Capture; Vanderbilt University) data collection system (site 1) or the Unipark data collection system (site 2). Participants were asked “How likely are you to recommend this app to other patients?” (original item: “How likely are you to

recommend this service?”) and could respond on an 11-point scale ranging from 0 (“Very unlikely”) to 10 (“Very likely”). Depending on the results, patients could be divided into 3 groups—“promoters” (rating 9 or 10), “neutral” (rating 7 or 8), or “detractors” (rating 0 to 6).

The TUQ contains six domains with a total of 21 items, which are thought to represent each individual usability factor (see also [Table 1](#)): (1) usefulness (n=3 items), (2) ease of use and learnability (n=3), (3) interface quality (n=4), (4) interaction quality (n=4), (5) reliability (n=3), and (6) satisfaction and future use (n=4).

Table 1. English and German versions of the TUQ^a for patients^b.

Item	English	German
Usefulness (German: Nützlichkeit)		
1	Telehealth improves my access to healthcare services.	Die App verbessert meinen Zugang zur Gesundheitsversorgung.
2	Telehealth saves me time traveling to a hospital or specialist clinic.	Durch die App spare ich Zeit in ein Krankenhaus oder zu einem niedergelassenen Arzt oder zu einer niedergelassenen Ärztin zu fahren.
3	Telehealth provides for my healthcare needs.	Die App kann mich bei meinen gesundheitlichen Anliegen unterstützen.
Ease of use and learnability (German: Benutzerfreundlichkeit und Erlernbarkeit)		
4	It was simple to use this system.	Die App lässt sich einfach bedienen.
5	It was easy to learn to use the system.	Die Bedienung der App war leicht zu erlernen.
6	I believe I could become productive quickly using this system.	Ich glaube, ich könnte die App schnell erfolgreich einsetzen.
Interface quality (German: Qualität der Benutzeroberfläche)		
7	The way I interact with this system is pleasant.	Die Benutzeroberfläche der App ist angenehm gestaltet.
8	I like using the system.	Ich bediene die Benutzeroberfläche der App gerne.
9	The system is simple and easy to understand.	Die Benutzeroberfläche der App ist einfach und leicht zu verstehen.
10	This system is able to do everything I would want it to be able to do.	Die Bedienung der Benutzeroberfläche ermöglicht alles, was ich von ihr erwarte.
Interaction quality (German: Qualität der Interaktion)		
11	I could easily talk to the clinician using the telehealth system.	Es war einfach, über die App mit dem Gesundheitspersonal zu sprechen.
12	I could hear the clinician clearly using the telehealth system.	Über die App konnte ich das Gesundheitspersonal klar und deutlich hören.
13	I felt I was able to express myself effectively.	Ich hatte den Eindruck, das Gesundheitspersonal hat mein Anliegen verstanden.
14	Using the telehealth system, I could see the clinician as well as if we met in person.	Über die App konnte ich das Gesundheitspersonal genauso gut sehen wie bei einem persönlichen Treffen.
Reliability (German: Verlässlichkeit)		
15	I think the visits provided over the telehealth system are the same as in-person visits.	Für mich sind Kontakte über die App gleichwertig mit Hausbesuchen.
16	Whenever I made a mistake using the system, I could recover easily and quickly.	Wann immer ich einen Fehler bei der Verwendung der App gemacht habe, konnte ich diesen schnell und einfach beheben.
17	The system gave error messages that clearly told me how to fix problems.	Die Fehlermeldungen der App sind eindeutig und hilfreich beim Lösen von Problemen.
Satisfaction and future use (German: Zufriedenheit und künftige Nutzungsabsicht)		
18	I feel comfortable communicating with the clinician using the telehealth system.	Ich fühle mich wohl, wenn ich über die App mit dem Gesundheitspersonal kommuniziere.
19	Telehealth is an acceptable way to receive health care services.	Es ist akzeptabel, Gesundheitsversorgung über die App zu erhalten.
20	I would use telehealth services again.	Ich würde die App wieder benutzen.
21	Overall, I am satisfied with this telehealth system.	Insgesamt bin ich zufrieden mit der App.

^aTelehealth Usability Questionnaire.

^bThe German version shown was used for assessing patients receiving PPHC. However, as for the English TUQ, items can be adapted to different health care settings. Pilot-testing resulted in the following change: item 4 was put in the past tense instead of the present tense as shown in the table. Additionally, item 4 was swapped with item 5 (not shown). This version and the translation of the TUQ for health care professionals are free to use following the Creative Commons license 4.0, see [Multimedia Appendix 4](#).

With respect to our initial definition above, the first domain, “usefulness,” measures perceived usefulness in health care. The “efficiency” attribute, proposed by Nielsen [12], aims to assess the “level of attainable productivity of the user after he has learned the system.” We see this attribute covered by TUQ item number 6—“I believe I could become productive quickly using this system” [33,34].

All other attributes are covered in the corresponding domains; however, Nielsen’s [12] “memorability” attribute of usability does not seem to be covered in the TUQ. The TUQ has a Likert scale of 1 “strongly disagree” to 7 “strongly agree” as a response option; there are no reverse-scored items. The development study reports good reliability of the usability factors (usefulness: Cronbach $\alpha=0.85$; ease of use: Cronbach $\alpha=0.93$; effectiveness: Cronbach $\alpha=0.87$; reliability: Cronbach $\alpha=0.81$; satisfaction: Cronbach $\alpha=0.92$) [33].

Statistical Analysis

Descriptive statistics were performed using SPSS (version 27.0; IBM Corp). EFAs were conducted in R (version 4.3.2; R Core Team [42,43]) using the packages lavaan, semTools, and psych [44,45]. The number of factors was determined using parallel analysis [46]. EFA models were estimated using full information and maximum likelihood information to account for occasional missing values (<5% per case and item). The initial factor solutions were rotated using an oblique Geomin rotation with 100 random starts for the gradient projection algorithm [47]. The Geomin parameter was set to 0.001, strongly favoring solutions with lower cross-loadings [48–51]. Based on the initial factor solution, a short scale was developed by removing items in order to achieve a simple structure and refine the substantive interpretation of the factors.

Ethical Considerations

The study was approved by the institutional review board of the Medical Faculty of the University of Erlangen-Nuremberg, Germany (22-425-Bm; January 25, 2023); the University of Kassel, Germany (202213; April 28, 2022); and University of Giessen (AZ 64/22; September 16, 2022). This study is registered in the German Clinical Trials Register (DRKS00030546). Participation in the survey was voluntary. All patients gave their written informed consent before study inclusion. All patients who participated in this study were coded with a consecutive number in a pseudonymization procedure. The data collected were stored and analyzed in a password-protected database. Only previously defined and authorized persons had access to this data. Patients had the option of withdrawing their participation in the study at any time, whereby all personal data were irrevocably deleted. The study was conducted in accordance with the ethical guidelines of the Declaration of Helsinki.

Results

Stage I: Translation, Cross-Cultural Adaptation, and Validity

The TUQ was translated in a step-by-step protocol shown in Figure 1. The expert committee discussed several minor cultural and linguistic differences, and the original developer approved

all the adjustments. Original TUQ item 4 “It was simple to use this system” was swapped with item 5 “It was easy to learn to use the system,” as multiple pilot user testers were irritated by this pair of questions.

The TUQ questionnaire is designed to assess different types of telehealth and, depending on which technological application is to be assessed, its wording can be adapted accordingly. There was a need to clarify the terms “telehealth,” “system,” and “telehealth system,” which were all replaced by the term “app” to make the questionnaire applicable to apps. See Table 1 for the complete translation.

Stage II: Development of a Short Scale: Psychometric Testing and Final-Item Selection

Patient Characteristics

In total, data from 390 patients were collected in Germany. A total of 41.2% (160/390) were male and the mean age was 41.79 (SD 13.55) years (see Multimedia Appendix 1). All patients used digital therapeutics, except for group 4, which comprised children, adolescents, and young adults with life-limiting illnesses living at home using a telemedical system for video consultation and auscultation [39,40].

Descriptive Statistics, Factor Analysis TUQ, and Construction of a TUQ Short Version for Patients (Telehealth Usability and Perceived Usefulness Short Questionnaire for Patients)

Multimedia Appendix 5 provides an overview of the descriptive statistics including the correlations of the items surveyed. Parallel analysis suggested a 2-factor solution, that is, substantially fewer factors than the 6 factors originally proposed for the questionnaire. We also explored 1 and 3-factor solutions but deemed a 2-factor solution most plausible from a substantive point of view. More specifically, the 3-factor solution was defined by a dominant factor that encompassed most of the items, a smaller factor that separated the items of the reliability subscale, and a minor factor that isolated the item “Telehealth saves me time traveling to a hospital or specialist clinic” (see Table 1, item 2). The 1-factor solution blended all aspects together but with 0 loading for item 2. In contrast, the 2-factor solution resulted in 2 equally strong factors. These two factors represented distinct aspects and they are (1) perceived usefulness in health care which refers to the app’s effectiveness in health care, including anticipated future use and (2) usability—pertaining to the user’s experience while operating the app. Both factors explained a substantial proportion of the observed variance (39.8% and 37.2%, respectively) and were positively correlated ($r=0.59$, 95% CI 0.56–0.63). The overall fit of the initial model was good (comparative fit index [CFI]=0.95; standardized root-mean-square residual [SRMR]=0.03; root-mean-square error of approximation [RMSEA]=0.13; $X^2(53)=385.07$; $P<.001$). Further details on the factor loadings and communalities can be found in Multimedia Appendix 6. However, the initial factor loading solution was characterized by many cross-loadings. We removed all items with high cross-loadings from the model in order to sharpen the interpretation, arriving at a short version with 3 items per factor (all considerations are reported in Multimedia

Appendix 6). The final version of the scale showed an excellent fit (CFI=0.99; SRMR=0.00; RMSEA=0.02; $X^2(53)=4.86$; $P=.30$). The correlation between the factors was 0.80 (95% CI 0.75-0.85), and the factors explained 41.6% and 40.3% of the total observed variances, respectively. The standardized factor

loadings of the final shortened version are displayed in Table 2. The reliability of the factors as estimated by McDonald ω was good for both factors (usability: 0.86 and perceived usefulness in health care 0.89) [52,53]. Cronbach α for the factor's usability (0.92) and perceived usefulness in health care (0.93) indicates excellent internal consistency.

Table 2. Telehealth Usability and Perceived Usefulness Short Questionnaire for Patients (TUUSQ) factor loadings (N=390)^a.

Item number	Factor loading		Communalities	Attributes
	F1, (95% CI)	F2, (95% CI)		
Perceived usefulness in health care				
Item number 1: The app improves my access to healthcare services.	0.97 (0.89 to 1.04) ^b	-0.1 (-0.19 to -0.02)	0.79	Usefulness
Item number 2: The app provides for my healthcare needs.	0.91 (0.86 to 0.96) ^b	0.04 (-0.01 to 0.08)	0.88	Usefulness
Item number 3: I would use the app again.	0.79 (-0.11 to -0.01) ^b	0.14 (0.96 to 1.03)	0.82	Future intention of use
Usability				
Item number 4: It was simple to use the app	-0.06 (-0.07 to 0.23)	0.99 (0.74 to 1.01) ^b	0.91	Ease of use
Item number 5: The way I interact with the app is pleasant.	0.08 (-0.07 to 0.26)	0.87 (0.58 to 0.89) ^b	0.87	User interface quality
Item number 6: Whenever I made a mistake using the app, I could recover easily and quickly.	0.09 (0.02 to 0.25)	0.73 (0.68 to 0.90) ^b	0.65	Reliability

^aEnglish Telehealth Usability Questionnaire (TUQ) items according to the German version referring to "the app." Factor loadings for the proposed Telehealth Usability and Perceived Usefulness Short Questionnaire for patients (TUUSQ). Factor 1=perceived usefulness in health care and factor 2=usability. The extraction method was oblique Geomin rotation. Adapted from Parmanto et al [33].

^bFactor loadings above 0.30.

The factors identified in the TUQ show very weak correlations with the NPS—perceived usefulness in health care and NPS— $r=0.11$ (95% CI -0.00 to 0.21); usability with NPS: $r=-0.11$ (95% CI -0.22 to -0.01). Furthermore, the NPS shows no correlation to the majority of the TUQ items and very weak correlations to 6 TUQ items (see Multimedia Appendix 7).

The low strength of these correlations makes it very unlikely that the construct measured by the NPS is similar to the constructs measured by the TUQ (see also Multimedia Appendix 7). To double-check possible relationships between the NPS and the TUQ items, we determined the Net Promoter Score on the basis of the NPS [15] and calculated the Kendall Tau-b coefficients (2-sided). A total of 9 significant negative correlations with small effect size [54] resulted—between items 3 and 11 with a range of $r=-0.10$ to $r=-0.19$.

Discussion

Stage I: Complete TUQ Now Available in German in a High-Quality Translation

The complete TUQ was translated into German and cross-culturally adapted. It is comprehensible and equivalent to the English version [33] (see Table 1).

Stage II: Development of the Telehealth Usability and Perceived Usefulness Short Questionnaire for Patients

We identified 2 factors ("perceived usefulness in health care" and "usability") in the TUQ which are sufficient to describe the patient's perception. The NPS does not allow an assessment of usability attributes. The TUQ could be shortened to 6 items without compromising its informativeness as discussed.

Factor Structure

The TUQ shows a 2-factor structure—on the one hand "usability," on the other hand "perceived usefulness in health care." Both factors correlate highly positively ($r=0.59$, 95% CI 0.56-0.63). The same factors were also shown as the main factors of the Spanish version of the TUQ by the working group of Bibiloni et al [36] in 2020. A factor analysis of the Thai version of the TUQ also resulted in a 2-factor model, comparable both to our study and Bibiloni et al [36,55]. The 2 factors were "accessibility" and "utility." To the best of our knowledge, no further data on the TUQ factor structure were found in other studies [34]. In line with this research, and despite the high correlation of the factors, we deemed the 2-factor solution plausible for 2 reasons—first, it is conceivable that a health care app is technically well-designed but does not fulfill its health-related purpose for the patients. Hence, these aspects are distinguishable, and a 2D questionnaire encourages respondents to think about these aspects separately. In that sense, the high

correlation may be an artifact of the context in which patients with highly specialized health care apps were asked to fill in the questionnaire. Second, previous research [56] has shown that factor analysis tends to err in the direction of extracting too few rather than too many factors, thus, the results underline the theoretical notion that there are 2 distinguishable factors in the TUQ.

We removed TUQ items (see Table 1; items 2, 5, 6, 8, 17, 19, and 21) largely due to high cross-loadings in order to sharpen

the interpretation, arriving at a short version with 3 items per factor (see Multimedia Appendix 8). As the TUQ, similar to many other usability questionnaires, also contains items measuring the perceived usefulness, we, therefore, propose a clear title stating the dual purpose of the short questionnaire, thus “Telehealth Usability and Perceived Usefulness Short Questionnaire for patients” (TUUSQ). Bibiloni et al [36] proposed a short version with 12 items to assess usability in telehealth focusing on video consultations. This short version shares 4 items with the TUUSQ (see Table 3).

Table 3. History of selected TUQ^a items^b.

^aTUQ: Telehealth Usability Questionnaire.

^bThe source of the selected TUQ items is shown, as these were originally developed by the authors of the PSSUQ, TSQ, and TAM questionnaires and afterward included in the TUQ [57-59]. TUUSQ items 1, 2, and 3 originate from the TSQ, items 4, 5, and 6 from the PSSUQ questionnaire. Items selected by Bibiloni et al [36] for assessing video consultations also originate from the TAM questionnaire [36].

^cTUUSQ: Telehealth Usability and Perceived Usefulness Short Questionnaire for patients.

^dPSSUQ: Post Study System Usability Questionnaire [57].

^eTSQ: Telemedicine Satisfaction Questionnaire [58].

^fTAM: Technology Acceptance Model [59].

Factor Perceived Usefulness in Health Care

The factor that we named “perceived usefulness in health care” was included in the TUUSQ with 2 items relating to health care access and support. In addition, 1 item regarding the intention of future use (Cronbach $\alpha=0.79$) loads this factor. We interpret this finding as the future intention of use is highly associated with perceived usefulness in health care and not with good usability experience. Other studies in other contexts also demonstrated that satisfaction and future intention of use show a high correlation [60-63].

Factor Usability

The second factor, “usability,” contains 1 item each regarding ease of use, reliability, and interface quality. The TUUSQ thus lacks the TUQ items addressing the usability attributes as defined by Nielsen [12], that is, “efficiency” (item 6), “efficacy” (item 2), and “satisfaction” (item 21). However, as our data show no benefit in adding further items, and that the feasibility of a 6-item questionnaire is very good; therefore, we advocate this short version. Interestingly, in contrast to the usability attributes, the TUQ item addressing interface quality showed the second-highest factor loading for the factor usability in our study. One of the first usability questionnaires, the “Post Study System Usability Questionnaire” (PSSUQ) showed a 3-factor model with the factors “interface quality,” “system usefulness,” and “information quality” [57]. Saeed et al [64] also showed that, in the context of telehealth home monitoring, the quality

of the user interface is of utmost importance for patient usability. Weichbroth [13] reported that among others less commonly assessed usability attributes for the mobile setting include navigation, operability, attractiveness, aesthetics, accessibility, and interaction [13]. Possibly our German translation of the TUQ item 7 “The way I interact with this app is pleasant” which means literally “the app’s user interface has a pleasant design” also relates to these attributes (see Table 1). This finding was also present in usability studies in other health care settings [65].

The original TUQ contains no items regarding memorability. We decided against adding an item to assess memorability as our study design as it does not allow testing for memorability, that is, ease of reusability of the applications after long periods of disuse. Of course, the usefulness of telehealth should be memorable and practical in the longer term, but this question was not part of this study. Further studies on this with a more extended use of telehealth should be carried out in the future.

NPS in Health Care

Interestingly, the NPS did not show moderate to strong correlations with either the 2 identified factors—perceived usefulness in health care and NPS: 0.105 (95% CI –0.00 to 0.21); usability with NPS: –0.11 (95% CI –0.22 to –0.01) or with any of the individual TUQ items. These results show that the underlying construct of NPS is not associated with any of the patient’s usability or perceived usefulness in health care

attributes covered by the TUQ in our studies. As the TUQ contains an item to assess satisfaction (item 21), our studies support the findings of Krol et al [15] that the NPS is not associated with patient satisfaction. The construct that is measured by the NPS in health care continues to remain elusive [66]. Future research assessing health care quality should include the NPS in conjunction with larger surveys [66]. This is necessary since single-item measures are notoriously unreliable—potentially explaining this null finding—and should not be used as a critical variable in high-stakes settings. Moreover, possibly a correlation to other attributes might reveal the underlying construct of the NPS and pave the way to evidence-based use in health care. Finally, it should be noted that Adams et al [66] suggest limiting the use of the NPS to certain health care settings, for example, where patients have a choice of provider. This was not the case in our study.

Origin and Quality of TUUSQ Items

The items selected from the TUQ for the TUUSQ originate from the PSSUQ and Telehealth Satisfaction Questionnaire (TSQ) questionnaires (see Table 3 [57,58]). All TUUSQ items addressing usability originate from the PSSUQ. The PSSUQ was reviewed by Sousa and Lopez [14] in 2017 and assessed as one of the best available usability questionnaires, although the TUQ was not included in this study [33]. The PSSUQ's items were generated using an empirical study and showed very good internal consistency (Cronbach $\alpha=0.97$). However, the quality assessment of validity, reliability, user-centeredness, sample size, and feasibility by Sousa and Rojjansrirat [38] yielded a medium-quality score due to low sample size and lack of reported user-centeredness during item generation. The PSSUQ is also sensitive to user-group and system differences [57].

The TUUSQ items assessing perceived usefulness in health care all originate from the TSQ. The TSQ shows a 3-factor model [58] and all items used by the TUQ and thus TUUSQ belong to the factor called “quality of care provided.” No review of the psychometric properties of the TSQ is available. The reported sample size was low and lacked reported user-centeredness but showed good internal consistency (Cronbach $\alpha=0.93$).

Limitations

The TUQ was translated in a way that has proven itself in research. Nevertheless, individual words may seem inappropriate for some target groups (eg, item 15—“Hausbesuche” for “in-person visits”). Depending on the context, “Vor-Ort-Termine,” for example, may seem more appropriate

here. We would like to point out that such adjustments can have an impact on the quality of the questionnaire.

The development of the TUUSQ short questionnaire was for the main part only examined patients who received digital therapeutics or used a telehealth system. Further studies are needed to evaluate whether the short questionnaire can be successfully applied more widely in the area of telehealth. Furthermore, the applicability of the TUUSQ may be limited in other cultural contexts, as this study only included patients from Germany. This limitation also applies to the original instruments (PSSUQ and TSQ) used as references. Cultural and contextual differences between the original settings of these instruments and this study could affect their relevance and accuracy in different populations. Thus, we encourage further studies using our translated version to analyze the factor structure in other datasets to investigate the generalizability of our conclusions.

Conclusions

The TUUSQ offers a short and highly feasible questionnaire for assessing and distinguishing the perceived usefulness and usability of telehealth. The TUUSQ contains solely generalizable items which allow for its use in many different telehealth contexts, as advocated by Sousa and Lopez [14].

Based on our results and the binary factor TUUSQ structure and the recommendations of Sousa and Rojjansrirat [38], we propose the following sequential approach for the assessment of telehealth apps—first, assess whether the app addresses a relevant health care need for patients. If not, and patients report no improved access to health care and health care support, or future intention of use is not reported, the scope of the app should be reevaluated. If perceived usefulness in health care is given, the TUUSQ provides software developers with concrete information on the app's usability giving feedback on ease of use, reliability, and the quality of the user interface.

Following our study, the TUUSQ can be used in Danish, German, Portuguese, Slovene, Thai, and Urdu, as validated TUQ translations are available for these languages [33,55,67,68]. The TUUSQ is free for commercial and noncommercial use following the Creative Commons license 4.0 [69]. If, besides perceived usefulness in health care and usability, the quality of the video connection during a video consultation, as well as the suitability of this medium are of interest to the researchers, we recommend using the TUQ short version as proposed by Bibiloni et al [36].

Acknowledgments

The authors thank the patients, families, collaborators, and pediatric palliative care teams for their participation in this study. The authors thank Madita Mannheims, whose contributions to stage I went toward her obtaining her masters degree in psychology, and all the translators for their valuable time and input. This research was funded by the Hessian Ministry for Social Affairs and Integration grant (18z4350-0001/2021/001).

Authors' Contributions

MD, JZ, HM, and FS wrote the draft paper. FS, JZ, and MD performed the statistical analysis. Translations were conducted by MD and JZ. Studies were conducted by TO (study 1), JK (study 2), HM (study 3), and MD and JZ (study 4). All authors (MD, JZ, HM, FS, JK, TO, HM, MN, and TV) reviewed the draft and provided comments for change. All authors approved the final paper.

Conflicts of Interest

Abstract

Background: Caregiver wellness programs need to be easily accessible to address caregivers' constraints to participation.

Objective: We aimed to assess the feasibility of 5Minutes4Myself app's mindfulness module (usability, usage, and impact on caregivers' levels of mindfulness and perceived stress).

Methods: Before and after participation in the 5Minutes4Myself program, 15 participants were asked to complete the Perceived Stress Scale (PSS) and Five Facet Mindfulness Questionnaire (FFMQ). Data on the usage of app-delivered meditations were collected electronically via the app, and app usability was rated on the Modified System Usability Scale. Analyses assessed participants' frequency of use of app-delivered meditations, app usability, and changes in participants' stress and mindfulness post intervention.

Results: Overall, participants completed 10.9 minutes of mindfulness meditations per week and rated the app 76.7, indicating above-average usability. Related samples *t* tests (2-tailed) found that group PSS ($t_{10}=1.20, P=.26$) and FFMQ ($t_{10}=-1.57, P=.15$) pre- or postintervention mean scores were not significantly different. However, a visualization of pre- and post-PSS and mindfulness scores suggested there was a group of responders who had decreased stress with increased mindfulness. This was confirmed via an individual change analysis. The effect size of the FFMQ scores ($d=0.47$) suggests there may be treatment effects with a larger sample. A hierarchical multiple regression analysis examined the degree mindfulness impacted perceived stress; 20% of the variance in participants' perceived stress could be attributed to increases in self-rated mindfulness ($P=.04$) when controlling for preintervention stress levels.

Conclusions: Caregivers found the app highly usable and on average used low-dose levels of mindfulness meditations (10 min/wk). For responders, increased mindfulness was related to stress reduction to population-based levels.

Trial Registration: ClinicalTrials.gov NCT03771001; <https://clinicaltrials.gov/study/NCT03771001>

Introduction

Wellness programs are critically needed for the many parent caregivers of children with autism spectrum disorder (ASD) who experience increased levels of stress, poorer health outcomes, and decreased quality of life compared to parents of children with other developmental disabilities or typical

development [1-6]. Caring for a child with ASD has been found to have a significant impact on the caregivers' overall well-being [7,8]. More than half of mothers of children with ASD report mental health problems, a substantially higher percentage than the general population [5]. Time-intensive care demands that remain high over time, challenging child behaviors, and social stigma limiting participation in community activities increase the need for wellness promotion while at the same time make

participation more difficult [5,8,9]. Caregivers often put their child and family's needs before their own self-nurturing and wellness-promoting activities [10]. Ideally, wellness programs for caregivers should be tailored to be widely available to the most caregivers and address common caregiving constraints that could limit participation such as lack of time and difficulties with attending regular programming and using effective evidence-based interventions.

Evidence suggests that mindfulness practices bolster wellness for caregivers. These programs emphasize acceptance of life circumstances and loving-kindness toward oneself and others despite challenges [11]. Multiple delivery formats, including individual, group, and self-guided mindfulness trainings, have been shown to be more effective than other stress reducing interventions for caregivers of children with ASD and other developmental disabilities [12-16]. Researchers have focused on designing mindfulness program features that support these parents' ability to participate consistently over time to provide much needed mental health and wellness benefits. Rayan and Ahmad [17] modified a mindfulness-based intervention (MBI) program for parents in Jordan [13]. The modified program was shortened to 5-weeks and included 33 hours of training, phone follow-up sessions, and text message reminders of assignments and support. Their quasi-experimental study (n=104) found caregivers of children with ASD who participated in the MBI intervention had significantly reduced stress compared to a control group. With their modified MBI, attrition rates decreased [13,17].

However, likely due to the intensity and time demands of caregiving and the occurrence of unexpected life events, some caregivers find it difficult to attend in-person mindfulness programs that require weekly in-person time commitment and travel to community sites [12,18,19]. Harnessing the usefulness of mindfulness practices for parents may require developing an alternative to the longer in-person mindfulness programs that may overcome some of the lifestyle and time barriers these caregivers experience.

Mobile platforms offer greater flexibility for delivering self-guided meditations compared to in-person or phone options. Mobile phone texts have thus far been used in this population to extend interventions delivered in in-person training sessions [17]. Tailored delivery to times and places that fit caregivers' lifestyles, may make mindfulness intervention more convenient and accessible and cost-effective [20,21]. Digital interventions that allow personalization, goal setting, and accountability may promote caregivers' participation in wellness promotion and reduce social health inequalities [22,23]. Given the significant need and current evidence for the usefulness of mindfulness approaches, we developed, through a collaborative recursive process with and for caregivers, a mobile app to create a more user-friendly and accessible mindfulness module for the 5Minutes4Myself caregiver wellness program [24].

This analysis used feasibility study data and was intended to examine the app usability and who may have benefitted from program participation by investigating whether there were changes in stress and mindfulness, specifically focusing on this new element of app-delivered mindfulness meditations. We

aimed to examine the app's usability, caregivers' usage of mindfulness content, and the effect of mindfulness meditations on participants' postparticipation levels of mindfulness and perceived stress. We recognized that other components of the 5Minutes4Myself wellness program may also have influenced perceived stress levels. We expected that (1) the app as designed with and by caregivers would be rated as acceptable, (2) the caregiver-tailoring and habit-building features of the app would encourage regular use of meditations at least twice weekly over 4 months' time, and (3) using the micromindfulness meditations of the modified 5Minutes4Myself wellness program would increase caregivers' mindfulness and reduce self-rated stress.

Methods

Study Design

This study examined the acceptability and usability of the smartphone app and its mindfulness meditations using a quasi-experimental mixed-methods design with pre- and postintervention assessments.

App Development

The 5Minutes4Myself wellness program was developed with and for caregivers of children with ASDs. We designed a collaborative research-informed approach. First in a focus group, we shared the best available evidence for wellness promotion and occupational science principles for lifestyle change with caregivers. Occupational sciences' core construct is that what we do each day (ie, how we "occupy" our time) matters, and how we balance our participation in a range of daily activities or occupations with different experiences can support or undermine our quality of life [24]. To create changes in our wellness requires leveraging and sustaining strategies to revise our often entrenched and comfortable daily routines. The evidence-based program principles and elements presented to caregivers focused on "doing" (eg, activities that promote pleasure or social connection) and lifestyle change strategies to achieve changes, "thinking" (eg, positive psychology practices) and "goal visioning" [24]. Second, we elicited caregivers' feedback on these principles and elements, confirmed caregivers' preferences and developed additional goal-visioning activities as requested. Third, we delivered the program. It included a lifestyle consultation to develop goals using motivational interviewing (MI), coaching over 4 months to pursue wellness goals, and "doing" content delivered via an iPad (eg, knitting tutorials, yoga, meditation, and activity trackers). Last, we evaluated the program in a postparticipation focus group.

After completing the program, the key change participants requested was the development of a mobile phone app to deliver mindfulness and other content that would be available to be used anytime and anywhere [24]. Further refinements caregivers requested to meet their needs and limited capacities to participate in a wellness program were to eliminate "doing" content, which was not well used on iPads, and add guilt-free goal accountability check-ins, goal profiles to remind them of their selected wellness goals and rewards to reinforce their efforts. Due to their frequent fatigue and limited technology experience, caregivers asked for simple app navigation such as prompts that

quickly redirected them to the next mindfulness meditation in the series, without having to remember where they left off, and intuitive navigation between screens, and calming color schemes. Given the request for a smartphone app, we polled the caregivers on their current technology and internet access. Due to their financial circumstances not all caregivers had smartphones, and many had older versions, and not all had home access to the internet. We recognized these would be issues that needed to be addressed in the app design.

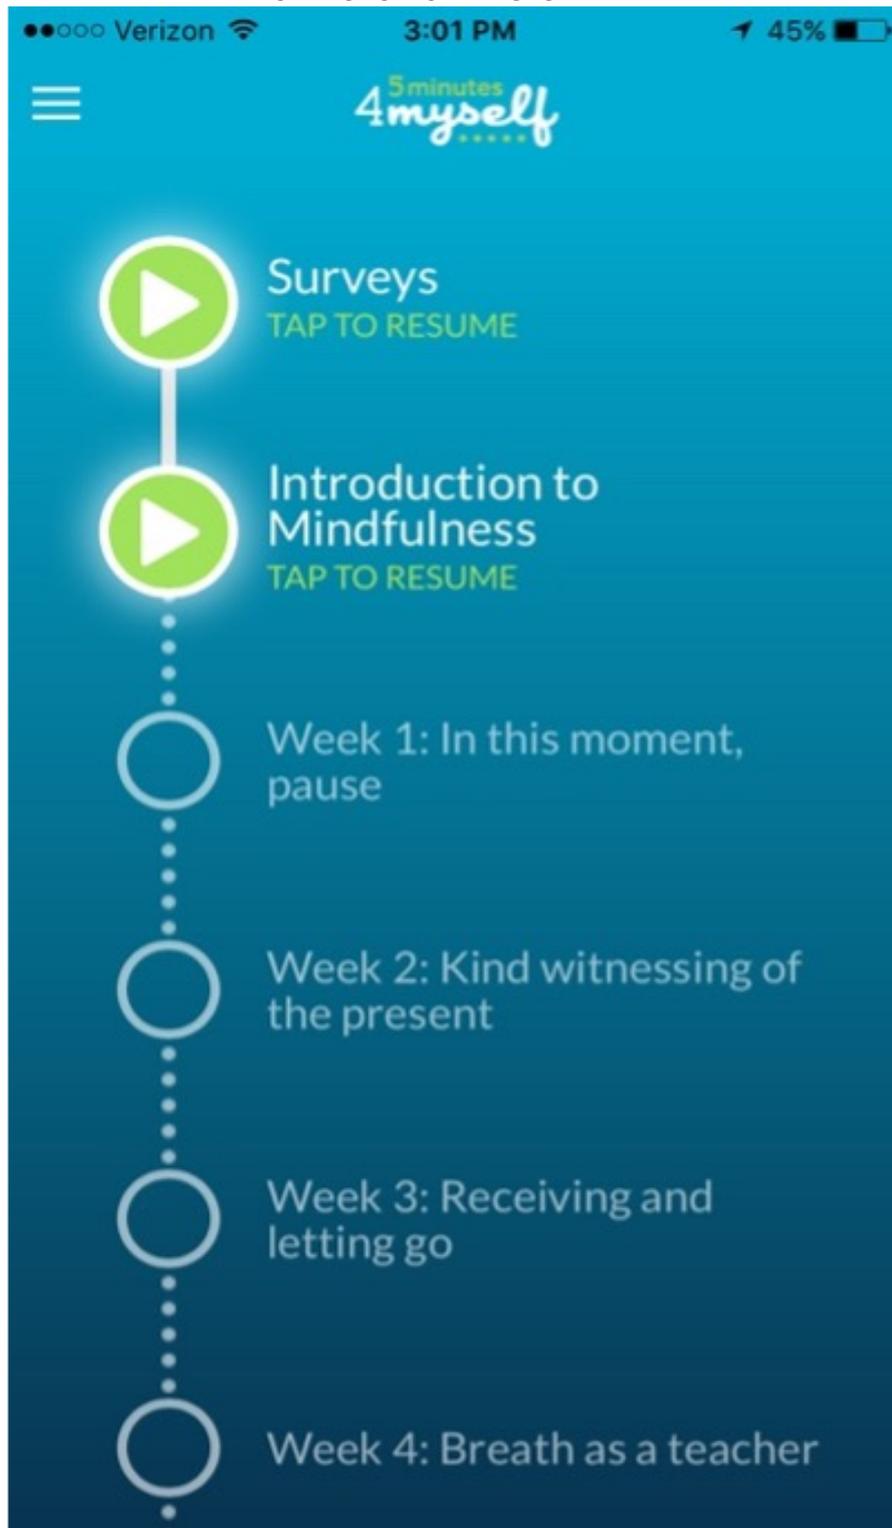

We worked with a local software start-up company to develop both an iOS and Android app version similar in content and design, and with an expert mindfulness-based stress reduction (MBSR) trainer or clinical psychologist to develop mindfulness content. We provided the software developers with several design and function parameters tailored for our caregiving participants: aesthetically pleasing interfaces, simple navigation, offline availability of content and reminders, usability on older phones, easy personalization of goal and notification reminders,

dashboard tracking of mindfulness meditation usage, request coaching help function, goal check-ins, guilt-free check-ins, and rewards for full or partial goal success. The software development team used Test Flight (Apple Inc) to deliver beta versions to our research team for testing and provided a link to a data dashboard that hosted meditation usage data and goal check-in submissions. The psychologist developed and recorded the mindfulness meditations that were specifically tailored for a caregiver. For example, loving-kindness meditations often included directing nonjudgmental and accepting thoughts toward themselves and their child. Recorded meditations were 4 - 21 minutes long (Table 1). The meditation series began with an introduction to mindfulness, and then alternated between meditations emphasizing awareness of the present, being aware of the physical body, and loving-kindness. For ease of navigation, the mindfulness meditations were presented in a vertical stream with a glowing dot highlighting the next meditation to be listened to (Figure 1).

Table 1. 5Minutes4Myself app-delivered meditations.

Title	Content	Length (min)
Introduction of mindfulness	Introduction to program and instructor	11
In this moment, pause	Being present	3
Kind witnessing of the present	Body scan	7
Receiving and letting go	Loving-kindness	5
Breath as a teacher	Being present	6
Awake with awareness and presence	Body scan	18
Resting in the breath	Loving-kindness	10
Simply choose to pause	Being present	6
Dropping into relaxation	Body scan	22
Release, letting go	Loving-kindness	16
Resting in the moment	Breath awareness	17
Kind witnessing of the present	Body scan	8
Resting in the breath	Breath awareness	10
Deep breathing	Breath awareness	12
Awake with awareness and presence	Body scan	18
Releasing, letting go	Loving-kindness	16
Dropping into relaxation	Body scan	22

Figure 1. Mindfulness meditation stream screen with glow highlighting current progress.

In total, 2 additional cohorts were delivered the 5Minutes4Myself program and confirmed the usefulness of these app elements (goal profile, self-timed reminders to do wellness activities, goal check-ins, goal achievement rewards, mindfulness meditations, and design or graphics) and requested navigation changes (ability to go forward as well as backward in the meditation stream) and moving goal check-ins to an opening screen [24]. Revisions were made to the app between

these 2 cohorts to address app instability and remove the request for coaching support feature that was not used.

Participants

Recruitment

Participants were recruited through email solicitation, posters, flyers, and brochures in the community and at conferences for families of children with ASD. Recruitment also occurred through social media advertising to ASD-specific groups.

Interested individuals were screened by phone interview to assure they met inclusion criteria. Informed consent was obtained from all individual participants prior to participation at focus groups or in individual meetings. In total, 15 individuals in cohorts participated in 4-month cycles, over 1 year's time. This sample was considered sufficient for proof-of-concept to assess the feasibility of the mobile app.

Inclusion and Exclusion Criteria

Caregivers were included if they were the primary caregiver of at least one child with a diagnosis of ASD aged between 8 - 21 years. We selected this age grouping with the assumption that families had established care routines and thus the caregiver had more capacity to alter their daily routines for wellness promotion. Caregivers had to have a desire to participate in a lifestyle wellness program, including a mindfulness component, and be willing to commit sufficient time to participate in the program. Exclusion criteria included (1) parenting a child younger than 8 or older than 21 years of age, or (2) a caregiver diagnosis of significant mental illness such as schizophrenia, bipolar disorder, schizoaffective disorder, pervasive developmental disorder, obsessive-compulsive disorder, panic disorder, posttraumatic stress disorder, or an eating disorder. We included participants who had or were being treated for depression since clinical or subclinical levels are highly prevalent in this caregiving group [25]. In total, 5 reported being currently treated for depression. Further, 40% (6/15) of the caregivers scored 16 or greater on the Center for Epidemiologic Studies Depression Scale Revised, suggesting they were at risk for depression (mean 17, range 8 - 43). A recent meta-analysis suggests that the use of stand-alone mindfulness practices, without the additional readings and instruction typically provided in MBSR programs, has been found to reduce depression and anxiety [26] thus the program could have benefits for caregivers with these diagnoses.

Measures

Overview

Ratings of the app usability, app usage, and pre- and postintervention measures of self-reported stress and mindfulness were used to examine app acceptability and the effects of the 5Minutes4Myself smartphone mobile app micromindfulness meditations on caregivers' mindfulness and stress. Measures used included the Modified System Usability Scale (MSUS), Perceived Stress Scale (PSS), Five Facet Mindfulness Questionnaire (FFMQ), and app meditation usage data. In addition, participants completed a survey that asked: their age, self-identified race or ethnicity, marital status (single, married, separated, or divorced), education (high school, associate, undergraduate, or graduate), average family income, children's names and ages, caregiving or work (full-time caregiver, part-time work, or full-time work), medical conditions and medicines taken. This information was gathered to understand the family resources and caregivers' health. Participants self-identified as White.

Modified System Usability Scale

The MSUS, a 10-item survey that yields a single score of overall usability, has been widely used to assess technology quality and

functionality [27,28]. It assesses effectiveness, efficiency, and user satisfaction [26-28]. While items are rated on a 5-point Likert scale, they are weighted so that the final scores range from 0 - 100 [26]. It is reliable, with $\alpha=.91-.92$ and with good concurrent validity ($\alpha=.806$) [26]. Scores of 68 are considered above average usability, and scores of 80.3 or greater are in the top 10% of MSUS scores [28]. Participants are asked to rate 10 statements such as "I thought the system was easy to use" or "I felt very confident using the system" from 1=strongly disagree to 5=strongly agree.

App Usage

To assure participants were using the meditations, data were collected via the app on the time spent listening to meditations and the number of meditations completed during the program. This allowed us to examine the dosage of mindfulness with accuracy.

About the PSS

The PSS is a reliable and valid self-report measure of stress (weak to moderate association criterion validity $r=0.11-0.67$, internal consistency $\alpha=.60-.91$, and test-retest reliability $r=0.55-0.86$) [29-31]. The PSS items ask participants to rate the degree to which they have experienced feelings and thoughts of unpredictability, uncontrollability, and overload in the last month. PSS captures both daily challenges and major events within the prior 30 days. Further, 10 questions measure the degree an individual appraises their life situations as stressful using a 5-point Likert scale from "0" (never) to "4" (very often). For example, participants rated statements such as "In the last month, how often have you felt difficulties were piling up so high that you could not overcome them?" or "In the last month, how often have you felt nervous and stressed?" Higher total scores on the PSS indicate more stress [29]. For this study, the PSS measured the self-reported level of stress experienced by the participants in the month before beginning and during the last month of participating in the 5Minutes4Myself wellness program. The 10-item version was used.

About the FFMQ

The FFMQ is an adequately valid, reliable, and internally consistent self-report measure of mindfulness practice in an individual's life ($\alpha=.73-.91$, $n=376$) [32-34]. The 39-item measure addresses 5 characteristics that have been identified as integral to mindfulness practice including: describing, observing, acting with awareness, nonjudging of inner experience, and nonreactivity to inner experiences. Questions are rated on a 5-point Likert scale ranging from "1" (never or very rarely) to "5" (very often or always). Items include "I find it difficult to stay focused on what's happening in the present," "I tell myself that I shouldn't be thinking the way I'm thinking," and "When I have distressing thoughts or images, I judge myself as good or bad, depending on what the thought/image is about." Higher total scores represent higher levels of mindfulness [32]. In the context of this study, FFMQ measured the degree of participants' mindfulness before and during the last month of participating in 5Minutes4Myself wellness program which included using the smartphone mobile app mindfulness podcasts.

Procedures

5Minutes4Myself Wellness Program

All cohorts completed equivalent procedures. The 5Minutes4Myself wellness program began with each cohort attending a community-building focus group where participants discussed what worked and did not work in their lives and completed health and well-being surveys using the mobile phone app. Participants unable to attend focus groups completed surveys using the mobile app at another time, or on paper and mailed in results (this was necessary due to an Android version app failure for downloading preintervention surveys). Next, each participant was assigned a coach trained in MI; the fidelity of MI use is reported elsewhere [35]. MI is a practice in which use of collaboration, evocation, and privileging participant autonomy are essential to eliciting participant-desired lifestyle change and supporting goal attainment [36]. Participants worked with coaches to select goals meaningful to them in the initial lifestyle consultation and created a plan for instituting the goals into her or his daily life over the 4-month program. Participants identified 3 to 5 goals, which included 1 goal of regular weekly mindfulness practice. The mindfulness goal was required of participants for this feasibility study since it was a key element of the application being developed. Coaches meet at least monthly with participants, either in person or on the phone, to discuss their goal progress and revise strategies as needed.

Postintervention focus groups were conducted after 4 month's participation. Caregivers again discussed what worked or did not work in their lives, were queried about their view of the program elements, and completed the same surveys as pre intervention as well as the MSUS. For this analysis, we used data from the MSUS, PSS, and FFMQ.

Smartphone Mobile App

Participants were trained to use the 5Minutes4Myself mobile app to access mindfulness meditations, to create their goal profile, to program goal reminders at preferred times, and to report weekly progress on goals via an electronic check-in. It was loaded onto participants' personal phones, either in Android or iOS format or if needed onto a loaned Android smartphone capable of operating in a wireless environment (no phone service was provided). The audio-recorded meditations were voiced by the licensed psychologist who developed them and ranged in length from 4 - 21 minutes, sequenced to increase in length over time. These began with a brief introduction to mindfulness concepts and were sequenced and available 1 per week; the focus of each meditation rotated through breath awareness, loving-kindness, and body awareness (body scans). Participants were free to choose when and where they listened to the offloaded meditations, available without an internet connection. Participants chose how often they wanted to be reminded of each of their goals: weekly, using a "guilt-free" check-in, participants for each goal included the mindfulness goal. After completing the designated week's meditation, the mobile app advanced to the next week's meditation; participants could revisit past meditations but could not progress to new ones until the following week. This was designed to facilitate ease of use and require no tracking on the users' part. After the first cohort

used the app, we revised the app to address bugs and improve features for following cohorts.

Data Collection, Management, and Analyses

Data gathered via the 5Minutes4Myself app were transferred from a secure third-party server from the application development company to the research team and removed from company servers. The software development personnel who managed the data completed the human participant research training. Caregivers with any missing data on stress or mindfulness measures were excluded from this analysis ($n=4$). Quantitative data were analyzed using statistical software IBM SPSS (version 24.0, IBM Corp). Descriptive statistics including means and SDs were calculated for participant demographics, and for perceived stress and mindfulness practice pre and post intervention. To contextualize the level of stress experienced, participants' perceived stress scores were compared to a population-based mean for the PSS for their age group [29].

To explore mental health outcomes of the feasibility study, related samples t tests (2-tailed) were used to evaluate whether participants' stress scores as a group (PSS) were statistically different after participating in the wellness program. A second related samples t test evaluated scores of mindfulness (FFMQ) before and at the end of the intervention to determine whether they were significantly different for the group. Next, to understand who benefitted from the program, we visualized the trends in these 2 measures from pre and post intervention. Responders were defined as having decreased PSS scores post intervention. In addition, to examine individual level change, an analysis was conducted using Norman and colleagues' [37,38] approach that considers clinically meaningful change as at or above half a SD of the initial group mean. After standard mean differences are calculated ($d = D_i / S_x$ where D_i is individual change, S_x is SD of group at baseline) they are grouped into "improved" ($d \geq 0.50$), "no change" ($-0.5 < d < 0.5$), and "worsened" ($d \leq -0.50$). Lastly, a hierarchical multiple regression was conducted to examine whether the pre-post change in mindfulness (change in FFMQ scores) explained variance in postparticipation perceived stress scores while controlling for preintervention stress levels with an α level of .05.

Ethical Considerations

The study was reviewed and approved by the University of Wisconsin-Madison Educational and Social/Behavioral Institutional Review Board (2015 - 1004). Participants were provided an informed consent form to review, given the opportunity to ask questions, and informed of their ability to opt out at any time. Participants who signed the consent form were invited to participate. In the compiled dataset, participants were assigned numbers; a participant key was created and stored on a password-protected computer. No compensation was provided.

Results

Characteristics of Participants

In total, 15 participants participated in the 5Minutes4Myself wellness program. While not all participants completed all 3 of

the coaching check-ins, program completion was deemed to be participation in the initial focus group or an introductory session, completion of the lifestyle consultation, and at least 2 of 3 monthly coaching sessions. Using this metric, 13 caregivers completed the 4-month 5Minutes4Myself program for a participation rate of 87% (13/15; 2/15, 13% dropout). Further, 2 participants were excluded from the analysis due to incomplete postintervention survey responses, which were due to a family emergency and scheduling conflict with the final focus group. Neither person responded to additional requests to complete the

postintervention surveys. Additionally, 11 participants completed both pre- and postintervention surveys used in this analysis. Sample characteristics and pre- and postintervention survey scores for mindfulness (FFMQ) and stress (PSS) are presented in Table 2. In this convenience sample of participants, most self-identified as White women, were married, reported caregiving full-time, were raising 2 children (one or more with an autism spectrum or other developmental disorder) with graduate school education.

App Quality and Usability

Overall, the mean caregiver rating of the app was 78.6 (range 55 - 100) on the MSUS (>65 is above average usability and >80 is the top 10% of all products tested using the MSUS) [39].

Usability ratings improved from the version used by the first cohort (mean 67.5, SD 22.6) to the second version used by the remaining cohorts (mean 86.2, SD 13.5). Further, 3 of the 11 caregivers rated it below the 65 threshold; all these participants were in the first cohort using the first version of the app. As is

common in app development, several issues led to the app being unavailable at times to all cohorts during their program. Specifically, software updates to the mobile app were performed during the intervention period and required resetting of goal reminders or resulted in limited availability of meditations.

App Usage and Frequency of Meditations

We aimed to support caregivers' adoption of the app-delivered program by providing reminder notifications and coaching support, to encourage meditations at least twice weekly over 4 months' time. Further, 1 participant met these criteria, and another nearly met it, but the remainder meditated twice weekly only 5 or less than 5 weeks' time over the course of the program. On average, they listened for 10.2 (SD 3.8) minutes per week to 20 meditations. Shorter tracks (~5 min in length) were most frequently listened to. The user data suggest that participants, as a group, attempted to listen more often (439 attempts) than they completed podcasts (314 complete or within 30 s of completion), pointing to potential app instability and preference for shorter meditations.

Levels of Stress and Mindfulness

Overview

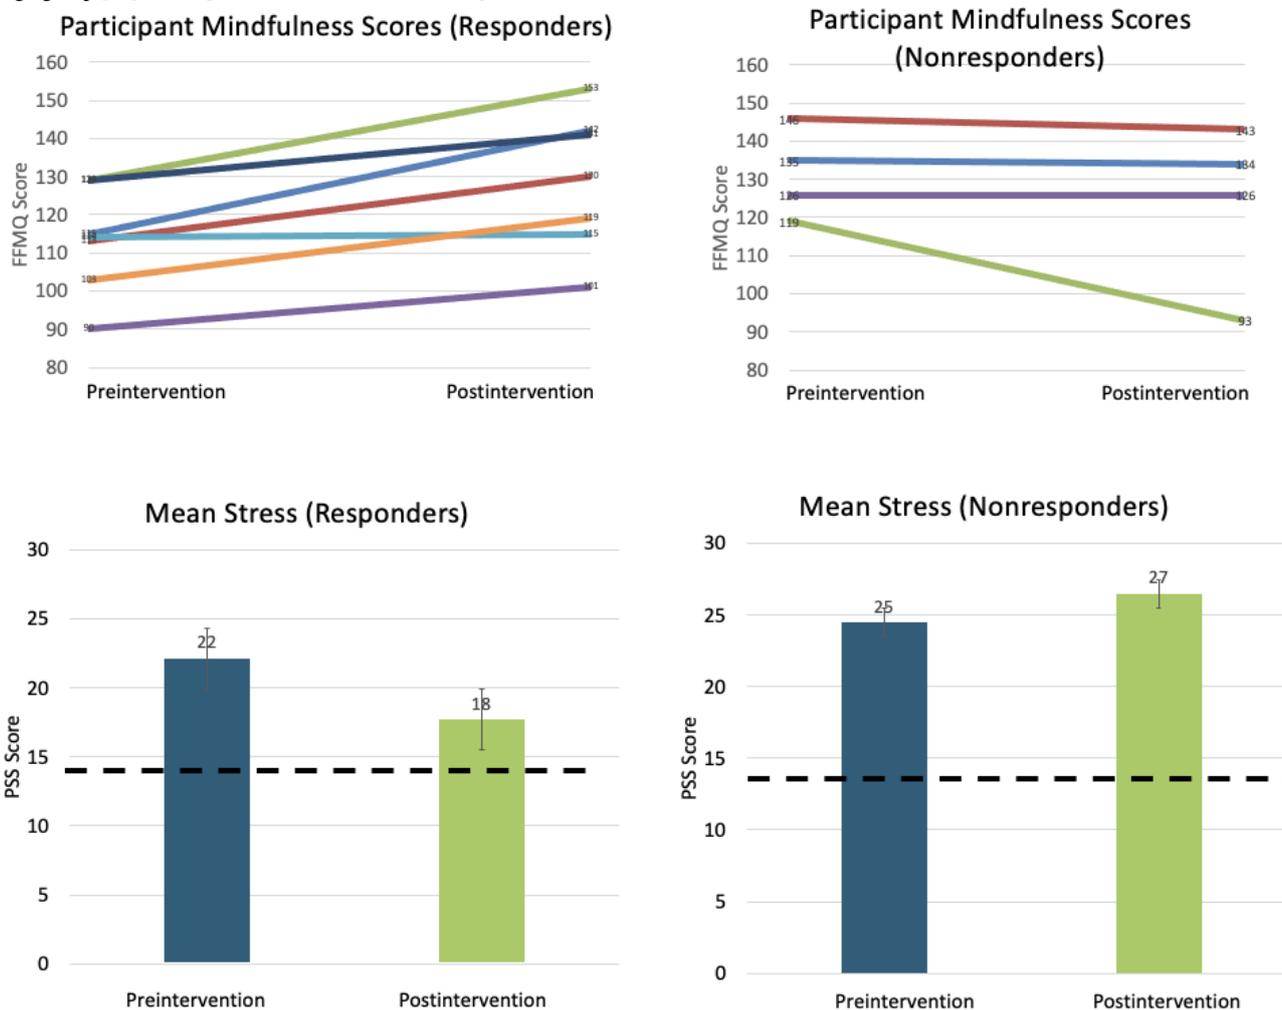

As a group, participants scored 23 (SD 4.45) on the preintervention measure of stress and 21 (SD 8.23) post intervention. As a reference, the normative mean for this age group, based on a Harris Poll of 2387 respondents, was 12.6 (SD 6.1) on the PSS 10 item [30]. Our reported values are

similar to baseline PSS 10 item scores for Bazzano and colleagues' [18] sample of caregivers (n=66, PSS mean 22.6, SD 6.2), and Conner and colleagues' [2] (n=67, PSS mean 20.73, SD 7.03). These PSS scores suggest that overall this was a highly stressed group, and these findings are similar to the level of stress found in other studies of caregivers of children with autism or disabilities. At baseline, 3 of 11 participants were over 2 SDs above the normative population mean; the remaining 7 participants were over 1 SD above the mean for population stress levels on PSS [30]. After completion of the 5Minutes4Myself wellness program, more than half of the participants (6 of 11) were within 1 SD of mean for population stress levels [30].

In terms of mindfulness, the preintervention group mindfulness mean was 119.91 (SD 15.49) and ranged from 90 to 146. Post intervention, the mean FFMQ scores were 127 (SD 17.71) with a similar range of 93 to 153. No population norms are available for the FFMQ for comparison to allow us to reflect on the meaningfulness of the participants' scores.

To assist in visualizing the data, participants were grouped into mindfulness responders and nonresponders. Responders were identified as individuals whose mindfulness scores improved over the intervention period whereas nonresponders' mindfulness scores either stayed the same or decreased. Figure 2 displays the individual mindfulness scores (FFMQ) at pre and post intervention and mean stress scores (PSS) for these 2 groups. The small error bars suggest the 2 groups of caregivers are similar to each other in terms of stress.

Figure 2. This figure groups scores into responders and nonresponders based on their mindfulness score (FFMQ). Responders' mindfulness scores on the FFMQ increased from pre intervention to post intervention, as hypothesized for 7 participants. Nonresponders' mindfulness scores decreased from pre intervention to post intervention for 4 participants. Each line represents 1 participant's mindfulness score (FFMQ) from pre intervention to post intervention. Corresponding group mean stress (PSS) scores are displayed below. The dotted line indicates a population-based mean for the PSS for this age group [29]. FFMQ: Five Facet of Mindfulness Questionnaire; PSS: Perceived Stress Scale.

In terms of individual change in the PSS, individual change calculations ranged from -1.57 to 2.02 (reverse coded so that positive numbers indicated reduced stress). When grouped according to Norman and colleagues' [38] guidelines, 4 participants experienced worse stress and 7 had reduced stress post participation. This affirms the responder visualization of the data.

Changes in Stress and Mindfulness Pre and Post Intervention

A related samples *t* test evaluated whether participants' PSS mean stress scores were significantly different before and after participating in the wellness program. Preliminary analyses of normality, random selection, and homogeneity of variances were conducted and ensured no assumptions were violated. The group PSS postintervention mean was not statistically and significantly different than the preintervention group mean ($t_{10}=1.20, P=.26$). The effect size *d* of 0.36 indicates a small to medium effect size. Given the small sample used for this feasibility study, these findings do not clearly indicate whether this change in PSS score was a meaningful difference for all or some of our participants [40].

For mindfulness, a related samples *t* test evaluated whether participants' FFMQ scores differed following participation in the program. The group mean FFMQ was not significantly different following participation in the program ($t_{10}=-1.57, P=.15$). However, in this case, the effect size was larger ($d=0.47$), suggesting that a treatment effect might be evident with a larger sample size.

Postintervention Stress as Predicted by Change in Mindfulness

Given that 1 effect size suggested some potential treatment effect and the trends noted in responders, a hierarchical multiple regression was used to assess the central question of how change in mindfulness (FFMQ) predicted levels of stress post intervention (PSS), after controlling for preintervention stress levels. Preliminary analyses were conducted and ensured all assumptions of multiple regression were met including linear relationship between variables, normal distribution of residuals, an independent sample, no multicollinearity, and homoscedasticity, despite the small sample size ($n=11$). The results of this regression are provided in Table 3. These results suggest that 20% of the variance in stress, beyond the 50% of

variance accounted for by prestress levels, can be attributed to pre-post changes in the FFMQ (or increases in mindfulness; $P=.04$). Therefore, change in the FFMQ was a significant

predictor of postintervention stress levels for these caregivers of children with ASDs.

Discussion

Principal Results

This study examined the usability and usage of an app designed to deliver mindfulness meditations and the effects of the mindfulness training on stress experienced by caregivers of children with ASD. The mobile app, as designed and then revised, was found to be above average in usability, especially the second version. Although caregivers did not use the mindfulness meditations as frequently as intended, they did use them on average for 10 minutes per week, a microdose compared to other mindfulness programs for caregivers.

While group differences in pre- and poststress and mindfulness scores were not significant in this analysis, 1 effect size offered tentative support for the impact of the 5Minutes4Myself program on mindfulness. As Cohen [41] suggests, statistical significance and calculations of effect size are useful only in so far as they can be used to interpret the meaningfulness of the score change to the participant [39]. This seems to be supported by the individual level analysis, where 7 of 11 caregivers showed improvement or decreased stress post participation. In addition, this study linked increased mindfulness to a reduction in stress; increases in mindfulness accounted for 20% of the individual variance in postintervention stress scores.

Limitations

The pre- or postintervention group changes in stress and mindfulness were statistically insignificant. While the individual change analysis did show benefits for some caregivers, this analysis does not identify if any specific characteristics indicate who might be more likely to benefit from the program. Further, the analysis relied on a small sample ($n=11$). Future analyses of larger samples may help us to better understand the effects of this wellness program on stress and the contribution of the mobile-mindfulness component.

While these preliminary findings support the use of a mobile app in the 5Minutes4Myself wellness program, the developing technology was a significant barrier for some caregivers.

Complications with application were a limitation of this study and accounted for lost postsurvey data for 2 participants.

We also did not conduct follow-up measures for this feasibility study. Long-term follow-up measures are needed to examine benefits of participation in the 5Minutes4Myself wellness program within the first- and second-year post participation. Further exploration of the 5Minutes4Myself wellness program will offer greater insight into how to best serve caregivers of children with ASD to support stress reduction and positive well-being outcomes.

Comparison With Prior Work

When compared to other studies, our caregivers showed similar percentages in reduction of stress (9% mean decrease) and increase in mindfulness (10% increase) as studies assessing larger populations of caregivers who reported statistically significant findings. For example, 2 traditional and more time-intensive MBSR programs found that caregivers' increased mindfulness was associated with a 7.4% reduction in self-rated perceived stress [19] and that parents and teachers of children with special needs had a 10% increase in mindfulness (as calculated from reported data) and an 8% reduction in stress [18].

Given that increases in mindfulness accounted for 20% of the individual variance in postintervention stress scores, this highlights the importance of mindfulness, be it a small dose, in diminishing stress. Benn and colleagues' [19] work corroborated that increased mindfulness was key to stress reduction. Using the same stress and mindfulness measures as in our study to assess outcomes of an 8-week MBSR-style training program for parents of children with special needs, Benn and colleagues [19] conducted a mediations analysis. Their analysis identified increased mindfulness as the mediator for positive changes in health and well-being outcomes.

Consistent with previous research that used much larger "doses" of mindfulness, such as those provided in MBSR-based programs [1,12,19], the results of this analysis suggest that a micromindfulness approach is a viable intervention for stress reduction for caregivers of children with ASD. Carmody and

Baer's [42] analysis seems to confirm that shorter mindfulness practices are indeed viable alternatives to the time-intensive MBSR programs. They found that in-class hours and treatment effect sizes were not significantly related for their population, suggesting low-dose practices, such as what we used in this program, can be an effective alternative for time-challenged individuals. Lunsy and colleagues [43] also noted that while most of the parents of children with ASD in their study attended only 4 of 6 sessions and reported brief and irregular home practice, these parents still derived psychological benefit with less distress post intervention compared to a control group. Berghoff and colleagues [44] examined dose for college students assigned to either 10- or 20-minute practices of mindfulness for 14 days; they found that significant reductions in stress were independent of the actual time practiced. The total dose for most students was only an hour over 2 weeks. While our caregivers did not listen as often as proposed, using a mobile app for this population appeared to be a feasible delivery system for brief mindfulness training and shorter meditations were more practical for this group. Our approach offered caregivers the flexibility to choose when and where they listened to brief (4 - 21 min) mindfulness podcasts while having regular guided practices such as class sessions.

Use of a mobile-delivery system for mindfulness practice opens the opportunity for an intervention that is client-centered and can be more readily incorporated into a participant's daily routine. Hollis and colleagues [45] suggest that mobile apps have the potential to transform service provision to clients by providing content, monitoring, and access to providers. Yet, findings from a large-scale study using a newly developed mindfulness application (VGZ Mindfulness Coach; VGZ Health Insurer N.V) appear to suggest flexible provision of easily accessible mindfulness content is not sufficient to encourage participation; only 58% of their participants used the application [46]. Engaging clients and clinicians to collaboratively design to meet unmet needs and to assure the usability of the technology is essential to not only develop strongly evidence-based

interventions but also assure their adoption by the targeted population [45,47,48].

Most mental health programs for caregivers of children with autism have been delivered solely in person, which may partially account for the high attrition rates ranging from 17% - 45% [49]. We choose to use an app to deliver content to increase the accessibility of this program for caregivers and decrease attrition, which in our small sample was 13%. Preliminary data suggest this mindfulness training provided stress reduction for some of the participating caregivers. In line with Latulippe and colleagues' [23] findings, we found that in designing an eHealth option for caregivers we needed to attend to user characteristics including (1) limits in financial and personal resources, (2) available access to internet, and (3) users' comfort in using and managing technology. In addition, for our app it was important to attend to caregivers' reported reduced problem-solving capacities which were likely due to the ongoing stress and the vigilance of caregiving. Using a collaborative participant-centered approach to app design helped ensure we created a highly usable application that was confirmed via caregiver ratings of above-average usability on the MSUS [10,27,39].

Conclusions

To our knowledge, this program is the first of its kind to use a mobile app to deliver a wellness program, that included mindfulness meditations, to caregivers of children with autism. The unique contribution of this wellness program, beyond these initial promising findings of increasing mindfulness and reducing stress, is its intentional design to easily fit into caregivers' challenging and time-demanding daily lives. The 5Minutes4Myself app can be used at anytime and anywhere without the need for traditional in-person mindfulness training. As this study suggests, use of the mobile-mindfulness component may be a feasible intervention for caregivers that allows them to participate in an evidence-based intervention for stress reduction at a time and place that is convenient and possible within their everyday lives.

Abstract

Background: Generative artificial intelligence has the potential to revolutionize health technology product development by improving coding quality, efficiency, documentation, quality assessment and review, and troubleshooting.

Objective: This paper explores the application of a commercially available generative artificial intelligence tool (ChatGPT) to the development of a digital health behavior change intervention designed to support patient engagement in a commercial digital diabetes prevention program.

Methods: We examined the capacity, advantages, and limitations of ChatGPT to support digital product idea conceptualization, intervention content development, and the software engineering process, including software requirement generation, software design, and code production. In total, 11 evaluators, each with at least 10 years of experience in fields of study ranging from medicine and implementation science to computer science, participated in the output review process (ChatGPT vs human-generated output). All had familiarity or prior exposure to the original personalized automatic messaging system intervention. The evaluators rated the ChatGPT-produced outputs in terms of understandability, usability, novelty, relevance, completeness, and efficiency.

Results: Most metrics received positive scores. We identified that ChatGPT can (1) support developers to achieve high-quality products faster and (2) facilitate nontechnical communication and system understanding between technical and nontechnical team members around the development goal of rapid and easy-to-build computational solutions for medical technologies.

Conclusions: ChatGPT can serve as a usable facilitator for researchers engaging in the software development life cycle, from product conceptualization to feature identification and user story development to code generation.

Trial Registration: ClinicalTrials.gov NCT04049500; <https://clinicaltrials.gov/ct2/show/NCT04049500>

Introduction

Health care has undergone a digital transformation, resulting in a growing reliance on software engineering for medical use cases, including health care research. However, little guidance

exists for health researchers on how to effectively develop digital health interventions [1]; in particular, software development challenges that include expertise gaps in coding, custom development needs, high costs, and time constraints result in

multilevel barriers to designing and deploying a usable, scalable, and sustainable digital health product [1].

Generative artificial intelligence (GenAI) technologies such as ChatGPT can potentially support researchers in health technology endeavors by providing foundational frameworks and processes for the software development life cycle [2]. These systems can help reduce time and enhance precision for technology-based research projects by supporting both nonprogrammers and experienced programmers in code development, troubleshooting, and cleaning [2]. Moreover, the ability to use GenAI to generate content from different perspectives (expert or nonexpert) can facilitate and improve communication between technical and nontechnical team members of multidisciplinary teams. For example, a nontechnical team member can write their ideas in natural text and then use GenAI to request assistance in creating discussion points to communicate to a technical team audience. GenAI tools may also help health technology researchers refine research questions, identify appropriate theoretical frameworks and models, and leverage popular implementation strategies such as design thinking to build effective, theory-grounded, and evidence-based digital health interventions. ChatGPT (OpenAI, Microsoft Corporation) has already demonstrated feasibility as a support tool for clinical decision support development in health care [3], and more broadly as a coding copilot in programming and engineering [4,5].

This study explores the use of ChatGPT to recreate a personalized automatic messaging system (PAMS), which was developed as part of a digital health research initiative to support patient engagement with a commercial digital diabetes prevention program (dDPP). We examine the capacity, advantages, and limitations of ChatGPT to support product ideation and conceptualization, intervention content development, and the software engineering process including software requirement generation, software design, and code production. This paper provides insights to support the GenAI-assisted development of computational tools that are usable, reliable, extensible, and in line with the standards of modern coding practices. The framework includes prompts for both the intervention conceptualization as well as the main phases of the software development process.

Methods

Settings and Intervention Development Context

In previous work [6], we described the development of PAMS, a novel integrated multicomponent communications platform, to promote patient-provider communication and patient engagement in a commercial dDPP (Noom; Noom, Inc). The PAMS intervention included early prototyping and user testing, a technical development phase, and a randomized controlled trial. The core content and user experience features of PAMS were identified, prototyped, and evaluated using the well-established design thinking “discover, define, design, and test” approach to iteratively gather information, define, design, and refine the engagement intervention [7]. Stakeholders included: patients with prediabetes and their support network (eg, caregivers and partners), primary care providers, health

technologists, programmers and computer scientists, behavioral change theorists and subject matter experts, the research administrative team, and dDPP product developers and coaches. The main components of this PAMS intervention include (1) a theory-driven behavior change messaging library, (2) a personalized automated message system delivery platform (SMS text messaging-based), and (3) EHR-integrated data visualizations. The PAMS messaging library uses an integrated framework that combines established theoretical models for behavior change with human-centered design strategies to maximize the evidence-based conditions for behavior change and the user acceptance and use of a digital health product. The technical development of PAMS followed an agile software development approach based on incremental 2-week sprint cycles consisting of requirement planning, design, development, and testing of a specific set of functional features. In this paper, we will recreate this development process using GenAI (ChatGPT).

ChatGPT-PAMS Experiment Design

To evaluate the effectiveness of using GenAI to support the development of digital tools in medical settings, our experiment is based on recreating PAMS using GenAI (ChatGPT) and evaluating human-generated vs ChatGPT-generated documentation. To accurately capture the ideation and development process, our multidisciplinary team reviewed all documentation and processes used in the early stages of PAMS conceptualization, including supporting theoretical models, content and features, and technical development. We then recreated these processes via a series of prompts for ChatGPT-4 to assist with the generation of theory, content, user stories, requirement documents, design diagrams, and the code for a subset of the requirements. Outputs from ChatGPT were reviewed and compared to human-generated documentation by 11 evaluating team members. Evaluators consisted of clinicians, behavioral scientists, programmers, and research staff working in digital health and technology for behavior change research. Collectively, they represent more than 50 years of clinical, research, design, and computer science experience. The evaluators independently rated the quality of various aspects of information provided by ChatGPT on a Likert scale, where higher ratings indicated greater quality of information (1: *very poor*; 2: *poor*; 3: *acceptable*; 4: *good*; 5: *very good*; N/A: *not applicable*). Aspects of evaluation included: understandability (Does this output make sense given the context of the study and prompts?), novelty (Were new ideas generated?) [3], usability (Does this create a usable output?), relevance (Does this create a useful output?), efficiency (Would having these outputs have saved time?), and potential for bias (What unintended consequences might arise from these outputs?) [6]. Evaluators were also asked to give an overall score on the quality of the ChatGPT output (Overall, how good would you say this output is?). Post review, a group debrief was conducted, using a semistructured interview guide to facilitate discussion regarding perceptions of outputs and rationale for ratings.

Ethical Considerations

Ethical considerations helped guide the initial development of research methods and reduce potential risks for participants in

the original study implementation with the PAMS intervention [7]. Recreating the technical development of a system previously built as part of the dDPP randomized controlled trial (NCT04049500) has not introduced any new risks to patients. Patients were not involved in this research examining the use of GenAI in the development of digital health care solutions. No patient data was used in the prompt generation phase.

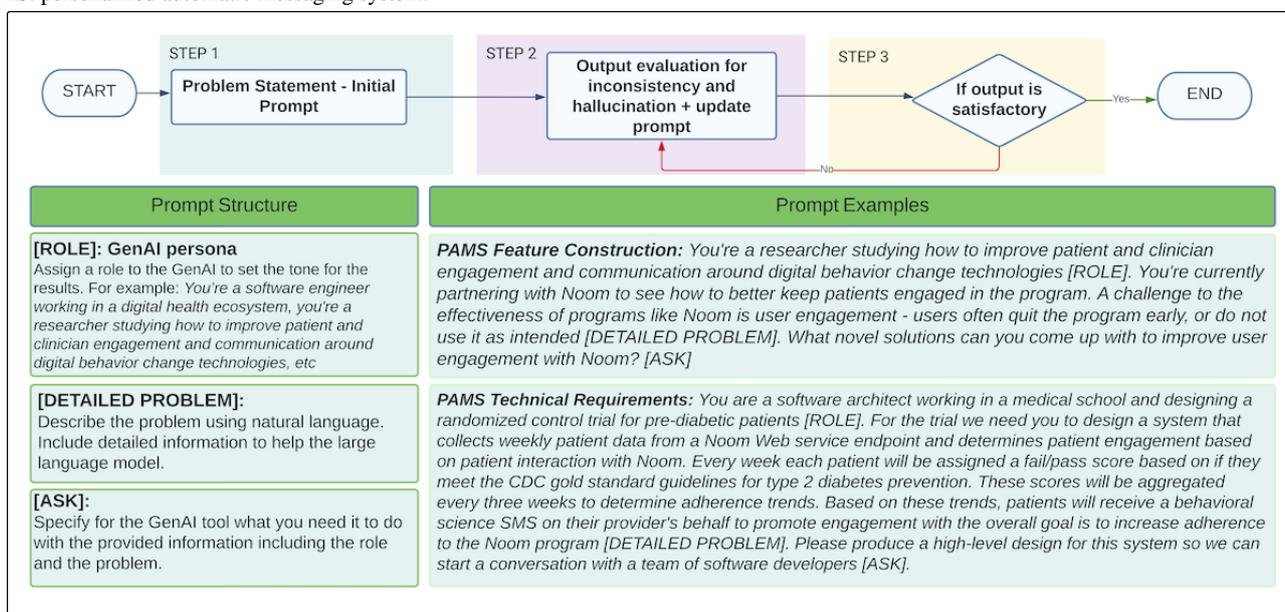

Regarding ethical considerations for the methods used in this paper, as an attempt to mitigate evaluator biases, we worked with a diverse team of evaluators who were aware of the initial study but were not necessarily involved in the technical development. Additionally, we understand the limitations and concerns of the use of ChatGPT including possible hallucinations and incorrect answers. Thus, we emphasize the

need for human expertise to identify correct and incorrect outputs and have flagged this as a study consideration. When developing the GenAI-based solution, we used the same considerations for data security, patient usability, accessibility, and data privacy used in the original human-developed solution.

Prompt Generation Framework

Prompt engineering focuses on the skill of designing and creating effective prompts that guide ChatGPT to produce the best possible output for your task. We followed existing literature [8-11] combined with our expertise and experimentation to provide a framework that yields the best result when developing a digital solution like PAMS (Figure 1).

Figure 1. ChatGPT prompt structure and prompt examples. CDC: Centers for Disease Control and Prevention; GenAI: generative artificial intelligence; PAMS: personalized automatic messaging system.

Results

PAMS Concept and User Experience Generation

Overview

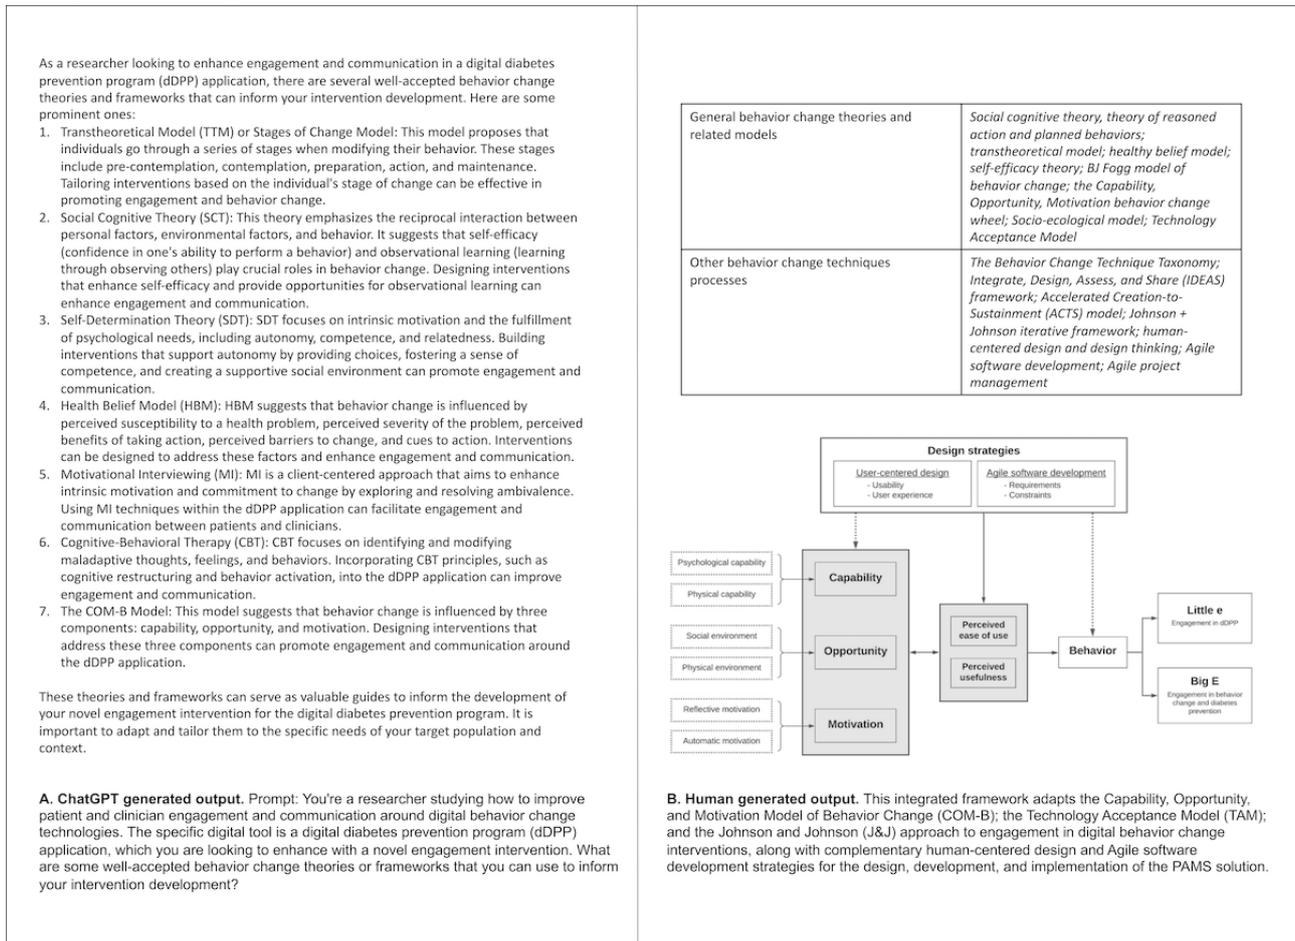

Core components of the PAMS intervention were conceptualized and designed via an underlying behavior change theory, design principles and personas, and a message content library.

Underpinning Behavior Change Theory and Approach

Human-Generated Solution

Leveraging behavior change literature review and interviews with behavior change theory content experts (n=4), the research team initially identified ten unique behavior change theories and six process models that were considered to be an appropriate fit for the aims of the overall intervention. A unique model was developed that captured (1) the relevant underlying behavior change theory, (2) implementation strategies, and (3) unique contexts of the technology environment (Figure 2A).

Figure 2. Underpinning behavior change theory and approach outcome of ChatGPT vs human-generated output. ACTS: Accelerated Creation to Sustainment; BJ: Brian Jeffrey; CBT: cognitive behavioral therapy; COM-B: capability, opportunity, and motivation model of behavior change; dDPP: digital diabetes prevention program; HBM: health belief model; IDEAS: Integrate, Design, Assess, and Share; J&J: Johnson and Johnson; MI: motivational interviewing; SCT: social cognitive theory; SDT: self-determination theory; TTM: transtheoretical model.

GenAI Solution

When prompted, ChatGPT identified seven relevant well-accepted behavior change theories and frameworks to inform a “dDPP support intervention” (Figure 2B). It did not provide information on the transtheoretical domains framework, or the taxonomy of behavior change techniques, but when prompted on these, identified both as acceptable strategies for use.

User Experience: Design Principles, Personas, and Messaging Content

Human-Generated Solution

The research team used a human-centered design approach to identify key design principles, defined as the set of considerations that form the basis of the PAMS product (Figure

3B). These were developed from insights gathered via a review of relevant digital behavior change research, consultation with content and theoretical experts in digital health and implementation science (n=3), and two group interviews (n=9). From these insights, five relevant fictional personas were designed to capture the various phenotypes of user engagement with the commercial dDPP, along with unique user journeys developed to describe their projected engagement with the program over time (Figure 3D). Overall, over 193 unique messages were developed, each grounded by a relevant behavior change technique and tailored to an individual phenotype's user journey. These elements were continuously revisited and refined during the testing phases of the dDPP research. This included a 6-month near-live user testing phase consisting of nine patients engaging with various iterations of the PAMS prototype, and a 12-month live single-arm pilot phase consisting of 25 patients using PAMS-beta with the commercial dDPP platform.

Figure 3. User experience: design principles, personas, and messaging content outcome of ChatGPT vs human-generated output. dDPP: digital diabetes prevention program; EHR: electronic health record.

<p>When developing a text messaging support system to enhance patient engagement in a digital diabetes prevention program like Noom, it's important to consider key design principles rooted in behavior change theory. Here are some principles to keep in mind:</p> <ol style="list-style-type: none"> 1. Personalization: Tailor messages to each individual's characteristics, preferences, and progress within the dDPP. Personalization can enhance relevance and increase the likelihood of message resonance and engagement. 2. Behavioral Goal Orientation: Align messages with specific behavioral goals and objectives of the dDPP. Messages should focus on promoting positive behaviors, reinforcing progress, and addressing barriers or challenges that hinder engagement or adoption. 3. Simplicity and Clarity: Keep messages concise, clear, and easy to understand. Use plain language and avoid jargon or complex terminology to ensure that messages are easily comprehensible and actionable. 4. Timing and Frequency: Deliver messages at appropriate intervals and timings that align with the individual's program schedule and preferences. Avoid overwhelming users with excessive message frequency, and consider timing messages to coincide with relevant program milestones or triggers. 5. Positive Reinforcement: Incorporate positive reinforcement techniques by highlighting achievements, progress, and successful behaviors. Positive messages can boost motivation, self-efficacy, and continued engagement with the dDPP. 6. Emotional Support: Recognize the emotional aspect of behavior change and provide supportive messages that acknowledge the challenges and offer encouragement. Empathetic and empathic messages can foster a sense of connection, understanding, and resilience. 7. Actionable Content: Include specific action-oriented content in the messages that guide users towards behavior change. Provide practical tips, suggestions, or step-by-step instructions that help users translate information into action. 8. Interactive Features: Integrate interactive elements within the messaging system to enhance engagement and interactivity. This can include options for users to respond to messages, set goals, or request additional support as needed. 9. Behavioral Triggers: Utilize behavioral triggers, such as reminders, prompts, or cues, to nudge users towards desired behaviors. These triggers can help individuals remember to engage with the dDPP and maintain their commitment to behavior change. 10. Iterative Improvement: Continuously monitor the impact of the text messaging intervention and gather user feedback to refine and improve the messages over time. Iterative evaluation and adaptation based on user insights can enhance the effectiveness and relevance of the intervention. <p>By incorporating these design principles into the text messaging support system, you can create an intervention that is effective, engaging, and supportive, ultimately promoting sustained engagement and improved outcomes within the Noom dDPP.</p> <p>A. ChatGPT generated output. Prompt: You are a healthcare researcher with expertise in behavior change theory. You are developing a novel text messaging support system that sends personalized, automated messages to patients who use the digital diabetes prevention program (dDPP) Noom. These messages are meant to keep people engaged in the Noom program and address pain points of poor engagement, non-adoption, and abandonment of dDPP. What are some key design principles that your team should keep in mind when developing this intervention?</p>	<table border="1" data-bbox="917 488 1412 631"> <tr> <td data-bbox="917 488 1109 631">Key design principles and potential solutions</td> <td data-bbox="1109 488 1412 631">Personalization, personalized messaging; just-in-time delivery; theory supported, evidence-based; positive framing ("carrot" over "stick"); multi-channel and/or universally accepted communication channel (eg. SMS); limited two-way interactivity (no chat-bots); enhancing patient-provider connection; largely automated/minimal burden on clinicians; EHR integrated; scalable for operational use across health system</td> </tr> </table> <p>B. <p>Certainly! Here are personas of different types of digital diabetes prevention program (dDPP) users, describing their individual journeys and experiences using dDPP:</p> <ol style="list-style-type: none"> 1. Active and Consistent User - Emily: Background: Emily is a 40-year-old working professional with a family history of diabetes. She is highly motivated to prevent diabetes and has embraced dDPP as a part of her proactive approach to health. Journey and Experience: Emily actively engages with dDPP on a daily basis. She diligently tracks her meals, physical activity, and progress towards her goals. She finds inspiration and support from the dDPP community, actively participating in discussions and sharing her success stories. The personalized messages and expert guidance keep her motivated and focused. Emily's consistent engagement with dDPP has resulted in positive lifestyle changes and steady progress towards reducing her diabetes risk. 2. Passive Observer/Limited Engager - Mark: Background: Mark, a 55-year-old individual, was recommended dDPP by his healthcare provider due to pre-diabetes. However, he has been struggling to find the time and motivation to actively engage with the program. Journey and Experience: Mark occasionally logs into dDPP to check his progress and explore resources. However, due to his busy schedule, he finds it challenging to dedicate consistent time to the program. Mark is aware of the benefits but has yet to fully tap into the interactive features and community support available. The personalized messages from the program serve as gentle reminders to re-engage and make the most of dDPP. 3. Goal-Oriented User/Trial User - Sarah: Background: Sarah, a 30-year-old individual, recently joined dDPP with a specific goal in mind - to lose weight and improve her overall health. Journey and Experience: Sarah actively engages with dDPP for a defined duration to achieve her goals. She utilizes the program's tracking tools, explores healthy recipes, and follows the personalized meal plans. Sarah finds the support of the program valuable, especially during challenging times. Once she achieves her weight loss and health goals, Sarah transitions out of dDPP, continuing her health journey independently. 4. Low Engager - John: Background: John, a 50-year-old individual, initially embraced dDPP with enthusiasm but gradually found it challenging to maintain consistent engagement due to personal and professional commitments. Journey and Experience: John's engagement with dDPP has been sporadic. He occasionally tracks his meals and engages with the program's resources when time permits. However, he struggles to establish a routine and tap into the full potential of the program. John receives gentle reminders and encouragement from the program to increase his engagement and harness the benefits of consistent usage. 5. Non-Adopter - Lisa: Background: Lisa, a 45-year-old individual, has been recommended dDPP by her healthcare provider, but she has yet to fully embrace the program. Journey and Experience: Lisa has not actively adopted dDPP due to reservations, skepticism, or lack of awareness about its potential benefits. Despite receiving messages and information about the program, she hesitates to take the initial step and fully engage. Lisa requires targeted support and education to understand the program's value and gain confidence in its ability to improve her health. <p>These personas represent different types of dDPP users, each with their unique journeys and experiences. Understanding these personas can help tailor interventions and support strategies to better meet the diverse needs and engagement levels of individuals using the dDPP.</p> <p>C. ChatGPT generated output. Prompt: Referring to the above prompt and responses: "What are the different engagement "phenotypes" of digital health tool users?" - create personas of different types of digital diabetes prevention program (dDPP) users that describe their individual journeys and experiences using dDPP.</p>	<table border="1" data-bbox="925 967 1401 1556"> <tr> <td data-bbox="925 967 1161 1093">Persona 1: the non-starter</td> <td data-bbox="1161 967 1401 1093">James is a 50 year old man with risk factors for diabetes. GenAI Solution

ChatGPT was prompted from multiple perspectives (researcher, clinician, and patient) to identify key design principles (Figure 3A) and sample solutions for the PAMS intervention. It also provided common engagement phenotypes for digital health tool users, based on patterns of use, frequency, duration, and "other elements." Of note, nonadopters were not identified within the initial round of phenotypes. ChatGPT also developed

personas for each of the identified engagement phenotypes, including persona names, backgrounds, and individual journeys. ChatGPT was able to produce five to ten unique messages targeted toward each phenotype and to adapt these messages based on various additional prompts. The user types or personas generated by ChatGPT are consistent with the human-generated users and cover all the phenotypes identified in our previous research (eg, mapping to a specific behavior change technique and reflecting a key design principle; Figure 3C).

PAMS Technical Development

Overview

The technical development includes a PAMS requirements document and architectural design and code.

Technical Requirements (User Stories)

Human-Generated Solution

Following the data collection and intervention design period, we created, as a team, a series of user stories ([Figure 4B](#)) which

were followed by system requirements to describe the intended use cases, features, and challenges of the proposed PAMS software. Initial system requirements represent the “minimum viable product” that was developed, piloted, and further refined ([Figure 4D](#)). Our development team followed software engineering principles to generate the requirements document.

Figure 4. User stories and technical requirements outcome of ChatGPT vs human-generated outputs. API: application programming interface; CDC: Centers for Disease Control and Prevention; EHR: electronic health record; PAMS: personalized automatic messaging system; REDCap: Research Electronic Data Capture; UX: user interface.

<p>1. As a patient, I want to be enrolled in the Noom app and provided with a Fitbit and a smart scale so that I can participate in the randomized control trial and track my progress towards preventing type 2 diabetes.</p> <p>2. As a patient, I want my data to be collected from the Noom web service endpoint on a weekly basis so that my engagement with the Noom program can be evaluated.</p> <p>3. As a patient, I want to receive a fail/pass score every week based on my adherence to the CDC gold standard guidelines for type 2 diabetes prevention so that I can track my progress and adjust my behavior accordingly.</p> <p>4. As a patient, I want to receive a personalized behavioral science SMS every three weeks based on my adherence trends to the Noom program so that I can receive suggestions for improving my engagement and preventing the onset of type 2 diabetes.</p> <p>5. As a healthcare provider, I want to be able to access reports and analytics based on patient data so that I can monitor patient engagement and adherence to the Noom program.</p> <p>6. As a researcher, I want to be able to access patient data to analyze the effectiveness of the program and draw conclusions about its efficacy in preventing type 2 diabetes.</p> <p>7. As a system administrator, I want to ensure that patient data is stored securely in a database and is compliant with data protection regulations to maintain patient privacy and confidentiality.</p> <p>A. ChatGPT generated output. Prompt: You are a software engineer working in a medical school and designing a system to support a randomized control trial for pre-diabetic patients aimed to increase patient adherence to the digital prescription, NOOM. In the trial, patients are consented and enrolled in the Noom app. Additionally, they are provided with a Fitbit and a smart scale to support data collection. You need you to design a system that weekly collects patient data from a Noom Web service endpoint and runs an internal algorithm based on gold standard use to determine patient engagement based on patient interaction with Noom. Every week each patient will be assigned a fail/pass score based on if they meet the CDC gold standard guidelines for type 2 diabetes prevention. These scores will be aggregated every three weeks to determine adherence trends. Based on these trends, patients will receive a behavioral science SMS on their provider's behalf to promote engagement with the overall goal to increase adherence to the Noom program. Please produce user stories for this system so we can start a conversation with a team of software developers</p> <p>Prompt for refined version below; Please refine these user stories considering that the roles are patient, provider, and research team. The role of the research team is to keep monitoring the progress if the project and get access to data such as messages going out and in , and patients data to update decisions.</p>	<p><i>As a dDPP user/patient...</i></p> <p>I want easy ways to access Noom I want Noom to utilize my existing technology preferences (eg. smartphone, tablet, email) I want to be motivated to use Noom regularly I want to know how I am doing in Noom/get regular feedback on how I'm doing in Noom I want to be able to connect with others using Noom/compare myself to others I want my doctor to know how I am doing in Noom I want to see the ongoing benefits of Noom to my health I want tailored support while I use Noom I want to be able to connect my existing health devices to Noom I do not want Noom to make me feel bad about myself I want support that is positive and encouraging</p> <p><i>As a primary care doctor...</i></p> <p>I want to know what digital health tools my patients are using I want to have easy access to Noom patient data that does not interfere with my current workflows I want my patients Noom data to be integrated into my existing EHR data I want to be able to make informed decisions based on my patients Noom data I want to be able to educate my patients on their health based on Noom I do not want Noom to negatively impact my workflows</p> <p><i>As a dDPP researcher...</i></p> <p>I want to be able to identify eligible patients I want to be able to contact eligible patients using existing technology (eg MyChart) I want to be able to track our patients Noom use I want to be able to have detailed patient engagement data from NOOM I want to remind patients to fill out necessary surveys and onboarding. I want to know (if) the participants have filled out the relevant study surveys, so I can nudge them if they haven't</p> <p>B. Human generated output.</p>
<p>Functional Requirements</p> <p>Retrieve Data Points</p> <ul style="list-style-type: none"> The system shall fetch the following data points from Noom's API: Physical Activity data, including exercise time and steps, Weigh-ins data, Articles read data, Social Activity data, including messages sent to coaches and group posts. The system shall ensure that the fetched data is properly structured and accessible for further processing. <p>Calculate Compound Metrics</p> <ul style="list-style-type: none"> The system shall combine the "patient daily exercise time" and "daily steps taken" data points into a single metric representing Physical Activity. The system shall combine the "messages sent to Noom coaches" and "group posts to Noom's user boards" data points into a single metric representing Social Activity. <p>Determine Weekly Adherence</p> <ul style="list-style-type: none"> The system shall calculate adherence for each week based on the following thresholds: For Physical Activity: Check if the total exercise time for the week is at least 1500 minutes or the total steps taken meet the recommended goal. For weigh-ins: Check if there is at least one weigh-in recorded for the week. For articles read: Check if there is at least one article read during the week. For Social Activity: Check if there is at least one message sent to a coach or one group post made during the week. <p>Determine Three-Week Adherence</p> <ul style="list-style-type: none"> The system shall analyze the weekly adherence data over the past three weeks to evaluate the overall engagement. The system shall calculate the percentage of weeks in which the patient met the adherence criteria for each behavior metric. The system shall determine if the patient has met the engagement criteria for each behavior metric over the three-week period. <p>Generate Nudges</p> <ul style="list-style-type: none"> Based on the calculated adherence for the past three weeks, the system shall categorize the patient's engagement level as "Passing" or "Not Passing." The system shall prepare nudge messages tailored to the patient's engagement level over the past three weeks. The nudge messages shall include personalized nudges related to each behavior metric based on the patient's performance. <p>Schedule Nudge Delivery</p> <ul style="list-style-type: none"> The system shall determine the timing for sending the nudges, following the requirement of sending messages once every three weeks. The system shall set up a scheduled task or job to send the nudges to the patient's mobile phone number via SMS. <p>Monitoring and Evaluation</p> <ul style="list-style-type: none"> The system shall continuously monitor and evaluate the effectiveness of the nudges in promoting patient engagement. The system shall collect and analyze data on patient responses, engagement levels, and behavior change outcomes. Based on user feedback and observed outcomes, the system shall iterate on the algorithm and nudge content to improve effectiveness. <p>Non-Functional Requirements</p> <p>Performance</p> <ul style="list-style-type: none"> The system shall fetch and process data from Noom's API in a timely manner to ensure real-time nudges generation. The nudges delivery task or job shall be scheduled and executed efficiently without delays. <p>Reliability</p> <ul style="list-style-type: none"> The system shall be robust and resilient, handling potential errors or exceptions during data retrieval, processing, and nudges delivery. The nudges delivery mechanism shall have fail-safe measures to ensure message delivery even in case <p>C. ChatGPT generated output. Prompt: Thanks for this. As a software engineer, give me a well-structured requirements document using the user stories you have already generated in the previous iteration.</p>	<p>The system should be able to connect to the Noom API for seamless data transfer.</p> <p>The system shall be able to store Noom data into internal data bases</p> <p>The system should be able to calculate a weekly adherence score using individual noom patient's data.</p> <p>The system shall be able to calculate "trends" using 3 weeks of data.</p> <p>The system shall be able to classify patients using calculated trends.</p> <p>The system should be able to comment to the twilio API for messaging functionality</p> <p>The system should be able to send messages to patients based on the adherence score</p> <p>The system shall be able to automatically trigger the message functionality</p> <p>The system shall be able to send messages on patient's individual dates such as [3 weeks into the study, birthday, etc]</p> <p>The system shall be able to send reminders for messages to fill surveys and discuss dDPP study during doctors' visits.</p> <p>The system shall be able to reply to patient messages</p> <p>The system shall be able to collect and store message replies in internal databases.</p> <p>The system should be able to connect to the REDCAP API for secure data transfer and storage</p> <p>The system shall be able to connect with the EHR (EPIC)</p> <p>The system shall be able to display the provider UX in EPIC for seamless integration.</p> <p>The system shall be able to provide an interactive UX for providers to interact with the system.</p> <p>The UX shall show Noom data, and all doctors requested information</p> <p>D. Human generated output. Main requirements involve the capacity to query, store, and safely manipulate patients' data; calculate engagement levels; categorize patients' according to engagement level; read, store, and manipulate a behavioral science-based message pool; send personalized messages based on patients' engagement, and generate a reporting dashboard for providers. Requirements include applying high-security data manipulation standards. Data consumed and generated by PAMS needs to be recorded for future evaluation and further analysis of the effect of messages in achieving engagement.</p>

GenAI Solution

We used the output of the "feature construction phase" to inform the GenAI output for requirements. During the initial stages of the prompting phase, we refrained from suggesting solutions, allowing ChatGPT to generate potential solutions autonomously. We reviewed and evaluated these outputs, eliminating impractical or incompatible solution paths that did not align with the intentions or capabilities of our team. Once we reached

a satisfactory outcome but faced uncertainty regarding the next steps, we instructed ChatGPT to assume a different "personality" (eg, software architect) and used the previous outputs as a foundation for the new role's initial prompts. Throughout this process, we encouraged each "personality" to seek clarifications by asking questions and provided feedback without biasing toward any predetermined solution. We repeated this process at least four times for each personality type, engaging in a

back-and-forth roleplay with multiple personalities (researcher, architect, and developer), transitioning to a different personality when it became evident that the current one could no longer progress without additional feedback (Figures 4A and 4C).

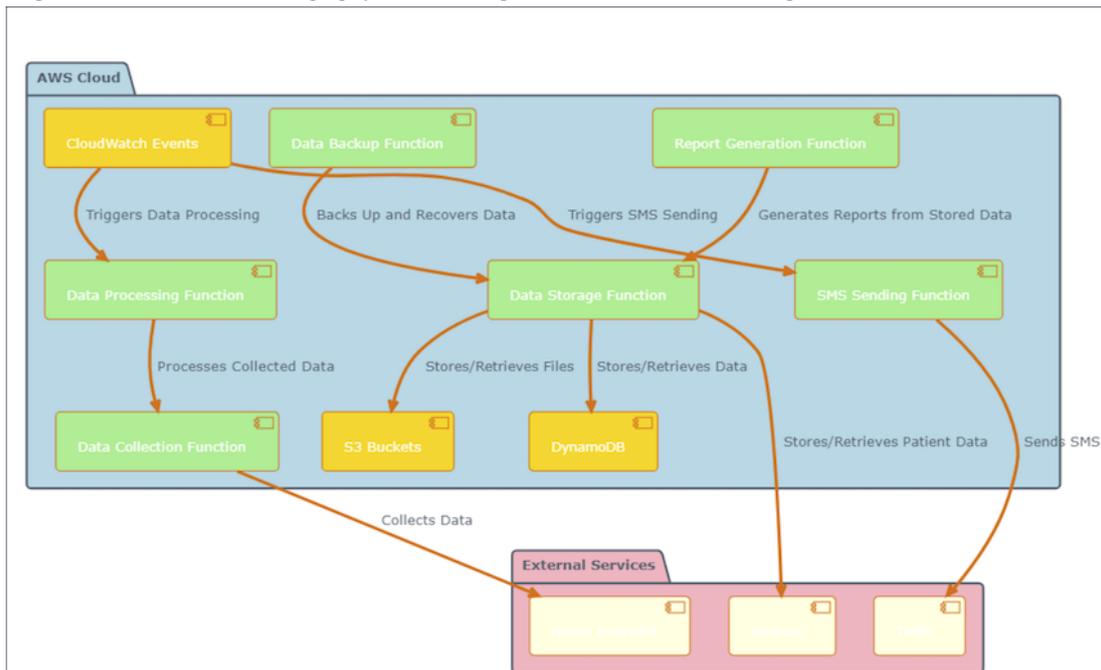

Architectural Design

Human-Generated Solution

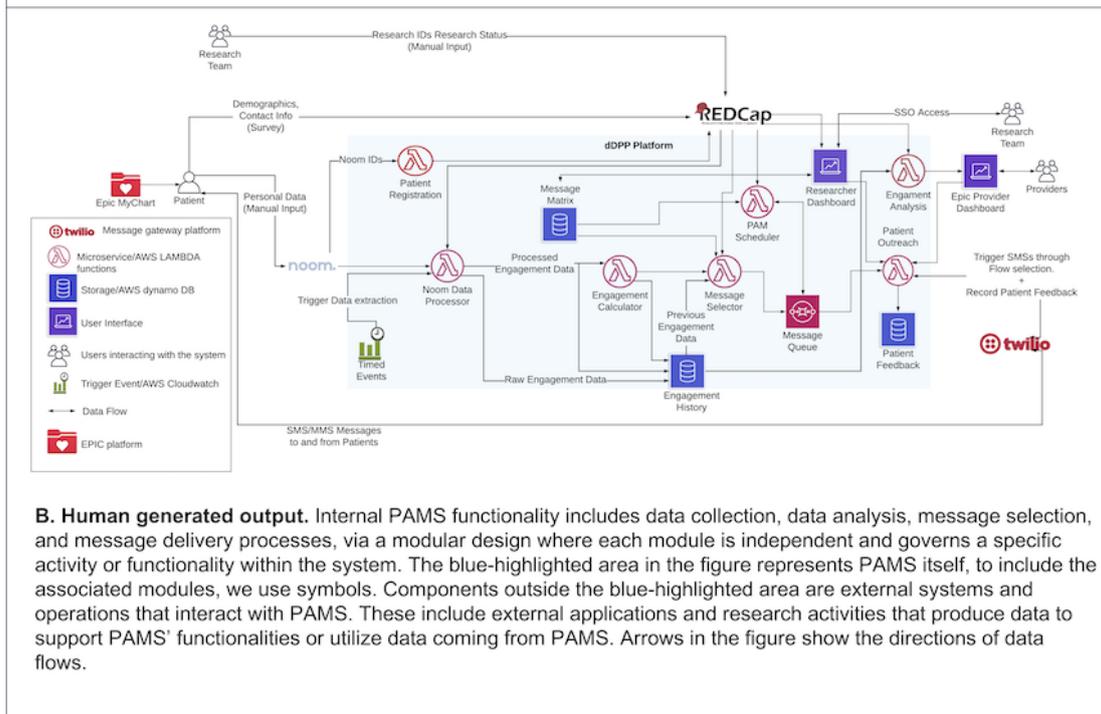

After the requirement phase, our software development team developed the PAMS architectural diagram, which is a graphical

representation of the system that includes (1) a set of components (eg, a database and computational modules) that will perform a function required by the system; (2) the set of connectors that will help in coordination, communication, and cooperation between the components; and (3) conditions for how components can be integrated to form the system (Figure 5B).

Figure 5. Architectural design for PAMS. ChatGPT vs human-generated output. AWS: Amazon Web Services; dDPP: digital diabetes prevention program; PAMS: personalized automatic messaging system; REDCap: Research Electronic Data Capture.

A. ChatGPT generated output. Prompt: Thanks for that. With the generated requirements, I will like for you to provide the necessary architectural diagrams for the system. Please consider the following: to develop the system, we want to use AWS and a micro-services approach, also patient data collected from the patients will be stored in RedCap, and we will use Twilio as the SMS gateway to deliver the text messages. Please redo the diagrams using this information.

B. Human generated output. Internal PAMS functionality includes data collection, data analysis, message selection, and message delivery processes, via a modular design where each module is independent and governs a specific activity or functionality within the system. The blue-highlighted area in the figure represents PAMS itself, to include the associated modules, we use symbols. Components outside the blue-highlighted area are external systems and operations that interact with PAMS. These include external applications and research activities that produce data to support PAMS' functionalities or utilize data coming from PAMS. Arrows in the figure show the directions of data flows.

GenAI Solution

For the GenAI-generated architectural design, we leveraged the outputs of the requirement phase and the available ChatGPT plugins to designate the GenAI model as a software engineer and proceeded to develop an architectural diagram. During this process, we engaged in iterative prompting and provided explicit instructions to ChatGPT, specifying the use of Amazon Web Services (AWS) for development, integration of external

systems such as Twilio (Twilio Inc) and REDCap (Research Electronic Data Capture; Vanderbilt University), and the adoption of a microservice approach to facilitate the efforts of our development team (Figure 5A).

Code

Human-Generated Solution

PAMS components include several lambda functions that execute its engagement or adherence algorithm, messaging, and data manipulation functionalities. Most of the functions are coded and developed using Python (Python Software Foundation) and Scala (École Polytechnique Fédérale Lausanne) as programming languages. AWS was used for the development

Figure 6. Code for the function that calculates patient adherence and engagement trends. ChatGPT vs human-generated outputs.

GenAI Solution

To facilitate the generation of the coded solution using ChatGPT, we assigned the role of a software engineer to the model and specifically requested it to generate Scala code for a specific functionality, namely the “calculate engagement trends” function. Consistent with the iterative nature of the GenAI-based software development process, we engaged in a back-and-forth interaction with ChatGPT, iterating over the prompt and its output while providing expert guidance to ensure optimal results. While allowing ChatGPT to generate free text, we evaluated each output for accuracy and adherence to the desired specifications (Figure 6A).

Internal Review of Human Vs GenAI Outputs

The 11 evaluators participated in the output review process. All had familiarity or prior exposure to the original PAMS intervention. Overall, evaluators rated the ChatGPT-produced outputs as positive for the theoretical background and design phase in terms of understandability, usability, novelty, relevance, and efficiency. For these two components, the question about completeness showed the most variability with divided opinion among “agree” and “disagree” and the bias was mostly categorized as “neither agree nor disagree.” For the first part of the technical development (user stories and requirement documents), most of the raters found the ChatGPT output

of PAMS [12]. Our developers followed our microservice approach design using an event-driven model [13,14]. The main components of PAMS are AWS lambda functions which are triggered by different events such as updates to S3 buckets, modifications on DynamoDB (AWS) tables, or CloudWatch (AWS) events. External interactions of PAMS use application programming interface calls, which secure effective data transfer (Figure 6B).

positive in terms of understandability, usability, and relevance. In terms of completeness and novelty, requirements were better rated than the user stories which represent an interesting output since requirements are derived from the user stories. We hypothesize that our raters were expecting better user stories, but once these were defined, they considered ChatGPT to be effective at turning these into the requirements. In terms of bias, similar to the theoretical background and design phase, the most popular answer was “neither agree nor disagree.” For the more technical pieces of the development that required software engineering knowledge, specifically the architectural diagram and code elements, results showed the highest N/A responses. These higher levels of N/As were associated with lower levels of expertise (eg, coding experience) since only 2 of the 11 evaluators had computer science backgrounds. However, the overall score excluding the N/As was positive for the technical component.

Discussion

Results Summary

This study leveraged ChatGPT-4 to recreate content features and software development of PAMS. ChatGPT served as a usable facilitator for researchers engaging in the software development life cycle, from product conceptualization to

feature identification, and user story development to code generation. GenAI technologies facilitated effective communication and understanding within our multidisciplinary team by providing well-described features and supporting the role of a software engineer. Our findings indicate that the ChatGPT-generated output is comprehensive, albeit with occasional ambiguities that required clarification or adjustment by the research team. The ChatGPT-generated output exhibited a high level of accuracy in capturing the intended requirements. We found that ChatGPT supported a highly efficient development process, producing over 5 days what initially required more than 200 human hours from content and technical experts. The results suggested that by efficiently prompting ChatGPT and leveraging the expertise of our team, we could have significantly reduced the time we invested in initial system modeling and conceptualization phases as well as technical phases of software development (coding). Overall, GenAI technologies like ChatGPT offer a promising approach to efficient software development.

While promising, some significant limitations to ChatGPT's outputs should be noted. In the design phase, while ChatGPT was able to provide general guidance in tool design (eg, app vs web-based vs EHR solution) it was unable to provide evidence to support its rationale for these choices. This lack of reference support has been well-documented and has a material impact on researchers looking to build upon an evidence base for their health technology interventions. Similarly, when asked to provide theoretical frameworks to support behavior change, it offered only a partial list, initially excluding the COM-B (capability, opportunity, motivation, behavior) model upon which the original PAMS intervention was based, and needed prompting from our behavior change expert to provide more specific guidance. In the context of code generation, we focused on testing a specific function, namely the Calculating Patient Engagement feature, which is the core functionality of our software. Initially, we tasked ChatGPT with generating a function to compute a 3-week patient engagement trend. However, the initially generated code deviated from the intended objective and instead calculated a weekly engagement score. Through subsequent iterations, we were able to obtain the desired code. However, the initial attempts exhibited nonidiomatic constructs and contained bugs (no efficient loops and wrong logic). Finally, we observed that ChatGPT overlooked certain suggested features during the design phase, resulting in the generated code occasionally demonstrating unnecessary complexity and disregarding some of the best practices and features of the target programming language. We believe that further iterations would have improved the code quality, encompassing better adherence to coding standards and the inclusion of desired business features, such as handling edge cases and capturing more nuanced engagement trends. Nevertheless, we reached a point of diminishing returns with ChatGPT where we determined that engaging an experienced developer would have expedited the code generation process and ensured a more robust implementation.

These limitations highlight the ongoing importance of human expertise in the development process, especially in scenarios where theoretical expertise, intricate coding practices, and

business-specific requirements are involved. The lack of rationale to support the generated results shows the value of having human experts on the team who can interpret the results. ChatGPT needs to be used as a support tool but not the source of truth; thus, we always trusted and relied on human experts to validate the ChatGPT-generated results before moving to the next phase. Overall, it is important to have human experts in the system development process to guide the outputs in terms of reprompting the system (support the decision-making on acceptable output) and ensuring their accuracy. Moreover, results are highly dependent on the quality of the prompts which emphasizes the role of prompt engineering. The results show that well-structured prompts (role + problem description + ask) that infuse human expertise into every iteration are key to obtaining good results (Figure 1). As part of our prompt framework described in the methodology section, results showed that detailed problem explanations, clear asks, and roleplaying are an excellent combination to guide accurate results. We suggest asking ChatGPT questions using different roles, asking for clarification if needed, and in cases of wrong outputs, redirecting the prompts.

Related Work

There is near-universal interest in understanding the impacts of GenAI and large language models (LLMs) on human social structures, including the experience of work and the production of work-related outputs in health care and more broadly [15,16]. In health care, LLMs are poised to impact everything from care delivery experience, diagnostic reasoning and cognitive skills, training and education, and the overall composition of the workforce [17]. These theoretical disruptions are tempered, however, by acknowledging that in its current state, GenAI tools remain suboptimal, with ongoing issues in accuracy, reliability, usability, cost, equity, and ethics.

In commercial spaces, ChatGPT-enabled products designed to assist with coding and software development are already being developed (eg, OpenAI Codex [OpenAI] and CodeGPT [CodeGPT]). These tools can help generate novel code, debug and analyze code issues, assist in code refactoring, and provide code documentation. As yet, however, their usefulness in terms of quality has not been extensively evaluated, and costs and other considerations may make them inaccessible to health care researchers. ChatGPT-enabled tools for front-end design (eg, integrating ChatGPT with Figma [Figma, Inc]), user testing (including synthetic user testing), and prototyping have also been created, all allowing health technology research teams with limited design resources to take advantage of tools from product and experience design to create their interventions. Overall, commercial LLMs have been demonstrated to improve worker efficiency and productivity, through "co-pilot" support services that automate low-skills tasks, organize and present information, and surface insights [18]. Brynjolfsson et al [18] found that a ChatGPT-supported tool providing conversational guidance for customer support agents increased worker productivity by almost 14%. The authors further found that these productivity benefits accrued disproportionately to less-experienced and lower-skill workers, allowing less-skilled or newer workers to experience more rapid gains; the authors posit that high-skill workers may have less to gain from artificial

intelligence assistance due to tacit knowledge reinforcement rather than new knowledge or skill development. Our work suggests that both less-experienced, lower-skill workers and high-skill workers can benefit, with novices benefitting more from new knowledge (if accurate) and skill development and experts benefiting from knowledge validation and offloading of high-effort low-value tasks.

In the academic computer science literature, ChatGPT has been evaluated as a tool for collaborative software design [4], including to improve code quality refactoring, requirements elicitation, and general design solutions [5], and fix programming bugs [19]. Similar findings are reflected in our work, including the caveats of requiring human oversight. Other authors have identified important ethical issues in using GenAI solutions for software engineering, which were not considered in this study [20].

Within health care, a growing body of research has explored the feasibility of GenAI tools (mostly ChatGPT) in a variety of use cases, including answering patient questions [3,21], creating suggestions to optimize clinical decision support [22], generating a history of present illness summaries [23], and overall examination performance [24]. In general, these papers find promising signals for the accurate and acceptable use of GenAI tools, but with many current-state caveats for their optimal, safe, and scaled use. Key areas of concern include reliability (particularly around hallucinations and citation fabrication), reproducibility, and recency of data inputs. While research in this area will continue to grow, as more test cases comparing GenAI performance to that of clinical staff will be undertaken, further work is needed to create validated and generalizable outcome measures. Future work must also ensure that the variety of GenAI tools (including general commercial LLMs, health care-specific LLMs, and internally developed tools) are equally evaluated.

Limitations

There are several limitations to this study. First, no research team members have expertise in prompt generation for GenAI tools; as a result, our prompting reflects the a priori perspectives, biases, and knowledge gaps of our team, and are therefore particularly subject to issues of framing, recall, and confirmation bias that may influence the interpretation of the results. Second, our research team members, who acted as prompt engineers in this study, were highly familiar with the project and participated in the human-based design process; thus, they were aware of what deviations from human-based design to address by reprompting the system. As a result, we have introduced bias in the prompting process and results reflect higher accuracy. Third, the absence of robust tools to objectively measure the “quality” of current ChatGPT outputs poses challenges to accurately and objectively assess its performance. Furthermore, in this case, the output reviewers were not blinded to the human vs ChatGPT outputs, given the complexity of this study and the

difficulty in providing enough research context to support independent blind review. Finally, broader limitations of the technology, such as potential hallucinations and concerns about behavioral changes of responses over time, deserve acknowledgment, as they could have implications for the practical applications and long-term viability of GenAI in health care research contexts. Future research efforts should address these limitations to enhance and replicate our findings.

Implications and Future Directions for Exploration

We are considering several future directions for the use of ChatGPT in our digital health intervention development. We envision increasing our expertise in prompt engineering (add expert prompt engineers to the team) to actively use ChatGPT to further develop PAMS features, particularly for additional messaging content. We anticipate this will save our research team considerable time and effort. We may also use ChatGPT to facilitate more time-consuming aspects of our research documentation, including both coding documentation and larger research archival work (eg, meeting minutes and recording intervention decision-making). Overall, we feel ChatGPT and related tools can be effectively leveraged within health care technology research teams with a spectrum of technical expertise, serving to both augment existing skills and supplement skill gaps. For those with expertise in computer science or programming, we imagine ChatGPT can assist by automating high-effort, low-impact tasks or repetitive work that is considered important but often deprioritized as more urgent tasks arise (eg, code documentation). For those without preexisting programming skills, we imagine ChatGPT can offer technical support, including educational tools and skill-building opportunities. Overall, this process will both validate existing knowledge and create new knowledge for teams, as well as potentially improve interteam communication and collaboration.

Conclusions

In this study, we explored the use of the GenAI tool ChatGPT to recreate a novel digital behavior change intervention which our research team had previously developed to support patient engagement and adherence to a commercial dDPP. Specifically, we reviewed and evaluated the capacity and limitations of ChatGPT to support digital health research intervention ideation, design, and software development, finding it a feasible and potential time- and resource-saving tool to support research teams in developing novel digital health products and technologies. At the same time, we identified gaps in ChatGPT outputs that may limit its effective use for both novel and advanced technology developers, particularly around the completeness of outputs. Future directions will include the development of more targeted artificial intelligence-based tools to support health care researchers with all levels of software or engineering skills, as well as the development of improved tools to objectively evaluate GenAI outputs.

Abstract

Background: The popularity of eHealth services has surged significantly, underscoring the importance of ensuring their usability and accessibility for users with diverse needs, characteristics, and capabilities. These services can pose cognitive demands, especially for individuals who are unwell, fatigued, or experiencing distress. Additionally, numerous potentially vulnerable groups, including older adults, are susceptible to digital exclusion and may encounter cognitive limitations related to perception, attention, memory, and language comprehension. Regrettably, many studies overlook the preferences and needs of user groups likely to encounter challenges associated with these cognitive aspects.

Objective: This study primarily aims to gain a deeper understanding of cognitive accessibility in the practical context of eHealth services. Additionally, we aimed to identify the specific challenges that vulnerable groups encounter when using eHealth services and determine key considerations for testing these services with such groups.

Methods: As a case study of eHealth services, we conducted qualitative usability testing on 2 online symptom checkers used in Finnish public primary care. A total of 13 participants from 3 distinct groups participated in the study: older adults, individuals with mild intellectual disabilities, and nonnative Finnish speakers. The primary research methods used were the thinking-aloud method, questionnaires, and semistructured interviews.

Results: We found that potentially vulnerable groups encountered numerous issues with the tested services, with similar problems observed across all 3 groups. Specifically, clarity and the use of terminology posed significant challenges. The services overwhelmed users with excessive information and choices, while the terminology consisted of numerous complex medical terms that were difficult to understand. When conducting tests with vulnerable groups, it is crucial to carefully plan the sessions to avoid being overly lengthy, as these users often require more time to complete tasks. Additionally, testing with vulnerable groups proved to be quite efficient, with results likely to benefit a wider audience as well.

Conclusions: Based on the findings of this study, it is evident that older adults, individuals with mild intellectual disability, and nonnative speakers may encounter cognitive challenges when using eHealth services, which can impede or slow down their use and make the services more difficult to navigate. In the worst-case scenario, these challenges may lead to errors in using the services. We recommend expanding the scope of testing to include a broader range of eHealth services with vulnerable groups, incorporating users with diverse characteristics and capabilities who are likely to encounter difficulties in cognitive accessibility.

KEYWORDS

eHealth; online symptom checkers; usability; cognitive accessibility; web accessibility; qualitative research

Introduction

Background

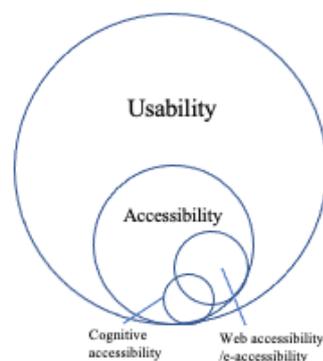

Given the widespread use and popularity of eHealth services, there is a growing need for more accessible services to all potential user groups [1]. In recent years, more emphasis has been placed on accessibility and inclusion; for example, the European Union Accessibility Act has been incorporated into and enforced as national law since June 2022 [2]. As health care services are often public services, it is important that they serve a broad range of users. Furthermore, usability has been recognized as a key component of eHealth applications, and users may face problems with using the applications due to their health conditions [3]. In addition, patients with chronic illness have been reported to encounter more cognitive challenges [4]. Thus, extra attention should be paid to the usability of eHealth applications.

Universal design and design for all address these requirements by aiming at designing services that are usable by and accessible

to all user groups regardless of their age, abilities, or possible disabilities [5]. Usability is a high-level term that indicates how a system can be used by specified users in a certain context of use to achieve specific goals with regard to effectiveness, efficiency, and satisfaction [6]. Accessibility, which is a part of usability, describes how a system can be used by people with the widest range of needs, characteristics, and capabilities [6,7]. Thus, accessibility covers all sorts of users with different limitations. A concept that has been addressed by several research papers [8,9] is web accessibility (or e-accessibility), which refers to the accessibility of web services.

In this paper, we address cognitive accessibility, which refers to accessibility beyond physical and sensory capabilities, and thus takes into account varied human characteristics such as intellectual disabilities, attention difficulties, reading problems, autism spectrum disorders, and low language skills [10]. Cognitive accessibility is an important aspect of web accessibility as it involves a large number of users and has a high impact on usability [10]. A summary of the relationship between these concepts is presented in Figure 1.

Figure 1. The relation of cognitive accessibility to usability and accessibility. Note that the sizes and positions of the circles are indicative.

This research focuses on cognitive accessibility within the context of the 2 most frequently used online symptom checkers in Finnish public primary care across numerous municipalities in Finland. Online symptom checkers are used by people seeking health-related guidance, and these services typically provide an urgent assessment and suggest guidance based on the symptoms reported by the user [11]. Patients can use the 2 examined symptom checkers to book appointment times for doctors and laboratory tests or obtain medical help for the most common health issues. First, patients report their symptoms and submit them to the health care center through the symptom checker. Health care professionals receive patient inquiries with an urgency rating, decide on actions to be taken, and inform patients.

Patients are generally highly satisfied with symptom checkers, but younger and more highly educated people have been more likely to use them [11]. For example, symptom checkers enable patients to access health care anytime and anywhere. Therefore, it is essential to ensure that all user groups, including individuals in vulnerable situations, can use these services effectively. Symptom checkers can also empower users as a means of facilitating their health care [12]. However, the accuracy of the symptom checkers depends on how well patients are able to communicate their symptoms when using the tools [13]. As

these services spread and are used by a wider range of individuals, it is crucial to also evaluate their usability and accessibility with a more diverse set of users.

Prior Work

Vulnerable Groups

Many public eHealth services and their poor usability and accessibility can cause challenges for certain user groups [14]. These user groups are, thus, in a potentially vulnerable situation in using the service and at risk of digital exclusion [1]. This is especially problematic because research has shown that digital exclusion can cause social exclusion [15]. Public health services must, thus, address the needs of potentially vulnerable groups, including people who are disadvantaged by health, economic, cultural, or social conditions [16], such as older adults, migrants, mental health service users, and the unemployed [16,17].

Older adults are the largest group to face challenges in using digital health services [18,19]. As people age, their cognitive abilities may weaken, with cognitive load being identified as the most significant accessibility barrier for older adults [20]. Memory changes can also affect learning, information processing, and language comprehension [21,22]. Additionally, older adults often struggle with focusing their attention, particularly when multitasking [21,22]. Moreover, older age

groups tend to use eHealth services less frequently than younger demographics. A Finnish study examining an online symptom checker (referred to as service A in this study) observed that individuals aged 20-39 years used the service more actively compared with older age groups, relative to their representation in the population [23]. This suggests that enhancing service usage entails prioritizing usability and accessibility from the perspective of older users as well.

Migrants represent a growing demographic that often faces challenges when accessing health services in their new country of residence [1]. Language barriers and a lack of digital skills are common issues encountered by this group [1]. Additionally, individuals with intellectual disability are another vulnerable population impacted by the digitalization of health services [24]. They have been noted to experience more difficulties in finding information on the internet and understanding online information compared with the general population [25].

Previous research suggests that vulnerable groups, such as older adults and individuals with mild intellectual disabilities, encounter cognitive challenges when using technology [26,27]. Therefore, the development of more accessible eHealth services would enable these groups to access health information more easily [25,28], thereby enhancing their sense of empowerment concerning their health issues.

The preferences or needs of older adults or individuals with mild intellectual disabilities are often overlooked in the majority of eHealth studies [29,30]. It is imperative to better consider these user groups during the design of eHealth services [17,28]. Many eHealth applications could greatly benefit from the application of universal design principles [29], which facilitate understanding the needs of potentially vulnerable groups and inform the design of more inclusive and usable services [31,32]. Consequently, this enables vulnerable groups to derive as much benefit from eHealth systems as the rest of the population [33,34]. Indeed, universal access approaches can offer benefits to anyone [35]. Therefore, to gain a better understanding of the challenges faced by vulnerable groups when using services, it is essential to conduct testing with a diverse group of users.

Usability Testing of Symptom Checkers

The usability of symptom checkers has been examined in prior research; however, there has been limited emphasis on potentially vulnerable user groups, such as older adults, migrants, and those with intellectual disability [36-38]. Moreover, research on usability in the eHealth domain frequently concentrates on quantitative aspects (eg, the number of errors, task completion times, and usability questionnaires) and typically involves a large number of users [12,36,38]. However, the qualitative aspect of usability studies is also crucial for gaining a deeper understanding of the thoughts and reasons behind errors, as well as capturing the patient's perspective at a broader level [3,39]. Additionally, while a System Usability Scale (SUS) questionnaire provides a numeric score for experienced usability, it alone is not adequate for evaluating usability. Instead, it should be complemented with other measures, such as task completion rates or more qualitative approaches, to ascertain which aspects of a service require improvement and how best to address them [39].

Marco-Ruiz et al [13] conducted research on symptom checkers and emphasized the significance of testing with real users to comprehend the cognitive processes involved when using a new system to record health data. Furthermore, they noted that the user base accessing symptom checkers is highly diverse, with some individuals possessing higher health literacy and experience in recording online information, while others may have very limited or no experience [13].

Goal of the Study

The goal of our study is to gain a deeper understanding of cognitive accessibility in the context of eHealth services. Therefore, our paper focuses on addressing the following research questions:

- What kind of challenges do vulnerable groups face in using eHealth services?
- What needs to be considered when testing with vulnerable groups?

The structure of this paper is as follows: In the next section, we describe the methods used in this study, followed by the presentation of results. Subsequently, we discuss the findings and overarching contributions of this study, concluding with our final remarks.

Methods

Approach and Researcher Background

Our qualitative study adopts a case study approach, wherein the cognitive accessibility of eHealth services was assessed through usability testing of 2 online symptom checkers. The research team comprised 3 researchers: The first researcher, a human-computer interaction student, conducted the initial 8 tests as part of their master's thesis work. Subsequently, a second researcher, a senior researcher with expertise in human-computer interaction (who served as the thesis advisor), conducted the remaining 5 tests. Additionally, a third senior researcher with backgrounds in human-computer interaction and eHealth oversaw the entire study.

Context and Study Setting

We conducted a usability test of 2 Finnish online symptom checkers in 2 phases in Finland during the Spring and Fall of 2021. The tested services were Omaolo (DigiFinland Oy) [40] and Klinik Access (Klinik Healthcare Solutions Oy) [41], which are the 2 most-used symptom checkers in Finnish public primary care. Omaolo has been actively used since 2019, while Klinik Access, which is also used internationally, has been in use since 2015. Both services are designed to assist patients in obtaining appropriate care. Users answer a set of questions regarding their symptoms, following which the symptom checkers use artificial intelligence to assess the urgency of care. If necessary, the services guide patients to contact emergency care services.

The Omaolo symptom checker comprises 15 specialized symptom checkers tailored for different types of symptoms, along with a generic symptom checker. Each symptom checker prompts the user with a specific set of questions and subsequently recommends the next steps they should take. Additionally, if the user provides their home municipality, the

service displays recommended actions specific to the area, offers contact details, and may even facilitate direct contact with health care professionals if deemed necessary. The Omaolo symptom checker served as the primary COVID-19 symptom checker in Finland, enabling users to schedule appointments for COVID-19 tests. Consequently, its user base experienced a significant surge [23].

The Klinik Access symptom checker enables users to initially select the part of the body where their main symptoms are located. Subsequently, it prompts for more specific symptoms. The responses can then be forwarded to the medical staff responsible for the patient’s care before their appointment, ensuring the patient is directed to the appropriate type of health care professional. The primary distinction between these services lies in their user interface (UI): Klinik Access features a more visual UI with a list of clickable symptoms, whereas Omaolo presents users with multiple-choice questions describing the symptoms. Henceforth, the Omaolo service will be denoted as service A, and Klinik Access will be referred to as service B. It is important to note that both services are classified as medical devices and must adhere to specific safety requirements, such as repetitive questions, which may impact usability.

Sampling Strategy

Purposive sampling [42] was used to recruit participants, who were sourced through personal contacts and various associations representing the targeted user groups. These associations included initiatives such as the Selkeästi meille, which focuses on enhancing cognitive accessibility, and Väylä ry, which is dedicated to improving the employment opportunities of

individuals with intellectual disability. It is important to note that the test facilitator did not have a close personal relationship with the participants, such as being a friend or family member, during any of the test sessions.

A total of 13 participants were recruited to partake in the study. Notably, an evaluation of sample sizes within the field of human-computer interaction has indicated that 12 is the most common sample size for usability studies [43].

Ethical Approval

The study received approval from the ethical review board of Aalto University (D/902/03.04/2021). Each participant provided informed consent by signing a consent form after confirming their understanding of the study’s purpose and how their information would be handled. Reporting has been conducted in such a manner that individual participants cannot be identified.

Data Collection Methods

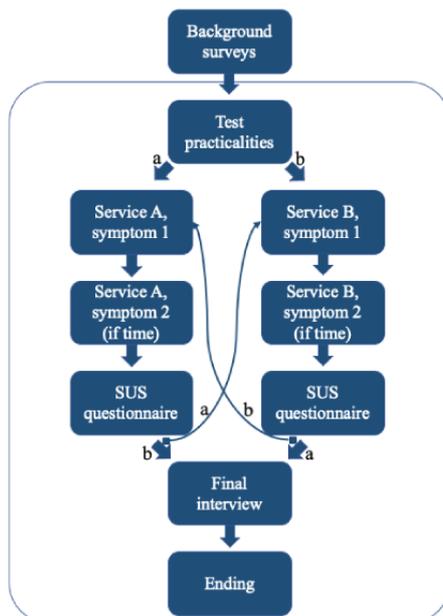

Overview

The main methods used in this study were thinking aloud, observations, questionnaires, and semistructured interviews. Before the actual tests, a pilot test was conducted to identify any potential inconsistencies and to ensure that the questions and instructions were comprehensible. Minor adjustments to the test setup were made based on the findings from the pilot test.

Test Procedure

An overview of the test sessions is presented in Figure 2.

Figure 2. An overview of the usability test sessions with older adults, mildly intellectually disabled individuals, and nonnative speakers (N=13). Half of the participants started with Service A and the other half with Service B.

Each participant tested both services, and the order of service usage was counterbalanced. During the testing phase, participants were presented with 2 symptom vignettes, each providing a brief description of the symptoms they were instructed to imagine having. These vignettes were used 1 at a time. Participants were then asked to open the service and

imagine they had the symptoms described in the first vignette, aiming to determine how they should proceed. The vignettes and mode of distribution between the participants are presented in Multimedia Appendix 1.

After using the first service, participants were instructed to take the second vignette and attempt to use the service again. However, if the first part of the test had exceeded 40 minutes, the second vignette was omitted for the first service to prevent the overall test time from exceeding 90 minutes. Following their interaction with each service, participants were asked to evaluate the respective service.

After testing the first service, participants were instructed to open the second service and follow the same procedure. Upon completion of both testing phases, participants were asked to compare the 2 systems and select the one they preferred.

Data Collection Instruments

Test Sessions

The test sessions were conducted via the Microsoft Teams videoconferencing platform, which facilitates screen sharing, screen recording, and voice recording functionalities. The decision to conduct remote testing was primarily influenced by the COVID-19 pandemic situation, but it also aligned well with the nature of the tests, as the services being evaluated were online. Participants used their personal computers to access the services during the testing sessions.

Symptom Vignettes

To streamline the usability test and eliminate the necessity for participants to input their personal medical information into the services, each participant was provided with 2 standardized clinical vignettes featuring predefined symptoms. These vignettes were selected from a list compiled by Semigran et al [44], encompassing a total of 6 conditions with varying severity levels. The selection included conditions with different severity levels to account for the fact that individuals may use symptom checkers in both urgent and nonurgent situations [45].

In line with the recommendations provided by Semigran et al [44], the selected vignettes encompassed 3 categories of triage urgency: conditions necessitating emergency care, conditions warranting nonemergency care, and conditions deemed unnecessary for medical visits, thus manageable with self-care. Moreover, we opted for conditions commonly observed within the age group under study to ensure relevance. These conditions encompass ailments such as acute bronchitis, back pain, and meningitis. To ensure clarity and relevance to the participants, the selected conditions were translated from English to Finnish and simplified. The English versions of the vignettes used can be found in [Multimedia Appendix 2](#).

Background Questionnaires

Before the actual test session, participants were requested to complete a brief background survey and the health literacy survey HLS-EU-Q16 [46]. The background information collected were the participant's gender; age; the frequency of doctor visits in the preceding 2 years; the number of doctor-diagnosed medical conditions; their previous usage frequency of digital health care services; and their frequency of digital device usage, such as smartphones or computers. These questions aimed to ascertain whether participants met the study's target demographic criteria in terms of age and their ability to independently use electronic devices such as

computers. The health literacy survey provided insights into participants' understanding of health-related topics.

Interview and Questionnaire

After interacting with each service, participants were asked to evaluate the tested services. This involved administering an SUS questionnaire [47] to gauge the perceived usability of the system, as well as posing 4 interview questions:

- Would you use the service again in the future?
- Were the summary and the instructions about what to do next clear enough?
- Would you actually follow the instructions given?
- Given the option, would you use the service using your phone?

Data Processing and Analysis

The test sessions were recorded using Microsoft Teams. The voice recordings of the initial 8 tests were transcribed in full, while for the remaining 5 tests, notes were taken from the recordings, and user comments were documented to streamline the process. An experienced researcher could identify the issues encountered by users as well as their comments without requiring a complete transcription. The notes and transcriptions underwent anonymization. Qualitative content analysis was used in this study. Using the notes and recordings, all usability issues were identified and compiled. This encompassed problems mentioned by participants as well as those observed during testing or evident from the recordings. The identified usability problems were coded and categorized based on their similarities. When new problems were identified, they were compared with existing ones, and if deemed similar, they were grouped under the same code. Eventually, these groups were consolidated under higher-level descriptive categories. Furthermore, user comments were collected to bolster the analysis and reporting process.

The background questionnaires were analyzed by aggregating the responses to obtain an overview of participant characteristics. Additionally, the health literacy surveys were analyzed according to the guidelines [46] to determine the groups to which participants belonged. The SUS questionnaires were analyzed by computing the SUS scores as per the guidelines [47], resulting in scores of up to 100 points, which were then compared with the general score.

To ensure the quality and trustworthiness of the study, a senior researcher (the second author) supervised the entire research process and provided support for the analysis work. Two other researchers (the first author and the master's thesis worker) conducted the actual tests and analyzed the data. Therefore, a total of 3 researchers participated in the process, ensuring that data gathering and processing proceeded appropriately.

Results

Overview

The subsequent sections present the principal findings of the study. We commence with an overview of the participants' characteristics, followed by an examination of the identified

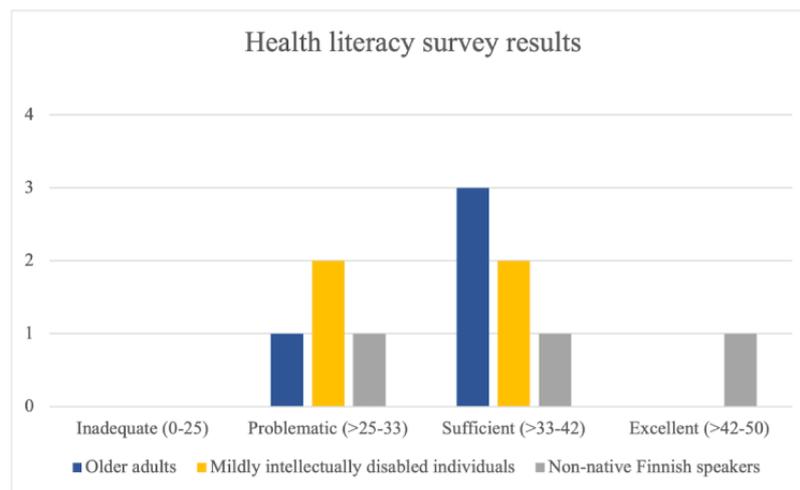

usability issues. Finally, we present additional findings that emphasize the characteristics of these user groups.

Test Participants

A total of 13 individuals participated in the study in Finland. Among them, 4 were individuals with mild intellectual disability, 4 were older adults (aged 75-79 years), and 5 were nonnative Finnish speakers. Therefore, all test users potentially encountered cognitive accessibility challenges with the services. The background characteristics of the participants are detailed in [Multimedia Appendix 3](#).

The HLS-EU-Q16 questionnaire results were calculated in accordance with the guidelines [46], with each participant receiving a score corresponding to a quartile representing their health literacy level. The results were computed only for participants who responded to at least 80% of the questions, as recommended in the guidelines [46]. The questionnaire includes an “I don’t know” answer option, which was interpreted as the question not being answered. Consequently, the results of 2 of the nonnative participants were excluded, as they chose this answering option too frequently. [Figure 3](#) depicts the distribution of health literacy among the 3 groups.

Figure 3. The results of the HLS-EU-Q16 health literacy assessment of older people, mildly intellectually disabled individuals, and non-native speakers divided into four categories.

Usability Problems

Cognitive Accessibility Issues

The study identified a total of 65 usability problems with the 2 systems. Specifically, 36 usability problems were discovered with service A, while 29 problems were identified with service B. These issues occurred across 99 and 91 individual user instances, respectively. The problems were classified into 14 usability problem categories. A comprehensive list of the usability problem categories is provided in [Multimedia Appendix 4](#). For the purpose of this discussion, we will focus on issues related to cognitive accessibility, primarily concerning terminology, text volume, and UI clarity.

Terminology-Related Issues

The most prevalent issues were associated with terminology and answering options. eHealth services frequently incorporate specialized language and specific terminology, posing challenges for users with cognitive limitations. Nearly all users encountered confusion with certain terms or inadvertently mixed them up with similar ones. Furthermore, lengthy words and extensive blocks of text, such as lengthy paragraphs, presented challenges, a sentiment that was also echoed during the interviews. Users with cognitive restrictions often encounter challenges when confronted with long words and extensive passages of text.

As one user commented,

It takes time to go through all the texts. [ID10, nonnative]

Related issues were reported and commented on by users across all user groups. In addition to contributing to usability problems, these issues slowed down the usage of the services and occasionally led users to select incorrect symptoms.

Issues Related to the Clarity of the UI

Another area where users encountered difficulties was with the visibility of information and the lack of clarity in the UI. It is crucial for the most important information and elements of the UI to be clearly visible, facilitating easy comprehension for users. Additionally, problems arose when users’ attention was diverted to unimportant features. These issues are especially pronounced among user groups with cognitive difficulties, as they require additional attention to comprehend the content and must focus more intently. Furthermore, some users found the input methods challenging; initially, they struggled to discern the type of information required for input in a field and how the inputting should be performed.

The most prevalent individual usability problems we identified regarding the logic and functionality of the UI, observed across all 3 user groups, are detailed in [Textbox 1](#).

Textbox 1. Individual usability problems identified.

1. **Users making an incorrect selection due to an item being highlighted in the user interface:**
Service A was, at the time of the study, the prevalent symptom checker for COVID-19 in Finland; COVID-19 was highlighted at the top of the home page of service A and was thus the first item to attract the users' attention and be selected.
2. **Difficulties in making the correct selection from a long list of items:**
Service A had a list of 15 symptom checkers from which the user had to choose, making it difficult for the users to select the correct symptom checker to continue with.
3. **Not remembering what questions needed to be answered after the questions disappeared:**
Service B presented questions as placeholders to describe symptoms in open answers, and these questions disappeared when the user started typing in the field; as a result, the user might not fully describe their symptoms.
4. **Being confused by long lists of apparently uncategorized symptoms:**
Service B had long lists of symptoms as selectable buttons that seemed to be unorganized and caused anxiety and confusion.
5. **The logic and functionality of submenus were not understood by the users:**
Service B had additional submenus and dialog boxes that were not fully understood by the users. There was a small arrow that opened the submenu and the logic of how the items were selected or the submenus opened was unclear.
6. **The users did not understand the logic of the input fields that combined several user interface items:**
The way in which service B required the duration of symptoms to be input meant that the user needed to enter the number in one field and then select the unit from different options. However, the unit selection was not clearly related to the textbox where the user inputs the number.

These individual usability problems highlight issues with how information is presented to users, with clarity being particularly emphasized among this user group. In some instances, the selection or input options were unclear, and the services featured lengthy lists of symptoms.

Clarity was a recurring theme in several test sessions. As one user commented:

...if you think about this in real life, if you have a fever and you're doing this and you start to scroll all these selection choices and you're evaluating which one would fit best, the options are quite broad, so it might be quite difficult to do in practice... [ID7, user with mild intellectual disability]

Similarly, one user suggested:

I don't know you could kind of put those in order like one row and another row, these are quite...your eye kind of jumps, but otherwise those are clear. [ID2, older adult]

One user preferred the structure of service A and, again, referred to the clarity with which the information is presented:

Well, [I prefer Service A] because it was maybe better organized, there was one thing and one question and then one answer. After this, the next question and so on. In the other one [Service B], you had to read all the small boxes and look for your symptom. [...] [ID8, user with mild intellectual disability]

Well, maybe what is the most [difficult], this one had so many small boxes that at least for me, it was difficult to find my own symptom, the one I needed to select from there. So, if I wanted to know what fit me, I had to read through them all and then, since they are not in any order, they just are there, I had to read

them all, to see if I could find the one I have at the moment. [ID8, user with mild intellectual disability]

It is worth noting that the symptoms were arranged in alphabetical order; however, the layout was such that users did not realize this ordering method had been used.

Differences Between the User Groups

Some differences between the user groups were evident, although the majority of the usability problems were consistent across all user groups. Nonnative Finnish speakers found the service to be particularly slow to use, often taking an extended period to read the texts. One user commented regarding service B that:

Reading and writing text is not easy for an immigrant. When you can click on an item it is easy, you don't have to write. [ID13, nonnative]

The older adults did not encounter as many issues with longer texts. Instead, they faced more challenges in understanding the logic of the services and remembering to scroll down to view all the provided information. However, this scrolling also frustrated some nonnative users; as one user commented:

And again, we're scrolling, this is terrible! [ID12, nonnative]

The task completion times were also measured and presented for the initial tasks of both services. As depicted in [Table 1](#), aside from the older adults, there were no significant differences in the completion times between the services. However, for the older adults, service B, which featured more clickable elements to choose from, appeared to be quicker to use. Nonnative speakers took the longest time to complete the tasks, primarily because they often needed to translate some of the terms used in the services. Three of the users used an online translator (eg, Google Translator), and at times, users asked the facilitator about specific terms. Overall, the task completion times were

quite lengthy, suggesting that these user groups require ample time to use these services effectively.

Table 1. Average task completion times (first task) for both services. For older adults there was a clear difference in favor of service B; for the 2 other groups service A got a slightly better time.

Task completion times	Service A, hh:mm:ss ^a	Service B, hh:mm:ss
Older adults	0:14:30	0:08:00
User with mild intellectual disability	0:14:54	0:16:00
Nonnatives	0:15:46	0:18:16

^ahh:mm:ss: hours:minutes:seconds.

For the few users who had the opportunity to test the services twice, the second time was generally much faster than the first, indicating good learnability. As one user mentioned:

Now I know that I need to select this and not the other, which I didn't know previously. [ID8, user with mild intellectual disability]

The SUS scores are provided in [Multimedia Appendix 5](#), illustrating how participants evaluated the usability of the services. The SUS score ranges from 0 to 100 points. It has been assessed for numerous services, and according to Bangor et al [48], a satisfactory SUS score is above 70, with superior products typically scoring 80 or higher. However, it is important to note that the interpretation of SUS scores can vary depending on the type of product and its development phase. When evaluating the SUS scores of the tested services, which are predominantly below 75, it is evident that the perceived usability was not considered very good, except for nonnative Finnish speakers, as their scores hovered around 80.

From the interviews, we found that older adults tended to prefer computers over mobile devices when using the symptom checkers, whereas nonnative speakers mostly preferred mobile devices. The preference among users with mild intellectual disability was evenly divided. Nonetheless, the advantage of this type of online symptom checker was evident, as all participants expressed willingness to use the services again. The nonnative participants particularly valued a service that enabled them to input information at their own pace, as opposed to speaking on the phone. However, their preference for the service they would use was fairly evenly split, with no clear consensus: 7 participants favored service A, while 6 participants favored service B.

Discussion

Principal Findings

Testing for cognitive accessibility with 2 symptom checkers revealed that older adults, individuals with mild intellectual disability, and nonnative speakers may encounter numerous challenges when using the services. Primarily, problems arise concerning the terminology used. This highlights the need for greater emphasis on ensuring that the vocabulary used in the health sector, while specialized, remains understandable to a broad audience when services are intended for universal use. Furthermore, complications arose from the intricate structure and layout of the services. The significance of simplifying services, minimizing lengthy lists, and using more

understandable terminology was highlighted in nearly all the test sessions. Implementing these improvements to the services would likely benefit a broader range of users [5].

There were distinct differences observed among the 3 user groups. Primarily, nonnative speakers assigned notably higher usability ratings to the services compared with the other 2 groups. One possible reason for this could be their overall satisfaction with the existence of such services, which enable them to seek help for their health issues without having to converse over the phone in a language that is not their native tongue.

One notable distinction between the user groups pertained to their preference for using either a computer or a mobile device. It was evident that older adults favored using computers, likely because of their larger screens and the familiarity that older adults have with them. Conversely, most nonnative Finnish speakers showed a preference for mobile devices, with some noting that they solely rely on their mobile devices and do not even own a computer. This preference may be influenced in part by financial constraints, which limit the number of devices a person can afford. Additionally, in our sample, older adults encountered fewer difficulties with processing long pieces of text compared with the other groups.

The promotion of online symptom checkers as a means to decrease unnecessary clinic visits [13] underscores the importance of ensuring they do not inadvertently increase contact with health care staff. Therefore, greater attention should be directed toward enhancing the cognitive accessibility of these tools, thereby enabling a wider range of users to use them effectively. In this study, users' incomplete understanding of the questions or answer options led them to select additional symptoms, resulting in more serious care recommendations and advising users to seek emergency health care.

In ensuring the cognitive accessibility of eHealth services, it is imperative to involve vulnerable groups in testing. Testing with vulnerable groups provides valuable insights. First, it emphasizes the need for well-planned test sessions with a manageable number of tasks. This approach ensures that participants can fully engage and provide meaningful feedback without being overwhelmed. All of these groups required considerable time to complete the test tasks, with most participants unable to finish both planned tasks with either service. Moreover, they necessitated more detailed instructions and support during the test sessions, as many participants within these groups were not at ease with using eHealth services.

Based on the findings of this study and as supported by the broader universal design literature [5], several design guidelines can be outlined. Foremost among these is the emphasis on clarity. (1) The options provided to the user should be clear and understandable. The user should understand what the differences between different options are and what actions are available for them. (2) It should be made clear to the user where they should be focusing on. This is particularly important in services that contain a lot of information and options. (3) Long or uncommon words and difficult compound words should be avoided. This is especially relevant in health-related terminology, as the user might not understand the special terms and might confuse different terms. (4) Navigating the services should be easy and effortless. The user should be presented with as few options as possible, and excessive scrolling should be minimized. This is because the user may inadvertently overlook relevant information.

Limitations

There are, naturally, some limitations to this study. First, the sample size of 13 participants was rather small, albeit quite typical for this type of qualitative study [43]. However, given the diverse nature of the user group and potential challenges related to cognitive accessibility, a more diverse participant pool could have been beneficial. Specifically, a wider age range of older adults could have been tested, considering their versatility as a group. Additionally, nonnative Finnish speakers could have been recruited from a more geographically diverse range of countries of origin. Moreover, testing should involve other diverse human characteristics, such as neurodiversity (including conditions such as attention-deficit/hyperactivity disorder, attention-deficit disorder, and various forms of autism). Given society's rapid transition toward digitalized services, it is crucial to broaden the scope to include other groups at risk of digital exclusion.

Another limitation of this study is its focus on only 2 online symptom checkers. While the range of available online symptom checkers is already extensive, it is important to include testing of other eHealth services designed for use by all citizens. Additionally, this study only examines a limited list of symptoms and assesses usage on a 1-time or 2-time basis.

In conclusion, we recommend conducting testing with a more diverse user group, with a specific focus on accessibility and cognitive accessibility. Additionally, adopting a broader test setup that encompasses a wider range of symptoms and includes other eHealth services intended for broad usage would be beneficial.

Comparison With Prior Work

Usability issues were efficiently identified during testing with special user groups. In a study by Liu et al [36], which involved 350 participants, similar problems were discovered with service A as found in our study. The authors observed comparable

challenges related to understanding questions and terminology, along with a need to enhance the visual layout and instructions for users. However, a notable disparity was observed in completion times: their participants completed the symptom checkers in an average of 4 minutes and 9 seconds, whereas users in our study required, on average, 3 times longer. In addition to uncovering issues that notably impact cognitive accessibility, our study identified similar usability problems as other assessments. Furthermore, as highlighted by Jormanainen et al [23], the same service was used over 1.5 million times for COVID-19 evaluation, suggesting its successful use by a vast number of users. Moreover, challenges with terminology have been recognized in other services [20].

This study has concentrated on cognitive accessibility with 3 distinct user groups. Comparable user groups have been used in other studies that center on eHealth services [1,29,30]. Upon comparing our findings with these studies, we observe that the necessity for clearer language and terminology, along with the clarity of the service, has previously been recognized through interviews and focus groups [1,29]. Our study provides more nuanced insights into how these issues manifest in practical usage.

Conclusions

In this study, we conducted a qualitative usability evaluation of 2 online symptom checkers, with a particular emphasis on the cognitive accessibility of the services. The evaluation targeted potentially vulnerable groups at risk of digital exclusion. Three distinct user groups participated in the tests: older adults, individuals with mild intellectual disabilities, and nonnative Finnish speakers. Our findings revealed that these groups encountered numerous difficulties with the tested services, particularly concerning their clarity and the language/terminology used. Furthermore, when testing with these groups, several key points must be considered: test sessions should be meticulously planned, instructions need to be clear, sessions should not be overly prolonged, and sufficient time must be allocated for each task.

In general, we found that testing with vulnerable groups was both useful and efficient. The rate of usability problems identified was notably high compared with the number of participants, and these issues were readily uncovered. These user groups encountered similar challenges related to information processing. It is imperative to provide them with better support through services that are clear, presenting less information and fewer options at once, and incorporating fewer long and complex words and selection lists. Additionally, following the principles of universal design, the proposed improvements are such that they will also benefit a more general user group. Therefore, we highly recommend testing with potentially vulnerable groups and, furthermore, expanding the user groups to include a representation of a broader variety of cognitive characteristics and challenges.

Acknowledgments

This research was conducted as part of the “Toward a Socially Inclusive Digital Society: Transforming Service Culture” project (DigiIN) and was funded by the Strategic Research Council at the Academy of Finland (grant numbers 352501 and 352503) and NordForsk (project 100477). We thank the service providers DigiFinland Oy and Klinik Healthcare Solutions for allowing us to test the services, and Selkeästi meille initiative (a joint project between The Finnish Association on Intellectual and Developmental Disabilities [FAIDD] and Kehitysvammatuki 57 ry) and Väylä ry for helping us to contact the test users. Finally, we thank Felipe González Carceller for his excellent contribution to the research.

Data Availability

The data sets generated during or analyzed during this study are not publicly available due to the sensitive nature of the data but the numeric data are available from the corresponding author on reasonable request.

Abstract

Background: Falls represent a large percentage of hospitalized patients with trauma as they may result in head injuries. Brain injury from ground-level falls (GLFs) in patients is common and has substantial mortality. As fall prevention initiatives have been inconclusive, we changed our strategy to injury prevention. We identified a head protection device (HPD) with impact-resistant technology, which meets head impact criteria sustained in a GLF. HPDs such as helmets are ubiquitous in preventing head injuries in sports and industrial activities; yet, they have not been studied for daily activities.

Objective: We investigated the usability of a novel HPD on patients with head injury in acute care and home contexts to predict future compliance.

Methods: A total of 26 individuals who sustained head injuries, wore an HPD in the hospital, while ambulatory and were evaluated at baseline and 2 months post discharge. Clinical and demographic data were collected; a usability survey captured HPD domains. This user experience design revealed patient perceptions, satisfaction, and compliance. Nonparametric tests were used for intragroup comparisons (Wilcoxon signed rank test). Differences between categorical variables including sex, race, and age (age group 1: 55-77 years; age group 2: 78+ years) and compliance were tested using the chi-square test.

Results: Of the 26 patients enrolled, 12 (46%) were female, 18 (69%) were on anticoagulants, and 25 (96%) were admitted with a head injury due to a GLF. The median age was 77 (IQR 55-92) years. After 2 months, 22 (85%) wore the device with 0 falls and no GLF hospital readmissions. Usability assessment with 26 patients revealed positive scores for the HPD post discharge regarding satisfaction (mean 4.8, SD 0.89), usability (mean 4.23, SD 0.86), effectiveness (mean 4.69, SD 0.54), and relevance (mean 4.12, SD 1.10). Nonparametric tests showed positive results with no significant differences between 2 observations. One issue emerged in the domain of aesthetics; post discharge, 8 (30%) patients had a concern about device weight. Analysis showed differences in patient compliance regarding age ($\chi_1^2=4.27$; $P=.04$) but not sex ($\chi_1^2=1.58$; $P=.23$) or race ($\chi_1^2=0.75$; $P=.60$). Age group 1 was more likely to wear the device for normal daily activities. Patients most often wore the device ambulating, and protection was identified as the primary benefit.

Conclusions: The HPD intervention is likely to have reasonably high compliance in a population at risk for GLFs as it was considered usable, protective, and relevant. The feasibility and wearability of the device in patients who are at risk for GLFs will inform future directions, which includes a multicenter study to evaluate device compliance and effectiveness. Our work will guide other institutions in pursuing technologies and interventions that are effective in mitigating injury in the event of a fall in this high-risk population.

Introduction

Frailty in aging is represented by a decline in functioning, with a risk of poor outcomes, including falls, which have implications for clinical practice and public health [1]. Falls are the primary cause of injury-related death in aging adults as 33% of adults 65 years and older fall each year [2,3].

Falls also represent a large percentage of hospitalized older patients as they may result in multiple injuries, including head trauma [4-6]. A head injury can be a common cause of disability and mortality and may be as mild as a bump, bruise (contusion), or cut and can be moderate to severe due to a concussion. Head injury may lead to premature nursing home admissions and increased hospital length of stay (LOS) with undesirable results for patients and hospitals [7,8]. Due to the aging population worldwide, the incidence of falls will continue to rise [9,10].

Studies have shown a clear pattern of increased health care costs associated with falls and frail individuals and various fall prevention initiatives have been promoted. Of the fall prevention interventions studied, some results have been favorable, such as those with well-developed educational programs [11]. However, others have been inconclusive [12-14], prompting our center to include head injury prevention, and therefore, we investigated a head protection device (HPD), similar to a helmet. In many fields, such as construction and sports, helmets have shown efficacy in preventing head injury risks, especially moderate to severe head injury [15-17]. The human head is vulnerable to even moderate impact as it can cause injury or death. A greater emphasis has been placed on job safety in industries like construction particularly to protect the head from injury, and hard hats and helmets have been required [18]. However, historically, helmets have not been used for normal daily living.

Health care systems are increasingly looking for contexts that provide accessible and efficient care and for medical devices and interventions to improve the patient experience and health outcomes [19,20]. Human factors, a scientific discipline, is important in clinical practice as it reveals how humans interact with interventions, such as devices, regarding expectations and limitations. User experience (UX) focuses on having a deep understanding of users and what they need and value [21-23]. UX research has been used to ascertain user domains such as adherence, usability, and perceived impact and has assisted with intervention development and refinement [24]. Adopting a UX research design will help ensure that new devices are easy to use and meet the needs of most patients.

Clinical practices should target effective strategies that improve individuals' quality of life and independence including screenings and interventions to manage injuries associated with falls [25,26]. Screenings that measure activities of daily living (ADLs) are essential, as the ability to perform daily tasks safely without exhaustion is a critical component of healthy aging, thus allowing older individuals to maintain their independence

and quality of life [27]. Measurement of daily activities is important as these may be predictors of early admission to assisted care facilities or the need for alternative living arrangements [28,29].

Recent literature advocates change toward tailored interventions that preserve an individual's independence by promoting furthering advancements in evidence-based treatment options and identifying cost-effective strategies [2,3]. Due to an increasing incidence of head injuries after ground-level falls (GLFs) in our trauma center, we designed a study that examined the effects of a low-cost HPD that has the potential to prevent head injury due to a fall.

The purpose of this UX research was to assess compliance by investigating the usability of an HPD from a patient's perspective in both acute care (hospital) and home contexts. We hypothesized that consented patients would follow the research protocol as recommended and wear the device in the hospital and at the 2 months post discharge. The primary limitation in an aging population is compliance, which we approached first. This in-hospital and home-based UX investigation concerning a low-cost treatment option may serve clinicians to better manage frailty and mitigate injury due to falls in their clinical practice.

Methods

Study Design

We considered the UX of frail individuals at this developmental, exploratory stage of a device to examine patient adherence and use. The UX assessment instrument adopted UX domains with a 5-point scale showing a more positive rating (rating of 5) and a lower rating (rating of 1). UX domains included device credibility, satisfaction, usability, adherence, effectiveness, relevance, and aesthetics. The primary outcome variable is patient compliance regarding wearing the device for 2 months. Additional data collected included the frequency of wearing the device during normal daily activities. Consistent with the literature, ADLs (such as ambulating and preparing meals) are critical for independence in aging populations [29].

Recruitment

Participants were recruited from among patients who were treated at our level 1 trauma center and subsequently admitted to the hospital for observation due to head injury. Protocol inclusion criteria included the following: patients admitted to the hospital with a fall sustaining a head injury, patients with fall risk (eg, patients who fell within the prior year or other physical conditions aligned with fall risk), and patients who were ambulatory and 55 years or older. Head injuries included in the study were patients with a concussion, contusion, lacerations, or loss of consciousness. The individuals recruited did not experience trauma that required surgical intervention. After signing the consent in the hospital, individuals were given an HPD at no cost to wear while ambulatory. After consenting

and wearing the HPD for in-hospital observation (and just before discharge), the hospital team asked whether the patients would wear the HPD at home. If the patient agreed, we indicated that the research team would follow up post discharge for additional observations using the UX survey.

Ethical Considerations

In total, 26 patients, who experienced a fall and sustained a head injury, wore an HPD in hospital, while ambulatory and were evaluated at baseline (before discharge) and at 2 months post discharge. The study protocol was approved by the institutional review board for research ethics and subsequently approved (IRB 1804935). Informed consent was obtained from the 26 patients who met the inclusion criteria and were willing to

participate. Confidentiality of information was maintained. The data are anonymized and patients are deidentified. Each patient was assigned a discrete number in the study and data are secured by the research scientist. There was no compensation for patient participation in the study.

HPD

The HPD includes an impact-resistant technological insert for additional head protection. It helps protect against bumps, scrapes, bruises, and other head injuries. The HPD is designed with ventilation to provide airflow for breathability without compromised protection. The HPD size can be adjusted with a hook and loop strap to give a quick, secure fit. [Figure 1](#) displays the HPD, which looks like a typical baseball cap.

Figure 1. Head protection device.

Usability Survey

A multidisciplinary health care team comprised of physicians, a research scientist, and physical therapists collaborated on the study design, developing a usability survey for patients who are at risk of fall, which led to a tangible and targeted intervention strategy. UX (usability) domain definitions were identified in the literature. Existing domain definitions were examined such as credibility, usability, and satisfaction [24], and additional domains were defined such as effectiveness, relevance, and aesthetics. The domains were refined, used on the usability

survey instrument, and functioned as outcome measures. [Textbox 1](#) shows the domains and UX definitions. UX domain data were collected on the instrument using a 5-point scale (5=strongly agree, 4=agree, 3=neutral, 2=disagree, and 1=strongly disagree). Patients were asked if they would recommend the HPD. The survey was intended to evaluate the HPD's usability and was administered after patients concluded their interaction with the HDP in the hospital. Those who agreed to wear the HPD at home were provided a device and were reevaluated post discharge.

Textbox 1. Domain and user experience definitions.

- Credibility: whether the user perceives the device to be trustworthy (eg, accuracy and quality of information presented in the patient consent)
- Satisfaction: the user's overall experience and interaction with the device
- Usability: the user's perceived ease of use of the device based on technical factors
- Adherence: whether the patient followed the device research protocol and continued to use the device as recommended (compliance) completing outcome measures
- Effectiveness: the extent the user perceives the overall value of the device, including safety and whether they would recommend it to another fall risk individual
- Relevance: the extent to which the device is appropriate for their situation and whether they perceive it meets their needs (provides protection to their head and helps them maintain a sense of independence)
- Aesthetics: factors such as color, pattern, size, shape, and weight

Data Collection

Quantitative data included demographics (age, sex, and race) and clinical data such as hospital LOS, number of GLFs, readmission to the hospital due to a GLF, and Glasgow Coma Scale. Data were also captured on the usability survey including domains such as device satisfaction, effectiveness, relevance, and aesthetics. Qualitative data were also collected on the usability survey, and patient comments were recorded regarding HPD benefits and opportunities for improvement.

Statistical Analysis

This UX research methodology included multiple patient observations and differences between observations were examined. Nonparametric tests, used to analyze ordinal and categorical data, were used for intragroup comparisons (Wilcoxon signed rank test). We used descriptive statistics, such that patterns might emerge from the data. Frequencies and percentages are reported for categorical variables. Medians and means with SDs are reported for continuous variables as appropriate. All computations included 26 patients. Group comparisons were made using chi-square tests or Fisher exact tests, where numbers were small and were reported as numbers (%). All variables were assessed for normality. Analyses of categorical variables (age) and patient adherence were tested using the chi-square statistic. Statistical tests are 2-tailed, with a significance level of an α of .05. All statistical analyses were performed using SPSS Statistics for Windows (version 28.0; IBM Corp).

Open-ended patient comments (qualitative data) were analyzed using a 3-step process: data reduction, data display, and conclusion drawing and verification. Data reduction helped sort and compile data excerpts (to organize the data) and assist in developing assertions regarding patient perceptions surrounding wearability (eg, comfort and weight) and modifications of HPD, if necessary. Excerpts were annotated with topics such as the benefits of HPD: positive feedback (aspects recorded as positive by the patient participants regarding HPD experience and interaction) and negative feedback (points considered negative by the patients pertaining to interaction with the device). As a next step, we analyzed the themes that emerged and categorized them based on whether they were related to the usability of the HPD or the health support the device offered.

Table 1. In-hospital and postdischarge intragroup domain differences.

User experience domains	Hospital, mean (SD)	Postdischarge, mean (SD)	<i>P</i> value
Credibility	3.91 (0.80)	4.01 (0.84)	.42
Satisfaction	4.15 (0.88)	4.80 (0.89)	.60
Usability	4.27 (0.66)	4.23 (0.86)	.80
Adherence	4.50 (0.86)	4.30 (1.06)	.06
Effectiveness (value)	4.62 (0.49)	4.69 (0.54)	.53
Relevance	4.42 (0.75)	4.12 (1.10)	.09
Aesthetics	3.38 (1.30)	2.96 (1.83)	.003

Results

Study Population

Among the 26 participants, 12 (46%) were female and 5 (19%) were non-White, with a median age of 77 (IQR 55-92) years. The average hospital LOS was 3.8 (SD 3.65) days. The majority (n=25, 96%) of patients who experienced head trauma were admitted to the hospital with a head injury due to a GLF (n=1, 4% were other types of falls); 22 (85%) had prior falls in the last 12 months and 16 (62%) had a hospital visit due to a head injury related to a fall within the year; 18 (69%) were on anticoagulants. The mean Glasgow Coma Score was 14.2 (SD 0.44). The age category was divided into 2 groups for analysis: age group 1 comprised of those who were 55 to 77 years and age group 2 comprised of patients 78 years and older.

Usability Survey Domain Results

In the hospital, all 26 consented patients wore the device with 0 falls recorded. After 2 months, 22 (85%) were wearing the HPD, had 0 falls, and had no hospital readmissions due to GLFs. At 6 months, 16 (62%) patients were compliant with wearing the device, with 0 falls and no hospital readmissions due to a GLF. The results showed positive scores, with no significant differences between ratings in hospital and post discharge regarding device credibility (0.42), satisfaction (0.60), usability (0.80), adherence (0.06), effectiveness (0.53), and relevance (0.09). A difference emerged for the domain of aesthetics. After the discharge, 8 (30%) patients had concerns regarding the device's weight, saying it was slightly heavier than a typical cap. Overall, users had a positive experience with the HPD and scores revealed that patients felt it was effective and relevant. Thus, post discharge, users would recommend the HPD to others at risk for falls (mean 4.52, SD 0.51). Users were compliant by wearing the device in hospital and at 2 months post discharge, supporting the research hypothesis. [Table 1](#) displays the UX domain means (SDs) for 2 observations.

Differences between categorical variables (age group 1: 55-77 years, group 2: 78 years and older, sex, and race) and protocol adherence were analyzed. Chi-square analysis showed differences in compliance regarding age ($\chi_1^2=4.27$; $P=.04$) but not sex ($\chi_1^2=1.58$; $P=.23$) or race ($\chi_1^2=0.75$; $P=.60$). Age group 1 was more likely to wear the device for normal daily activities.

Patient Device Use in Daily Activities

The usability survey data captured patient device use during typical ADLs at 2 weeks and at 2 months post discharge. Users were provided a list of daily activities and were asked to rate the frequency of wearing the device. Consistent with the literature, ADLs, such as ambulating and preparing meals, are

critical for independence in an aging population [29]. The highest score on the usability instrument was a “5” which indicated that the patient would wear the HPD “most often.” In-home contexts, patients indicated they most often wore the device ambulating and when driving (to meals and doctor appointments) and less often for personal hygiene. Table 2 shows within-group differences in device use in daily activities.

Table 2. Within-group differences in device use in daily activities.

Daily activities	Two weeks, mean (SD)	Two months, mean (SD)	P value
Ambulating	4.31 (0.92)	4.15 (1.12)	.47
Driving (or being driven)	4.04 (0.77)	4.12 (0.76)	.16
Grocery shopping or shopping	3.69 (1.28)	3.58 (1.23)	.54
Relaxing (TV)	4.00 (1.06)	3.31(1.10)	.20
Housekeeping	3.35 (1.09)	3.27 (1.00)	.67
Preparing meals	2.77 (0.99)	2.50 (1.06)	.07
Personal hygiene	2.42 (0.94)	2.27 (0.96)	.49

Positive Patient Feedback

Open-ended questions on the usability instrument elicited patient qualitative comments regarding HPD benefits and opportunities for improvement. As a result, 2 dominant themes emerged, namely HPD usability and HPD as health support (protection). Usability was associated with the use of the device and functionality in terms of wearability. Health support included themes that were aligned with head protection for a patient.

Usability and relevance from the patients’ perspective translated into wearability, and the majority of patients wore the device after 2 months post discharge. Participants felt that the HPD was comfortable and easy to wear. However, 8 (30%) patients mentioned that the HPD was not as light as a typical cap due to the protective “technology insert” and suggested the HPD could be lighter in weight. One male participant stated,

The cap is heavier than a usual baseball cap and it took me longer to get used to it. I would like it a bit lighter in weight if possible and more air vents to let in air.

Health support from the participant’s perspective sufficed as the primary benefit, as 18 (69%) commented that the device protected their head in the event of a fall. Patients called the device a “cap” as it resembles a baseball cap. One patient stated, “Protection for my head is important. I will wear it going out to eat and to doctor appointments.” Another female participant indicated, “I wear it eight hours a day to protect my head.” Two patients (male and female) indicated post discharge, they hit their heads on cabinets, as 1 commented:

I already bent over and hit my head on a cabinet; it protected me from another head injury. Since wearing the cap, I have not had a fall, only a bump and I had on my cap.

A 74-year-old female participant stated, “I fell last year and I will wear this walking whenever possible. It protects my head.” A male participant noted, “The device is protective and

comfortable; I forgot I had it on.” From patient comments, the HPD is cognate with head protection.

Discussion

Principal Findings

Using a UX design, we investigated the usability of a novel HPD on patients with head injury in acute care and home contexts to predict future compliance. All 26 patients provided positive scores for the HPD post discharge regarding satisfaction, usability, effectiveness, and relevance. Nonparametric tests showed positive results, with no significant differences between 2 observations at 2 months. Chi-square analysis showed a significant difference in HPD compliance regarding age but not sex or race as age group 1 was more likely to wear the device for normal daily activities. Patients most often wore the device ambulating and head protection was identified as the primary benefit. Thus, patients were most likely to recommend the HPD to others at risk of GLFs.

Due to the consistently high rate of head injuries after GLFs in our center, the targeted team strategy for an HPD and UX research design was developed. We realized that patient compliance in the geriatric population has been a limiting factor and approached that aspect first. Patients adhered to the research protocol by wearing the device in the hospital and post discharge, in the home, supporting the research hypothesis. At 2 months, 22 (85%) patients wore the device with 0 falls recorded and no readmissions due to falls.

Our multidisciplinary team, a diverse group of medical professionals, consisting of physicians, research scientists, and physical therapists, studied a device to be worn during daily activities in home environments. Recent literature has advocated for home care strategies [30] and interventions to be used in home contexts where falls most often occur [31]. Managing falls in this high-risk population is complex, requiring a systemic and collaborative approach directed by a multidisciplinary team focused on improving patient outcomes [3].

Limitations

Accuracy is critical regarding the collection of patient data, and the in-hospital data collection was conducted under medical supervision. However, the limitations of the UX research included the nature of self-reporting by participants post discharge at 2 and 6 months. One measure to counter this bias was to include a family member during the evaluation to corroborate the patient's self-reported data and responses. Another issue and limitation, we noted, was the difficulty of trying to reconnect or contact this population at follow-up due to cognitive decline, the extent and severity of head trauma, and other injuries associated with a GLF.

Conclusions

The results show our proposed HPD intervention will have a high compliance rate in those at risk for GLFs as it was considered usable, protective, and relevant. Managing individuals with fall risk may include future investigations of specific interventions and low-cost devices that preserve a patient's independence and physical function, and research that contributes to further advancements in evidence-based treatment options. The feasibility and wearability of the device in patients with GLF with head injuries will inform future directions, which includes a multicenter study to evaluate compliance and device effectiveness. Our work will guide other health care institutions in pursuing cost-effective treatments and technological interventions that are usable and effective in improving outcomes for this fall risk population.

Abstract

Background: Optimal rehabilitation programs for orthopedic joint replacement patients ensure faster return to function, earlier discharge from hospital, and improved patient satisfaction. Digital health interventions show promise as a supporting tool for re-enablement.

Objective: The main goal of this mixed methods study was to examine the usability of the AIMS platform from the perspectives of both patients and clinicians. The aim of this study was to evaluate a re-enablement platform that we have developed that uses a holistic systems approach to address the *de-enablement* that occurs in hospitalized inpatients, with the older adult population most at risk. The Active and Independent Management System (AIMS) platform is anticipated to deliver improved patient participation in recovery and self-management through education and the ability to track rehabilitation progression in hospital and after patient discharge.

Methods: Two well-known instruments were used to measure usability: the System Usability Scale (SUS) with 10 items and, for finer granularity, the User Experience Questionnaire (UEQ) with 26 items. In all, 26 physiotherapists and health care professionals evaluated the AIMS clinical portal; and 44 patients in hospital for total knee replacement, total hip replacement, or dynamic hip screw implant evaluated the AIMS app.

Results: For the AIMS clinical portal, the mean SUS score obtained was 82.88 (SD 13.07, median 86.25), which would be considered *good/excellent* according to a validated adjective rating scale. For the UEQ, the means of the normalized scores (range -3 to +3) were as follows: attractiveness=2.683 (SD 0.100), perspicuity=2.775 (SD 0.150), efficiency=2.775 (SD 0.130), dependability=2.300 (SD 0.080), stimulation=1.950 (SD 0.120), and novelty=1.625 (SD 0.090). All dimensions were thus classed as *excellent* against the benchmarks, confirming the results from the SUS questionnaire. For the AIMS app, the mean SUS score obtained was 74.41 (SD 10.26), with a median of 77.50, which would be considered *good* according to the aforementioned adjective rating scale. For the UEQ, the means of the normalized scores were as follows: attractiveness=2.733 (SD 0.070), perspicuity=2.900 (SD 0.060), efficiency=2.800 (SD 0.090), dependability=2.425 (SD 0.060), stimulation=2.200 (SD 0.010), and novelty=1.450 (SD 0.260). All dimensions were thus classed as *excellent* against the benchmarks (with the exception of novelty, which was classed as *good*), providing slightly better results than the SUS questionnaire.

Conclusions: The study has shown that both the AIMS clinical portal and the AIMS app have *good to excellent* usability scores, and the platform provides a solid foundation for the next phase of research, which will involve evaluating the effectiveness of the platform in improving patient outcomes after total knee replacement, total hip replacement, or dynamic hip screw.

Introduction

Background

According to the World Health Organization's 2019 Global Burden of Disease study, approximately 1.71 billion people globally experience musculoskeletal conditions. Low back pain is the most common condition, affecting an estimated 568 million people [1]. In the United Kingdom, it has been estimated that musculoskeletal conditions affect >20 million people, approximately a third of the population [2]. Musculoskeletal conditions are the second greatest contributor to disability worldwide and is a significant burden to the individual and society [3]. It is expected that the impact of musculoskeletal conditions on the health service and on society will continue to rise as life expectancy increases [4]. Many different approaches have been explored to reduce this burden, including medical interventions, work-related approaches (reducing stress at work as well as improving health and safety regulations), social education (improving awareness of exercise and healthy eating), and the use of technology.

Musculoskeletal conditions comprise >150 different disorders, diseases, and syndromes that affect bones, joints, muscles, the spine, and soft tissues [3]. While some conditions are short lived, such as sprains and fractures, others can be lifelong conditions requiring ongoing treatment. Pain is a common symptom of musculoskeletal conditions. Back and neck pain, osteoarthritis, rheumatoid arthritis, and fractures are among the most disabling conditions and can be a significant barrier to healthy aging [5]. Musculoskeletal conditions can be classified by the body part affected (eg, knee pain and shoulder pain), whether the condition is noninflammatory (such as osteoarthritis) or inflammatory (such as rheumatoid arthritis), and whether the condition is restricted to the musculoskeletal system or more widespread (such as systemic lupus erythematosus) [4]. To compound matters, musculoskeletal issues tend to be associated with other diseases, such as heart or respiratory disease and stroke, and lead to an increase in disabilities and deaths [6-8]. It has been estimated that musculoskeletal conditions account for up to 21% of annual general practitioner consultations across England [9], and health service costs from inability to work and sickness absence in the United Kingdom are approximately £100 billion (US \$125 billion) annually [10]. It is important to find solutions that will help reduce the significant burdens on the individual, society, the economy, and the health service. While many solutions will be of a medical nature, technology has a significant part to play in easing the burdens. In the next subsection, we discuss some digital health interventions (DHIs) for musculoskeletal conditions.

A number of different terminologies exist in the health domain for software solutions generally. The terms eHealth and mobile health (mHealth) have been used for a number of years. More recently, the more encompassing term *digital health* has been

introduced. This is defined as “encompassing eHealth [which includes mHealth] as well as developing areas such as the use of advanced computing sciences (in the fields of ‘big data,’ genomics and artificial intelligence, for example)” [11]. Examples of digital health solutions include primary and secondary care IT systems; patient portals that provide secure web-based access to a range of health services, such as My Diabetes My Way and PatientView [12]; personal health data stores such as Mydex [13]; telehealth systems such as Attend Anywhere and Near Me [14]; and health-related mobile apps. It is believed that these systems can benefit health care delivery by improving different outcomes, such as effectiveness, efficiency, accessibility, safety, and personalization [15]. There has been a growing public interest in DHIs because they can allow individuals to monitor, manage, and improve their health and quality of life in a more personalized way, potentially more cost-effectively, and at a time that suits them [16-18].

Optimal rehabilitation programs for orthopedic joint replacement patients ensure faster return to function, earlier discharge from hospital, and improved patient satisfaction [4,19-21] as well as prevent further deconditioning [22]. The aim of this study was to evaluate the usability of a re-enablement platform called Active and Independent Management System (AIMS) that was developed to address the *de-enablement* that occurs in hospitalized inpatients for one of the groups considered to be most at risk, that is, older adults. The platform is capable of delivering digital rehabilitation plans and tracking the progression of the plans in real time; in addition, it can be used both in hospital and at home after a patient is discharged. The rationale for using such a system is to help reduce the time spent in hospital and improve patient satisfaction through self-management.

Re-Enablement DHIs

This subsection examines some recent literature related to the use of DHIs for total knee replacement (TKR) or total knee arthroplasty (TKA) and total hip replacement (THR) or total hip arthroplasty (THA). Hussain et al [23] developed a TKR platform comprising a mobile phone app, a wrist-worn activity tracker, and a clinical web portal. The purpose-built iOS and Android apps included weekly psychoeducation sessions and tasks that were delivered by a program guide via text and voice recordings. By obtaining the data from the tracker and the app, the clinician could monitor patient progress and the configured physiotherapy programs, while the patient care team could review the progress and the designated programs using the web portal. Physiotherapy programs were mostly from a library of videos created for TKR rehabilitation, which were made available in the app once set by the clinician. The authors planned to conduct a 13-month multisite unblinded randomized controlled trial in which participants were assigned to 1 of 2 study groups [23]. The participants for the experiment were patients who underwent TKR, and the study included an active

intervention period from the time the patients were scheduled for surgery (approximately 4 weeks before surgery) to 12 weeks after the surgery, followed by a 40-week free-living period until 1 year after surgery.

Timmers et al [24] investigated the effect of a mobile app for day-to-day postoperative care education on TKR patients regarding the level of pain compared to those who only received standard information about their recovery through the app. The study involved 114 patients in the intervention group and 99 patients in the control group. In the intervention group, 93 patients downloaded and used the app. The results showed that, in comparison with standard patient education, the active education and coaching of patients on a day-to-day basis via the app in the 4 weeks after TKR resulted in a significant decrease, among other things, in the patients' levels of pain and a significant improvement in patients' physical functioning and quality of life, as well as their ability to perform physiotherapy exercises and activities of daily self-care.

Van Dijk-Huisman et al [25] developed a mobile app to prevent the negative effects of inactivity in hospital. The app supported objective activity monitoring, gave patients a view of their recovery progress, and offered a customized exercise program. The aim of the study was to investigate the potential of the app to enhance physical activity levels and functional recovery after orthopedic surgery discharge. In all, 97 patients undergoing TKA and THA were recruited for the evaluation. The control group (n=64) received standard physiotherapy, while the intervention group (n=33) used the mobile app in addition to physiotherapy. The time spent in active and functional recovery on postoperative day 1 (POD1) was measured. The app use, corrected for age, resulted in patients standing and walking on POD1 for an average increase of 28.43 (95% CI 5.55-51.32) minutes. The odds of achieving functional recovery on POD1 were 3.08 times higher (95% CI 1.14-8.31) with the use of the mobile app. The authors concluded that a mobile app combined with an accelerometer demonstrated the potential to enhance patients' activity levels and functional recovery during their hospital stay [25].

Wijnen et al [26] investigated the effectiveness of a home-based rehabilitation program using a tablet app and remote coaching for patients after THA. Existing data from 2 studies were combined: patients from a single-arm intervention study were matched with the historical controls from an observational study. Patients aged 18 to 65 years who had undergone THA were included. The intervention group had a 12-week home-based rehabilitation program with instructional videos on a tablet device and remote coaching. Patients were asked to perform strengthening and walking exercises at least 5 days a week. The intervention group was compared with a control group that included patients who received usual care. Effectiveness was measured at 4 points (preoperatively and 4 weeks, 12 weeks, and 6 months postoperatively) by means of functional tests and self-reported questionnaires. The intervention group performed functional tests significantly faster at 12 weeks and 6 months postoperatively and also scored significantly higher on the subscales *function in sport and recreational activities* and *hip-related quality of life* of the Hip Disability and Osteoarthritis Outcome Questionnaire, as well as on the subscale *physical*

role limitations of the Short Form Health Survey-36 at 12 weeks and 6 months postoperatively. Large effect sizes were found on functional tests at 12 weeks and 6 months, endorsed by effect sizes on the self-reported outcomes. The authors concluded that the results demonstrated larger effects in the intervention group than in the historical controls, indicating that a home-based rehabilitation program using a mobile app after THA can be more effective than usual care [26].

Bell et al [27] ran a controlled pilot study for TKR patients, investigating the feasibility and effectiveness of interACTION, a remote (wearable) rehabilitation monitoring platform developed for use by patients after TKR. The InterACTION platform has portable motion sensors placed on either side of a joint to collect joint orientation data using a custom mobile app and then send the data to the clinician's web-based portal. The mobile app also contains 30 knee-specific home exercises for TKR rehabilitation that the physical therapist can personalize remotely through a web-based clinical portal. The study compared 2 groups: 19 patients who used the interACTION platform and a control group with 19 patients who used standard postoperative outpatient rehabilitation with a physical therapist (2-3 sessions per week over a maximum of 10 weeks), supplemented with a home exercise program. The primary outcome measured was value, operationally defined as the change in the activities of daily living scale of the Knee Outcome Survey at 10 weeks divided by the total cost of rehabilitation (determined from the total number of physical therapy sessions and the billable charges for each session during the 10 weeks the patients were enrolled in the study). In terms of this measure, no statistical differences were found between the groups. The study showed relatively low and not significant differences between the groups in terms of attrition rates, indicating that both interventions were acceptable. There was a small decrease in clinic visits by patients in the interACTION group, and all patients and physical therapists in the group indicated that they would use the system again.

Bäcker et al [28] developed a mobile app with a GenuSport sensor that allows isokinetic exercises to improve postoperative quadriceps weakness and knee motion. The sensor was placed underneath the patient's knee, and gamified exercise routines were presented through the app consisting of two exercises: (1) *high striker game*, where the patient has to push the knee onto the sensor for 5 seconds; and (2) *flight simulator*, where the player is supposed to keep the knee in the air for 100 seconds. The authors carried out a randomized controlled trial with a 2-year follow-up to evaluate the effectiveness of the app-based rehabilitation for patients after TKA [28]. In all, 35 patients completed the study and were randomly assigned to 2 groups: 20 patients received the app-based exercise program, and 15 patients were included in the control group. Patients in the app group used an external device to measure knee range of motion starting on the day of surgery, whereas patients in the control group underwent regular physiotherapy. Functional outcome scores using the Knee Injury and Osteoarthritis Outcome Score, the Knee Society Scoring System, and a visual analog scale for pain were analyzed. The results showed that, in the short term, the app group performed significantly better than the control group when taking a 10-minute walk, with less pain. In the

longer term, the app group also performed significantly better, with higher Knee Society Scoring System scores as well as requiring fewer painkillers. In addition, the app group participants were more likely to participate in sports.

Colomina et al [29] developed an mHealth system for older patients with complex chronic conditions undergoing elective THA or TKA. The mHealth system formed part of the Personalized Connected Care for Complex Chronic Patients platform, which contained a web-based smart adaptive case management system for health care professionals that seamlessly integrated with a patient self-management mHealth system that supported communication between health care professionals and patients. The authors assessed the effectiveness and cost-effectiveness of implementing an mHealth-enabled integrated care (IC) model for patients with complex chronic conditions undergoing TKA or THA versus usual care [29]. A prospective pragmatic 2-arm parallel implementation trial was conducted in the rural region of Lleida in Catalonia, Spain, for 3 months. A total of 29 patients with complex chronic conditions undergoing TKA or THA and their caregivers received the IC program, while 30 patients with statistically comparable baseline characteristics, such as age, sex, and type of arthroplasty, were recruited for the usual care group. The results suggested that both treatment models significantly improved the physical and mental health status of the patients; however, IC significantly reduced the number of unplanned visits related to the surgery procedure and consequently significantly lowered the patients' expenses.

Rian et al [30] presented a web tool called Eir for symptom registration at home after knee arthroplasty. Given that the system was previously used in cancer care, a separate patient module was designed for patient-reported postoperative symptom assessment and medication registration after fast-track TKA that consisted of measurements of pain and side effects, as well as detailed registration of the use of analgesic drugs. The authors conducted a usability and feasibility study using a randomized controlled trial involving 134 participants [30]. The tool's usability was assessed with the use of the System Usability Scale (SUS) by 119 of the 134 participants, while the feasibility data were collected qualitatively. The results showed that 70% of the participants managed to use the tool at home without any technical support, although they indicated technical challenges related to the log-in procedure or internet access. The usability was rated high, with a mean SUS score of 89.6 (median 92.5; range 22.5-100).

Two literature reviews assessing the use of app-based rehabilitation for TKA or THA were conducted recently [31,32]. Bäcker et al [31] examined the functional outcomes of app-based rehabilitation of patients after TKA or THA. The review identified 420 entries from MEDLINE or PubMed and Google databases, but only 9 publications met the inclusion criteria, covering 518 patients in the intervention groups and 549 patients in the control groups. Five studies used app-based exercise instructions delivered via a mobile device, and 4 studies used a sensor or motion tracker. The average follow-up was 9.5 (SD 8.1; range 3-23.4) months. Overall, significantly lower activity visual analog scale values were observed for the interventional groups in the short term ($P=.002$). There were no other

significant differences observed between the 2 groups. The study found that there were significant short-term improvements in the mobile app group. The authors concluded that mobile apps provide an alternative to in-person sessions that may improve access to physical activity for patients after TKA or THA, and, in combination with a Bluetooth-enabled sensor for isometric exercises, patients can additionally receive real-time feedback after TKA or THA [31].

Constantinescu et al [32] conducted a systematic literature review on the use of commercially available smartphone apps and wearable devices to assist rehabilitation interventions after TKA from the PubMed, Cochrane Library, MEDLINE, and Web of Science databases. Of the 60 full-text studies identified (published between January 2020 and September 2021), a total of 15 met the inclusion criteria, of which 4 studies used smartphone apps, 7 used wearable devices, and 4 used both to monitor physical activity and patient status after TKA. In terms of primary outcomes, 3 studies examined device accuracy, 3 recovery prediction, 2 functional recovery, 2 physical activity promotion, 2 patient compliance, 2 pain control, and 1 study examined health care use. The authors concluded that commercially available apps and wearable devices can capably monitor physical activity and improve patient engagement after TKA, making them approaches that support or replace traditional rehabilitation programs [32]. Using different strategies in interventions, such as setting step goals, using app-based patient engagement platforms, and establishing patient-specific benchmarks for recovery, can enhance the effectiveness of the treatment.

The AIMS Platform

It is well established that musculoskeletal conditions contribute to a large number of disabilities worldwide, and the projections show that this number will continue to rise. Initiatives are ongoing to combat this problem proactively (eg, reducing stress, improving health and safety regulations, exercising, and healthy eating). Furthermore, reactive approaches of optimal prehabilitation and rehabilitation programs are also undergoing development to optimize operations and ensure the best use of available resources while improving patient satisfaction. The aim of this study was to evaluate a rehabilitation platform in an effort to combat the lack of enablement in hospitalized older adults considered more vulnerable. The platform is capable of delivering digital rehabilitation plans and tracking the progression of these plans in real time; in addition, it can be used both in hospital and at home after patient discharge. The rationale for using such a system is to help reduce time spent in hospital and improve patient satisfaction through self-management.

The AIMS platform helps manage patients' rehabilitation programs. Each patient is registered by a clinician at the beginning of their patient pathway, and the system collects certain relevant information about the patient as they move through their journey. Rehabilitation clinicians use this platform to create, monitor, and adjust a patient's rehabilitation package as and when required. A team consisting of stakeholders is assigned to each patient and is responsible for the delivery of the program. A library of physiotherapy exercises and

educational videos (eg, the use of a walking aid or how to apply a patient’s splint) have been recorded and uploaded into the system (Figure 1). Each staff member can attach a series of video exercises specific to the patient’s needs that can help the re-enablement process.

The platform consists of 2 components: a web content management system used by clinicians to create rehabilitation plans for postoperative patients and a mobile app designed to deliver these rehabilitation plans to the patients with a series of exercises to be completed by them.

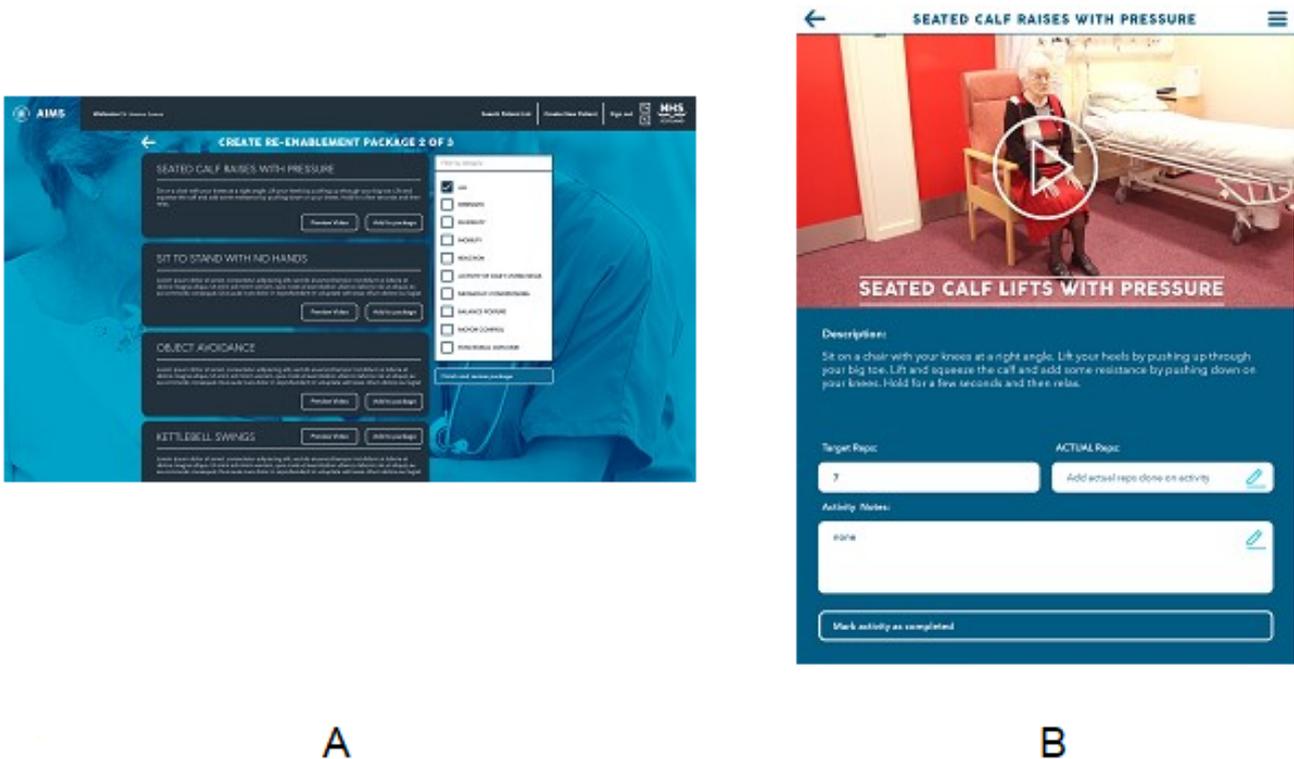

The clinician starts by creating a user account for a patient (all patient information is anonymized with a random unique ID number that is later used to gain access to the rehabilitation plan through the app; Figure 1). The clinician then sets up a specific rehabilitation plan for this patient according to their needs. The clinician can search from all available exercises by using general search terms to filter what is available and also preview the associated video to make sure the appropriate plan is created (Figure 1A). The clinician must then determine the number of repetitions for each exercise and the frequency at which they need to be performed each day, usually 4 sessions a day. After the plan is complete, it becomes active on the patient’s device, and the clinician then demonstrates to the patient how to use the app. This enables the clinician to monitor a patient and their progress each time they complete an exercise. There is also capability for the patient to comment on any particular issues with any of the exercises, and the clinician will be able to view the comments using the content management system and modify the plan accordingly. A typical example of a rehabilitation plan for a patient consists of some simple but very effective exercises

(eg, heel slides, knee extensions, and knee flexions). The patient would be asked to perform 10 repetitions of all exercises in 4 daily sessions. The rehabilitation process starts after the operation for as long as the patient remains in hospital, and there are physiotherapists available to offer assistance during the patient rehabilitation process; the app does not prompt patients to complete their daily rehabilitation plan because these sessions are already scheduled in the hospital ward. It is up to the patient to continue using the app for rehabilitation after hospital discharge (the app is available for free download from app stores).

The patient uses a tablet device provided by the hospital to gain access to the AIMS mobile app and work on their rehabilitation plan. Each user is given a random ID number generated by the clinician that is required to log in to the app; no password is required because all information is anonymized. After this, the user can use the app and work on their specific rehabilitation plan and set of exercises and also view their daily plan progress. The patient is provided a textual description of the exercise and a video with audio explaining how it should be performed and how many repetitions should be performed (Figure 1B). At the bottom of the page featuring each exercise, feedback can be provided on how many repetitions were achieved as well as any comments if there were any issues when performing the exercise.

Typically, the app would be used by a member of the staff or a member of the family during visiting hours to help the patient with their exercises by encouraging them or participating with them and achieving successful completion of the rehabilitation plan.

Figure 1. (A) The Create Rehabilitation Re-Enablement Package Screen, and (B) the patient exercise screen.

Aims of the Study

The aim of this study was to investigate the usability of the AIMS platform from the perspectives of both clinicians and patients. Two well-known instruments were used to measure usability: the SUS [33] with 10 items and, for finer granularity, the User Experience Questionnaire (UEQ) [34] with 26 items.

The evaluation aims to answer the following 2 research questions (RQs):

- RQ1: does the AIMS clinical portal provide a solution that could be usable by clinicians?
- RQ2: does the AIMS app provide a solution that could be usable by patients?

Methods

Overview

The World Health Organization defines evaluation as “the systematic and objective assessment of an ongoing or completed project [with the aim of determining] the relevance and fulfilment of objectives, development efficiency, effectiveness, impact and sustainability” [35]; and the guide for monitoring and evaluating DHIs outlines 7 stages of DHI maturity, ranging from preprototype to full deployment. This project is considered to be at the prototype stage of maturity, which would include usability testing. Ways to improve the system would also be investigated.

Usability is recognized as a significant quality indicator that determines the success of software applications [36-39]. Johnson et al [40] defines three main approaches to evaluate usability: (1) user based (a sample of prospective users use the system), (2) expert based (≥ 1 usability or human-computer interaction experts evaluate the system), and (3) model based (formal methods are used to predict user performance). Our health board members were keen on using the user-based approach to evaluate the DHI; hence, this approach was chosen.

Many validated usability instruments have been proposed in the literature with varying numbers of questions. In this study, we used 2 well-known validated instruments: the SUS and the UEQ. The SUS [33] consists of 10 statements (5 positive and 5 negative) that the users rate on a scale ranging from 1=*strongly disagree* to 5=*strongly agree*. The questionnaire alternates between positive and negative statements to avoid random answers. The aggregated score out of 100 can be compared with the average SUS benchmark score of 68.0. To represent SUS scores, Bangor et al [41] defined a 7-point adjective rating scale: *best imaginable*, *excellent*, *good*, *OK*, *poor*, *awful*, and *worst imaginable*.

The UEQ assesses the extent to which (1) the product meets expectations and (2) a product can be compared with other systems using a published benchmark. Schrepp et al [42] developed an adjective rating scale for benchmarking, and a mean score of >1.75 would be considered in the 10% best results. While the UEQ provides finer detail than the SUS, it

was felt that asking busy clinicians to rate 26 statements may result in a smaller number of responses compared to asking them to rate 10 SUS statements; therefore, it was decided to use the SUS with all participants and the UEQ with a small number of participants.

Some qualitative information was also gathered using open-ended questions to gain a deeper understanding of participants' views of the AIMS platform.

Ethical Considerations

Ethics approval for this study was obtained from Hairmyres University Hospital, Lanarkshire. One of the conditions of approval was that all personal information from the study should be removed and that patient information should be kept private and safe (Data Protection Impact Assessment Questionnaire for Active Independent Mobility System [AIMS] Pilot Study Hairmyres University Hospital, Lanarkshire; May 29, 2019). All participants provided consent before participating in the study.

Participants

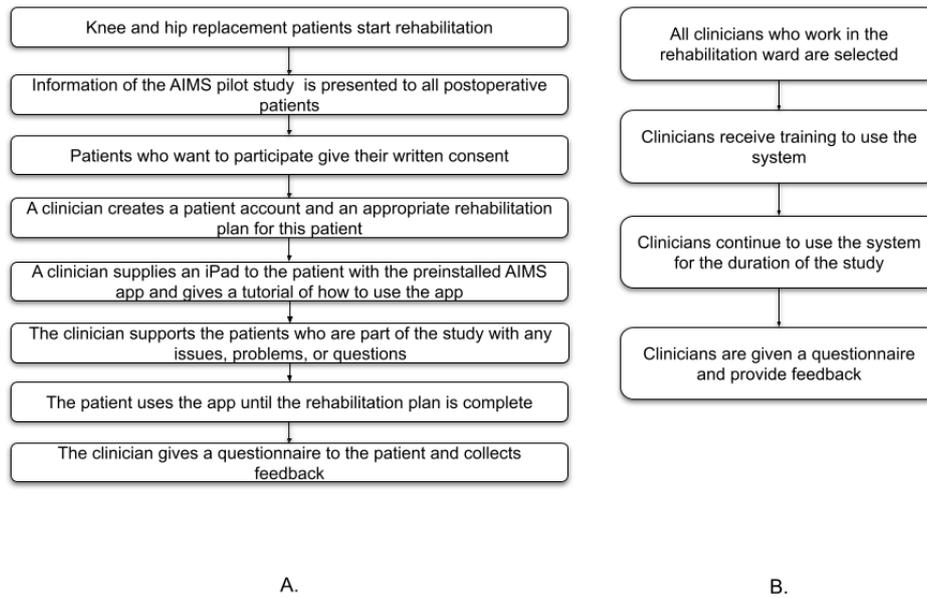

In all, 26 physiotherapists and health care professionals volunteered to evaluate the AIMS clinical portal; and 44 patients in hospital for TKR, THR, or dynamic hip screw (DHS) agreed to participate in evaluating the AIMS app. The study was carried out on May 5, 2019, or November 14, 2019.

Test Protocol

The 6-month-long study was undertaken in the rehabilitation ward in an Hairmyres University Hospital, Lanarkshire, that specializes in TKR or THR surgery. Only clinicians had access to the patients during their stay in the hospital, and a member of the team of clinicians (lead study clinician) had oversight over recruiting and running the experiment. Technical support was provided by the study team to all clinicians during the rehabilitation sessions in the hospital, but this was not in the rehabilitation ward. Questionnaires were given to the participants in a paper-based form, which they were asked to complete and hand back to the lead study clinician toward the end of their rehabilitation stay. The study was conducted using 10 hospital-supplied second-generation iPad Air 2 devices running iOS 10.3 with a 9.7-inch display in portrait orientation (refer to the patient test protocol presented in [Figure 2A](#)).

Clinicians of the rehabilitation team in the hospital were all given training on how to use the portal to create rehabilitation packages for patients and how they would look in the app. They were also involved in the development and design process with focus groups and early prototyping, which enabled most of them to develop a good understanding of the AIMS platform. As the study was taking place alongside patients who were not part of the study, everyone had to be able to help the patients, which is why they were all trained to use the system. Clinicians were given a questionnaire to complete after they had used the platform a few times (refer to the clinician test protocol presented in [Figure 2B](#)).

Figure 2. (A) Patient test protocol. (B) Clinician test protocol. AIMS: Active and Independent Management System.

Results

For the SUS, the analysis was carried out using Excel (Microsoft Corp); and for the UEQ, the analysis was carried out using the standard UEQ spreadsheet.

AIMS Clinical Portal: SUS Results

All 26 participants completed the SUS questionnaire (100% response rate). The mean SUS score obtained was 82.88 (SD 13.07), with a median of 86.25. This score would be considered *good/excellent* according to the adjective rating scale developed by Bangor et al [41]. A breakdown of the participants' answers to the SUS questions regarding the AIMS clinical portal is provided in Table 1.

Table 1. Participants' answers to the System Usability Scale (SUS) questions for the Active and Independent Management System clinical portal (n=26).

Statements	Participants agreeing, n (%)	Participants disagreeing, n (%)	SUS scores, mean (SD)
Positive statements			
I think that I would like to use this system frequently	23 (88)	2 (8)	4.00 (0.76)
I thought the system was easy to use	24 (92)	1 (4)	4.50 (0.77)
I found the various functions in this system were well integrated	22 (85)	2 (8)	4.50 (0.96)
I would imagine that most people would learn to use this system very quickly	23 (88)	1 (4)	4.19 (0.65)
I felt very confident using this system	24 (92)	1 (4)	4.38 (1.42)
Negative statements			
I found the system unnecessarily complex	2 (8)	23 (88)	2.04 (0.73)
I think that I would need the support of a technical person to be able to use this system	1 (4)	24 (92)	1.50 (0.77)
I thought there was too much inconsistency in this system	0 (0)	23 (88)	1.62 (0.86)
I found the system very cumbersome to use	3 (88)	21 (81)	1.73 (1.05)
I needed to learn a lot of things before I could get going with this system	0 (0)	24 (92)	1.42 (0.65)

AIMS Clinical Portal: UEQ Results

Invitations were sent to 12 (46%) of the 26 participants. Of these 12 participants, 10 (83%) completed the UEQ questionnaire. The means of the normalized scores (range -3

to +3) for the AIMS clinical portal were as follows: attractiveness=2.683 (SD 0.100), perspicuity=2.775 (SD 0.150), efficiency=2.775 (SD 0.130), dependability=2.300 (SD 0.080), stimulation=1.950 (SD 0.120), and novelty=1.625 (SD 0.090). Figure 3 shows the bar chart of the results for the AIMS clinical

portal against the benchmarks, showing all dimensions classed as *excellent* and confirming the results from the SUS questionnaire. Table 2 provides the mean (SD) and variance of the normalized values for the items in the UEQ questionnaire

for the AIMS clinical portal. In most cases, the values are very encouraging, with the exception of *conservative* and *innovative*, although this is still rated *good*. Figure 4 shows the bar chart of the data grouped into the 6 UEQ dimensions.

Figure 3. Bar chart of the Active and Independent Management System clinical portal User Experience Questionnaire results against the benchmarks.

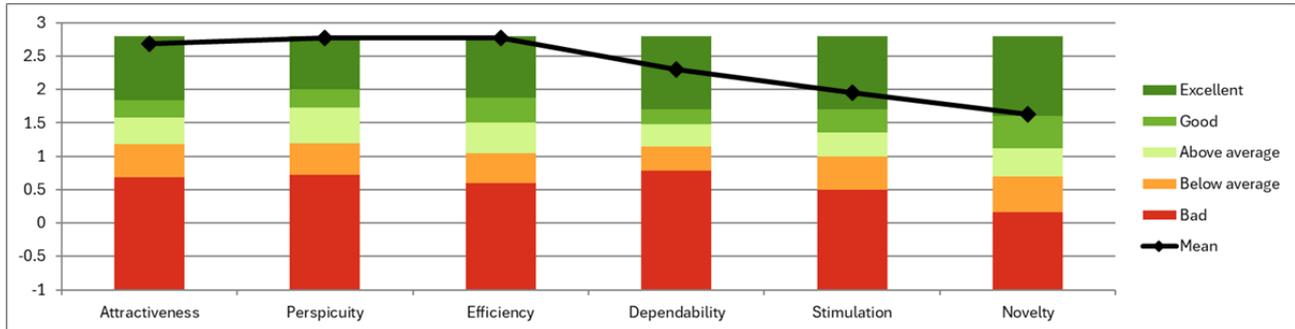

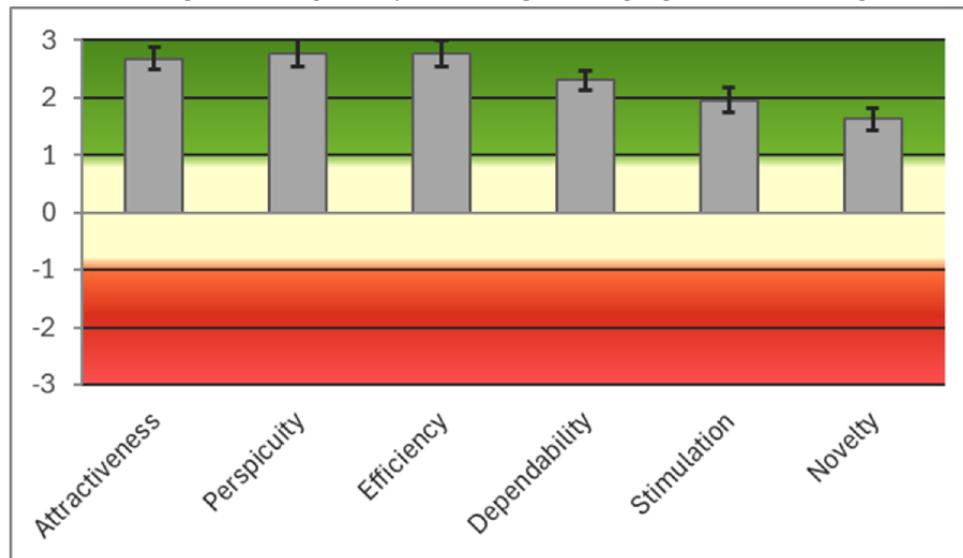

Table 2. Mean (SD) and variance of the normalized values for the items in the User Experience Questionnaire (UEQ) for the Active and Independent Management System clinical portal (n=10).

Scale	Left anchor of the scale	Right anchor of the scale	UEQ scores, mean (SD)	Variance
Attractiveness	Annoying	Enjoyable	1.9 (0.3)	0.1
Perspicuity	Not understandable	Understandable	2.6 (0.7)	0.5
Novelty	Creative	Dull	1.9 (0.3)	0.1
Perspicuity	Easy to learn	Difficult to learn	2.9 (0.3)	0.1
Stimulation	Valuable	Inferior	2.2 (0.6)	0.4
Stimulation	Boring	Exciting	1.5 (0.5)	0.3
Stimulation	Not interesting	Interesting	2.1 (0.6)	0.3
Dependability	Unpredictable	Predictable	1.8 (0.4)	0.2
Efficiency	Fast	Slow	2.8 (0.4)	0.2
Novelty	Inventive	Conventional	1.9 (0.3)	0.1
Dependability	Obstructive	Supportive	2.2 (0.6)	0.4
Attractiveness	Good	Bad	2.8 (0.4)	0.2
Perspicuity	Complicated	Easy	2.7 (0.5)	0.2
Attractiveness	Unlikable	Pleasing	2.7 (0.5)	0.2
Novelty	Usual	Leading edge	1.2 (0.4)	0.2
Attractiveness	Unpleasant	Pleasant	2.9 (0.3)	0.1
Dependability	Secure	Not secure	2.5 (0.5)	0.3
Stimulation	Motivating	Demotivating	2.0 (0.5)	0.2
Dependability	Meets expectations	Does not meet expectations	2.7 (0.5)	0.2
Efficiency	Inefficient	Efficient	2.8 (0.4)	0.2
Perspicuity	Clear	Confusing	2.9 (0.3)	0.1

Figure 4. Bar chart of the Active and Independent Management System clinical portal data grouped into the 6 User Experience Questionnaire dimensions.

AIMS Clinical Portal: Qualitative Feedback

To gain further insight into how users perceived the AIMS clinical portal, 3 additional questions were asked (refer to the following subsections).

Q1: What Do You Think Are the Advantages of This Portal?

Of the 26 participants, 20 (77%) answered this question. All clinicians (20/20, 100%) who answered the question thought that providing customized exercise videos after an operation was very useful, particularly for patients being able to use the system at home; 15 (75%) of the 20 clinicians also suggested that receiving immediate feedback on how patients were coping with the exercise regime was very helpful and meant that the regime could be easily customized for each patient based on how they were coping, which was a key advantage. In addition, 60% (12/20) of the clinicians considered ease of use an advantage. Example comments were as follows:

Really liked the exercise videos for the patients; they were professionally produced and highly relevant for rehabilitation. [Physiotherapist A]

I'm pleased to see that patients automatically receive some feedback on how they are progressing with the rehabilitation exercises. [Physiotherapist B]

Q2: What Do You Think Are the Disadvantages of This Portal?

Of the 26 participants, 12 (46%) answered this question. Of these 12 clinicians, 7 (58%) thought that the integration of the portal with the current IT systems may be a challenge, 3 (25%) thought that getting the staff to agree to use the portal may be a possible issue, and 2 (17%) thought that some staff members would need training on how to use it. Example comments were as follows:

One big issue that will have to be addressed at some point is integrating the software with hospital systems, as we ultimately need to have the patient progress

data in their EHR [electronic health record].
[Physiotherapist B]

While the current system was intuitive and easy to use, I wonder whether some training will need to be provided when the features to add further videos and provide more customised feedback are added.
[Physiotherapist C, an academic]

Q3: Would You Change Anything?

Of the 26 participants, 17 (65%) answered this question. Of these 17 clinicians, 12 (71%) suggested that the ability to create more self-help advice for patients would be useful, and 5 (29%) suggested that having a larger data bank of exercise regimes would be helpful. Example comments were as follows:

It would be very helpful if more self-help could be added to the app to reduce the dependency on the volume of information sheets we provide to patients.
[Physiotherapist D]

The current set of videos are very relevant and of a high quality; however, it would be beneficial to be able to have a wider selection of videos to be able [to] select from. [Physiotherapist E]

AIMS App: SUS Results

The participants were selected during their first postoperative rehabilitation session (opportunistic recruitment). The recruitment of patients was carried out by a physiotherapist who would ask patients during their first session whether they were willing to participate in the study. The physiotherapist provided an information leaflet that explained what the study was about and how it could be used. All postoperative patients automatically qualified for the study; no one was excluded based on age, sex, or technical competency. The study did not collect any age- or sex-related information (a condition of the ethics approval for the study); therefore, it was not possible to provide information about patient demographics.

Of the 44 patients, 38 (86%) completed the SUS questionnaire. The mean SUS score obtained was 74.41 (SD 10.26), with a median of 77.50. This score would be considered *good* according

to the adjective rating scale developed by Bangor et al [41]. A breakdown of the participants' answers to the SUS questions

for the AIMS app is provided in Table 3.

Table 3. Participants' answers to the System Usability Scale (SUS) questions for the Active and Independent Management System app (n=38).

Statements	Participants agreeing, n (%)	Participants disagreeing, n (%)	SUS scores, mean (SD)
Positive statements			
I think that I would like to use this system frequently	34 (89)	1 (3)	4.16 (0.68)
I thought the system was easy to use	31 (82)	1 (3)	4.13 (0.62)
I found the various functions in this system were well integrated	34 (89)	1 (3)	4.16 (0.68)
I would imagine that most people would learn to use this system very quickly	32 (84)	2 (5)	3.92 (0.67)
I felt very confident using this system	33 (87)	2 (5)	3.97 (0.68)
Negative statements			
I found the system unnecessarily complex	1 (3)	32 (84)	2.00 (0.66)
I think that I would need the support of a technical person to be able to use this system	1 (3)	32 (84)	1.92 (0.71)
I thought there was too much inconsistency in this system	1 (3)	32 (84)	2.11 (0.56)
I found the system very cumbersome to use	1 (3)	28 (74)	2.24 (0.59)
I needed to learn a lot of things before I could get going with this system	2 (5)	26 (68)	2.32 (0.66)

AIMS App: UEQ Results

Invitations were sent to 12 (27%) of the 44 participants. Of these 12 patients, 10 (83%) completed the UEQ questionnaire. The means of the normalized scores (range -3 to +3) for the AIMS app were as follows: attractiveness=2.733 (SD 0.070), perspicuity=2.900 (SD 0.060), efficiency=2.800 (SD 0.090), dependability=2.425 (SD 0.060), stimulation=2.200 (SD 0.010), and novelty=1.450 (0.260). Figure 5 shows the bar chart of the

results for the AIMS app against the benchmarks, with all dimensions classed as *excellent* (with the exception of *novelty*, which was classed as *good*), providing slightly better results than the SUS questionnaire. Table 4 gives the mean (SD) and variance of the normalized values for the items in the UEQ questionnaire for the AIMS app. In this case, all values are very encouraging. Figure 6 shows the bar chart for the data grouped into the 6 UEQ dimensions.

Figure 5. Bar chart of the Active and Independent Management System app User Experience Questionnaire results against the benchmarks.

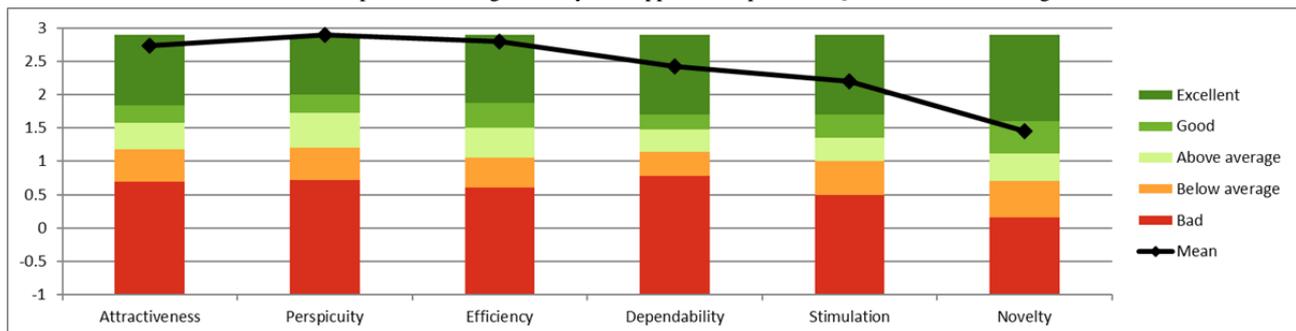

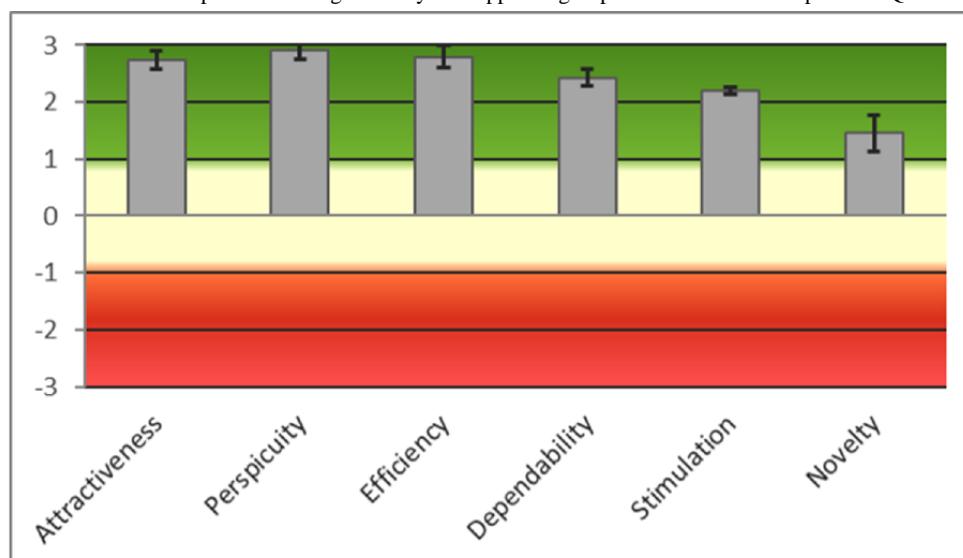

Table 4. Mean (SD) and variance of the normalized values for the items in the User Experience Questionnaire (UEQ) for the Active and Independent Management System app (n=10).

Scale	Left anchor of the scale	Right anchor of the scale	UEQ scores, mean (SD)	Variance
Attractiveness	Annoying	Enjoyable	1.9 (0.3)	0.1
Perspicuity	Not understandable	Understandable	2.6 (0.7)	0.5
Novelty	Creative	Dull	1.9 (0.3)	0.1
Perspicuity	Easy to learn	Difficult to learn	2.9 (0.3)	0.1
Stimulation	Valuable	Inferior	2.2 (0.6)	0.4
Stimulation	Boring	Exciting	1.5 (0.5)	0.3
Stimulation	Not interesting	Interesting	2.1 (0.6)	0.3
Dependability	Unpredictable	Predictable	1.8 (0.4)	0.2
Efficiency	Fast	Slow	2.8 (0.4)	0.2
Novelty	Inventive	Conventional	1.9 (0.3)	0.1
Dependability	Obstructive	Supportive	2.2 (0.6)	0.4
Attractiveness	Good	Bad	2.8 (0.4)	0.2
Perspicuity	Complicated	Easy	2.7 (0.5)	0.2
Attractiveness	Unlikable	Pleasing	2.7 (0.5)	0.2
Novelty	Usual	Leading edge	1.2 (0.4)	0.2
Attractiveness	Unpleasant	Pleasant	2.9 (0.3)	0.1
Dependability	Secure	Not secure	2.5 (0.5)	0.3
Stimulation	Motivating	Demotivating	2.0 (0.5)	0.2
Dependability	Meets expectations	Does not meet expectations	2.7 (0.5)	0.2
Efficiency	Inefficient	Efficient	2.8 (0.4)	0.2
Perspicuity	Clear	Confusing	2.9 (0.3)	0.1
Efficiency	Impractical	Practical	2.7 (0.5)	0.2
Efficiency	Organized	Cluttered	2.8 (0.4)	0.2
Attractiveness	Attractive	Unattractive	2.9 (0.3)	0.1
Attractiveness	Friendly	Unfriendly	2.9 (0.3)	0.1
Novelty	Conservative	Innovative	1.5 (0.5)	0.3

Figure 6. Bar chart of the Active and Independent Management System app data grouped into the 6 User Experience Questionnaire dimensions.

AIMS App: Qualitative Feedback

To gain further insight into how users perceived the AIMS app, 3 additional questions were asked (refer to the following subsections).

Q1. What Do You Think Are the Advantages of This App?

Most of the participants (33/44, 75%) answered this question. Of the 33 participants, 26 (79%) thought that the exercise videos provided after an operation were very useful, 30 (91%) considered clinicians having immediate access to patient progress an advantage, and 24 (73%) considered ease of use an advantage. Example comments were as follows:

Having exercise videos that I can use both in the hospital and at home is a great help. While there is help on hand in the hospital if needed, being able to view the videos while at home is great. [Patient A]

Loved the being able to access the videos on the tablet, was very helpful and the app was so easy to use. [Patient B]

Q2. What Do You Think Are the Disadvantages of This App?

Only 8 (18%) of the 44 participants answered this question, and very few disadvantages were listed: 1 (13%) participant thought that the app could include some embedded videos for generic stretching exercises; 1 (13%) thought that the app might be too simple, and more functionality was required; and 6 (75%) thought that a self-help section would be beneficial. An example comment was as follows:

While the hospital provide[s] a number of leaflets on what to expect after the knee replacement, it would be handier of [sic] these were part of the app. [Patient C]

Q3. Would You Change Anything?

Of the 44 participants, 17 (39%) answered this question. Of these 17 participants, 6 (35%) suggested more self-help, and 5 (29%) suggested having the ability to keep a daily or weekly diary of symptoms or pain. An example comment was as follows:

Would it be possible to have a section in the app to record how I am getting on with the videos and make notes on any symptoms I'm getting after the operation, particularly once I'm home? [Patient D]

Discussion

Principal Findings

The main goal of this mixed methods study was to examine the usability of the AIMS platform from the perspectives of both patients and clinicians. Two well-known validated instruments were used to measure usability: the SUS and the UEQ. In all, 26 physiotherapists and health care professionals evaluated the AIMS clinical portal; and 44 patients in hospital for TKR, THR, or DHS evaluated the AIMS app. In terms of the RQs, the study has shown that both the AIMS clinical portal (RQ1) and the

AIMS app (RQ2) have *good to excellent* usability scores, and this platform provides a solid foundation for the next phase of research, which will involve evaluating its effectiveness in improving patient outcomes after TKR, THR, or DHS. In addition, useful qualitative information was obtained from participants through a set of open-ended questions.

On the basis of the literature reviewed in the Re-Enablement DHIs subsection, it seems that smartphones and the web are the 2 main platforms used to provide re-enablement DHIs after TKA or THA. The platforms have been identified to be used by patients who will receive the instructions in the form of video, text, and interactive game as well as by clinicians who can create custom treatment plans for patients. The AIMS platform provides similar functionality to the systems found in the literature, with a web-based clinical portal and a mobile app for patients. The AIMS platform mainly presents content in video and text, which is similar to the majority of the systems discussed in the Re-Enablement DHIs subsection. Text and video are considered to be effective in presenting rehabilitation content to patients because they allow a wider level of proficiency in information and communications technology. Compared to static images, we considered videos to be more engaging, although further research should be conducted to investigate this. Some studies, such as those by Hussain et al [23], van Dijk-Huisman et al [25], and Bell et al [27], used sensors from wearable devices and mobile phones, while Bäcker et al [28] developed their own custom sensor. Personalization features that allow the system to customize activities for patients were only evident in the studies by Hussain et al [23], van Dijk-Huisman et al [25], and Bell et al [27]. Currently, the AIMS platform does not use sensors or have any personalization features, but these will be considered for the next phase of the research. A summary comparing the literature reviewed with our study can be found in [Multimedia Appendix 1 \[23-30\]](#).

In terms of limitations, to overcome major privacy concerns, a condition of the ethics approval for the study was that all data had to be anonymized; therefore, neither could we perform a demographic analysis nor conduct follow-up monitoring of the progress of a more informed patient after they left the hospital. As this study's main focus was on usability, the recruitment of participating patients was carried out during rehabilitation sessions. This method did not allow us to conduct a randomized study, and there were no control and experimental groups. Furthermore, due to ethics approval restrictions, we were not able to directly observe the experiment and had to use questionnaires and interviews conducted by the clinicians during the rehabilitation sessions. The experiment did not use any additional sensing technologies to monitor user progress and relied on the patient's input and feedback. Future studies will aim to overcome these limitations.

Since this study was carried out, the platform has been improved to include additional support videos for patients, ideas for which emerged from the qualitative feedback, and a second usability study is underway to ensure that results are consistent with this initial study ([Multimedia Appendix 1](#)).

Conclusions

This study aimed to assess the usability of a re-enablement platform called AIMS, designed to address the *de-enablement* often experienced by hospitalized older adults most at risk. Usability was measured using 2 common validated instruments: the 10-item SUS and, for more detailed analysis, the 26-item UEQ. The AIMS clinical portal was evaluated by 26 physiotherapists and health care professionals; and 44 patients

undergoing TKR, THR, or DHS assessed the AIMS app. Overall, both the AIMS clinical portal and the AIMS app received *good to excellent* usability scores, providing a solid foundation for future research on their effectiveness in improving patient outcomes after joint replacements. Optimal rehabilitation programs for orthopedic joint replacement patients can lead to a quicker return to normal function, faster hospital discharge, and higher patient satisfaction.

Abstract

Background: The fastest-growing neurological disorder is Parkinson disease (PD), a progressive neurodegenerative disease that affects 10 million people worldwide. PD is typically treated with levodopa, an oral pill taken to increase dopamine levels, and other dopaminergic agonists. As the disease advances, the efficacy of the drug diminishes, necessitating adjustments in treatment dosage according to the patient's symptoms and disease progression. Therefore, remote monitoring systems that can provide more detailed and accurate information on a patient's condition regularly are a valuable tool for clinicians and patients to manage their medication. The Parkinson's Remote Interactive Monitoring System (PRIMS), developed by PragmaClin Research Inc, was designed on the premise that it will be an easy-to-use digital system that can accurately capture motor and nonmotor symptoms of PD remotely.

Objective: We performed a usability evaluation in a simulated clinical environment to assess the ease of use of the PRIMS and determine whether the product offers suitable functionality for users in a clinical setting.

Methods: Participants were recruited from a user sign-up web-based database owned by PragmaClin Research Inc. A total of 11 participants were included in the study based on the following criteria: (1) being diagnosed with PD and (2) not being diagnosed with dementia or any other comorbidities that would make it difficult to complete the PRIMS assessment safely and independently. Patient users completed a questionnaire that is based on the Movement Disorder Society-sponsored revision of the Unified Parkinson's Disease Rating Scale. Interviews and field notes were analyzed for underlying themes and topics.

Results: In total, 11 people with PD participated in the study (female individuals: n=5, 45%; male individuals: n=6, 55%; age: mean 66.7, SD 7.77 years). Thematic analysis of the observer's notes revealed 6 central usability issues associated with the PRIMS. These were the following: (1) the automated voice prompts are confusing, (2) the small camera is problematic, (3) the motor test exhibits excessive sensitivity to the participant's orientation and position in relation to the cameras, (4) the system poses mobility challenges, (5) navigating the system is difficult, and (6) the motor test exhibits inconsistencies and technical issues. Thematic analysis of qualitative interview responses revealed four central themes associated with participants' perspectives and opinions on the PRIMS, which were (1) admiration of purpose, (2) excessive system sensitivity, (3) video instructions preferred, and (4) written instructions disliked. The average system usability score was calculated to be 69.2 (SD 4.92), which failed to meet the acceptable system usability score of 70.

Conclusions: Although multiple areas of improvement were identified, most of the participants showed an affinity for the overarching objective of the PRIMS. This feedback is being used to upgrade the current PRIMS so that it aligns more with patients' needs.

Introduction

Background

Overview

The fastest-growing neurological disorder is Parkinson disease (PD) [1]. PD is a progressive neurodegenerative disease that affects 10 million people worldwide [2]. The incidence and prevalence of PD is rising sharply in countries with aging populations, and in the last 2 decades, the burden of PD has more than doubled, with estimations predicting 1,238,000 cases in North America by 2023 [3,4]. The disease affects the basal nuclei in the central nervous system causing the progressive deterioration of dopaminergic neurons. The loss of these neurons causes motor and nonmotor dysfunctions [5]. Motor system deficits result in symptoms such as tremor, rigidity, bradykinesia, and postural instability [6]. Other symptoms include cognitive problems, gastrointestinal upset, and urinary control issues [7]. Due to these mal effects, PD is linked to morbidity, high economic burden, and decreased quality of life for patients and caregivers. The annual estimated direct and indirect costs of the condition in the United States alone are close to US \$52 billion [8]. Neurologists are struggling to manage the increasing prevalence of PD, leading to clinician burnout [9] and lengthy appointment wait times for patients [10]. However, studies show that the management of these symptoms in the early stages of the disease can achieve positive results. In contrast, the consequences of late or faulty diagnoses negatively impact patients and the health care system [11-13].

Medication Management

PD is typically treated with levodopa, an oral pill taken to increase dopamine levels, and other dopaminergic agonists. However, as the disease progresses, the effects of the drugs wane. This requires medication dosage adjustments to properly manage symptoms throughout the day [14]. This can be a difficult task for physicians as symptoms are constantly fluctuating and may appear and disappear throughout the day with a hard-to-establish pattern. Some physicians ask their patients to keep diaries where they note the time of day and a description of their symptoms. However, adherence to this method is typically poor and does not provide meaningful information [15]. Therefore, remote monitoring systems that provide more detailed and accurate information on a patient's condition regularly are a valuable tool for clinicians and patients to manage their medication.

Evaluation of PD

The evaluation of PD is commonly performed using clinical rating scales that are essential to the quantification of neurological disorders [16]. These rating scales enable clinicians and researchers to evaluate PD symptoms, progression, treatment efficacy, and disease severity [16,17]. One of the most widely used clinical scales for PD assessment is the Movement Disorder

Society-sponsored revision of the Unified Parkinson's Disease Rating Scale (MDS-UPDRS) [18].

The MDS-UPDRS is a revised form of the original Unified Parkinson's Disease Rating Scale [17] and incorporates both motor and nonmotor aspects into the assessment. It consists of 65 elements and, on average, requires approximately 30 minutes of administration time. There are four parts to the questionnaire: (1) nonmotor experiences of daily living (13 elements), (2) motor experiences of daily living (13 elements), (3) motor examination (33 elements), and (4) motor complications (6 elements) [18]. Elements are scored from 0 to 4, where 0=normal, 1=slight, 2=mild, 3=moderate, and 4=severe. There are some elements that patients could possibly administer themselves as they are multiple-choice questions asking about personal symptom experience, whereas others are rated by an examiner (typically a neurologist or other clinician) based on observation and physical examination.

While the MDS-UPDRS represents the international gold standard in PD rating scales and has undergone strict validation through clinical studies, it still remains a clinician-based scale; this means that a clinician assigns a score based on their own personal qualitative observations of a patient. Therefore, the assessments are often subjective and biased to the examiner's skill and knowledge. The assessments will also vary from one examiner to the other in this way [19-21]. Studies have shown that there is variability between assessments conducted by nurses and neurologists [22,23]. In these situations, it is difficult to compare and interpret the scores, as they may differ based on a patient's condition or simply due to the clinician performing the assessment. The MDS-UPDRS is also time consuming for clinicians. It requires approximately 30 minutes of an examiner's time, which makes it impractical for routine practice [18]. Examiners must also be highly trained to improve the validity of the scores. Many of the elements in the MDS-UPDRS must be completed by a patient themselves, which adds to the time burden of the questionnaire when performed in a clinician's office. The typical assessment performed in a clinical setting rarely assesses a patient's day-to-day symptoms, which usually vary over time, and only captures a snapshot of an individual's condition at the moment of their appointment [24]. Patients also typically have long wait times in between their appointments, which makes it difficult to remember their symptoms since their last visit [10]. This way, medical decisions are now influenced by recall bias and patient attitudes instead of by reliable patient data. In addition, it is an inconvenience for patients to travel to clinics due to transportation, long commutes, and their conditions, especially if they are in the advanced stages of PD. Therefore, there is a need for objective, accurate, and reliable assessment tools that can help increase the chance of effective treatment. These could aid patients with their disease management, thus cutting down on health care costs [25].

Digital Health Technologies and the Parkinson's Remote Interactive Monitoring System

An emerging solution to some access to health care issues are video-based visits. These bring care directly into a patient's home, which improves access in a patient-centered manner and minimizes the burden on people with PD and their caregivers [26]. In addition, due to the largely visual nature of a PD examination, it tends to work well in a video-based visit. Studies have shown that web-based appointments with neurologists are feasible and valuable [27,28]. It has also been shown that a modified version of the MDS-UPDRS motor examination (excluding the test of rigidity and postural stability) can be successfully administered remotely [29]. However, as virtual visits still require a clinician's time, they still only provide a brief snapshot of a patient's condition. There need to be other methods of assessing PD without occupying already overburdened clinicians.

Digital health technologies that alleviate the need for medical professionals to assess disease progression have been on the rise. These technologies offer possibilities for self-assessment and improved health care [30]. Some of the technologies developed for PD include wearable sensors and mobile apps. These devices have been used extensively to monitor motor symptoms and complications of people with PD in their home environments [31]. These wearable sensors and mobile apps can accurately track the progression of PD [32-34] and other neurological conditions [35]. Examples of these devices on the market are the Global Kinetics Corporation's Personal KinetiGraph Watch [36,37] and Rune Labs' StrivePD mobile app [38]. APDM Wearable Technologies has also developed multiple sensors that can accurately monitor tremor and dyskinesia symptoms of PD that have been used in many clinical studies [32,34,39,40]. Other wearables that collect contextual data include DynaPort MiniMod Hybrid (a sensor worn on the lower back), Shimmer (records gait), SENSE-PARK (records walking, hypokinesia, dyskinesia, and sleep), activPAL, and StepWatch (gait and basic movement parameters) [20,41-45]. The problem is that these technologies only generate a small amount of patient data (mainly tremors and other motor symptoms, moods, and sleep characteristics). Therefore, although these devices provide an objective means of tracking PD characteristics, they do not provide a complete assessment of the condition. Wearable sensors also have inherent risks [46] and do not follow the gold standard clinical scales such as the MDS-UPDRS. These risks encompass potential interference with the daily activities of patients with PD, impacting their natural movements and behaviors. In addition, behavioral modifications stemming from the feedback provided by sensors can yield both positive and negative outcomes. On the positive side, such modifications may encourage beneficial lifestyle changes and provide meaningful data. However, as a downside, they may also contribute to increased anxiety and foster a dependency on the wearable device [46].

To address the need for reliable tools to objectively assess PD symptoms that do not require a clinician's involvement, the Parkinson's Remote Interactive Monitoring System (PRIMS) was developed. The PRIMS is a digitized version of the MDS-UPDRS in the form of a desktop application that people

with PD can complete themselves. This way, the PRIMS provides a complete picture of PD assessment via its capacity to comprehensively measure both motor and nonmotor symptoms without the need for wearable sensors and its potential to serve as a valuable tool in a clinical or home setting. If validated through further investigation, the PRIMS has the potential of delivering a standard in PD assessment. The PRIMS also has the potential to be valuable in a home setting, offering a user-operated system capable of capturing a significant portion of the MDS-UPDRS (considered the gold standard). The system provides patients with a means of tracking their condition remotely and offers clinicians reliable data for better medication management. This comprehensive approach enhances understanding and facilitates more effective monitoring of the progression and individual symptoms of a patient.

Usability Testing

The development of any system that is used by patients and clinicians for the management of biomedical data should always involve usability evaluations, which aim to understand whether such a product is easy to use and has the appropriate functionality for the users. *Usability* is a term used to define how easily people can use a tool or object to accomplish a specific task [47,48]. In this way, when developing interfaces, it is imperative that they can be learned quickly and are easy to navigate. The system's layout should avoid and manage operational errors efficiently and provide users with appropriate feedback [47]. Usability must also address user satisfaction and provide solutions to the problem that the system was designed to solve [49]. A common method of assessing usability is the System Usability Scale (SUS). The SUS has been used in multiple studies, such as the evaluation of a mobile app for people with PD [50]. Structured interviews are common practice for these types of studies [51]. Field notes can also be a valuable tool for qualitative researchers to collect and analyze [52]. Observational notes can capture information such as the nonverbal reactions of users while they interact with the system. This study used multiple methods to assess the usability of the PRIMS.

Study Objectives

This study aimed to assess the functionality, usability, and user experience aspects of the most recent version of the PRIMS in a clinical setting from the perspectives of people with PD. Use issues identified in this study will guide designers in creating a more effective commercial product. Using multiple methods, including interviews and field notes along with SUS surveys, we evaluated the user experience of the PRIMS.

Methods

Participants

Participants were recruited from a user sign-up web-based database owned by PragmaClin Research Inc. The study was also advertised by the Parkinson Society Newfoundland and Labrador on their weekly newsletter. Interested participants who contacted us were given a questionnaire that determined their eligibility for the study. The inclusion criteria for study participation were the following: (1) being diagnosed with PD

and (2) not being diagnosed with dementia or any other comorbidities that would make it difficult to complete the PRIMS assessment safely and independently. Participants were recruited on a first come, first served basis. Informed consent was obtained from all participants via a web-based consent form emailed to them before study completion. Paper copies were also available to participants at the time of their scheduled session.

Ethical Considerations

This study received ethics approval from the National Research Council of Canada Institutional Review Board (protocol 2021-137). Informed consent was obtained, and the possible consequences of the study were explained. All data were deidentified. No compensation was provided to participants.

Description of the PRIMS

The PRIMS was developed by PragmaClin Research Inc and was designed on the premise that it will be an easy-to-use digital system that can accurately quantify motor and nonmotor symptoms of PD remotely. The PRIMS has the capability to interact with patients in real time, delivering results promptly through a dedicated patient dashboard. Patients can access their dashboard by logging into the web-based platform to see a history of their assessments. Patient users complete a questionnaire that is based on the MDS-UPDRS. The

questionnaire comprises 4 sections shown in Figure 1. Of these sections, 3 are multiple-choice questions based on daily living experiences; an example is shown in Figure 2, and there is also a motor examination where users perform tasks similar to those outlined in the MDS-UPDRS. Data are captured via 2 depth cameras (Intel models D435 and D455) that track a patient's movement in 3D. Before completing the motor examination, there is a series of ability questions that determine whether the user can safely perform all motor tasks; an example is shown in Figure 3. Motor tasks are explained in written form on the screen along with a demonstration video that presents users with a visual walk-through of the movement; an example is shown in Figure 4. The intelligent software scores each motor task based on the same parameters as the MDS-UPDRS. However, it is important to note that the system's scoring has not yet been validated. After users complete the 4 sections, a participant's responses are analyzed to put an individual on a PD rating scale from 0 to 4 (0=normal, 1=slight, 2=mild, 3=moderate, and 4=severe). A summary of a user's scores is presented on the home page, which can be seen in Figure 5. The survey was intentionally crafted and edited from the original MDS-UPDRS to use layperson language for easy comprehension. Although some technical terms appeared in titles or examples, they were not essential for answering questions or comprehending instructions.

Figure 1. The 4 sections of the Parkinson's Remote Interactive Monitoring System (PRIMS) questionnaire based on the Movement Disorder Society-sponsored revision of the Unified Parkinson's Disease Rating Scale.

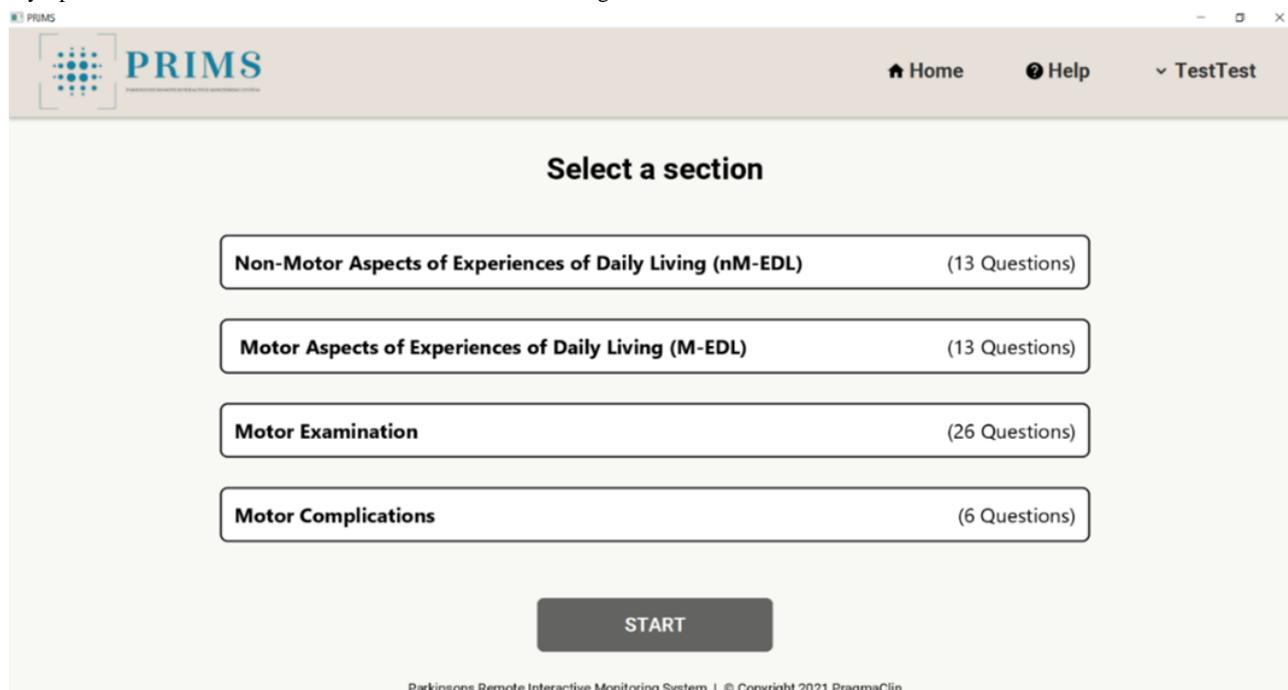

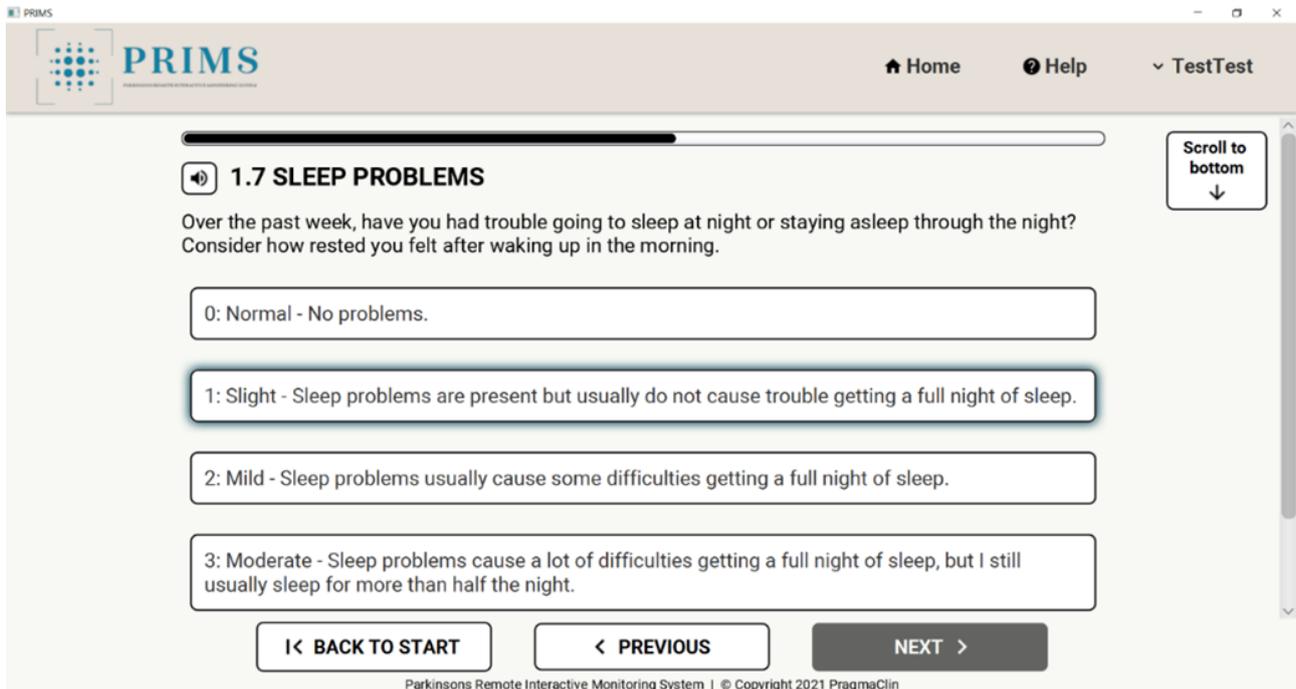

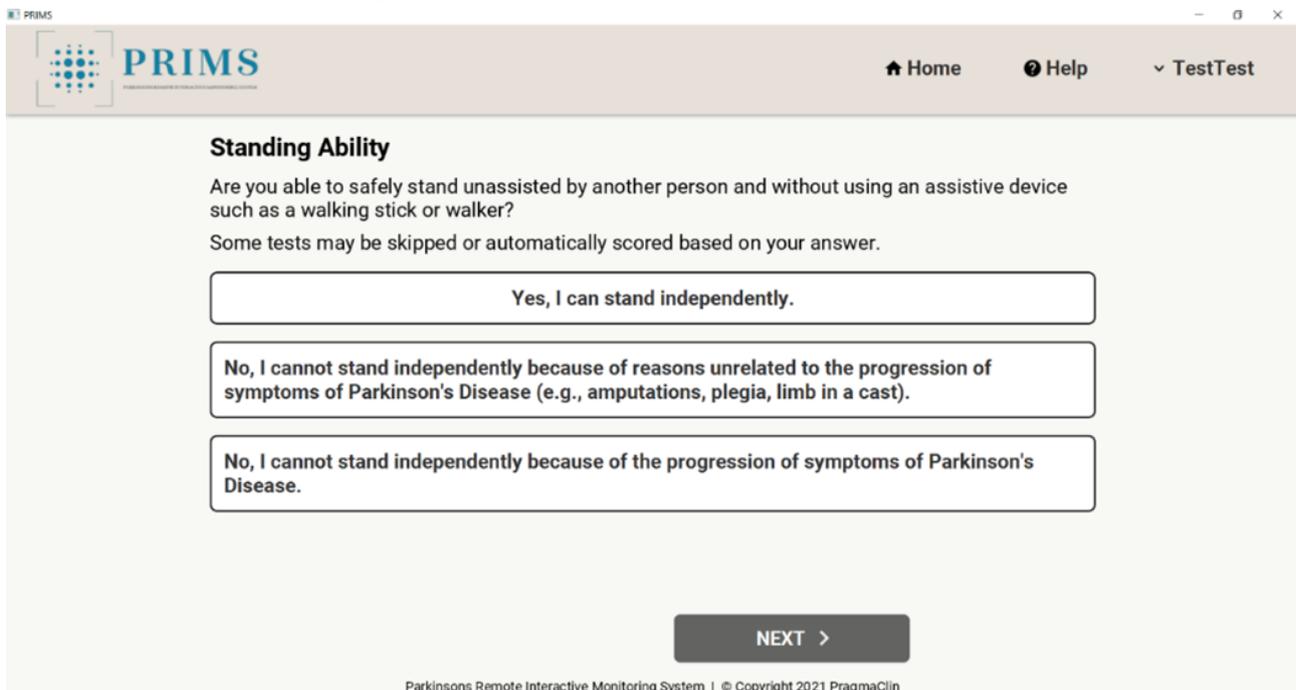

Figure 2. Example multiple-choice question.

The screenshot shows the PRIMS (Parkinsons Remote Interactive Monitoring System) interface. At the top, there is a navigation bar with the PRIMS logo on the left and 'Home', 'Help', and 'TestTest' on the right. Below the navigation bar, a progress bar is visible. The main content area features a question titled '1.7 SLEEP PROBLEMS' with a speaker icon. The question text reads: 'Over the past week, have you had trouble going to sleep at night or staying asleep through the night? Consider how rested you felt after waking up in the morning.' There are four radio button options: '0: Normal - No problems.', '1: Slight - Sleep problems are present but usually do not cause trouble getting a full night of sleep.', '2: Mild - Sleep problems usually cause some difficulties getting a full night of sleep.', and '3: Moderate - Sleep problems cause a lot of difficulties getting a full night of sleep, but I still usually sleep for more than half the night.' At the bottom of the question area, there are three buttons: 'BACK TO START', 'PREVIOUS', and 'NEXT'. A 'Scroll to bottom' button is located on the right side of the question area. The footer of the interface reads 'Parkinsons Remote Interactive Monitoring System | © Copyright 2021 PragmaClin'.

Figure 3. Multiple-choice question assessing an individual's ability to stand.

The screenshot shows the PRIMS interface with a question titled 'Standing Ability'. The question text reads: 'Are you able to safely stand unassisted by another person and without using an assistive device such as a walking stick or walker? Some tests may be skipped or automatically scored based on your answer.' There are three radio button options: 'Yes, I can stand independently.', 'No, I cannot stand independently because of reasons unrelated to the progression of symptoms of Parkinson's Disease (e.g., amputations, plegia, limb in a cast).', and 'No, I cannot stand independently because of the progression of symptoms of Parkinson's Disease.' At the bottom of the question area, there is a 'NEXT' button. The footer of the interface reads 'Parkinsons Remote Interactive Monitoring System | © Copyright 2021 PragmaClin'.

Figure 4. Example of a motor task page.

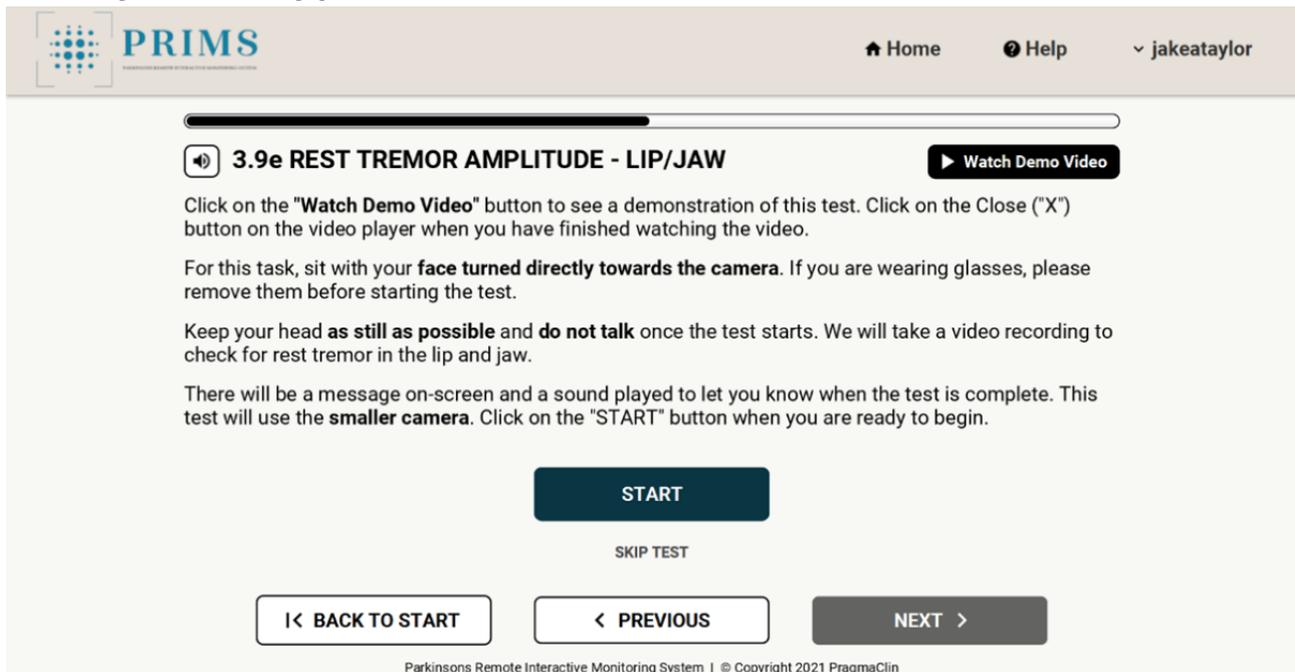

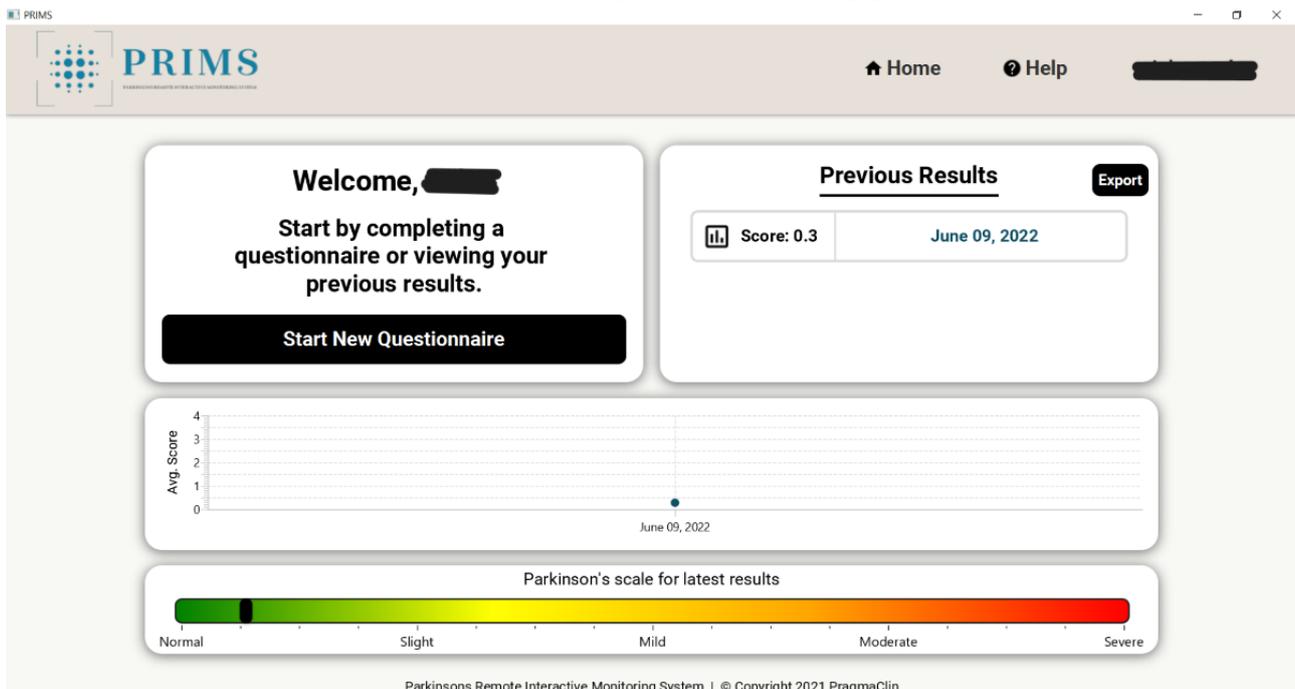

Figure 5. Screenshot of the Parkinson’s Remote Interactive Monitoring System (PRIMS) home page.

Equipment

The PRIMS was run on a Dell G15 laptop computer, and Intel RealSense D435 (small—stand-alone mini tripod beside the laptop) and D455 (large—mounted on the computer) depth cameras were used. Participants sat on a contemporary midback task office chair with wheels for the entire questionnaire and had the option of using a Kensington Pro Fit wireless computer mouse. Interviews were recorded using a HyperX SoloCast stand-alone microphone. Audacity (Muse Group) was used as an audio recording and processing software. The computer-assisted qualitative coding software Delve (Twenty to Nine) was used for thematic analysis. All audio files were

transcribed into Word (Microsoft Corp) before being uploaded to Delve. Qualtrics XM (Qualtrics International Inc) was used to administer the SUS survey and the virtual consent form.

Usability Testing Protocol and Procedure

Usability testing occurred at PragmaClin Research Inc’s office site and was carried out by a trained research assistant (RA). Before the start of testing, the RA explained the study objective and research protocol to the participants. The RA also provided detailed information about the test procedures and described the purpose of the PRIMS. The example script is provided in [Multimedia Appendix 1](#). As the research team was interested in how participants interact with the system when there is no

one present to assist them, the RA was not allowed to help unless deemed necessary. The necessity to intervene in the form of helpful hints or prompts or manipulating the system was operationally defined as any circumstance in which the participant was unable to progress through the system without aid. An observer was present during the entire session. All participants used the PRIMS only once and reported user experience from this single use.

After the participants gave informed consent, they were instructed to start using the PRIMS. The initial PRIMS developed by PragmaClin Research Inc was used during the usability testing. While participants worked their way through the assessment, they were encouraged to vocalize any confusion or ask any questions.

Data were recorded in the form of field notes, a short qualitative interview, and an SUS survey administered to participants after they completed the PRIMS questionnaire. Recorded data were used to identify a set of usability issues.

Field Notes

Structured observation was used to analyze the users' interactions with the system. During the session, the RA was instructed to observe and note any issues that arose along with any user critiques, comments, questions, difficulties, or observations about their interaction with the system. Thematic analysis was performed on these notes in Delve. Usability issues were identified via this method of analysis of the written notes.

Qualitative Interviews

After participants were finished with the PRIMS, they completed a short qualitative interview. The interview consisted of six questions: (1) What things did you like most about the PRIMS? (2) What things did you like least about the PRIMS? (3) Were there things about the PRIMS that you found confusing or frustrating? (4) What would you like to change about the PRIMS? (5) Are there any features that you would like to see added to the PRIMS? (6) Do you have any overall comments on the PRIMS?

Audio was transcribed and analyzed in the qualitative coding software Delve. Thematic analysis was performed following the framework by Braun and Clarke [53]. The themes were discussed, reviewed, and interpreted by the research team.

SUS Survey

After the interview was finished, participants completed a short-answer quantitative questionnaire following the standard SUS approach devised by Lewis and Sauro [54] in 2018. A copy of the survey is provided in [Multimedia Appendix 2](#).

SUS scores were output in Qualtrics XM and then analyzed in Microsoft Excel. To calculate the SUS score, first the score contributions from each item (question) were summed. Each item's score contribution ranged from 0 to 4. For items 1, 3, 5, 7, and 9, the score contribution was the scale position minus 1. For items 2, 4, 6, 8, and 10, the contribution was 5 minus the scale position. We multiplied the sum of the scores by 2.5 to obtain the overall value of the SUS score. SUS scores have a range of 0 to 100. SUS scores of >70 points are considered acceptable usability (according to various other usability studies), and scores of >85 are regarded as excellent usability [55]. The curved grading scale by Lewis and Sauro [54] that was used to interpret the scores from the SUS is provided in [Multimedia Appendix 3](#).

Results

Participants

A total of 11 people with PD participated in our study (female individuals: n=5, 45%; male individuals: n=6, 55%; age: mean 66.7, SD 7.77 years). Data from 91% (10/11) of the participants were fully analyzed as 1 user dropped out during the testing session. The 10 participants took, on average, 67.7 (SD 16.4) minutes to complete the motor examination and 84.2 (SD 23.3) minutes to complete the entire PRIMS questionnaire. Participants skipped 2.9 (SD 1.97) motor tests on average (total of 29 skipped tests). [Table 1](#) shows which tests were skipped the most and how many times they were skipped.

Table 1. Number of times each motor test was skipped (tests ranked from the highest to lowest number of skips).

Field Notes

Thematic analysis of the observer's notes revealed 6 central usability problems associated with the PRIMS. These were the following: (1) automated voice prompts are confusing, (2) the small camera is problematic, (3) the motor test exhibits excessive sensitivity to the participant's orientation and position in relation to the cameras, (4) the system poses mobility challenges, (5) navigating the system is difficult, and (6) the motor test exhibits inconsistencies and technical issues.

Automated Voice Prompts Are Confusing

The RA noted on multiple occasions that the participants found the automated voice prompts to be confusing. Frequently, participants would begin the test and align themselves in a good position; however, when presented with audio prompts such as "make sure hand is not tilted" or "adjust hand position or angle," users would move in all directions:

The automated voice prompts were confusing and making it difficult. Even though P8 was turned in the right direction, the system still prompted him that he was turned the wrong way.

A lot of automated verbal instructions were getting fired at P8, this made the task confusing and frustrating since they will be in the correct position and the software tells them wrong direction, turn right, etc.

The prompt "Adjust hand position or angle" was especially frustrating and confusing to participants. Many verbalized their confusion with the statement. On multiple occasions, the RA noted that participants were becoming frustrated with the motor tests when the audio prompts began giving them instructions:

The prompt—no hand detected—is vague and confusing. P6 was in a good position, with their hand

fully in view...Plus, P6 did not move and then immediately after there is a prompt saying—no hand detected...the audio prompts confused and frustrated P6.

The RA also noted that some participants complained that the voice commands were authoritative and unfriendly:

...get in position and stand still—is a little authoritative! P8 mentioned this, participant did not like the automated voice instructions, said it needs to be more comforting / friendly. The automated voice prompts were authoritative P3 mentioned.

Comments also often noted the repetitiveness of the automated voice prompts. They were repeated too often and in bizarre patterns, which caused confusion and frustration among users:

"don't move body in good position" was constantly repeating...was repeated ~5 times over, and the test wouldn't start.

"Make sure hand is fully in view" is repeated even when the hand is fully in view, The system was prompting repeatedly "make sure hand is not tilted," motor test was very particular on positioning here. This made hand and body measurements very difficult for P2. They were moving their hand in all directions trying to figure out what tilted meant.

Overall, participants found the automated voice prompts to be vague and irritating, as they rarely provided useful corrective feedback.

The Small Camera Is Problematic

The RA frequently noted problems associated with the tests that used the small camera or issues directly related to the small camera itself. The narrower field of view was an issue for

multiple tests; participants frequently moved out of the camera view midway through a task:

Finger to nose movements were difficult for P7, they had a hard time staying in the cameraview. They would be prompted that they are in a good position, then move out of the cameraview when performing their finger to nose movements. Hand moves out of frame...when the participant does hand rotations...small camera issue. P4 had great difficulty staying in the cameraview for these hand rotation tasks.

The system would frequently tell users that they were in a good position, but when they started performing the task, they would move out of the camera view. The setup of the small camera also created problems for users. Users had to manipulate and adjust the small camera on the tripod to align themselves in a proper position. Frequently, this would lead to participants becoming uncomfortable due to the poor ergonomics of the system:

Face measurements using the small camera were not comfortable for P4. Small camera moved P4 into an uncomfortable position.

The fact that P3 had to look at the camera for the test but look at the screen to get into position was causing difficulties.

Getting into position was difficult for P9. Again, ergonomics is poor here for performing the test on two different sides when the camera is on one side.

The tests that asked users to adjust the small camera were especially problematic. The RA frequently noted that people who pulled the cords out when laying the camera down for the final 2 tests did the following:

P2 moved the tripod/small camera, it was sloppy and difficult to work with. P2 pulled the cord out while adjusting the small camera.

P11 unplugged the camera when they moved it for 3.15...issue with adjusting camera.

Overall, the RA noted far more issues with the tests that used the small camera compared to those that used the larger camera.

The Motor Test Is Excessively Sensitive

It was clear from the RA's notes that participants had difficulty getting into what the system would consider to be valid positions to score during the motor examination. At times, the system would prompt users to stay still:

P9 had difficulty with hand measurements, they were unable to hold their hand still (issue since the software is for PwP). System is far too particular. The hand and body measurements require users to stay still to capture the measurement; P11 had great difficulty with this. System is far too particular on positioning here, which is just not feasible for those with PD.

The system in its current state is very sensitive, which posed challenges for users:

The software is too picky on the positioning, participant's dyskinesia made it very difficult to stay in position, when the software told P7 that they were in a good position, they only had to move very slightly for the software to tell them that they needed to "adjust hand position or angle."

A slight tilt is all it took for P8 to move out of position. The system was very particular on the positioning of the limb.

The RA noted on multiple occasions that the system would repeat certain prompts when users were close to getting into the correct position:

"Don't move, hand is in good position" repeats a lot when P6 was "on the edge" of a good position. And when you start rotating your hand "no hand detected."

"Don't move, hand is in good position" repeated a lot when P5 was "on the edge" of being in a good position.

The system is far too sensitive, "Don't move face is in good position" kept repeating even though P3's face was in a good position. The motor test is too picky, its needs to be able to get the measurements from a broader range of places.

Overall, it was clear from the recorded field notes that the motor examination was difficult for users:

3.14, and 3.15 P9 had a lot of difficulty keeping their hand in the correct position, P8 had difficulties getting their hand perfectly parallel to the camera face, The fact that P3 had to look at the camera for the test but look at the screen to get into position was causing difficulties.

The System Poses Mobility Challenges

The setup of the PRIMS posed various mobility challenges for users. The RA noted on multiple occasions that users felt that the chair and constant movement of users were both issues. In its current state, the PRIMS requires participants to move back and forth from the computer to go from one task to another. The RA noted on several occasions that this posed a challenge for users:

Moving back and forth from the computer was difficult...the system requires too much movement of the chair, and to and from the computer, P7 vocalized this.

This, coupled with the fact that users are constantly moving the chair in and out of the camera view, made the motor examination tiring for participants:

There is constant movement to and from the system that was tiring P8.

The chair was difficult to work around due to the nature of the test; the RA noted repeatedly that participants failed to complete tests due to the chair obstructing the camera view:

...chair was in cameraview during these tests, posed an issue, was also difficult for participants to work around it.

Some participants were also obstructed by the legs of the chair:

P5 needed to work around the chair legs for the arising from chair task, they vocalized this. The legs of the chair were in the way.

Multiple participants also pointed out that they thought the chair was a safety issue:

The chair with wheels concerned P2. They thought it was a safety issue.

P3 mentioned a few times that people with PD are told NOT to use chairs with wheels.

For safety reasons, the chair with wheels is a huge problem, P7 vocalized this.

Overall, the maneuvering required to complete the motor examination was an issue for users.

Navigating the System Is Difficult

There were frequent comments made by the RA on navigational issues users had while working through the system. Many participants had issues with the required amount of scrolling:

Scrolling is too difficult. a bigger screen would allow the entire survey to fit on one screen. P5 found the scrolling to be a challenge right away.

P9 again demonstrated issues with scrolling and navigation, they had trouble scrolling to the bottom of the screen to select next on multiple tasks.

Some users even found that they made mistakes due to the need to scroll to the bottom of the page:

P7 found that the scrolling led to mistakes. Choices they didn't mean to select.

The RA also noted that the amount of clicking was an issue, specifically accurate clicking:

Skip test button is too small. Navigation issue, P9 had trouble clicking it due to dyskinesia, since it was so small.

P7 had trouble closing the demo videos. Too much accurate clicking / total clicking required.

Users also had issues with the computer mouse and mentioned that a touch screen interface would be preferred:

P9 had significant difficulties with the mouse. They said that they would prefer a touch screen.

P2 didn't like using the mouse...Stated right away that they wanted to use a touch screen.

The test window and demonstration video window also caused issues for users. Demonstration videos would frequently open in inconsistent sizes and locations of the screen, making them difficult to close:

Demo videos were opening in small windows at the top of the screen. Made them difficult to close and to watch.

The test window did not show a married image of the person, which made it confusing to get into position:

Screen being non-mirrored is an issue. P5 had trouble moving into position because of this.

The RA also noted that, as the software was not entirely full screen, users would frequently open other programs by accidentally clicking on the bottom task bar:

Full screen should eliminate the lower task bar (desktop), P4 ended up clicking things below or bringing up the news.

Overall, users had difficulty navigating the system to progress.

The Motor Test Exhibits Technical Issues

There were frequent notes made on the system not operating correctly. Users would perform tests correctly or be told that they were in a good position yet would still be asked to try again as the system did not capture enough valid measurements to score:

Hand movements test stated that there were not enough valid measurements to score, after the participant did everything correctly.

There were also occurrences in which users would perform tasks incorrectly and the test would still function:

Postural stability test worked even though the participant was not in the correct position at all.

The foot tapping test ran even though P3 tapped the wrong foot, the system still gave him a score. They performed the measurement incorrectly, yet the system still considered it to be valid.

This would lead to confusion among users as they would go through tests being told that they were in a good position without any other corrective feedback only to be asked to try again:

P6 performed the test correctly without any prompts to change position yet the system still prompted them to try again. The test will prompt people to start walking, and will run through without any corrective feedback, but may still state that there were not enough valid measurements to score.

Some tests also tended to shut off very early and inconsistently. Other tests would often produce nonsense automated voice prompts:

...while performing the finger to nose movements: the audio prompt "multiple hands detected" was repeated even though there was only one hand in the camera view.

Overall, the motor test presented frequent glitches causing usability trouble for participants.

Qualitative Interviews

Thematic analysis of qualitative interview responses revealed 4 central themes associated with participants' opinions on the PRIMs. These were (1) admiration of purpose, (2) excessive system sensitivity, (3) video instructions preferred, and (4) written instructions disliked.

Admiration of Purpose

Most of the participants showed an affinity for the overarching objective of the PRIMS:

I know what the main objective is, and I applaud that, that is a good objective. [Participant 8]

They were excited about the system being available to people with PD:

I think it is awesome that people will have access to this. [Participant 11]

I just like the fact that this is available for people. [Participant 11]

I am sure a lot of people would be thrilled to have this at their doctor's office. [Participant 11]

The intended purpose of the PRIMS was also well received and understood. Participants liked the idea that this will give their physicians a better view of their condition and support their ability to do their job:

Doctors often don't have a lot of time to do the examination in depth. My in-person examinations with my Neurologist are very fleeting, and scratching the surface in my view, but if that is the norm, and my Neurologist got a good reputation, then something like this would be very very helpful. [Participant 8]

I like how then your doctor would have a better idea of what you are doing really, rather than based on that little scope of time kind of thing. Yea...that would be good. [Participant 6]

I like that it can be used for long distance. And in our new post covid medical system, we need to free up time for our doctors. [Participant 3]

Overall, participants admired the system and what it is trying to achieve and were excited to see the finished product in the future:

I think it would be worthwhile, if it was something that was worked out, if all the bugs and stuff were worked out it could be used as a tool... [Participant 4]

Overall, I think it's a pretty good system. I think it will help patients or people. [Participant 1]

Excessive System Sensitivity

Most participants found that the motor examination was very sensitive, which made it difficult to get into the proper position for the tests:

Yea like I say it's too sensitive, cause we have Parkinson's, and most people, you know you can be [shaky] and there's no way you are going to be able to stop it [tremors]. [Participant 2]

Users also found it frustrating and time-consuming:

Well I didn't like how it kept telling me that my hand is in a good position and then it's not or they don't detect it or those kinds of things, it can get a bit frustrating. [Participant 1]

The only thing is the actual working of it in those couple of times where no matter what I did or didn't do, everything was as still as I could make it and it says you are fine then it says nope you have to start again...oh my gentle god...maybe it's just too sensitive or something. [Participant 2]

It is time consuming too. [Participant 11]

It is long and...you know...as Parkinson's patients you get tired easily. [Participant 6]

The frustration seemed to stem from the fact that the system was very particular on how it wanted users to be positioned. Participants had the greatest trouble with the hand movements and tasks that required users to stay still:

The ones we have the most difficulty with are the hand. [Participant 8]

Because holding still is a challenge for some people with Parkinson's...some people have tremor, and some don't. For those that do, holding still is a real challenge. [Participant 11]

Overall, users found that the system was difficult to use in its current state due to its sensitivity:

I think that that [PRIMS] would be difficult for some people...unless you had extensive training. [Participant 4]

Video Instructions Preferred

Users found that the demonstration videos were far more helpful, and much less confusing, than the written instructions:

The video was a good tool because we have a lot of brain fog, and reading can be confusing and looking at the video makes things much easier. [Participant 3]

...you are able to see a video of the man actually doing what you are supposed to do you know is quite helpful too I thought. [Participant 8]

There are a lot of words there, in the instructions, again I think if you had it in bullet form maybe. It's a lot easier to watch the video. [Participant 1]

The video was good to show how to do the testing. [Participant 1]

Users suggested more video instructions and less written instructions and even suggested an introduction video outlining what the system entails:

Instead of just jumping right in there, if you had, well I guess it would be a video, but if you had a synopsis of what the testing involved. Maybe if we had a 10-minute video overlooking the whole test at first. [Participant 1]

Overall, the videos were one of the most liked aspects of the entire system:

The things that I thought worked best were the videos. [Participant 5]

I like how there is a video...watching what they do is much more clear. [Participant 11]

Written Instructions Disliked

Many participants found that the written instructions were vague and confusing:

Some of the tests I found confusing, but again that was the written instructions that were somewhat confusing. [Participant 5]

The instructions were really kind of vague. [Participant 1]

Multiple users stated that these instructions were annoying and far too wordy:

Too much instruction, yea, but I know you have to have the instruction down, but it was a lot of reading. [Participant 1]

I would say all the text that open on the screen, yea it's like going to a presentation...mostly just the instructions, I mean you're asking me, in my gut, kind of what I found to be annoying about it...and...the text was annoying. [Participant 7]

Participants suggested that more concise bullet-point instructions would be preferred over written paragraphs:

I think the instructions was too many...If it was concise and shorter instructions, I think it would make it a little better. [Participant 1]

SUS Survey

The average SUS score was calculated to be 69.2, which corresponds to a C on our curved grading scale [54]. The PRIMS failed to meet the acceptable SUS score of 70.

Discussion

Principal Findings

We conducted a multiple methods study to assess the usability, functionality, and user experience of the PRIMS. Thematic analysis of interview transcripts and field notes revealed multiple themes and usability issues, respectively, that describe the tested product. An SUS survey also gave us a key objective insight into the system and its user experience.

One of the key findings of this study was that video instructions were preferred over written instructions. Thematic analysis of interview transcripts revealed these 2 themes (*written instructions disliked* and *video instructions preferred*). Multiple participants stated that the video instructions were much less confusing and much more informative than the on-screen text. The written instructions were designed to give all the necessary information to complete the task. This may have resulted in users feeling unmotivated to read the entire set of instructions as there was an intimidating amount of text present on-screen. Other investigations comparing video to written instructions have found similar results. Cosford et al [56] evaluated the effectiveness of video and handout instructions during a veterinary student examination. Their findings revealed that students using video instructions achieved notably higher scores, suggesting a better understanding of the tasks compared to those using handouts [56]. Shah and Gupta [57] found that video instructions were significantly more effective than written

instructions in teaching inhaler use technique. Video instructions provide both a visual and audio description of each task, which can make the instructions both clearer and less time-consuming.

Another principal finding was that the PRIMS motor examination was too sensitive and particular on users' body positions during the tests. Thematic analysis of field notes and interview transcripts unveiled 2 areas of issues, namely, system sensitivity and the motor test's positioning specificity, which exhibited alignment in their respective scopes. To quantify each motor task performed during the PRIMS questionnaire, the depth cameras would require participants to be oriented in a "good position." From the RA's observational notes and the interview transcripts, it was clear that the system asked too much of users, which led to frustration and difficulties. Systems designed for those with movement disorders must be accommodating to their needs. The PRIMS, in its current state, asks users to stay still in certain situations and adopt specific and uncomfortable positions to score their movements. Future versions of the PRIMS will need to address this in their design and implementation.

Another theme revealed from analysis of field notes was that the automated voice prompts that are used during each motor test are confusing to participants (*automated voice prompts are confusing*). The prompts would also do more harm than good when it came to helping participants align themselves in the correct position for each motor test. It was noted that users tended to move in all directions in response to the automated voice. This could be due to the vague nature of the instructions provided by the prompts. They also led to frustration and confusion, making them an ineffective tool to guide users through the tests. Some users even stated that they found the automated voice to be authoritative and unfriendly, which only increased their frustration with the system. The consensus of this key finding was that these automated prompts did not provide any useful corrective feedback and only led to confusion and frustration among participants. Mays et al [58] delved into how people in the United States perceive automated communication, such as interactive voice response systems. They found that older respondents especially did not enjoy the automated voice system and exhibited greater levels of frustration toward it [58]. Most people with PD are older individuals; therefore, it would be best practice to tailor the system's instructions and prompts to their typical preferences.

Our next key finding is that the small camera tended to cause more problems for users than the large camera. Thematic analysis performed on field notes revealed this theme (*the small camera is problematic*). The smaller-depth camera (Intel D435) has a narrower field of view and was primarily used for the hand movement tests during the motor examination. A common problem that users faced was staying within the camera view for these tests. As the RA noted on several occasions, it was common for participants to have difficulties with the narrow view. The position of the small camera also caused trouble for users. Unlike the larger camera, the smaller camera is placed on a tripod on either side of the computer (Figure 6). It was noted frequently in the field notes that users had to manipulate and adjust this camera to align themselves in the proper position. The placement of the camera also negatively impacted the

system's ergonomics. In addition, for tests 3.14 and 3.15, users were prompted to flip the tripod down so that the camera was facing the ceiling. Frequently, users accidentally disconnected the cords from the camera when moving it. In general, a setup

in which users do not have to adjust any equipment would be preferential. To our knowledge, there is no direct study to compare this finding to.

Figure 6. Diagram of hardware setup showing the position of the laptop and 2 depth cameras.

Another principal finding of our thematic analysis was that the PRIMS has associated mobility challenges for users. A big issue that the design of the system has is the constant movement to and from the computer to go from one task to another. At times when the users' feet or whole body had to be visible to the camera, participants would have to move backward until this was the case. To move onto the next task, users would have to return to the laptop to select it. This way, users are constantly moving to and from the computer and frequently being obstructed by the chair. Several users even pointed out that they felt as though others would have problems with the back-and-forth nature of the system. When designing systems for those with movement disorders, it is important to consider the user experience as a whole.

Thematic analysis of field notes also revealed that users had difficulties navigating the system (*navigating the system is difficult*). In its tested state, the PRIMS was operated using a standard computer mouse or laptop touchpad (depending on user preference). Navigating the system using either of these tools caused difficulty among participants. Scrolling or clicking to move in between sections of the questionnaire was frequently noted as a challenge for users and even led to mistakes in some circumstances. The accuracy of the clicking to move through the system was also a big issue and would often lead to opening other applications or closing the PRIMS software. It is important to remember that, when designing systems for those with movement disorders, there must be special considerations taken. A viable option could be a touch screen device featuring prominently sized buttons, eliminating the need for scrolling. However, it is worth noting that touch screens can lead to increased postural discomfort during use [59]. Thus, offering a variety of system operation methods might be the most effective way to cater to diverse user needs and preferences. Enhancing usability is paramount not only for optimizing human-computer interactions but also for ensuring the system's social and practical acceptance [48]. A system's usability should be of a

standard that facilitates effortless task execution by the user. Given that the PRIMS posed challenges for users in performing certain tasks, there is a clear need for usability enhancements.

Another principal finding that came from analyzing the field notes is that the motor examination did not function perfectly or as intended. Similar to any new software system, the PRIMS had its share of technical issues. One of the most frequent issues noted by the RA was that users would perform tests correctly yet the system would fail to score their movements. This is a problem especially when the system does not prompt any corrective feedback yet still informs users that there were not enough valid measurements to score. The software issues caused frustration among the participants and led to multiple usability issues. Usability is tied to functionality, although they are not exactly the same. When a product is not functioning correctly, it ultimately impacts its usability. Thus, ensuring that the system works as it is intended must be a priority for future developers to improve its usability.

Through the analysis of interview transcripts, a prominent theme of appreciation emerged in relation to the PRIMS. Designed with the primary objective of enhancing care for individuals living with PD, the PRIMS was met with significant enthusiasm. Users recognized the immense potential of such a remote monitoring solution, expressing eagerness about its availability. This positive reception underscores the importance of aligning the product's design with the needs of its intended users. The participants' commendation of both the system and its mission suggests that the overarching principle of the product is robust. Previous studies have emphasized the pivotal role of consumer perspectives in determining the success of a product [60]. Given this context, such a positive reception indicates a promising trajectory for the future deployment of the PRIMS.

Our last principal finding from this usability study was that our recorded SUS score was 69.7, which failed to meet our acceptable usability score of 70. There are several reasons that

could explain why participants felt that the system was not as user-friendly as it should be. Binyamin et al [61] used the SUS to evaluate a learning management system in an educational setting. Their system also failed to meet an acceptable usability score of 70. A distinct aspect of their study was that participants engaged with the system repeatedly throughout a summer term. They observed a direct relationship between the frequency of system use and the SUS score, suggesting that increased familiarity led to improved usability ratings [61]. Drawing from this, it is conceivable that, if participants in our study had interacted with the system over an extended duration, as intended for the PRIMS, the SUS score might have been more favorable due to enhanced user familiarity by the study's conclusion.

Severity of Usability Problems

Within the spectrum of presented usability problems, a hierarchical assessment of severity becomes imperative considering factors ranging from potential risks to participant safety to issues causing minor hindrances in task completion. We ranked the issues posing threats to safety and mobility as top priorities to be addressed, followed by those that led to difficulty and frustration, with minor issues that may have slowed participants down being of the least concern.

Foremost among the identified challenges were those associated with mobility constraints, standing out as the most severe due to their inhibiting impact on participants with mobility challenges. Beyond impeding the use of the PRIMS, these challenges pose a risk to participant safety by potentially placing individuals in vulnerable positions. Notably, the constant need for movement to and from the computer for task transitions emerges as a top priority for resolution.

A usability problem of a lesser degree of severity pertains to the system's sensitivity, specifically in quantifying motor tasks during the PRIMS questionnaire. The requirement for participants to be consistently in a "good position" proved overly demanding, leading to frustration and difficulties, as observed in RA notes and interview transcripts. This underscores the importance of designing systems for individuals with movement disorders to be accommodating to their unique needs. The current state of the PRIMS, requiring users to stay still in certain situations and adopt uncomfortable positions, resulted in skipped tests, increasing the priority of addressing this issue.

Issues that made completion difficult included challenges in navigating using the computer mouse and occasional malfunctions in the motor examination. These concerns, while not as severe as mobility-related issues or the system's sensitivity, warrant attention as they contribute to user frustration and impact task completion.

Finally, minor difficulties associated with operating the small camera and managing automated voice prompts and written instructions require fine refinements rather than constituting significant hurdles. While not impeding overall system navigation, these issues contributed to slower completion and user frustration. In the hierarchy of severity, they represent areas for enhancement rather than critical concerns requiring immediate attention.

Implications

This study conducted a comprehensive evaluation of a system specifically tailored for individuals with motor and cognitive conditions, shedding light on critical considerations for the development of technology for this population. First, we advise against the use of desktop applications requiring a computer mouse, scrolling, and intricate clicking, recognizing the potential challenges faced by users. Furthermore, our findings emphasize the superiority of visual instructions over written ones, also suggesting that automated voice prompts should be used judiciously and presented in a friendly manner and offer clear instructions, especially during confirmation processes. To address the mobility challenges commonly faced by this population, systems necessitating movements in front of a camera should minimize the need for multiple adjustments as these can introduce errors. In addition, our study underscores the importance of system flexibility, allowing for a significant margin of error in data capture without imposing the requirement for participants to remain perfectly still during calibration—an often-unattainable feat for those with motor conditions. As we navigate future developments of the PRIMS, these insights will serve as a guide in creating a product that effectively addresses the outlined issues, emphasizing a visually guided interface requiring minimal effort for seamless operation, aligning with the unique needs of our target user base.

Limitations and Future Investigation

There were several limitations to this study. Our small sample size may not have revealed all the usability issues [62,63] as testing with a small number of participants tends to only reveal the major flaws or glitches in the system. However, our main objective was to uncover the biggest areas of concern rather than identifying every problem associated with the system.

Another limitation to this study was our methodology. Other common qualitative data recording techniques for usability studies include the think-aloud technique [64] and focus groups. The think-aloud technique is the process in which users are encouraged to verbalize their perceptions as they interact with the system [64], which can provide insight into the user experience. Focus groups with study participants following the interviews could have produced richer information. This would have given users the opportunity to compare their ideas and thoughts on the PRIMS. However, while conducting this study, we made a deliberate decision not to use the think-aloud technique. This choice was grounded in our consideration for the unique challenges faced by individuals with PD, particularly those with motor and speech difficulties. The think-aloud technique traditionally involves participants verbalizing their thoughts as they navigate through a system. However, given the potential speech impediments, tremors, and other motor-related challenges associated with PD, we anticipated that asking participants to vocalize their thoughts could introduce unnecessary stress and frustration, and we did not want to pile on any extra cognitive load. To ensure a more comfortable and authentic testing environment for individuals with PD, we opted for direct observation followed by an interview after they were finished using the system, allowing

us to carefully note any challenges users encountered as they interacted with the software.

We also acknowledge that other methods, for example, mixed methods research [65], are applicable for usability and user experience research. Mixed methods may allow for a more comprehensive understanding of a user's experience, which can enable researchers to identify specific usability issues [66]. There are also other scales that we could have used to quantify user satisfaction, for example, the Post-Study System Usability Questionnaire [67]. As our product is in the early stages of development, we opted for a simpler multiple methods study to uncover the major flaws in our system. Future usability studies on the PRIMS can use a mixed methods design to gain a deeper understanding of usability issues.

Considering the intricacies involved in designing systems for users with movement disorders, a promising direction for future research could entail conducting user-centered design studies to tackle the identified usability challenges. This approach, which is advocated by other authors as an effective methodology for achieving a usable product, aims to design products that consider the needs and interests of end users [68-71]. Salinas et al [72] have reviewed the techniques and tools used in the successful redesigns of graphical user interfaces of software products following the user-centered design approach. While some of these techniques align with those used in our evaluation, the key lies in using these techniques throughout the design process instead of solely during product testing. Commonly reported methods of user testing include prototyping, pre- and postdesign interviews, heuristic evaluation, and surveys or questionnaires [72]. Therefore, upcoming research endeavors concerning the redesigned PRIMS should embrace a user-centered design methodology to guarantee the satisfaction of end users' needs and explore the integration of the aforementioned effective techniques. Moreover, future investigations could concentrate on crafting customizable interface options enabling users to tailor their interaction

experience according to their individual capabilities and preferences. This might entail the incorporation of adjustable settings for font size, button layout, and navigation pathways such as voice activation or remote controllers to cater to a diverse range of users.

The current iteration of the PRIMS faces practicality challenges for home use. A more feasible adaptation would necessitate enhanced usability, reduced equipment costs, and minimal space requirements. Substantial updates are imperative to transform the PRIMS into a valuable home-based tool. This entails enhancing user-friendliness, optimizing the product to function seamlessly on common smartphone or tablet cameras, and refining the interface for a user-friendly experience.

It is important to emphasize that a direct score comparison between the PRIMS and a clinician was not conducted in this study. The PRIMS did assign scores to each movement in the motor test using an algorithm developed by PragmaClin Research Inc. However, it is essential to clarify that this study exclusively focused on usability and did not assess the validity of the scoring process. The validation of scoring algorithms remains a subject for future investigations.

Conclusions

In conclusion, the PRIMS currently exhibits several usability challenges that hinder its efficient use by individuals with PD. For the system to achieve successful implementation and gain broad acceptance, it is imperative to address these identified issues. Feedback from this study is being used to upgrade the PRIMS so that it better aligns with patients' needs. This study contributes significantly to the growing literature on usability testing, particularly emphasizing design nuances for systems tailored to those with movement disorders. Moving forward, it would be beneficial for future research to explore diverse interaction methods with digital devices, aiming to pinpoint optimal usability practices.

Acknowledgments

The authors would like to thank the Parkinson Society Newfoundland and Labrador for assistance with recruitment and the Mitacs Accelerate program for funding this project. They also extend their heartfelt gratitude to the participants, whose invaluable contributions have been instrumental in shaping this research endeavor. This study is one of several manuscripts that will collectively contribute to BB's PhD thesis.

Data Availability

The data sets generated during and analyzed during this study are available in the Memorial University Dataverse-Borealis repository [73].

Conflicts of Interest

BB and JT are employees of PragmaClin Research Inc, the company that developed the Parkinson's Remote Interactive Monitoring System. All other authors declare no other conflicts of interest.

Abstract

Background: Cognitive functional ability affects the accessibility of IT and is thus something that should be controlled for in user experience (UX) research. However, many cognitive function assessment batteries are long and complex, making them impractical for use in conventional experimental time frames. Therefore, there is a need for a short and reliable cognitive assessment that has discriminant validity for cognitive functions needed for general IT tasks. One potential candidate is the Trail Making Test (TMT).

Objective: This study investigated the usefulness of a digital TMT as a cognitive profiling tool in IT-related UX research by assessing its predictive validity on general IT task performance and exploring its discriminant validity according to discrete cognitive functions required to perform the IT task.

Methods: A digital TMT (parts A and B) named Axon was administered to 27 healthy participants, followed by administration of 5 IT tasks in the form of CAPTCHAs (Completely Automated Public Turing tests to Tell Computers and Humans Apart). The discrete cognitive functions required to perform each CAPTCHA were rated by trained evaluators. To further explain and cross-validate our results, the original TMT and 2 psychological assessments of visuomotor and short-term memory function were administered.

Results: Axon A and B were administrable in less than 5 minutes, and overall performance was significantly predictive of general IT task performance ($F_{5,19}=6.352$; $P=.001$; $\Lambda=0.374$). This result was driven by performance on Axon B ($F_{5,19}=3.382$; $P=.02$; $\Lambda=0.529$), particularly for IT tasks involving the combination of executive processing with visual object and pattern recognition. Furthermore, Axon was cross-validated with the original TMT ($P_{\text{corr}}=.001$ and $P_{\text{corr}}=.017$ for A and B, respectively) and visuomotor and short-term memory tasks.

Conclusions: The results demonstrate that variance in IT task performance among an age-homogenous neurotypical population can be related to intersubject variance in cognitive function as assessed by Axon. Although Axon's predictive validity seemed stronger for tasks involving the combination of executive function with visual object and pattern recognition, these cognitive functions are arguably relevant to the majority of IT interfaces. Considering its short administration time and remote implementability, the Axon digital TMT demonstrates the potential to be a useful cognitive profiling tool for IT-based UX research.

Introduction

Cognitive functional ability is a fundamental factor widely recognized to influence IT usability [1-3]. The classical approach to control for cognitive functional ability is to target participants according to general demographics based on age, education, or other factors [4,5]. However, this approach intrinsically precludes the ability to control for or assess how cognitive functional ability impacts IT usability in individual users, thereby limiting the extent which insight can be gained within a demographic or for an individual. Moreover, this approach is incongruent with the rapid advancement of IT toward products that adapt to individual user characteristics, thus necessitating a more granular understanding of individual cognitive abilities [6-8].

To obtain a granular characterization of individual cognitive function, hitherto, research has typically used cognitive assessment batteries [9-11]. Dumont et al [12] used the National Institutes of Health Toolbox, which is a battery of cognitive tests that can be completed in 40 minutes [13] to develop a cognitive analysis grid to be able to draw statistical parallels between the cognitive demands of an information systems interface and the performance of a user. Other batteries of tests were also used, such as the Kit of Factor-Referenced Cognitive Tests [10], which was used by Wagner et al [1] to study the impact of age on website usability and by Allen [14] in his research to study the combination of users' cognitive abilities and specific information system functionalities that can be implemented to create system usability. This battery is typically administered in 144 minutes [15]. Another approach for assessing individual cognitive ability is to use clinically administered tests such as the Montreal Cognitive Assessment (MoCA) or the Mini-Mental State Examination (MMSE). Although typically used in medical settings to evaluate cognitive impairment in patients with neurological disorders [9,11], MoCA and MMSE have been reportedly used to measure the cognitive abilities of participants in human-computer interaction experiments [3,16-18]. However, while detailed and accurate, these cognitive assessment batteries are too lengthy to practically administer during typical user experience (UX) testing time frames [19,20]. Furthermore, while clinically administered tests such as MoCA and MMSE are comparatively shorter than other assessment batteries, they require a trained administrator to administer and score the test [3]. This level of expertise may not always be available, particularly in UX research settings where mostly nonclinically trained research personnel are conducting the experiments.

Correspondingly, there have been calls from across health, UX, and IT domains for a more practical yet accurate means of assessing cognitive function [12,21,22]. One solution would be to identify a short test with reduced scope but which nevertheless targets cognitive functions important for using IT. Based on research conducted to understand the impact of cognitive functions on the use of technology by older people [23,24], and on existing models of cognitive architecture in human-computer interaction [25], we identified 5 key cognitive functions important for IT use: visual perception, motor function, executive function, inhibitory control, and working memory.

Visual perception is important for finding relevant information cues on a web page [23]. Motor functions are involved in tasks such as data entry using the keyboard, navigation using the mouse, or other tool to perform a digital task [26]. Executive functions come into play in order to make decisions and prioritize action [23]. Inhibitory control, also called "response inhibition" [27], is the functional ability to inhibit or override motor commands or other executive processing, such as when an external stimulus interferes with goal-driven behavior as in a task-switching situation [28,29]. Finally, short-term or working memory capacity may be important in IT task performance, for example, for remembering options or system output at a later stage [23].

One potential preexisting cognitive assessment candidate that targets these cognitive functions related to IT use is the Trail Making Test (TMT). First developed for the Army Individual Test Battery [30], the TMT is one of the most widely used instruments in neuropsychological assessment as an indicator of cognitive processing speed and executive functioning [31-35]. Many studies have been conducted to determine which cognitive abilities are engaged during the completion of this 2-part test (TMT-A and TMT-B). After a comprehensive review of the literature on the topic, Sánchez-Cubillo et al [36] explored the contributions of certain cognitive functions and found that part A of the TMT (TMT-A) mainly requires visual-perceptual abilities, and that part B (TMT-B) reflects primarily working memory, executive function, and task-switching ability. Finally, although its contribution in the TMT has been questioned by the study of Sánchez-Cubillo et al [36], it is interesting to note that psychomotor ability has been mentioned numerous times as one of the abilities required for both parts of the TMT (Groff and Hubble [37] in both parts, Schear and Sato [38], Gaudino et al [39], and Crowe [40] in part B). The primary objective of this study was to test the validity of using the TMT as a cognitive profiling tool to predict or explain the variance in IT task performance. With an interest in a practical tool for cognitive profile assessments in UX testing of digital artifacts, we chose to use a digital version of the TMT. To further support and explain our results, we additionally cross-validated the digital TMT with the original TMT, a visual search task assessing visuomotor processing [41,42], and a hidden path learning task assessing visuomotor-processing speed, spatial working memory, and error-monitoring ability [43]. We had two hypotheses: (1) TMT times would be predictive of general IT task performance and (2) that the predictive power of the TMT would be stronger for tasks requiring the use of cognitive functions that are congruent with those assessed by the TMT.

Methods

Sample

To test our hypothesis, we conducted a laboratory experiment with 27 healthy participants (12 men and 15 women), between 18 and 36 (mean 24, SD 4.22) years of age, who were mostly university students (n=22, 85%).

Ethical Considerations

Written informed consent was obtained from all subjects via a signed form at the beginning of the experiment. This project

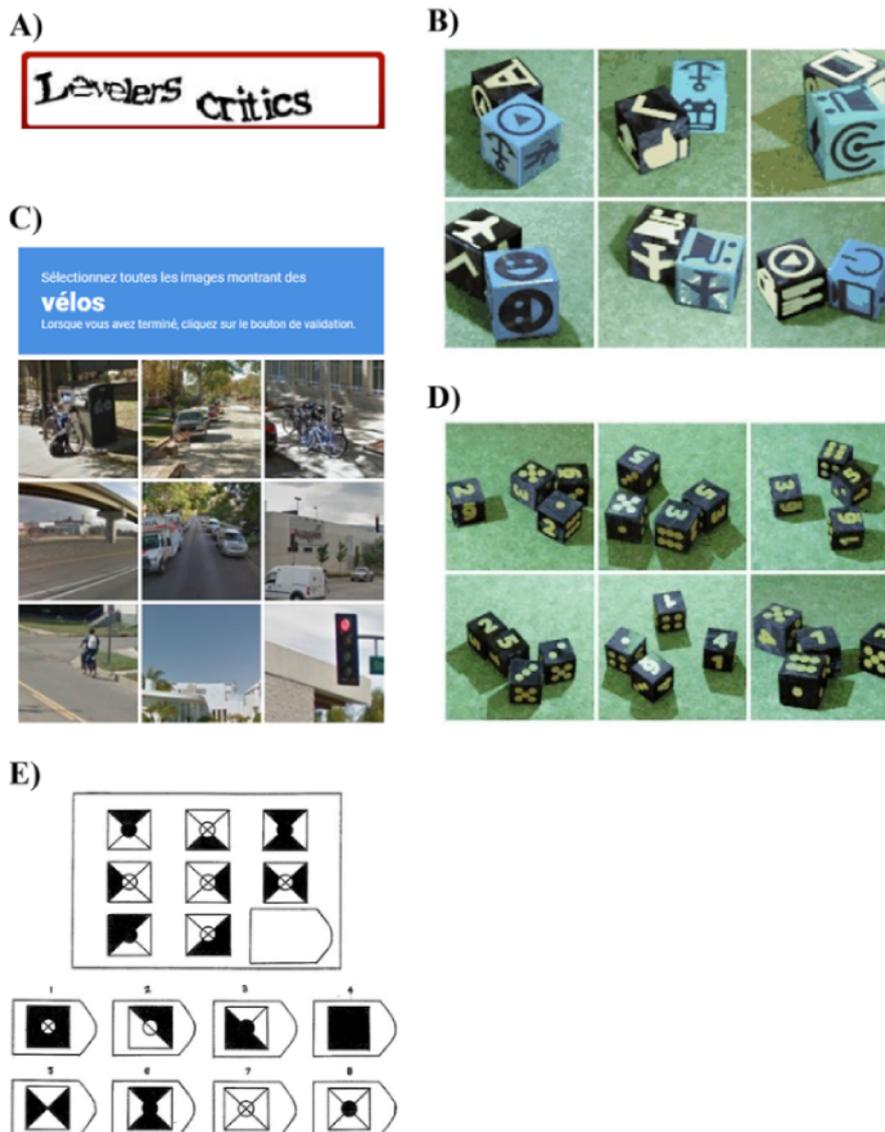

was approved by our institution’s research ethics committee (#2021-4108). A monetary compensation of CAD \$25 (US \$18.35) was provided to each subject upon completion of the experiment. Data from 1 subject were lost due to technical issues, thus leaving data from 26 participants available for analysis. All data were anonymized prior to analysis and stored in encrypted servers only accessible by authorized researchers.

IT Tasks

Two types of general IT tasks were used in the experiment. One type of IT task was based on CAPTCHA (Completely Automated Public Turing Tests to Tell Computers and Humans Apart). This type of Turing test is widely used in IT to ensure the cybersecurity of many internet services, as they prevent a number of attacks from automated programs (often referred to as bots), by distinguishing legitimate users from computer bots while requiring minimal effort by the human user [44]. Four

CAPTCHAs were based on typical existent CAPTCHAs and included Google reCAPTCHA (Google), pictogram recognition (PicRec), numerical recognition (NumRec), and text recognition (Text). A Fifth task was taken from Raven’s Progressive Matrices (RPM) and presented in a CAPTCHA format. RPM are a collection of widely used standardized intelligence tests consisting of analogy problems in which a matrix of geometric figures is presented with 1 entry missing, and the correct missing entry must be selected from a set of answer choices [45]. A 3x3 RPM was selected as it was considered that it offered the best trade-off between cognitive effort and the time required to complete it. The final 5 IT tasks, shown in Figure 1, were embedded on a Qualtrics questionnaire. For this study, we targeted IT task completion time, measured as the time from the display of each task to when subjects responded and pressed the “next” button, based on 30 fps screen recordings.

Figure 1. The 5 information technology tasks. (A) Text-based Completely Automated Public Turing tests to tell Computers and Humans Apart (CAPTCHA): subjects had to type the 2 words in an input field below the text image. (B) Pictogram recognition CAPTCHA: subjects had to recognize and click on the image showing the 2 dice with the same pictogram on the top face. (C) Google reCAPTCHA: subjects had to recognize and click on the images showing the bicycles. (D) Number recognition CAPTCHA: subjects had to recognize and click on the image showing dice summing to 14 on the top faces (numerals and dots combined). (E) Raven’s Progressive Matrix: subjects had to click from among the 8 proposed images the one which most appropriately fit in the missing corner of the basic matrix.

The other type of IT task was a website design evaluation to assess perceived usability using Aladwani and Palvia's [46] user-perceived web quality measurement scale. Screenshots of the home pages of the following 5 websites were used: Vignerons d'Exception [47], Renaud-Bray [48], LesPAC [49], [50], and [51]. One website was presented subsequent to each CAPTCHA. Participants were told that the website evaluation was the primary task of the experiment and that the CAPTCHAs were present as a security measure to access our database housing the website screenshots. However, the website evaluations were actually dummy tasks, and participant responses were not analyzed. The IT tasks really targeted and analyzed in this study were the CAPTCHAs.

Cognitive Function Characterization of CAPTCHAs

The principal reason CAPTCHAs were chosen as our general IT tasks is because they are ubiquitous in IT and because they are often distinguishable from one another according to

task-specific demands such as math, 3D orientation, text recognition, and visual search, suggesting that different underlying cognitive processing required them. However, there is a paucity of studies regarding the examination of the specific cognitive functions of CAPTCHAs. Therefore, we formed a panel of 11 trained, nonexpert evaluators to rank the selected CAPTCHAs on a 5-point agreement scale according to the 5 cognitive functions mentioned in the Introduction section, which have been deemed relevant to IT tasks and the TMT: visuospatial perception, motor function, executive function, inhibitory control, and working memory. The evaluation scores permitted each CAPTCHA to be assigned a rank according to the extent the cognitive functions required to perform it overlapped with those of the TMT. In order of highest to lowest alignment, the rankings were as follows: (1) RPM, (2) NumRec, (3) PicRec, (4) Google, and (5) Text, as shown in Table 1. For details of how this evaluation was conducted and how the process was validated, see Multimedia Appendix 1.

Table 1. Convergence ranks of IT tasks with the TMT^a.

IT task	RPM ^b (E)	NumRec ^c (D)	PicRec ^d (B)	Google (C)	Text (A)
Executive function, mean (SD)	5.00 (0.00)	4.91 (0.30)	4.45 (1.04)	4.45 (1.04)	3.82 (1.4)
Visual object recognition, mean (SD)	4.09 (0.70)	4.27 (0.65)	4.64 (0.67)	4.82 (0.60)	4.18 (1.17)
Visual pattern recognition, mean (SD)	4.91 (0.30)	4.45 (0.93)	4.64 (0.67)	3.82 (0.98)	4.64 (0.67)
Working memory, mean (SD)	4.18 (0.60)	3.91 (1.38)	2.91 (1.51)	2.45 (1.21)	2.73 (1.27)
Evaluation score for reliable convergent dimensions, mean (SD)	4.55 (0.48)	4.39 (0.42)	4.16 (0.84)	3.89 (1.04)	3.84 (0.81)
Convergence rank with TMT following the evaluation ^e	1	2	3	4	5

^aTMT: Trail Making Test.

^cNumRec: numerical recognition.

^dPicRec: pictogram recognition.

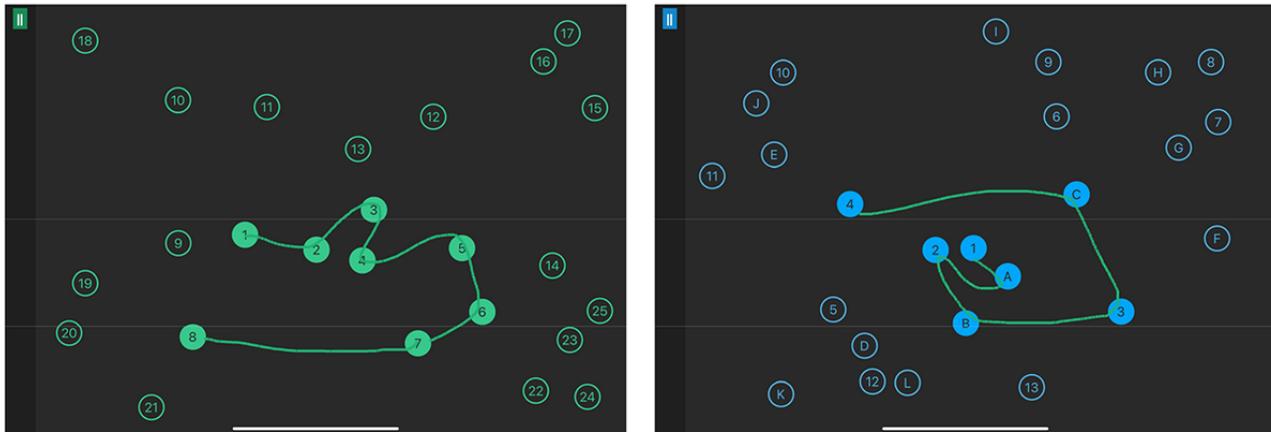

^eBased on the average evaluation scores of IT tasks on the reliable cognitive dimensions considered convergent with the TMT. A, B, C, D, and E refer to the labels of the IT tasks presented in Figure 1.

Digital TMT

Because we are interested in cognitive assessment for UX testing of IT and because it was convenient to present all the tasks on the same device, we chose to use a digital version of the TMT called "Axon" (Language Research Development Group). This version emulates the original TMT as an iPad app, allowing the user to draw the trail on the touch screen with 1 finger. The 2 parts (A and B) of the TMT were completed, each with 25 circles to connect. Axon TMT was designed with a canvas generation algorithm, meaning that the test canvas for each subject for each TMT A and B was different. As shown in Figure 2, both tests were presented in full screen on the iPad with 25 circles of 1-cm diameter placed randomly on the digital canvas

in a homogeneous way. The rules of Axon were identical to those of the original TMT, as outlined by Bowie and Harvey [52]. Participants had to connect the circles in ascending order: from 1 to 25 for part A and from 1 to 13 for part B, alternating numbers and letters in ascending order (ie, 1, A, 2, B, 3, C, etc). Errors such as lifting the finger off the screen, crossing trails, or connecting a wrong circle resulted in the line for the latest segment to be automatically erased and subjects had to return to the last successfully reached circle in order to continue. The measures chosen for this study were the completion time for each of the 2 parts of the test, from the moment the layout was displayed until the last circle was reached. These measures were exported from the app after the completion of the study and used in our statistical analyses.

Figure 2. Screenshots of Axon A and Axon B. Subjects had to draw to connect the circles in ascending order (from 1 to 25 for part A and from 1 to 13 and A to L for part B, alternating numbers and letters) on a single line, without crossing paths or lifting their finger from the screen. In case of errors in drawing, the app automatically guided subjects back to the last correct circle from which they continued the test.

Cross-Validation of the Digital TMT

Overview

To better support and explain our results, we cross-validated Axon with the original TMT and a working memory and a visual search task.

Original TMT

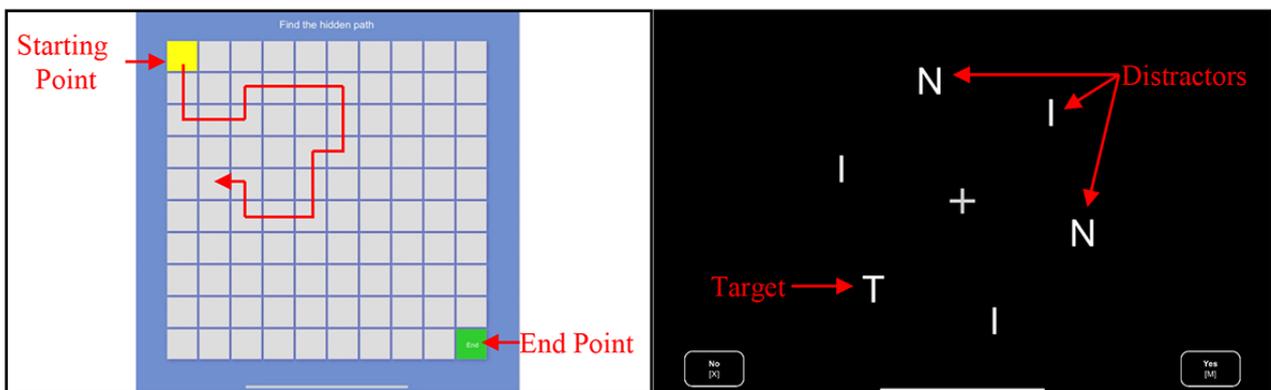

The original TMT was administered as outlined by Bowie and Harvey [52] at the end of the study. The practice step was skipped in the interest of time and with the knowledge that the subject had already performed the digital TMT earlier in the study.

Hidden Path Learning Task

To cross-validate Axon’s ability to measure working memory and spatial ability, we administered a hidden maze learning

task, based on the Groton Maze Learning Test developed by Pietrzak et al [43]. Our task was called the “hidden path learning” task and was based on a 10 × 10 grid. Five trials were administered on the iPad via the Cognition Lab platform (BeriSoft, Inc), following similar guidelines as the Groton Maze Learning Test [43]. The hidden path learning task is particularly targeted at working memory, as the user has to call on it to navigate between tiles and remember any errors they may have made before [53,54]. Correspondingly, working memory ability is associated with the extent to which completion time decreases over trials, revealing a learning curve. Thus, the metrics used for these analyses were the difference between the completion times of each consecutive trial on the task. A depiction of the hidden path learning task is shown in Figure 3 (left). Measures were automatically collected on the Cognition Lab server.

Figure 3. Cross-validation tasks. In the hidden path learning 10×10 matrix (left), subjects had to go from the yellow starting point to the green end point 1 tile at a time. In the visual search task (right), there were 6 items, with 1 target and 5 distractors. In the I+N sequence (shown), participants had to touch “Yes” at the bottom-right if they saw the target, “No” at the bottom-left otherwise.

Visual Search Task

To cross-validate Axon’s ability to measure visuomotor function, we administered a visual search task on the Cognition Lab platform (BeriSoft, Inc). This task was based on the work by Treisman and Gelade [42] and involved finding a target among distractors. Participants had to touch the right side of the screen when they saw the target, the left side otherwise,

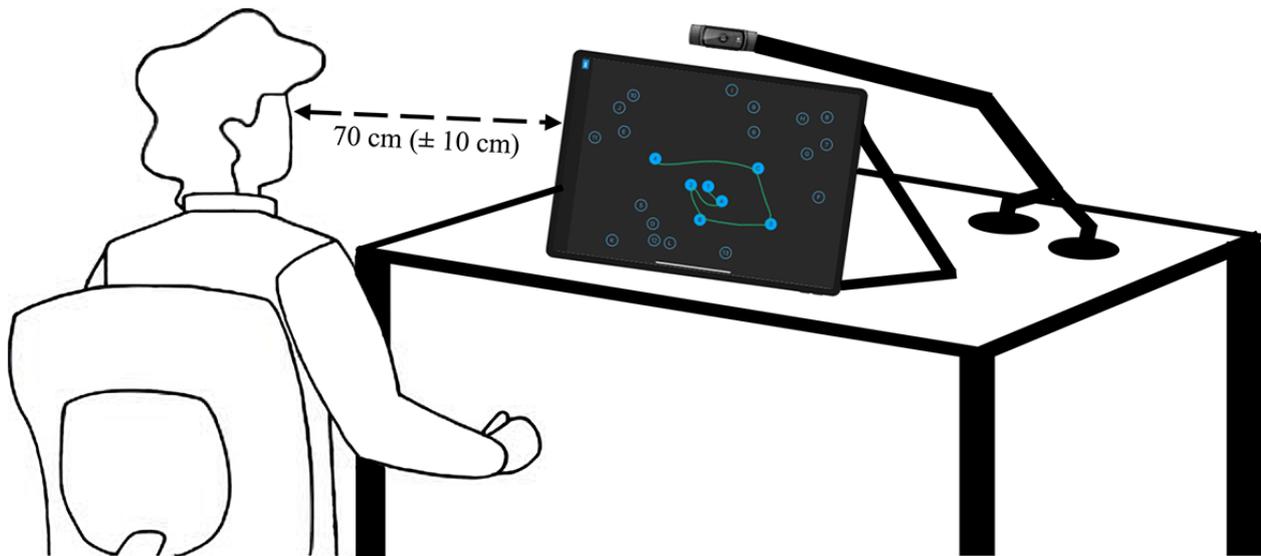

therefore involving visual and psychomotor response ability. Three stimuli configurations were used, with 3 distractor sets. Configurations were displayed with 24 trials for each stimulus, leading to a total of 72 trials. For each trial, 3, 6, or 9 symbols were displayed (letters or shapes), with even and randomized distribution among each stimulus sequence. A depiction of this task is shown in Figure 3 (right). Again, measures were

automatically collected on the Cognition Lab server. Reaction times were used for the present analyses.

Procedures

Upon arrival and after signing the informed consent form, subjects were asked to sit on a chair facing the iPad Air (fourth generation) running on iPadOS 15.3 (Apple Inc) placed on a desk and were asked to adjust the chair's height so that they were comfortable using the iPad, and they were within the camera recording frame. The experimental setup is presented in Figure 4. They were asked to move the chair closer or further away to maintain an approximate distance of 70 (± 10) cm

Figure 4. Experimental setup diagram. The subject was seated at a chair in front of a desk where the iPad Air 4 was placed. A Logitech C920 camera was independently fixed to the desk via a camera stand and duct tape.

After completing parts A and B on the Axon app, participants were administered the hidden path learning and the visual search tasks. Then, participants commenced the IT task portion of the experiment. As previously mentioned, participants were told that the primary objective was to evaluate 5 interfaces of more or less popular websites, each interface being on a secure server accessible only after the completion of a CAPTCHA. Thus, subjects completed a CAPTCHA, observed a web interface for a few minutes, and then completed the user-perceived web quality measurement scale [46]. This sequence was repeated 5 times, with the tasks presented in random order, each preceded by a distinct CAPTCHA. At the end of the study, for ethical reasons, subjects were told orally that they were in fact being evaluated on their performance on the CAPTCHAs.

Statistical Analyses

To test the ability of the Axon TMT to predict performance on the 5 CAPTCHA IT tasks, a repeated-measures multivariate analysis of covariance (RM MANCOVA) was performed with Axon A completion time and Axon B completion time as independent predictors and the completion time for each of the 5 IT tasks as the dependent covariates.

To further interpret our results, we tested the relationship between Axon TMT completion times and visuomotor function by performing an RM MANCOVA with Axon A and Axon B times as independent predictors and the mean reaction time of

between their eyes and the iPad screen to give enough space for hand movement during the tasks. The camera was fixed independently from the iPad to avoid unwanted movements on the video when the participant presses the screen while doing the tasks. After a presentation of the study and the tools used, the participants were asked to complete the 2 parts of the TMT (A and then B) on the Axon app. Task instructions were given in a protocol format to ensure that all participants received the same instructions and that the data would be comparable. Participants were verbally and visually guided through the rules of the TMT using a tutorial embedded in the app.

each of the 3 visual search tasks (the shape of an arrow as a target among the triangle shapes as distractors, the letter T as a target among the letters I and N as distractors, and the letter T as a target among the letters I and Z as distractors) as the dependent covariates. In addition, we tested the relationship between Axon TMT completion times and working memory function by performing an RM MANCOVA with Axon A and Axon B times as independent predictors and the difference between the completion time of each consecutive trial on the hidden path learning task as the dependent covariates. Finally, we cross-validated the relationship between the Axon TMT and the original TMT using 2 Pearson correlation tests, 1 each for tests A and B.

For all RM MANCOVAs performed in the analysis, omnibus results and multivariate results for each independent predictor are reported. In the case of significant multivariate results, simple main effects based on parameter estimates are reported for dependent covariates, which were significantly predicted by Axon.

All statistical analyses were conducted using the IBM SPSS Statistics software (version 28.0.1.1; IBM Corp) with a threshold for statistical significance set at $P \leq .05$, using the Bonferroni correction to adjust for multiple comparisons.

Results

Axon TMT Cross-Validation

Axon Versus Original TMT

The mean scores of Axon A and B were 48.04 (SD 25.80) and 56.88 (SD 25.53) seconds, respectively. The mean scores on the original TMT A and B were 29.22 (SD 12.26) and 51.62 (SD 19.07) seconds, respectively. Pearson correlation tests revealed that Axon is highly correlated with TMT results, with a significant positive correlation between Axon A and TMT A ($r=0.688$; $P_{\text{corr}}=.001$) and a significant positive correlation between Axon B and TMT B ($r=0.505$; $P_{\text{corr}}=.017$).

Axon TMT Versus Hidden Path Learning

The difference in consecutive trial times was (2–1) –29.87 (17.70), (3–2) –5.48 (6.01) seconds, (43) –4.30 (4.80) seconds, and (5–4) –1.50 (4.25) seconds. The omnibus test of the RM MANCOVA revealed that Axon A and Axon B combined are significant to explain the variance in the decrease in completion times across consecutive trials ($F_{4,20}=4.119$; $P=.01$; $\Lambda=0.548$). However, multivariate results revealed that the decrease in completion times across trials was not predicted by Axon A ($F_{4,20}=1.923$; $P=.15$; $\Lambda=0.722$) or Axon B ($F_{4,20}=1.106$; $P=.38$; $\Lambda=0.819$) alone. Thus, a predictive relationship appears to exist between Axon and working memory in the hidden path learning task as a function of Axon A and B combined.

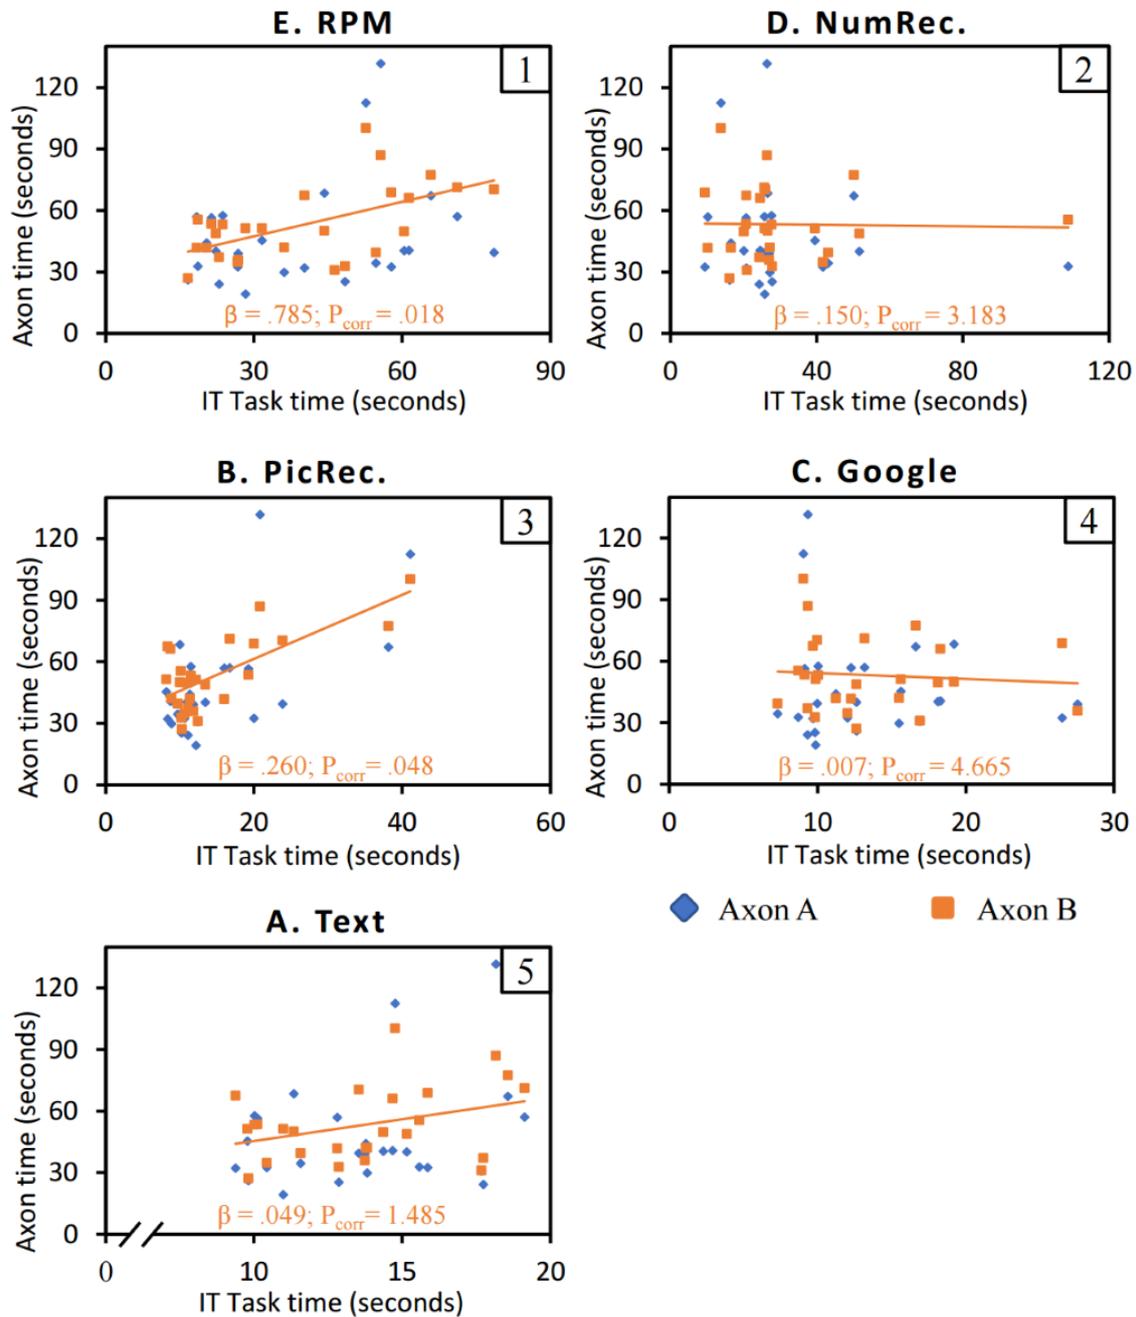

Axon TMT Versus Visual Search

Reaction times for the T among letters I and N, T among letters I and Z, and arrow among triangles were 0.80 (0.14) milliseconds, 0.78 (0.15) milliseconds, and 0.68 (0.14) milliseconds, respectively. The omnibus test of the RM MANCOVA revealed that Axon A and Axon B combined significantly explained the variance in visuomotor function assessed with reaction time to the 3 stimuli in the visual search task ($F_{3,21}=3.125$; $P=.048$; $\Lambda=0.691$). Multivariate results revealed that this result was driven mainly by Axon A ($F_{3,21}=3.220$; $P=.043$; $\Lambda=0.685$) rather than Axon B ($F_{3,21}=0.502$; $P=.69$; $\Lambda=0.933$). Parameter estimates revealed that Axon A was marginally significantly predictive of reaction times to the letter T among letters I and N stimulus ($\beta=3.573$; $t_{21}=2.767$; $P_{\text{corr}}=.055$) and significant for letter T among letters I and Z ($\beta=4.353$; $t_{21}=3.156$; $P_{\text{corr}}=.02$) and arrow among triangles ($\beta=3.725$; $t_{21}=3.158$; $P_{\text{corr}}=.02$) stimuli.

Axon TMT Predicts Overall IT Performance

The primary hypothesis assumed that there was a positive predictive relationship between TMT performance and IT task performance. The omnibus test of the RM MANCOVA revealed that Axon A and Axon B combined significantly explain the variance in IT tasks performance ($F_{5,19}=6.352$; $P=.001$; $\Lambda=0.374$), thereby supporting the primary hypothesis. Multivariate results revealed that this effect was driven by performance on Axon B ($F_{5,19}=3.382$; $P=.03$; $\Lambda=0.53$). [Figure 5](#) shows the distribution of Axon completion times in relation to IT task completion times.

Figure 5. Distribution of Axon A and B completion times in relation with the completion times of the 5 IT tasks (N=26). Axon B trendlines and parameter estimates (β and P) show the relationship between Axon B IT task performance. Number in upper right corner of plot area is hypothesized convergence rank (Table 1). IT: information technology; NumRec: numerical recognition; PicRec: pictogram recognition; RPM: Raven’s Progressive Matrices. Letters A through E refer to the labels used for each task in Figure 1.

Axon TMT Better Predicts Performance on Convergent IT Tasks

The second hypothesis assumed that the predictive relationship between TMT performance and IT task performance would be stronger if the cognitive abilities involved in the performance were congruent. To test our hypothesis, we analyzed the parameter estimates for the multivariate results of Axon B. These revealed that Axon B was significantly predictive of IT task C (RPM task; $\beta=.785; t_{19}=3.240; P_{corr}=.018$) and IT task B (PicRec task; $\beta=.260; t_{19}=2.824; P_{corr}=.048$). However, IT task D (number recognition task), which was rated the second most congruent task with Axon, was not significantly predicted

by Axon B ($\beta=.150; t_{19}=0.479; P_{corr}=3.183$). Our secondary hypothesis is therefore partially supported. These results are shown in Figure 5, where the effects of individual factors of Axon B on performance on IT tasks are represented (β and P values).

Discussion

Principal Findings

Cognitive functional ability may well affect task performance in UX and other research experimentation, leading to variance in performance measures among the target population and confounding the effects of experimental factors. Although

detailed cognitive assessment batteries exist and can be used to control intersubject differences in cognitive abilities [12], they are not time efficient and thus impractical to implement within typical experimental time frames. Here, this study tested the validity of using the Axon TMT, which takes only a few minutes to administer, to predict or explain the variance in IT task performance in an age-homogenous subject population.

The mean age of the subject population of this sample was 24 (SD 4.22) years. This is typical of many research studies, UX related or otherwise, relying on student recruitment through the parent institution [55-57]. Despite the relatively low SD of age, the SD in Axon TMT scores was broad, at 25.80 (mean 48.04) and 25.53 (mean 56.9) seconds, respectively, for Axon A and B, suggesting a large distribution of cognitive functional abilities among this age-homogeneous neurotypical population. Notably, the means and SDs for the Axon TMT, particularly for Axon A, were higher than what is typically reported in the literature for neurotypical subjects in this age bracket [58-60]. This may be due to the fact that, unlike in the implementation of the paper-based TMT, subjects did not practice a mini version of the test before performing Axon A or B. Thus, some portion of the time taken to complete the test must be attributable to familiarization with task demands. This would also explain why the mean scores for Axon B, whose task demands are similar to Axon A in many respects, are closer to typically reported TMT B means. Nevertheless, for the purposes of this study, it is not absolute Axon TMT scores that are important. Rather, it is the relative distribution of the variance in Axon scores and their correlation to other metrics that is essential. To that end, both Axon A and B significantly correlated to their respective paper-based TMT counterparts showed a combined predictive validity toward working memory via the hidden path learning task. Furthermore, it was Axon A, not B, which was the predominant driver of the significant correlation with visual search performance. This is logical, as the visual search task does not involve working memory-related processing [42,61]. Instead, it requires an emphasis on target identification, cognitive control, and motor output, precisely the dominant cognitive functions involved in TMT A [36,39,40]. Thus, far from being problematic, implementing Axon A and B without a preliminary minitest for practice was time-efficient and yielded a reliable distribution of scores, which could be cross-correlated with expected cognitive functions.

This cross-validation lends credibility to our observation that Axon A and B combined were significantly predictive of IT task performance, supporting our primary hypothesis. Interestingly, for the IT tasks chosen, it was Axon B that appeared as the stronger driver of predictive validity, suggesting that it may be more powerful in capturing the executive decision-making involved in an ecologically valid IT task. Moreover, simple main effects tests revealed that Axon B significantly correlated with 2 out of the top 3 tasks ranked as requiring congruent cognitive functions as the TMT, thereby partially supporting our secondary hypothesis. Contrary to our expectations, the NumRec task, which had the second-highest congruence rank, was not significantly correlated with Axon B. We speculate that the confound here relates to the underlying mathematical operations involved in solving that CAPTCHA.

Although raters classified this as executive decision-making, it certainly can be said that neither TMT A nor TMT B requires arithmetic. Therefore, there must be cognitive processes involved that are simply not recruited during the performance of the TMT, which our ranking system was not granularized enough to capture, hence explaining the lack of correlation between the NumRec task and Axon B. Meanwhile, Axon B was most strongly correlated with the RPM and PicRec task, suggesting that it is well suited for tasks involving visual pattern and object recognition in combination with higher-order executive processing to orient this visual information. These kinds of processing are arguably crucial for interface navigation, virtual reality, gaming, or using simulators, which are extremely common IT tasks investigated in UX research [62-64]. Thus, while Axon does appear to be better aligned with IT tasks involving convergent cognitive processing, such tasks may well comprise a major proportion of those studied in UX research.

Finally, there are a few points worth emphasizing. First, the complete administration of Axon took less than 5 minutes, far shorter than the strategy used by Dumont et al [12] or any other cognitive assessment that we are aware of. Second, considering Axon's ability to differentiate from among an age-homogeneous neurotypical population, it would likely perform even better among populations where a larger variance in cognitive function would be expected, such as in older adults, children, stroke survivors, or other individuals with atypical cognitive function. This is important because understanding how to design appropriate and accessible IT for these populations has become a topic of increasing concern in UX research [65-67]. Moreover, Axon is suitable for remotely moderated experimentation, a popular strategy since the COVID-19 pandemic [68] and one that mitigates subject recruitment challenges for all population types. Finally, the current advancement in technology, particularly in the field of artificial intelligence, is trending toward a more personalized and user-centric approach, adapting technology to individual user characteristics such as preferences and interests [8,69,70]. Part of this personalization could be to tailor technology according to the cognitive abilities of users. Axon could potentially facilitate this advancement, serving as a quick and reliable metric to train the artificial intelligence technology adaptation algorithm.

Limitations

There are some limitations that should be acknowledged with this study. First, because the Axon app is designed to produce TMT canvases according to an algorithm with every test instance, the Axon A and B canvas layouts were not constant across subjects. This means that some of the variance in Axon A and B times is intrinsically attributable to factors such as differences in the straight-line drawing path length of the test or the extent of visual interference between each drawing segment. On the other hand, the fact that Axon A and B were significantly cross-validated with the original TMT and the visual search and hidden path learning tasks in spite of canvas layout differences between participants suggests that the variance these differences cause is small and does not detract from the use of Axon as a cognitive profiling tool in UX testing. Second, this study tested the predictive validity of Axon on simple and discrete IT tasks. This was necessary as a proof of

concept for our hypotheses. However, readers should use caution when generalizing the present results. Further research is needed to investigate the extent to which Axon retains predictive validity for more complex IT tasks in different contexts and across various user demographics, including neuroatypical and cognitively impaired users.

Conclusions

This study tested the ability of the Axon digital TMT to predict performance on discrete IT tasks. The results indicate that

variance in IT task performance among an age-homogenous neurotypical population can be related to intersubject variance in cognitive function as assessed by Axon. Although the findings suggest that Axon's predictive validity may be strongest for IT tasks involving the combination of decision-making with visual object and pattern recognition, these types of cognitive processing would arguably be relevant to the majority of IT interfaces. Considering its short administration time and remote implementability, the Axon digital TMT has the potential to be a useful cognitive profiling tool for IT-based UX research.

Acknowledgments

The authors would like to thank David Briegne, Salima Tazi, Xavier Côté, and all the operational staff at the Tech3Lab for their operational assistance in the execution of this study. This study was made possible thanks to funding from NSERC (ALLRP 571020-21), Prompt (176_Sénécal-BNC, CAE, CN, SRC_2021.02), and Mitacs (IT18280).

Abstract

Background: Dementia-related impairments can cause complex barriers to access, use, and adopt digital health technologies (DHTs). These barriers can contribute to digital health inequities. Therefore, literature-based design principles called DEMIGNED have been developed to support the design and evaluation of DHTs for this rapidly increasing population.

Objective: This study aims to apply the DEMIGNED principles in usability evaluation methods to (1) capture usability problems on a mobile website providing information resources for people visiting a memory clinic, including those living with subjective cognitive decline (SCD), mild cognitive impairment (MCI), or dementia, and (2) investigate the realness of usability problems captured by the DEMIGNED principles in expert testing, specifically for mobile websites that act as a means of providing DHTs.

Methods: First, a heuristic evaluation was conducted, with the DEMIGNED principles serving as domain-specific guidelines, with 3 double experts (experienced in both usability and dementia) and 2 usability engineering experts. Second, think-aloud sessions were conducted with patients visiting a memory clinic who were living with SCD, MCI, or dementia.

Results: The heuristic evaluation resulted in 36 unique usability problems. A representative sample of 7 people visiting a memory clinic participated in a think-aloud session, including 4 (57%) with SCD, 1 (14%) with MCI, and 2 (29%) with dementia. The analysis of the think-aloud sessions revealed 181 encounters with usability problems. Of these encounters, 144 (79.6%) could be mapped to 18 usability problems identified in the heuristic evaluation. The remaining 37 (20.4%) encounters from the user testing revealed another 10 unique usability problems. Usability problems frequently described in the think-aloud sessions encompassed difficulties with using the search function, discrepancies between the user's expectations and the content organization, the need for scrolling, information overload, and unclear system feedback.

Conclusions: By applying the DEMIGNED principles in expert testing, evaluators were able to capture 79.6% (144/181) of all usability problem encounters in the user testing of a mobile website for people visiting a memory clinic, including people living with dementia. Regarding unique usability problems, 50% (18/36) of the unique usability problems identified during the heuristic

evaluation were captured by the user-testing sessions. Future research should look into the applicability of the DEMIGNED principles to other digital health functionalities to increase the accessibility of digital health and decrease digital health inequity for this complex and rapidly increasing population.

Introduction

Background

Digital health technologies (DHTs) have the potential to improve health outcomes, information access, patient monitoring and self-management, treatment adherence, and disease diagnostics and prevention [1-4]. However, susceptible patient groups, such as older adults or people with disabilities, can experience challenges with accessing DHTs, creating digital health inequities [5,6]. Besides well-known accessibility issues such as financial or geographical barriers, human factors such as insufficient digital skills, poor motivation, low health literacy, poor health conditions, low socioeconomic status, and declining cognitive and physical abilities can also decrease the accessibility of DHTs [5,7-9]. These factors may also result in specific challenges to using DHTs that should be accounted for during the development of DHTs to increase their usability. Usability is defined as the extent to which DHTs can be used to achieve specified goals with effectiveness, efficiency, and satisfaction [10]. Problems related to the usability of DHTs arise when their design is not tailored to the needs of specific end users, thereby hampering their acceptability, user engagement, adoption, and successful use [2,11-13].

A vulnerable patient group that can experience challenges with accessing and using DHTs is people living with dementia. The prevalence of dementia is increasing globally as the population ages, making it a significant public health concern. It is expected that >150 million people in 2050 will be living with dementia, with 10 million new cases each year [14]. There are many underlying causes of dementia. Therefore, different types of dementia can be distinguished, such as dementia due to Alzheimer disease, vascular dementia, Lewy body dementia, and frontotemporal dementia [15]. People living with dementia face specific barriers when trying to use DHTs, which can worsen disparities in digital health care access [9,16]. These barriers relate to their cognitive, perceptive, and physical decline; changing frame of mind; and decreasing speech and language skills [9]. Even though these barriers to using DHTs for people living with dementia exist, the availability of DHTs increases, as they are suggested to improve the quality of life for this population by providing, among others, assistance with activities of daily living; improve their social engagement; and monitor their cognitive functions [17-19].

Objectives

To improve the usability and accessibility of DHTs for people living with dementia, their design can benefit from context-specific design guidance. While accessibility standards presented in, for example, International Organization for

Standardization Technical Specification 82304-2 [20], the Web Content Accessibility Guidelines [21], and xCerta Guidelines [22] can serve as valuable foundations for inclusive design, “understanding user diversity and applying this in the development process” [23], their use during the development of DHTs and evaluation is currently limited [24]. In addition, these standards and guidelines may not comprehensively address the complex, unique, and multifaceted needs of vulnerable populations, such as people living with dementia or other cognitive and physical impairments [24-26]. Ensuring the accessibility and usability of DHTs for such vulnerable user groups necessitates the implementation of additional context-related and detailed design specifications, something often missing in traditional guidelines and principles [24]. Therefore, in previous research, we developed literature-based design principles, or DEMIGNED principles, to be considered when developing DHTs for this population [27,28]. However, empirical evidence needs to be collected to further investigate the applicability of the DEMIGNED principles and their potential refinements. To collect this empirical evidence, this study aimed to apply the DEMIGNED principles in usability evaluation methods to (1) capture usability problems on a mobile website providing information resources for people visiting a memory clinic, including those living with subjective cognitive complaints, mild cognitive impairment (MCI), or dementia, and (2) investigate the realness of usability problems captured by the DEMIGNED principles in expert testing, specifically for mobile websites that act as a means of providing DHTs.

Methods

Study Design

Investigating the realness of usability problems captured by the DEMIGNED principles can encompass usability evaluation research [29]. According to Hartson et al [30], a usability problem is real if it is “a predictor of a problem that users will encounter in real work-context usage and that will have an impact on usability (user performance, productivity, and/or satisfaction)” [30]. Therefore, in the first part of this study, usability issues on a mobile website for patients visiting a memory clinic, including people with dementia, were captured by applying the DEMIGNED principles. This was conducted through a heuristic evaluation approach. A heuristic evaluation is a low-cost method where usability or domain experts evaluate a system’s navigation structure, screen layout, and interaction structure, typically on a set of predefined generic heuristics or guidelines [31]. This resulted in a list of unique usability problems that violate a specific heuristic or guideline. To investigate the realness of these usability problems, these findings were used to map the results from inclusive user-based

testing with patients visiting a memory clinic with subjective cognitive decline (SCD), MCI, or dementia. As there are challenges to inclusive-based user testing with people living with dementia, we applied considerations proposed by human factors experts to build trust and decrease potential stress [32]. To conduct the 2 usability evaluations, the mobile website of Alzheimer Center Amsterdam, a diagnostic and treatment center for (early-onset) dementia, was examined [33]. Their website contains information and other resources for people who are diagnosed with (or concerned about having) dementia and their relatives, researchers, funders, and others interested in learning about dementia (research). On the basis of the findings, recommendations for redesign are presented.

Heuristic Evaluation Approach

By applying the heuristic evaluation method, the overall user interface and structure of the mobile website of Alzheimer Center Amsterdam were assessed. In this study, potential usability problems were captured by assessing violations of the DEMIGNED principles (Table 1). These principles were developed by TE, LWPP, and MWMJ [27,28]. The design principles have been mapped to the categories of the mobile health for older adults with dementia–usability framework (MOLDEM-US), which captures barriers to using DHTs, specifically mobile health technologies, for people living with dementia [9]. These categories of barriers relate to cognition, perception, frame of mind, and speech and language.

Table 1. Overview of the DEMIGNED design principles for digital health technologies for people living with dementia.

Category and design principle	Abbreviation ^a
Cognition	
Support the monitoring of action progress	C-monitoring
Provide tutorials with short instructions to guide the digital tool	C-tutorials
Provide functionalities and actions adjustable to the user's cognitive abilities	C-abilities
Allow easy navigation to functions and content in a digital tool	C-navigation
Implement representative and understandable icons	C-icon use
Perception	
Provide visually compartmentalized user interfaces	P-compartmentalize
Provide appropriate system feedback	P-system feedback
Implement distinguishable colors	P-color use
Allow distinguishable clickable and nonclickable areas	P-click ability
Allow easily processable elements	P-elements
Frame of mind	
Provide continuous support	F-support
Ensure no time pressure	F-time
Provide positive feedback for correct action completion	F-positive feedback
Implement app settings adjustable to personal preferences	F-preferences
Provide attractive and respectful content	F-content
Speech and language	
Ensure the use of understandable words and sentences that feel comfortable	S-understandability
Allow user input through both speech and text	S-user input

^aEach principle has an abbreviation presented with the first letter of the category, followed by a keyword describing the principle.

Participants and Procedures

Previous heuristic evaluations have shown that 3 to 5 experts can identify 74% to 87% of usability problems [34]. This evaluation was performed by 5 evaluators: 3 double experts, TE, SH, and LWPP (knowledgeable in both usability engineering and dementia), and 2 usability engineering experts (Table 2). After confirming participation, TE familiarized the evaluators with the DEMIGNED principles in an introductory session where the evaluators were able to discuss and ask for clarifications on the principles.

A total of 3 use cases were determined based on the information presented on the website: patient care, scientific research, and information about dementia. The evaluators assessed these use cases in an overall manner to gain a sense of the website's navigation and structure before a more thorough assessment of the user interface components. Because of the high number of pages on the website and the uncertainty of which pages participants will encounter in the think-aloud session, example tasks were composed for each use case to guide the evaluation (Table 3).

The DEMIGNED principles were used as a set of heuristics by the evaluators and applied to check the design of the website's user interface and structure. If a principle was violated, it was given a severity rating based on the following scales, defined by Nielsen [35]: "(0) I do not agree that this is a usability problem at all (1) Cosmetic problem only: need not to be fixed unless extra time is available on project, (2) Minor usability problem: fixing this should be given low priority, (3) Major

usability problem: important to fix, so should be given high priority or (4) Usability catastrophe: imperative to fix this before the product can be released." Moreover, the evaluators reported for each identified usability issue the location on the website and the violated DEMIGNED principle. Usability issues can be related to multiple DEMIGNED principles, allowing the experts to report >1 principle for a unique usability issue.

Table 2. Overview of experts participating in the heuristic evaluation.

Degree	Sex	Research expertise	Experience (years), n	Occupation
PhD	Female	Human factors engineering in health care	20	Senior researcher
MSc	Female	User experience	8	UX ^a designer and university lecturer

Data Analysis

The identified usability problems were coded by performing a deductive thematic analysis. The DEMIGNED principles were used to predefine usability themes in which issues could arise. All usability issue encounters were combined in 1 master list by SH, after which duplicates were summed independently by TE and SH. The issues were summed overall rather than per task, as the aim was to obtain an overall report of the usability issues the DEMIGNED principles can capture on a mobile website. This led to a final set of unique usability issues on which consensus was reached with LWPP. The severity ranking

for each unique issue was calculated by taking the average severity given by the evaluators who identified the usability issue. It was decided to report an average severity score rather than a consensus score to moderate potential extreme views in assessing usability problems, given the novelty of the DEMIGNED principles. This offers a balanced representation of the severity score, eliminating the need for evaluators to reach a consensus.

Think-Aloud Method

Participants

For the think-aloud sessions, participants were recruited at Alzheimer Center Amsterdam. The aim of the recruitment was to include a representative sample of the (heterogenous) population that is most likely to use the website of Alzheimer Center Amsterdam: those who visit the memory clinic to seek support for their cognitive complaints. Alzheimer Center Amsterdam has a focus on patients living with dementia at a younger age (<65 years). Within this group, the most frequent diagnosis is SCD, followed by dementia and MCI [36]. Therefore, for the sample to be representative, more people with SCD were recruited, followed by people with dementia and MCI. All participants were presented as patients at the memory clinic of Alzheimer Center Amsterdam, where they received a standardized dementia diagnostic workup. Clinical diagnosis was made in a multidisciplinary meeting and discussed with patients during a second appointment. Subsequently, patients were offered annual or biannual follow-up. People scheduled for such a follow-up appointment were called to participate when they had previously given permission to be approached for research; had an appointment on June 5, June 8, or July 6, 2023; were not already participating in other research (that day); and were Dutch speaking. Patients who were unable to give informed consent were excluded from participation. Those who showed interest in participating received an information letter. In addition, a follow-up telephone call was scheduled to answer any questions and confirm participation after participants had the opportunity to read the information letter in depth.

Study Procedures

After confirming participation, a think-aloud session was scheduled either before or after the participant's appointment at Alzheimer Center Amsterdam. We aimed to adopt an empathetic approach to ensure there was trust between the participant and the evaluators (LWPP, SH, and TE) and to make

the participant feel comfortable [32]. After a short informal chat, participants provided informed consent and completed a paper-based questionnaire about their age, sex, and technology use. Thereafter, the think-aloud session started. The participant was then asked to sit behind the smartphone. The researcher sitting next to the participant first explained the goal of the session and showed how to verbalize thoughts through an example task on the smartphone provided by the researcher (eg, "Find what the weather will be this Saturday."). Participants were then asked to complete 7 tasks on the mobile website while verbalizing their thoughts (Textbox 1). For each use case, these tasks were derived from the example tasks for the heuristic evaluation but were specified to specific end points deemed relevant to the end users, such as information resources. The completion of the tasks was monitored by a second researcher, sitting behind the computer that recorded the session and across from the participant. If a partner or relative was present, they were instructed to only provide motivational reactions if the participant became silent. Therefore, only usability problems detected by the participants were gathered and analyzed. Even though this may introduce bias, this decision was made to make the participant feel more comfortable and simulate a more real-life setting for the participant [32].

The facilities at eHealth Living & Learning Lab Amsterdam were used to both audio record and video record the think-aloud session. This allowed researchers to capture rich data from both the user's interactions with the mobile device and the verbalizations from the think-aloud session. The facilities used to capture these data include (1) a video camera to record the participant's hand interaction with the smartphone, (2) a voice recorder to record the verbalized thoughts of the participant, (3) a smartphone device for the participant to access the mobile website, and (4) two laptops. One laptop was used to capture the screen from the smartphone through screen casting. The other laptop was used for Viso software (Noldus) to bring together the video recording, the screen capture recording, and the audio recording [37].

Textbox 1. The 7 tasks conducted in the think-aloud sessions.

Tasks

1. Find the date of the next event of Alzheimer Center Amsterdam
2. Find the 4 health care professionals scheduled for the screening day
3. Find information about the nurse consultants
4. Find the video about lumbar puncture
5. Find the conversation guide for the screening day
6. Find information about hersenonderzoek.nl
7. Find details about a fitness to drive statement

Data Analysis

First, all audio recordings were transcribed. Segments that did not convey verbal thoughts, such as instances when the participants read the website, were excluded. Second, the video recordings were analyzed and used to amplify the transcribed audio recordings. Third, the resulting transcripts were openly

coded first and axially encoded afterward. Finally, the frequency of problems per category was registered. The resulting usability problems were mapped onto the findings from the heuristic evaluation by TE, SH, and LWPP. Each usability problem encounter was mapped onto a theme from the DEMIGNED principles (cognition, perception, frame of mind, or speech and language). Afterward, if applicable, a subtheme from the

heuristic evaluation findings was linked to the usability problem encounter, followed by a specific issue. Findings from the think-aloud sessions that could not be verified with the findings from the heuristic evaluation will be presented separately.

Ethical Considerations

The study was approved by the Amsterdam University Medical Center medical ethical review committee with the number 2023.0240. All participants received detailed information about the study and provided written informed consent before participation in the think-aloud study. All data used in analysis have been anonymized. Each participant in the think aloud sessions received a €10 (US \$10.90) gift card.

Results

Heuristic Evaluation Approach

A total of 4 evaluators completed the heuristic evaluation. One evaluator conducted only the example tasks related to patient care and was further involved in the development of the master list. The heuristic evaluation resulted in a final set of 36 unique usability issues, as shown in [Multimedia Appendix 1](#). The usability issues identified in the cognition theme can impact people living with dementia when interacting with the website. The malfunctioning search function, nonintuitive navigation processes, misaligned information headings, inconsistent

structures, nonlinear pathways, duplicated content, and scrolling difficulties can lead to confusion and fatigue. In addition, the lack of logical menu structures, faulty filter functions, and challenges in finding essential features such as the information videos and the patient portal can exacerbate cognitive impairments associated with dementia, hindering effective navigation and information retrieval. Furthermore, external navigation links may disrupt the user's cognitive flow and understanding.

Think-Aloud Method

A total of 7 participants were included in the think-aloud sessions, composing a representative sample of people visiting the memory clinic at Alzheimer Center Amsterdam ([Table 4](#)). Each session lasted approximately 30 to 50 minutes. A total of 5 audio recordings and 7 video recordings were used in the analysis.

The think-aloud sessions revealed 181 usability problem encounters, of which 144 (79.6%) were mapped to 18 usability problems identified during expert testing ([Multimedia Appendix 1](#)). Most frequent usability problem encounters that verified the findings from the heuristic evaluation relate to the user expectations (48/181, 26.5%), information overload (20/181, 11%), system feedback (19/181, 10.5%), search function results (12/181, 6.6%), and scrolling (9/181, 5%). Examples of these issues are provided by means of quotes in [Table 5](#).

Table 5. Example quotes from transcript analysis for the most frequently encountered usability problems during the think-aloud sessions.

Usability problem	Example quote from transcript analysis
User expectations	<ul style="list-style-type: none"> “I wouldn’t know how to search for this and under which heading it falls. [Read aloud: about dementia, patient care, professionals, scientific research]. I don’t see a section called ‘what if you’ve received a diagnosis.’ I can’t find it; I wouldn’t know” (Participant 3). “My Record [Dutch: ‘MijnDossier,’ a patient portal]. When I click on that, there’s nothing about me personally. My record means my record, but there are general things there. And I would like to access my record, and it exists because it’s listed here below, if I see it correctly” (Participant 1).
Information overload	<ul style="list-style-type: none"> “Well, I just saw it, and I’m just trying to remember where. They’re, of course, trying to provide a lot of information” (Participant 2). “Forms of dementia. [Looks at the menu screen for a while]. Yes, there’s so much on it; it’s making me a bit fidgety, and then I think, what was it I wanted to look up again? I’m getting completely distracted by all those things” (Participant 5).
System feedback	<ul style="list-style-type: none"> “What I notice here is that there are long lists, and you’re working with people who have dementia or the caregivers, of course. With those long lists, you touch them, and nothing happens, but then the information is listed below” (Participant 4). “Yes, I was just there earlier. Then we go back to the preparation. [Clicks three times on ‘preparation’ in the menu but doesn’t see anything change]” (Participant 2).
Search function	<ul style="list-style-type: none"> [Searches for “lumbar puncture” in the search bar; clicks on a result.] “I have the protein research here, so that’s a lumbar puncture. That’s what you’re looking for, right? Or are you looking for what it looks like?” (Participant 3) “Let me see. I’ve entered your question, and I actually expect an answer, but it’s not doing that. Yes, because when I do this on Google, I get 20 answers, and then I can choose. But here, I don’t get there” (Participant 1).
Scrolling	<ul style="list-style-type: none"> “They naturally have a lot of information, and then you click on this, and it’s listed below [under the menu], and personally, you know, I just want to see it at the top because, yeah. I’ve had times when I thought ‘I’m not there or something,’ but it’s actually there.” (Participant 2). “Yes, you see, I have to go down (scroll) every time. Lumbar puncture, well, look” (Participant 1).

Additional Usability Issues Identified Through the Think-Aloud Analysis

A total of 37 usability problem encounters, solely identified in the think-aloud analysis, were thematically categorized into 10 unique usability problems and further classified into 7 themes (Table 6).

The findings revealed additional issues with identifying and using the search function, such as (recovering from) typing errors; the use of too many search terms leading to an overload of search results; and confusion caused by the visibility of the search history from the mobile device, rather than solely the

queries on the website’s search engine. Some participants limited their mental model for information finding solely to the search engine, leading to insecurities when asked to apply other navigation structures, such as clicking through the menu structure. Moreover, irrelevant search results or typing errors caused difficulties with remembering the task they were asked to perform. Finally, 3 additional usability issues related to the participants’ frame of mind while interacting with the website were identified: insecurity, stress, and habit. Participants verbally conveyed questions about their own ability to interact with the website and stressful responses while conducting tasks, and these were coded as shown in Table 6.

Table 6. Usability issues identified only through the think-aloud analysis.

Theme and usability problem	Impact	Severity score ^a , average	Frequency of the problem, n
Touch screen sensitivity			
The touch screen of the smartphone is too sensitive for participants who experience slower performance speed.	It causes unwanted user actions, such as accidentally pressing external links or pressing too hard instead of swiping or scrolling.	2	2
Search function issues			
Typing errors in a search query when using the search function leads to no or unwanted search results.	When typing error goes unnoticed, the user does not understand why information cannot be found, leading to frustration and inability to complete tasks.	4	6
The search function cannot be accessed via the home page and can be accessed only after clicking on the menu icon.	If a user limits their mental model for information finding solely to the search function and this cannot be found, it prevents them from completing tasks.	4	3
Too many search terms in a search query lead to an overload of results.	When the user types “driving and dementia,” many results are shown, including all pages that include “and,” leading to frustration and inability to complete tasks.	4	3
Search history is shown from when typing a search query.	When a user wants to type a search query in the search bar but the search history appears below the bar, this can be seen as a dropdown menu with an option to select from, causing confusion.	2	1
Return button			
The return button is placed under the menu structure but above the content of the page, making the user miss information.	When a user sees the return button under the menu structure, they expect there is no more content on the page when they do not scroll down. Therefore, they might miss valuable information, preventing them from completing an action.	3	3
Insecurity			
Users verbally question their own interactions with the website while performing tasks.	Insecurity can lead to decreased motivation and willingness to use the website.	2	5
Stress			
Users verbally convey stress while interacting with the website.	Stress can lead to decreased motivation and willingness to use the website.	2	10
Habit			
Users verbalize having their own habits while using websites, which are not aligned with the website under evaluation, such as changing a search query, only using Google search and button recognition.	When a user is too stuck in such habits, it makes it difficult to adjust to the website’s design, causing difficulties in completing a task.	2	3
Clicks			
The user needs too many clicks to find the desired information, while the user expects to find information faster.	The user cannot reach the page to complete a task.	3	1

^aAverage severity score based on Nielsen’s severity ranking [35].

Discussion

This study aimed to apply the DEMIGNED principles in usability evaluation methods to (1) capture usability problems on a mobile website providing information resources for people visiting a memory clinic, including those living with subjective cognitive complaints, MCI, or dementia, and (2) investigate the realness of usability problems captured by the DEMIGNED principles in expert testing, specifically for mobile websites that

act as a means of providing DHTs. In addition, this study provided insights for the future refinements of these principles.

Principal Findings

The mobile website of Alzheimer Center Amsterdam underwent both heuristic evaluation and evaluation through the think-aloud method to investigate the realness of usability problems detected by applying the DEMIGNED principles in expert testing. To this end, usability problems derived from user testing were mapped to findings from expert testing. The heuristic evaluation,

covering most of the website's pages, revealed 36 distinct usability issues. Subsequently, during the think-aloud sessions with people living with SCD, MCI, or dementia, 18 unique usability problems were mapped to the findings from the heuristic evaluation. In addition, the think-aloud sessions revealed 10 new usability issues. Despite potential differences in the number of pages viewed between the heuristic evaluation and the think-aloud session, given the uncertainty surrounding the information-seeking strategies of participants in the think-aloud session, these results suggest a 50% (18/36) validity score for the DEMIGNED principles in an expert test based on the usability evaluation method validity score measurement [30]. However, this first investigation aimed to explore the realness of usability problems that can be captured by applying the novel DEMIGNED principles, gaining insights into the use of the DEMIGNED principles. Follow-up research should determine the usability evaluation method effectiveness of applying the DEMIGNED principles to detecting usability issues through heuristic testing. Nevertheless, a validity score of 50% (18/36) in this study suggests the potential of the DEMIGNED principles for future heuristic evaluation approaches. This contrasts with other research showing a validity score of 40% when using commonly used heuristics [38]. Moreover, looking at the number of times a usability problem was encountered, 79.6% (144/181) of the usability problem encounters were captured by experts using the DEMIGNED principles.

The findings indicate the potential for the DEMIGNED principles to be further used as a set of guidelines for a heuristic evaluation of DHTs for people living with SCD, MCI, or dementia. This can be valuable, as current sets of heuristics may not sufficiently capture usability issues experienced by people living with dementia. Over time, numerous sets of heuristics have been devised to assess the usability of mobile devices, focusing primarily on their physical attributes and phone interfaces [39,40]. Widely acknowledged heuristics of Nielsen [34] are valuable for evaluating general usability in website interfaces. Nevertheless, these guidelines do not fully encompass the unique challenges associated with designing DHTs for people living with dementia. Heuristics to capture usability problems in the design of DHTs related to cognitive decline, such as memory loss, reduced attention span, and decision-making difficulties, are lacking. Similarly, heuristics proposed by Neto and da Graça Pimentel [41], inspired by Nielsen [34], focus on assessing the usability of mobile apps but lack specific heuristics to capture usability problems experienced by people living with dementia. These heuristics are tailored for general mobile interface design and do not comprehensively address specific barriers to using DHTs for this population, such as attention deficits and challenges in learning and adapting to new interfaces. For medical devices, heuristics proposed by Zhang et al [42] are commonly used. However, these might not be entirely suitable for evaluating DHTs for people living with dementia. Heuristics proposed by Zhang et al [42] prioritize the detection of usability issues for medical devices, such as issues with accuracy, reliability, and safety. However, these are not attuned to capture usability problems caused by, for example, emotional fluctuations or cognitive decline.

Refinement of the DEMIGNED Principles

The think-aloud sessions revealed 10 usability problems that were not found through expert testing that may require further refinement of the DEMIGNED principles. First, 3 (30%) of these problems relate to the frame of mind of the user. It was observed that interacting with the website can cause verbal reactions of stress and insecurities. This was also the case when a participant had a certain habit of finding web-based information that was not in line with how the evaluated website can be searched. These barriers may lead to unsuccessful task completion and should, therefore, be accounted for and included in the DEMIGNED principles. However, the 3 usability issues related to the frame of mind seemed to be related to navigational structure, suggesting that a more linear navigational structure might make information easier to find and, therefore, reduce stress and insecurity. Second, the design of the search function was revealed to be a critical usability problem that prevented successful task completion. Even though 2 potential usability problems were identified by one of the evaluators during the heuristic evaluation, 3 more issues were revealed in the think-aloud analysis when people with SCD, MCI, or dementia used the engine. Using the search function revealed issues with typing errors, too many search terms leading to an overload of results, and a misunderstanding of the search history. Therefore, the DEMIGNED principle of navigation should provide design guidelines specific to search functions. Finally, 3 usability problems were encountered by a few participants. First, the amount of clicking was found to be too much to find the information they were looking for, which was also found in other studies where participants showed problems finding content because of the navigation structure [43,44]. Limiting the amount of clickable content on a single screen may support directing the users to relevant information [43]. Second, the sensitivity of the touch screen led to unwanted actions, which were caused by the device itself. Currently, the DEMIGNED principles only focus on user interface and structures rather than the hardware; therefore, this problem may not have been found by the evaluators in the heuristic evaluation. However, touch screen sensitivity could be tackled by providing visible or audible system feedback when a user clicks too fast or a pop-up to confirm an action [28]. Third, it was observed that the position of the "return" button above the content caused challenges, as one of the participants mistakenly perceived that no additional information was available below the button. This provides insights into further refining the DEMIGNED principles, such as icon use and system feedback, with guidelines regarding button placement as part of the content organization.

Recommendations for Redesign

Overview

The website of Alzheimer Center Amsterdam not only is informative for people living with SCD, MCI, or dementia and others having an appointment at the memory clinic but also contains information for researchers, funders, family members, etc. However, these recommendations aim to enhance the website's accessibility and user experience for people living with dementia. Moreover, they can also benefit those interested in redesigning for improved digital health accessibility in this

context. Overall, it is suggested to redesign the website with general principles that can improve accessibility, such as by adding an option to read text out loud to the user, increasing the font size without decreasing readability, and magnifying options for images and other graphics. Furthermore, 5 specific areas of redesign were identified based on the findings from this study, namely navigation, information overload, scrolling, content and user experience, and system feedback.

Navigation

Navigation often requires sufficient decision-making skills, the awareness of location, and a sequence of clicks. These skills may decline due to memory impairment, decreased learnability, and difficulties with processing information. Therefore, it is recommended to implement linear navigation. This means the user can move only forward or backward through the website and its content. Starting with the home page, it is recommended to redesign this to full-screen navigation, showing clickable main options to navigate to “patient care,” “scientific research,” and “living with dementia.” After selecting one of these main options, a full-screen menu with suboptions to choose from should open. This may tackle the usability problem of users not noticing that the “main option” is also a page with unique information. Additional research prioritizing information needs and formulating clear suboptions may support this redesign, given the perceived discrepancies between the current information headings and accompanying content. In addition, this requires removing potentially irrelevant, outdated, or duplicate information and empty pages to ease the process of scanning and finding information.

Furthermore, participants experienced challenges with using the search function. In general, people often rely on searching as their main strategy [45]. In this study, those who relied solely on the search function experienced difficulties when navigating the website. Familiarity with search engines such as Google may make them more inclined to use the search feature as their default interaction method [43]. Overall, the availability of a function that eases information finding on a website is important for people living with dementia [43,44]. However, some participants experienced difficulties finding the search function, as it was accessible only after clicking on the menu icon, or using the function, as it did not work as expected. This led to confusion, frustration, poor user experience, and hindered task completion during think-aloud sessions. This reduced mental model of finding information may be caused by barriers related to the user’s frame of mind, such as a lack of trust in their abilities or perceived complexity [9]. In addition, a reason for using the search function as the default interaction method may be due to affected language and communication skills. Therefore, it is suggested to redesign the search function to prevent typing errors, too many and irrelevant results, and the presentation of results in an illogical order. Implementing a Google-like search function with positive system feedback can be considered, where suggestions for typing errors are made, an overview of the most relevant results are presented, and selecting for filters that are of relevance to the user is possible. Such a search function could also be relevant for the “team” page to ease the user’s process of finding information about

their physician. Moreover, the search function can be placed on the home page to increase its accessibility.

Information Overload

An excessive amount of information on a single page and in the menu (eg, the number of subpages to choose from) can not only overwhelm users living with cognitive problems, making it challenging to process and remember the content, but also impair decision-making skills by hindering the ability to effectively filter out the relevant information. This creates a poor user experience and can cause frustration and disorientation. In addition, it can compromise the usefulness and accessibility of such web pages because users may struggle to find the specific information they need within a cluttered interface, hindering their ability to use the website effectively. To increase usefulness and decrease information overload for people living with dementia, it is suggested to provide content that is comprehensive, practical, and reassuring [43]. Moreover, categories should be less broad and listed alphabetically [44].

Scrolling

The need for scrolling caused participants to miss useful information and prevented successful task completion during the think-aloud sessions. A user with cognitive impairments can experience challenges in remembering the need to scroll every time a new web page is loaded. In addition, excessive scrolling can lead to increased cognitive load, as it requires processing information sequentially, potentially overwhelming the working memory. It has been suggested from observational data that reducing the cognitive load of a web page (eg, less information on a page) can contribute to tackling scrolling issues, as scrolling appears to have a high cognitive load [46]. Moreover, the physical need for scrolling may be challenging and cause fatigue [46].

Content and User Expectations

It was found that 48 usability problems related to user expectations were primarily caused by the discrepancy between user expectations and actual content organization. This led to frustration and confusion among participants, making it difficult to locate the information they sought. The findings emphasize the importance of accurately representing content and containing words that users feel comfortable with, especially in dementia-friendly DHTs. Future iterations of redesigning the website should focus on aligning user expectations with content presentation through co-design, which involves people living with dementia from the start of the process. This has been shown to be beneficial for both the person living with dementia and the design process itself [47-50]. However, a recent systematic review found that only 23% of studies involved people living with dementia in their design approach [51]. Additional recommendations to better align the content with the user expectations include considering a potential artificial intelligence-generated language check to ensure that all information relevant for patients is provided at the B1 level using: (1) a clear title and subheadings, (2) an active writing style with examples, (3) simple words that everyone knows, and (4) short and clear sentences. Moreover, terminology should be consistent, familiar, and comfortable and in Dutch (avoid

English terms; for example “second opinion” was found to be confusing).

System Feedback

Incomprehensible or seemingly invisible system feedback can lead to confusion and difficulties with navigating a website. For example, this occurred when clicking on a main item on the home page or the menu that refreshes the current page without any visible changes. It hinders the ability to understand the system's responses, making it challenging to navigate the website effectively. This lack of clarity also reduces users' confidence in their interactions, potentially causing them to make errors. Providing visually clear, short, and positive instructions may improve the understanding of users living with MCI or dementia about the system feedback on their interactions with the website [9,43]. In essence, clear and meaningful system feedback is essential for providing guidance and minimizing user errors. To tackle these issues, it is recommended to clearly distinguish the clickable and nonclickable areas to prevent confusion or endless clicks. After pressing a clickable area, the consequences of this click should be clearly visible or audible. This distinction can be made with colors, icons, buttons, vibrations, or audible beeps.

Limitations

This study had several limitations. First, the goal of the study was to conduct a heuristic evaluation with the DEMIGNED principles to investigate the reality of these principles in capturing usability problems that people living with dementia may experience. The realness was determined by mapping the findings from the think-aloud sessions to the findings from the heuristic evaluation. These insights suggest that 50% (18/36) of the findings by the experts were real usability problems experienced by potential end users. Even though this shows the potential of the DEMIGNED principles in heuristic evaluations, it may be possible that some usability issues identified from the heuristic evaluation were too subjective and hence not encountered in the user-testing method. This can be caused by methodological differences between the subjective nature of heuristic evaluations (as they predominantly rely on expert judgment founded on the DEMIGNED principles) and the objective user feedback derived from think-aloud tests involving direct user interactions. Second, an explanation as to why some usability problems from the heuristic evaluation were not encountered in the think-aloud sessions may be the fact that 18 tasks to guide the evaluators through most of the website were performed during the expert testing, while only 7 tasks were performed during user testing. Conducting 18 tasks was deemed to be too challenging in terms of cognitive overload, concentration, and motivation of the participants. The think-aloud tasks were composed with the aim of catching most of the pages that were evaluated during the heuristic evaluation. However, such a variety in the number of tasks could introduce bias in agreement scores calculations, such as Cohen κ , and was, therefore, left out of the analysis. Third, the software used for capturing the think-aloud sessions introduced some limitations. Due to the setup, participants were to use the smartphones provided by the researchers. This allowed the researchers to set up the screen-sharing function of the

smartphone rather than going through the participants' smartphone, which might cause stress or anxiety related to their privacy before starting the think-aloud session. This may introduce bias to the results, as the smartphone could be new for the participant. However, the study was conducted within an internet browser consistent across various smartphones. In addition, due to unannounced software updates, the sixth and seventh think-aloud session recordings suffered from audio issues. Therefore, only the observations from the video recordings were used in the analysis. However, saturation was reached, as no new usability issues were encountered during these sessions, which is important in think-aloud research [52]. Nevertheless, dementia does present a wide range of symptoms, so it might be possible that additional usability problems would arise for those with symptoms varying from the symptoms the participants experienced during the think-aloud sessions. Fourth, 1 user profile for the think-aloud session was created that captured a representative sample of people most likely to use the website of Alzheimer Center Amsterdam: those who visit the memory clinic to seek support for their cognitive complaints. The most frequent diagnosis for people aged <65 years, which is the focus of Alzheimer Center Amsterdam, is SCD, followed by the diagnoses of dementia and MCI [36]. This was reflected in the included sample for user testing. Therefore, we assume that with this group of participants, most usability issues were detected. However, these varying diagnoses may also influence the types and severities of usability problems. Nevertheless, in this study, the reality of the principles has been examined for this group as a whole, given the novelty of the DEMIGNED principles and their scientific basis of study, including people living with varying cognitive complaints, MCI, or dementia. Nevertheless, an approach to further investigate the reality of the DEMIGNED principles could be to compare the detected usability problems between people with varying levels of cognitive abilities and those without such cognitive issues to rule out the possibility that usability problems exist independently of cognitive abilities. Fifth, 1 evaluator only conducted approximately 50% of the tasks in the heuristic evaluation due to time constraints. This may have influenced the number of times a usability problem was encountered. However, the researcher was involved in the further analysis of the heuristic evaluation data. Finally, the sessions were conducted at the memory clinic. Even though we emphasized to the participants to imagine that they were in a home setting and allowed them to ask their partner or loved one for support, results may be different when this study is conducted in a home setting.

Future Research

Future research should focus on further evaluating the use of the DEMIGNED principles in expert reviews to assess their effectiveness in identifying real usability issues experienced by people living with varying types and stages of dementia. For example, digital health tools for people living with dementia that offer different functionalities from those offered by the mobile information resource evaluated in this study should be evaluated using the DEMIGNED principles, such as health monitoring, medication management, or participating in leisure or social activities. This may support categorizing the

applicability of DEMIGNED principles per digital health functionality, as not all principles apply to each digital health tool. For example, in this study, the principle “ensure no time pressure” was not violated, as it was not applicable for the website. In addition, it is important to further evaluate the relevance of DEMIGNED principles for other types of user interactions, such as input controls (text fields, dropdown lists, toggles, etc) and serious games. This hopefully leads to more accessible digital health tools and the validation and refinement of the DEMIGNED principles. In the short term, the recommendations for redesign should be implemented into a new prototype for the website. The prototype should again be evaluated to ensure its usability. To enrich this evaluation, eye tracking and emotion readers could be used in think-aloud sessions to obtain more insights into the user experience because verbalizing what they are doing can be challenging for people living with dementia [53]. The emotion readers could also support in further investigating potential stress reactions of these people while conducting tasks on the website. Moreover, more extensive user testing could be conducted with the redesigned website, including metrics such as task completion rates and times, to gain more insights into the usability of the website. These metrics have been suggested to produce the most reliable

results when conducting user testing with people living with dementia [53]. Finally, the literature suggests that an early decline in cognitive function may be detected from the input that people deliver when using a search engine [54]. The findings from this study related to using the search functionality initiate future research opportunities to optimize the search engine’s functionality and explore opportunities to use this in research to detect cognitive decline.

Conclusions

This study showed that applying the DEMIGNED principles in expert testing can capture usability problems that people living with SCD, MCI, or dementia can experience when using a mobile website. The think-aloud analysis revealed 10 additional usability issues that were not captured in the heuristic evaluation approach. This shows the importance of involving end users in usability evaluations. Moreover, these findings provided insights into refining the DEMIGNED principles, mainly related to the use of a search function and barriers caused by the user’s frame of mind. Future research should look into the applicability of the DEMIGNED principles for other functionalities that DHTs provide to increase the accessibility of digital health and decrease digital health inequity for this complex and rapidly increasing population.

Abstract

Background: Artificial intelligence (AI) is widely used in various medical fields, including diagnostic radiology as a tool for greater efficiency, precision, and accuracy. The integration of AI as a radiological diagnostic tool has the potential to mitigate delays in diagnosis, which could, in turn, impact patients' prognosis and treatment outcomes. The literature shows conflicting results regarding patients' attitudes to AI as a diagnostic tool. To the best of our knowledge, no similar study has been conducted in Saudi Arabia.

Objective: The objectives of this study are to examine patients' attitudes toward the use of AI as a tool in diagnostic radiology at King Khalid University Hospital, Saudi Arabia. Additionally, we sought to explore potential associations between patients' attitudes and various sociodemographic factors.

Methods: This descriptive-analytical cross-sectional study was conducted in a tertiary care hospital. Data were collected from patients scheduled for radiological imaging through a validated self-administered questionnaire. The main outcome was to measure patients' attitudes to the use of AI in radiology by calculating mean scores of 5 factors, distrust and accountability (factor 1), procedural knowledge (factor 2), personal interaction and communication (factor 3), efficiency (factor 4), and methods of providing information to patients (factor 5). Data were analyzed using the student *t* test, one-way analysis of variance followed by post hoc and multivariable analysis.

Results: A total of 382 participants (n=273, 71.5% women and n=109, 28.5% men) completed the surveys and were included in the analysis. The mean age of the respondents was 39.51 (SD 13.26) years. Participants favored physicians over AI for procedural knowledge, personal interaction, and being informed. However, the participants demonstrated a neutral attitude for distrust and accountability and for efficiency. Marital status was found to be associated with distrust and accountability, procedural knowledge, and personal interaction. Associations were also found between self-reported health status and being informed and between the field of specialization and distrust and accountability.

Conclusions: Patients were keen to understand the work of AI in radiology but favored personal interaction with a radiologist. Patients were impartial toward AI replacing radiologists and the efficiency of AI, which should be a consideration in future policy development and integration. Future research involving multicenter studies in different regions of Saudi Arabia is required.

Introduction

Introduction to Artificial Intelligence

Artificial intelligence (AI) is a branch of computer science focused on creating systems that mimic human intelligence, enabling machines to learn, solve problems, and understand language and visuals. The aim is to develop machines capable of performing cognitive tasks traditionally associated with human intelligence. It is anticipated that this revolution in data science and technology will provide practical advantages in many areas [1]. AI has many subsets, including algorithmic machine learning and autonomous decision-making. AI is used in diverse specialties, including health care [2]. In health care, AI decreases the workload of health care providers [3] and improves disease prevention, diagnosis, management, and treatment; thereby, improving patient outcomes and decreasing the economic burden [1,2].

Numerous studies have explored the implementation of AI in diverse aspects of medicine [4-6]. AI-based technologies have been used in surgery, observation of pulmonary metastasis on computed tomography scans, diagnosis and evaluation of diabetic retinopathy, Alzheimer disease, heart arrhythmias, onychomycosis, vertebral compressions, cerebral aneurysms, brain neoplasms, assessment of psoriasis, detection of subarachnoid hemorrhage, and for glioblastoma prognosis after bevacizumab treatment [5-8]. AI is also expected to show advancements in differentiating lung diseases and improvements in breast and skin cancer detection and screening [4,7,9]. However, to integrate AI appropriately, it is crucial to grasp the viewpoints of various stakeholders, including patients and health care professionals like students, physicians, and caregivers, regarding the use of AI in clinical practices.

Implementation of AI in Radiology

Radiology is an important digital data generator. Due to advancements in technology, increasing rates of diagnostic procedures among older patients in an aging population, and improvements in screening programs [1,2], there is a notable rise in the number of scans to be evaluated and diagnosed. However, this demand coincides with a lack of trained radiologists in certain specialties [10]. As a result, radiologists face an increased workload, leading to marked delays in diagnosis and reduced interpretation power. Such delays could affect patients' prognosis and treatment outcomes [10-12].

Saudi Arabia has prioritized changing this practice to be more time efficient and improve the health care system, especially for clinical cases where time is crucial for quick diagnosis and immediate management (stroke, trauma, and cancer). In radiology, a surge of evidence has demonstrated the potential of AI to outperform physicians in some clinical aspects. The use of AI would decrease the time between patient diagnosis and administration of treatment. Fewer delays in diagnosis and

treatment can help mitigate legal implications, such as malpractice cases, where timely and accurate diagnoses supported by AI can minimize the risk of misdiagnoses or delayed treatments that may result in patient harm [10]. Consequently, the implementation of AI in radiology became a heated debate and a subject of discussion in around 800 related published papers in 2017 [13]. AI developers have increased efforts to provide trustworthy technologies that aid image recognition and diagnostic tasks minimizing radiologists' workloads [12]. AI can achieve faster-customized diagnoses and recommendations equal to or superior to highly qualified radiologists for performance [4,7,11,14,15], precision, and accuracy [8], thus increasing diagnostic reliability [3].

The use of AI also involves ethical, legal, and societal concerns, which are essential and must be addressed. These involve protecting autonomy, ensuring transparency and accountability, and promoting human well-being, safety, and equity. Legal concerns include adhering to protection laws, establishing principles for the use of AI in health, and complying with bioethics regulations [16]. Recognizing these concerns, it is crucial for developers to engage all stakeholders, especially the patients that AI intends to serve [11,14,15]. The World Health Organization [16] states the public should be informed about the development of AI in health care as it will facilitate their understanding of data use and allocation and help them voice their concerns and anticipation of the use of AI technologies. The public should be encouraged to have further knowledge of AI technologies to determine those acceptable for use. Therefore, there is an increasing need to explore patient attitudes toward using AI in radiology and address social and ethical considerations.

Patients are important stakeholders in the decision-making process and understanding their perspective is necessary to ensure widespread implementation of these technological advances. By studying patients' attitudes, we can uncover potential barriers and facilitators to the integration of AI, ultimately informing strategies to enhance patient engagement, trust, and satisfaction. Moreover, exploring patients' viewpoints adds a crucial dimension to the discourse on AI in health care, fostering patient-centered approaches and ensuring that AI implementations align with patients' needs and preferences [4,7]. Positive patient attitudes to AI as a diagnostic tool will indicate readiness and support, whereas a lack thereof will indicate patient education is necessary. To the best of our knowledge, no studies have examined patients' attitudes toward the use of AI in radiology or health care in Saudi Arabia.

This study aimed to investigate the attitudes of patients toward the use of AI in diagnostic radiology at King Khalid University Hospital (KKUH) in Riyadh, Saudi Arabia, and to evaluate potential associations between patients' attitudes and specific sociodemographic factors. Our study could influence future policy making on the integration of AI into health care by

defining critical points of supervision, it will guide program development and primary education on a national level, ensuring AI implementation caters to societal needs.

Methods

Recruitment

This was an analytical cross-sectional study conducted between July and December 2022 at the tertiary care hospital KKHU, Riyadh, Saudi Arabia. Eligible participants were outpatients scheduled for any type of radiological imaging involving any part of the body, aged ≥ 18 years old, literate, and able to speak Arabic or English. Mental health patients were excluded. We used convenience sampling techniques for ease of recruitment and cost-effectiveness. Participants were approached for enrollment in the radiology waiting rooms by 1 of 6 investigators. Participants who voluntarily agreed to participate and provided their explicit consent were provided a brief description of the role of AI in diagnostic radiology and asked to complete a self-administered electronic questionnaire via Google form in Arabic or English based on their preferences. Questionnaires were completed by participants from August 9, 2022, to September 1, 2022.

Study Variables

The main outcome of the study was patients' attitudes to using AI in radiology at KKHU. Demographic and socioeconomic data (age, sex, nationality, marital status, education level, place of residence, family income, employment status, specialty, self-reported health status, and self-reported prior knowledge about AI, and experience of diagnostic errors) were collected.

Survey Tools

The questionnaire had 2 sections, sociodemographic data and attitude toward AI in radiology. The first section had participant characteristics, including age, sex, nationality, marital status, education level, place of residence, family income, employment status, and field of specialization, and additional information such as self-reported health status, self-reported prior knowledge about AI, and experience of diagnostic errors.

The second section measured attitudes toward AI in radiology using a validated questionnaire (Multimedia Appendix 1) developed by Ongena et al [17]. It is a 39-item tool that calculates the average score of 5 dimensions, which are distrust and accountability (15 items), procedural knowledge (8 items), personal interaction (7 items) and communication, efficiency (5 items), and ways patients are informed of their imaging results and prognosis (4 items). Respondents assessed each item on a 5-point Likert scale ranging from "Strongly Disagree" to "Strongly Agree." The mean of statements within each factor was then calculated. Subsequently, the scores for the 5 factors were categorized into levels of attitude: "Strongly Negative Attitude" (1.00-1.80), "Moderately Negative Attitude" (1.81-2.60), "Neutral Attitude" (2.61-3.40), "Moderately Positive Attitude" (3.41-4.20), and "Strongly Positive Attitude" (4.21-5.00), using criteria corresponding to the Likert scale values. The higher scores indicate being more negative toward the use of AI in radiology.

The tool was originally developed in English and conceptually translated into Arabic by a certified translator whose first language is Arabic and who is fluent in English. A panel of 12 experts (radiologists, public health consultants, epidemiologists, and family and community medicine consultants) reviewed the Arabic version of the questionnaire and compared it with the original English version. The panel provided several suggestions for improving the translation. A pilot study was conducted and responses from the pilot study were excluded from the analysis.

Statistical Analysis

Based on previous reports of a 1.10 difference between participants' attitudes toward AI [17], the minimum sample size consisted of 384 participants in total and had more than 80% power ($\alpha=.05$) to detect small differences between participants. Ten percent was added to account for nonresponses, yielding a total sample size of 423 participants.

Data were analyzed using the SPSS (version 27; IBM Corp). Descriptive statistics (frequencies, percentages, means, and SDs) were used to describe the categorical and quantitative variables. The hypothesis testing was 1-tailed. Associations were determined between the patients' attitudes to using AI in radiology and demographic and socioeconomic data (such as age, sex, nationality, marital status, and education level) through a bivariate analysis using the student *t* test for independent samples or a one-way analysis of variance followed by post hoc analysis to test for quantitative outcome variables to compare the mean values in relation to the categorical study variables, which have 2 and >2 options, respectively. Common confounders, such as sociodemographic factors, were analyzed either via student *t* test or ANOVA as appropriate. The Pearson correlation coefficient was used to determine the association between continuous quantitative study variables (age) and the outcome variables.

Multivariable Analysis

Multivariable regression models examined whether any associations between the sociodemographic variables and common confounders and quantitative outcome variables were retained after controlling for selected covariates. Sociodemographic variables that were found statistically significant (or approaching significance level) in bivariate analysis were entered as predictors in the multivariable regression model. Four regression models were built (factors 1, 2, and 5, overall score). Factors 3 and 4 only had one significant (or approaching significance) predictor, therefore multivariable analysis was not warranted. Categorical predictors were included with the most suitable category being chosen as the reference category. For each regression model, we reported the overall model fit, significance of each predictor (omnibus ANOVA), regression coefficients (including 95% CI and standardized estimate), and checked for multicollinearity assumption (variance inflation factor values). Variance inflation factor values <5 indicate no presence of multicollinearity.

A level of significance of 0.05 was used for all inferential analyses. The 95% CI was reported where applicable. *P* values were reported for inferential tests, with $P<.05$ interpreted as statistically significant. Missing data such as occupation and

social status were collected from patients' files through the electronic system for integrated health information (e-SIHI). Invalid entries were excluded from the analysis, such as patients who had nondiagnostic radiological imaging or those who were not waiting for a radiology appointment regarding their own health.

Ethical Considerations

The study was approved by the Institutional Review Board of the College of Medicine at King Saud University on July 24, 2022 (research project number E-22-6966). All participants were verbally informed and were given sufficient time to read the consent form and give written consent before enrollment ([Multimedia Appendix 1](#)). Participation was voluntary, and subjects retained the autonomy to withdraw from the study at any point without incurring any adverse consequences.

Results

Descriptive Statistics

There were 382 completed surveys with a nonresponse rate of $\approx 11\%$. Participants were 18-86 years old (mean 39.51, SD 13.26 years), 273 (71.5%) women and 109 (28.5%) men, 281 (73.6%) were married, and 293 (76.7%) were college-educated individuals. There were 180 (47.1%) employed participants and 131 (34.3%) of participants had a monthly household income of US \$ 2666-5331. The participants' detailed demographic information is in [Table 1](#).

The participants were scheduled for ultrasound imaging (209/382, 54.7%), magnetic resonance imaging (46/382, 12%),

x-rays (43/382, 11.3%), computed tomography scans (40/382, 10.5%), mammograms (20/382, 5.2%), echocardiography (18/382, 4.7%), and angiography (6/382, 1.6%). Some participants (8.6%) had previously experienced diagnostic medical errors ([Table S1, Multimedia Appendix 2](#)). Most respondents evaluated their prior knowledge of AI as average (36.1%) or very good (27.7%; [Table S2, Multimedia Appendix 2](#)). The top 3 sources of their AI information were internet sources (80.4%), social media (66.2%), and friends and peers (42.7%; [Table S3, Multimedia Appendix 2](#)).

[Table 2](#) presents the average scores for patients' attitudes toward AI in radiology per statement and factor. Participants were neutral in their trust of AI taking over radiologists' diagnostic interpretation tasks for accuracy, communication, and confidentiality, 3.16 was the average score for factor 1 (distrust and accountability). The average score for factor 2 (procedural knowledge) was 4.08, signifying that patients are interested in understanding how radiological images are obtained, interpreted, and disseminated. The average score for factor 3 (personal interaction) was 4.06, indicating that patients favored personal interaction with a radiologist over AI-based communication. The average score for factor 4 (efficiency) was 2.89, suggesting patients were ambiguous about AI improving the diagnostic procedure. Factor 5 (being informed) had an average score of 3.65, showing patients favor obtaining full disclosure of their medical findings and predictions of any future diseases they might develop, in addition to full-body scans performed by AI rather than scans of selected parts of the body.

Table 2. Results of the 39 questionnaire statements that provide scores for 5 factors.

Items	Score, mean ^a (SD)
Factor 1 (distrust and accountability)	3.16 (0.59)
1. A computer can never compete against the experience of a specialized doctor (radiologist)	3.19 (1.04)
2. Through human experience, a radiologist can detect more than the computer	3.30 (0.99)
3. Humans have a better overview than computers on what happens in my body	3.52 (0.97)
4. It worries me when computers analyze scans without interference of humans	3.31 (1.12)
5. I wonder how it is possible that a computer can give me the results of a scan	2.88 (1.11)
6. Artificial intelligence makes doctors lazy	2.83 (1.18)
7. Humans and artificial intelligence can complement each other	2.70 (1.04)
8. I think replacement of doctors by artificial intelligence will happen in the far future	2.98 (1.12)
9. I would never blindly trust a computer	3.30 (1.08)
10. Artificial intelligence can only be implemented to check human judgment	3.56 (1.10)
11. I find it worrisome that a computer does not take feelings into account	3.50 (1.13)
12. It is unclear to me how computers will be used in evaluating scans	3.19 (1.02)
13. Even if computers are better in evaluating scans, I still prefer a doctor	3.31 (1.15)
14. When artificial intelligence is used, my personal data may fall into the wrong hands	3.01 (1.16)
15. Artificial intelligence may prevent errors ^b	2.77 (0.98)
Factor 2 (procedural knowledge)	4.08 (0.71)
1. I find it important to have a good understanding of the results of a scan	4.16 (0.83)
2. I find it important to be able to ask questions personally about the results of a scan	4.17 (0.84)
3. I find it important to talk with someone about the results of a scan	4.19 (0.87)
4. I find it important that a scan provides as much information about my body as possible	4.18 (0.88)
5. I find it important to get the results of a scan as fast as possible	4.13 (0.85)
6. I find it important to ask questions on the reliability of the results	4.11 (0.92)
7. I find it important to be well informed about how a scan is made	4.02 (0.94)
8. I find it important to read how radiologists work before I get a scan	3.68 (0.99)
Factor 3 (personal interaction)	4.06 (0.71)
1. When discussing the results of a scan, humans are indispensable	4.16 (0.91)
2. Getting the results involves personal contact	3.96 (0.93)
3. As a patient, I want to be treated as a person, not as a number	4.14 (0.87)
4. When a computer gives the result, I would miss the explanation	3.69 (1.12)
5. I find it important to ask questions when getting the result	4.18 (0.85)
6. Even when computers are used to evaluate scans, humans always remain responsible	4.13 (0.92)
7. Humans and artificial intelligence can complement each other	4.17 (0.94)
Factor 4 (efficiency)	2.89 (0.46)
1. As far as I am concerned, artificial intelligence can replace doctors in evaluating scans ^b	3.08 (1.04)
2. The sooner I get the results, even when this is from a computer, the more I am at ease	3.50 (1.01)
3. Because of the use of artificial intelligence, fewer doctors and radiologists are required ^b	2.61 (1.07)
4. Evaluating scans with artificial intelligence will reduce health care waiting times ^b	2.30 (0.95)
5. In my opinion, humans make more errors than computers ^b	2.95 (0.93)
Factor 5 (being informed)	3.65 (0.62)
1. If it does not matter in costs, a computer should always make a full-body scan instead of looking at specific body parts	3.56 (1.07)

Items	Score, mean ^a (SD)
2. If a computer would give the results, I would not feel emotional support	3.53 (0.98)
3. A computer should only look at body parts that were selected by my doctor	3.48 (1.05)
4. When a computer can predict that I will get a disease in the future, I want to know that no matter what	4.02 (0.97)

^aThe mean score of statements measured on a 5-point scale (strongly disagree-strongly agree). For all factors, higher scores indicate being more negative toward the use of artificial intelligence in radiology.

^bItems marked are recoded to measure in the same direction.

Associations

The associations of factors with participant characteristics are presented in Table 3. Factor 1 was significantly associated with the participants' study specialization, the level of distrust in AI was lower among individuals in the administrative field (2.88, SD 0.62) compared with those specializing in humanities (3.20, SD 0.58; $P=.003$), health sciences (3.28, SD 0.63; $P=.005$), and those with no specialty (3.36, SD 0.61; $P<.001$). Factor 1 was significantly related to employment status ($F_{4,377}=2.74$, $P=.03$) and self-reported health status ($F_{3,378}=2.88$, $P=.04$). However, post hoc analysis did not reveal a significant difference between employment status and the self-reported health status subgroups.

With regard to self-reported health status, a statistically significant difference was noted in the mean scores of factor 5. Participants who reported an excellent health status (3.50, SD 0.62) had significantly lower scores for factor 5 than those who evaluated their health status as average (3.74, SD 0.70, $P=.03$) or fair/poor (4.17, SD 0.59; $P=.002$).

Factors 1, 2, and 3 showed a statistically significant association with marital status on univariate analysis; divorced and widowed individuals showed a higher level of distrust of AI in radiology (factor 1, 3.46, SD 0.72), a higher need for active engagement (factor 2, 4.42, SD 0.50), and a higher appreciation for personal interaction (factor 3, 4.40, SD 0.55) when compared with married individuals (factor 1, 3.15, SD 0.57, $P=.02$; factor 2, 4.04, SD 0.75, $P=.02$; factor 3, 4.02, SD 0.74, $P=.02$). Divorced or widowed individuals had a higher level of distrust of AI in radiology than unmarried participants (factor 1, 3.08, SD 0.59, $P=.01$).

On univariate analysis, factor 1 was weakly positively associated with age ($r=0.124$, $P=.02$; Figure 1). When participants were categorized into different age groups, no significant differences were observed. None of the factors showed statistically significant associations with sex, nationality, residence, education level, income, or self-reported knowledge about AI.

Table 3. Comparison of mean scores of the 5 factors in relation to sociodemographic and health characteristics of the participants.

Variable	Factor 1	Factor 2	Factor 3	Factor 4	Factor 5
Age group (years), mean (SD)					
18-19	3.09 (0.56)	4.05 (0.45)	4.29 (0.58)	2.83 (0.55)	3.72 (0.45)
20-29	2.98 (0.39)	4.14 (0.74)	4.11 (0.62)	2.82 (0.45)	3.66 (0.64)
30-39	3.16 (0.56)	4.11 (0.71)	4.06 (0.72)	2.90 (0.49)	3.60 (0.61)
40-49	3.14 (0.65)	4.01 (0.66)	4.00 (0.77)	2.91 (0.46)	3.66 (0.62)

Regression Models

Overall, model 1 (factor 1, distrust and accountability) was statistically significant ($F_{15,356}=3.48$, $P<.001$) with a coefficient of determination (R^2) of 0.128. The model explains a 12.8% variability in factor 1 scores. Out of 5 predictors (age, marital status, field of specialization, employment, and self-reported health status), only marital status and field of specialization were statistically significant ($P=.04$ and $P<.001$, respectively). Controlling for other factors in the model, participants who specialized in scientific and administrative fields still showed lower levels of distrust compared with those with no specialty; the scores were 0.27 lower ($P=.047$) and 0.44 lower ($P<.001$) than that of no-specialty participants, respectively. Divorced or widowed participants also showed higher scores when compared with married participants by 0.29 ($P=.01$), controlling for other factors in the model (Table 4).

Overall, model 2 (factor 2, procedural knowledge) was statistically significant ($F_{3,378}=3.41$, $P=.02$) with a coefficient of determination (R^2) of 0.026. The model explains only 2.6% variability in factor 2 scores. Out of 2 predictors (marital status and living region), only marital status was statistically significant ($P=.03$). Divorced or widowed participants showed factor 2 scores 0.36 higher compared with married participants ($P=.01$), controlling for living region (Table 4).

Overall, model 3 (factor 5, being informed) was statistically significant ($F_{6,374}=3.99$, $P<.001$) with a coefficient of determination (R^2) of 0.060. The model explains only 6.0% variability in factor 5 scores. Out of 3 predictors (age, marital status, and self-reported health status), only self-reported health status was statistically significant ($P=.004$).

Compared with excellent health status, participants with very good, average, fair/poor health status reported significantly higher factor 5 scores by 0.17 ($P=.02$), 0.23 ($P=.01$), and 0.58 ($P=.002$) respectively, controlling for age and marital status (Table 4).

Overall, model 4 (overall score) was statistically significant ($F_{10,362}=3.22$, $P<.001$) with a coefficient of determination (R^2) of 0.082. The model explains 8.2% variability in the overall scores. Out of 3 predictors (marital status, field of specialization, and self-reported health status), only marital status and health status remained statistically significant ($P=.004$ and $P=.02$ respectively). Divorced or widowed participants reported overall scores 0.28 higher compared with married participants ($P<.001$), controlling for field of specialization and self-reported health status. Compared with excellent health status, participants with very good, average, fair/poor health status reported significantly higher overall scores by 0.13 ($P=.01$), 0.12 ($P=.04$), and 0.29 ($P=.02$) respectively, controlling for field of specialization and marital status (Table 4).

Discussion

Principal Findings

To the best of our knowledge, this is the first study in Saudi Arabia to examine the attitudes to AI as a diagnostic tool from the patient's perspective. In this cross-sectional study with 382 participants, patients in the radiology waiting rooms at KKHU had a moderately positive attitude toward the use of AI as a diagnostic tool in radiology. This was similar to our hypothesis with reference to Jutzi et al [8] and Young et al [18] and contrary to Ongena et al [17] and Lennartz et al [4].

Regarding factor 1 (distrust and accountability), even though patients were neutral in their trust of AI taking over radiologists' diagnostic interpretation tasks; they believe that AI might enhance the accuracy of radiological diagnosis. This finding is similar to the conclusion by Jutzi et al [8], Young et al [18], and Lennartz et al [4] that AI is perceived to enhance the accuracy of radiological diagnosis and uses the latest in diagnostic procedures. As we had hypothesized that patients would show a positive attitude toward perceiving the knowledge behind radiological diagnosis and personal interaction with average scores of around 4.5 and 4.4, respectively; and in line with previous studies [4,17,18], we found that patients were interested in understanding how radiological images are obtained, interpreted, and disseminated, they favored personal interaction with a radiologist over AI-based communication, were ambiguous about AI improving the diagnostic procedure, and favored obtaining full disclosure of their medical findings and predictions of future diseases they might develop, in addition to full-body scans performed by AI rather than scans of selected body parts.

With regards to the associations between age and patients' attitudes toward AI as a diagnostic tool, our study showed a weak positive association between age and factor 1 (distrust and accountability) on univariate analysis although multivariable analysis showed no statistical significance. Ongena et al [17] indicated that age was weakly positively associated with factor 2 (procedural knowledge) and weakly negatively associated with factor 4 (efficiency). Young et al [18] reported that younger university students had more positive attitudes toward AI as a

diagnostic tool and aimed to use AI as a diagnostic tool in radiology. Contrary to the findings of Young et al [18], who reported that males were more accepting of AI as a radiological diagnostic tool and Jutzi et al [8] who reported female participants had a more positive attitude toward the use of AI in radiology than males, our study and that of Ongena et al [17] showed no significant associations between sex and the factors determining attitudes to AI as a diagnostic tool in radiology.

While Ongena et al [17] observed an increase in trust in AI-based technologies with higher levels of education, our study found no significant association between education levels and patients' attitudes toward AI use in radiology. Nevertheless, our results align with the findings by Jutzi et al [8]; the similarity in educational backgrounds, with a notable percentage of participants in both studies holding undergraduate or postgraduate degrees (121 participants, 40.6% in Jutzi et al [8] and 293 participants, 76% in our study), coupled with a middle-aged demographic, suggests a potential wariness towards AI. This wariness may stem from concerns about privacy invasion, or limited digital skills and financial resources required for technology use [19].

The field of specialization showed a statistically significant association (*P*<.001) with patients' trust in the use of AI in radiology. Participants in scientific and administrative fields reported lower levels of distrust in AI compared with participants with no specialty (*P*<.001). People who are well educated in a certain subject tend to build more trust in it. Thus, AI experts showed greater confidence and positivity in their views about AI implementation in medicine and health care when compared with the general public in the United States [20]. These results might be due to their previous exposure to AI for work or study, which facilitated the intention to use it in health care.

Participants who reported excellent health status have also expressed a higher need to obtain full disclosure and be informed by the AI diagnostic tool about their overall health status when compared with participants who reported their health status as average or fair/poor (*P*<.05). This was consistent with Lennartz et al [4], who reported that patients with severe disease had a negative attitude toward the use of AI in diagnosis. However,

Jutzi et al [8] observed that patients with melanomas were more likely to accept the AI diagnosis than healthy people.

Although the relationship between prior knowledge of AI and patients' attitudes toward the use of AI in radiology is the most influential determinant of its acceptance in radiological diagnosis [4], such a relationship was not statistically significant ($P > .05$) in our study. This could be a result of our participants' age and level of education, which made them less interested in AI and learning about it [19].

Divorced or widowed participants had a higher level of distrust of AI use in radiology and expressed a greater need for active engagement when compared with married participants. This could be due to the minimal health assistance they receive from family members in their household. Without the support of a partner, they carry a heavier burden of disease and could be unaware of the minor health-related details that are usually picked up by a partner [21]. Divorced patients are more prone to illness anxiety disorders, including hypochondriasis [22,23].

According to the World Health Organization, efficient implementation of AI requires a good interpretation of the patient's attitudes toward the use of AI in medicine in order to build their trust. One of the objectives of this study is to understand patients' perspectives on these technologies to ensure their widespread implementation. This research may aid in adding insight into future integration policies and ensuring the suitability of AI programs to meet societal needs. The strength of this study is that we recruited participants from a large specialized referral hospital in Riyadh. Thus, the population of this study had different health statuses and needed different scans. We also considered sociodemographic differences and social determinants of health.

Limitations

This study is subject to certain limitations, notably selection bias introduced by the convenience sampling method and potential variability in participants' comprehension of the topic.

The selection of waiting rooms for our convenience sampling approach might be influenced by several factors, including the frequency of x-ray and magnetic resonance imaging examinations performed in each facility, waiting time as well as the availability of waiting areas conducive to survey administration. While x-ray examinations are indeed more commonly performed procedures, our higher percentage of participants waiting for magnetic resonance imaging scans (or longer waiting time) may be attributed to the specific scheduling patterns and patient volumes observed during the data collection period. Additionally, variations in appointment scheduling and patient flow within different departments or clinics may have influenced the distribution of participants across waiting areas. Future research in this field should include a multicenter study population and studies that examine the predictors of distrust among patients in different hospitals, as well as identify useful methods for addressing the lack of knowledge and misconceptions that few patients hold with regard to AI.

Conclusions

In conclusion, patients were keen to understand the work of AI in radiology but favored personal interaction with a radiologist. If an AI system was implemented, patients would prefer full-body scans and full disclosure of medical findings. Patients were impartial toward AI replacing radiologists and the efficiency of AI. This preference expressed by patients for AI could have implications for clinicians and policymakers. Clinicians may consider incorporating these preferences into the design and implementation of AI systems in radiology, ensuring that the technology aligns with patient preferences for imaging procedures and information disclosure. Policymakers, on the other hand, may use this feedback to inform regulations and guidelines surrounding the use of AI in health care, emphasizing patient-centric approaches and ethical considerations in the integration of AI technologies. Therefore, our findings provide insight for future integration policies and help adapt AI to societal needs.

Acknowledgments

The authors convey special thanks for the support of the College of Medicine Research Center, Deanship of Scientific Research, King Saud University Riyadh, Saudi Arabia. The authors express our gratitude to Yfke P Ongena, Marieke Haan, Derya Yakar, and Thomas C Kwee for their contributions in providing the standardized questionnaire used in this study.

Abstract

Background: Digital health tools have demonstrated promise in the treatment and self-management of chronic diseases while also serving as an important means for reducing the workload of health care professionals (HCPs) and enhancing the quality of care. However, these tools often merely undergo large-scale testing or enter the market without undergoing rigorous user experience analysis in the early stages of their development, leading to frequent instances of low use or failure.

Objective: This study aims to assess the usability of and satisfaction with a mobile app designed for the clinical monitoring of patients with chronic obstructive pulmonary disease undergoing pulmonary rehabilitation at home.

Methods: This study used a mixed methods approach involving two key stakeholders—patients with chronic obstructive pulmonary disease and HCPs—across three phases: (1) mobile app mock-up design, (2) usability testing, and (3) satisfaction evaluation. Using convenience sampling, participants were grouped as HCPs (n=12) and patients (n=18). Each received a tablet with mock-ups for usability testing through interviews, with audio recordings transcribed and analyzed anonymously in NVivo12.0, focusing on mock-up features and usability insights. Task difficulty was rated from 1 (very easy) to 5 (very difficult), with noncompletion deemed a critical error. Usability satisfaction was measured on a 5-point Likert scale from 1 (strongly disagree) to 5 (strongly agree).

Results: The research indicated a notable difference in app usability perceptions: 66% (8/12) of HCPs found tasks “very easy,” compared to only 22% (4/18) of patients. Despite this, no participant made critical errors or withdrew, and satisfaction was high. HCPs completed tasks in about 20 minutes, while patients took 30. Older adults faced challenges with touch screens and scroll menus, suggesting the need for intuitive design aids like auditory support and visual health progress indicators, such as graphs. HCPs noted potential data delays affecting service, while non-native-speaking caregivers faced interpretation challenges. A secure pairing system for privacy in teleconsultations proved difficult for older users; a simpler icon-based system is recommended. This study highlights the need to consider stakeholder abilities in medical app design to enhance function implementation.

Conclusions: Most HCPs (11/12, 91%) found the app intuitive, though they recommended adding icons to show patient progress to support clinical decisions. In contrast, 62% (11/18) of patients struggled with tablet navigation, especially with connectivity features. To ensure equitable access, the design should accommodate older users with diverse abilities. Despite challenges, both groups reported high satisfaction, with patients expressing a willingness to learn and recommending the app. These positive usability evaluations suggest that, with design improvements, such apps could see increased use in home-based care.

Introduction

Background

Chronic pulmonary diseases severely impair the respiratory system and impact the daily activities of those affected [1-4]. With approximately 3 million deaths annually, chronic pulmonary diseases rank among the top 3 global causes of death [5,6]. Chronic obstructive pulmonary disease (COPD) is a major subset of chronic pulmonary diseases, with nearly 36% of patients developing comorbidities, such as hypertension and cardiovascular diseases [7]. Globally, 1 person succumbs to COPD every 10 seconds; in Taiwan, over 5000 deaths are attributed to COPD annually [8]. Severe cases of COPD may lead to systemic manifestations, emphasizing the urgency of interventions [9,10]. Patients, particularly older adults, often struggle with dyspnea and thus experience a diminished quality of life [11]. Depressive symptoms also commonly arise along with the aforementioned problems [12,13]. The significant impact of chronic pulmonary diseases on respiratory function and overall well-being highlights the urgency of addressing this issue. COPD presents with 3 major symptoms: cough, sputum production, and wheezing and is therefore, often mistaken as the common cold [14,15]. Coupled with low awareness of obstructive lung diseases among the public, individuals frequently underestimate their condition, leading to a delayed diagnosis and treatment as well as a significantly elevated risk of health deterioration [16,17].

Exercise is recognized as one of the most effective therapies for chronic pulmonary diseases [18]. It serves to alleviate respiratory symptoms, enhance cardiorespiratory function, improve quality of life, and consequently increase the overall well-being of patients [19,20]. Statistics indicate that individuals with COPD face a reduced life expectancy of 6 to 10 years [21]. In Taiwan, the 1-year mortality rate after the first hospitalization for obstructive lung diseases is as high as 20% [22]. To prevent recurrent hospitalizations due to acute deterioration in pulmonary function, postdischarge priorities for patients with chronic pulmonary diseases include maintaining regular exercise habits and receiving precise exercise prescriptions tailored to their conditions [23,24]. This approach aims to train and enhance pulmonary capacity, thereby extending life expectancy [20,25]. To ensure that home-based pulmonary rehabilitation exercises meet clinical requirements, digital health (eHealth) tools are considered potential aids in the treatment of chronic diseases because they assist patients in self-managing their conditions [26,27]. Simultaneously, these tools can provide real-time assistance to patients, caregivers, and health care professionals (HCPs) in achieving the vision of individual disease management and monitoring [28,29]. Moreover, eHealth tools serve as the optimal instruments for HCPs to provide real-time guidance to patients at home in developing health care skills and managing chronic diseases, especially during circumstances when in-person treatments are challenging (such as during the COVID-19 pandemic) [30]. Research confirms that the application of eHealth tools not only effectively reduces incidence rates, disease exacerbation, and recurrent hospitalizations but has also proven to be an efficient means of alleviating the clinical workload of HCPs [31,32].

Chronic diseases are a primary driver of the global increase in health care and caregiving expenditures [32,33]. In this context, eHealth tools could benefit various stakeholders (including HCPs, patients, and caregivers) by offering a health service [34,35]. However, these tools often face challenges in achieving seamless operations among the stakeholders involved, leading to outcomes below expectations [36]. Consequently, patients after their discharge exhibit low adherence to using these tools, hindering the comprehensive realization of their intended benefits [37,38]. Therefore, the design of eHealth tools should prioritize a methodology centered on user experience [32,39,40].

Objectives

For the aforementioned reasons, this study conducted a user experience-based evaluation of the usability of a home-based pulmonary rehabilitation app. The assessment focused on operational proficiency, information comprehension, interface design, and system acceptance among discharged patients and HCPs. User feedback and results were collected, and based on the survey findings, posttrial design modifications were implemented to enhance the effectiveness and user adherence to the eHealth tool. The objective was to ascertain the usability of and satisfaction with the mobile app in tracking home-based pulmonary rehabilitation exercise therapy for users.

Methods

Overview

This study was a nonpharmacological clinical trial that used a questionnaire-based interview approach to evaluate the operational usability of a mobile app designed for remote health care delivery. The evaluation involved 2 key stakeholder groups: the HCPs and the patients. The insights gained from this assessment will be used as a reference for refining the design of eHealth tools, ensuring their applicability for both clinical and home-based remote health care delivery.

Ethical Considerations

This study received approval from the Institutional Review Board of the Chang Gung Medical Foundation (registration number: 202200070B0) prior to its implementation. Before the commencement of the experiment, informed consent was obtained from all participants, who signed the necessary consent forms. To protect participants' privacy, all personal information was de-identified and stored with encoded data for analysis. Throughout the data collection and processing, strict adherence to confidentiality and privacy protection principles was maintained. Furthermore, all participants voluntarily joined the study, and no monetary compensation or gifts were offered to ensure the objectivity and impartiality of the experiment.

App Development and Usability Testing

Before initiating this study, the researchers conducted a survey on the construction requirements of a home-based pulmonary rehabilitation system. The aim was to establish the fundamental elements of system design based on user experience and needs. Building upon the outcomes of the preliminary research, 2 apps were developed: one for HCPs to clinically monitor exercise activities and another for patients or caregivers to execute the

prescribed exercises at home. This study concentrated on assessing the usability of these apps for the 2 participant groups. The survey results of this study will contribute to refining the design of the home-based pulmonary rehabilitation app. The research investigation comprised the following two stages: (1) observing and recording user interactions to understand the ease of use regarding system functionalities and (2) conducting usability tests through app operations to elucidate user satisfaction with the app design. This study was conducted at the Chang Gung Hospital in Taiwan with convenient sampling. The HCP group consisted of respiratory care and pulmonary care professionals, including physicians, therapists, and nurses (n=12), who (1) were aged ≥25 years with at least 1 year of experience in respiratory or pulmonary disease care, (2) had provided care for patients with chronic pulmonary diseases in the past 3 years, and (3) had experience in tracking patient rehabilitation. The patient group comprised patients with chronic pulmonary diseases (n=18) who (1) were aged ≥58 years, (2) had been diagnosed with chronic pulmonary diseases for ≥3 years with a history of hospitalization and had experienced pulmonary rehabilitation, (3) willingly participated and signed an informed consent form, and (4) possessed the ability to express themselves independently.

Considering the participants were older adults, the questionnaires were administered and filled out by the trial executor. Figure 1 illustrates the main functionalities of the app and the information distribution on each screen. Usability tests were conducted on the 10 key functional pages of the app, representing the most crucial functions of the system. The details of these tasks are outlined in Textbox 1. Throughout the testing process, when participants encountered notable operational challenges, the researcher proactively inquired about their difficulties or potential consideration for discontinuation. If participants successfully accomplished a task, it was documented as “operation success” on the questionnaire. Conversely, if participants failed to complete a task in 3 consecutive attempts without adhering to instructions, the researcher categorized it as “operation failure.” Irrespective of the participants’ success, posttask feedback was collected, and a Likert scale was used to evaluate task difficulty, using the following ratings: 1=very easy, 2=easy, 3=moderately easy, 4=difficult, and 5=very difficult. To evaluate app usability satisfaction, a survey was developed by adapting and modifying validated questionnaires from previous studies to align with the objectives of this research. Regarding the satisfaction of app usability, the survey comprised 10 questions each for the HCPs and the patients (Textbox 2). Responses were assessed on a 4-point Likert scale, ranging from 1 (totally disagree) to 4 (totally agree).

Figure 1. Usability test mock-ups. (A) App’s functional interface for health care professionals. Professionals can prescribe exercise regimens based on the patient’s condition, adjusting them dynamically by referencing clinical data and psychophysical states. This aids in facilitating the self-management of postdischarge patients at home. (B) App’s functional interface for patients. The interface for the home pulmonary rehabilitation app guides patients through lung exercises at home using visualizations and encompassing features, such as receiving exercise prescriptions, activity tracking, and progress monitoring.

Textbox 1. Usability test items.**Usability test items for assessing app functionality for health care professionals**

1. Create an account
2. Log in
3. Patient information management including entering or adding the patient's name, age, sex, contact number, and a brief description of the patient's physical condition
4. Prescription management: set patient prescriptions and transmit them to the patient's end
5. Record review and analysis: view the patient's exercise history records, including visualizing graphs showing trends in clinical signs
6. Clinical monitoring: monitor patient cycle variations, including whether the heart rate falls within the "safe heart rate" range
7. Remote monitoring: establish a connection and pair it with the patient's end for we-based monitoring of the patient's exercise status
8. Consultation and reporting: view exercise outcome reports and conduct web-based consultations
9. Prescription adjustment: online adjustment of exercise prescriptions, including intensity and difficulty.
10. Record management: view, edit, or delete member records

Usability test items for assessing app functionality for patients

1. Log in
2. Select personal information to view individual details
3. Generate a pairing code to connect with the hospital's end
4. Retrieve exercise prescription
5. Review exercise prescription details
6. View personal exercise history records (including visualizing graphs showing trends in clinical signs)
7. Pause the exercise (can be paused at any time if discomfort is experienced)
8. Examine exercise cycle variations, including checking safe heart rate and heart rate variability
9. Receive remote connection requests for web-based consultations
10. Complete web-based questionnaires (eg, Borg Rating of Perceived Exertion scale)

Textbox 2. Usability satisfaction assessment of the app.

Response items for health care professionals

1. Overall, this app is user-friendly.
2. The app interface is well-designed and aligns with clinical information needs.
3. On the basis of patient-generated data, the graphs are easy to interpret.
4. The app substantially assists clinical care professionals.
5. The app facilitates monitoring the home-based exercise rehabilitation of postdischarge patients.
6. Would you recommend colleagues to use a similar app?
7. The operations of the app are straightforward and easy to remember.
8. The actions performed, whether on the web or offline, are straightforward to me.
9. The app design is comprehensive with no missing or incorrect information.
10. I believe that it is safe for patients to use at home.

Questions for patients

1. Overall, this app is user-friendly.
2. The app has a simple and easy-to-understand interface.
3. The app facilitates easy recall of exercise prescription information at home.
4. The app comprehensively records the entire exercise process, ensuring no loss of vital information.
5. When encountering issues, I can easily resolve them.
6. Virtual reality contributes to my increased focus and enjoyment during rehabilitation.
7. I intend to continue using this app.
8. Even without assistance, I can operate the app on my own.
9. I feel safe using this app at home.
10. I find some features a bit complex.

In addition, to ensure the accuracy of the participants' feedback, the entire experimental process was recorded with meticulous time control to ensure that each participant completed the interview within the designated time frame (50-60 minutes). Participants had the opportunity to express their perspectives, opinions, and experiences regarding the tasks during the experiment (such as the difficulties or simplicity in the task). Subsequently, this information underwent verbatim transcription analysis with relevant usability keywords marked. Detailed information on participants' sociodemographic and clinical characteristics can be found in subsequent sections. Furthermore, the quantitative data of this study were analyzed using the statistical software SPSS (version 22.0; IBM Corp).

Results

Overview

This study collected data from two groups: HCPs (n=12) and patients (n=18). The majority (8/12, 66%) of HCPs were respiratory therapists with an average age of 46 (SD 5) years. They had >1 year of experience in respiratory care within the past 3 years. The majority (16/18, 89%) of patients with chronic lung disease were male, with an average age of 66 (SD 5) years. They had a history of chronic lung disease for >3 years and had undergone pulmonary rehabilitation for ≥3 years. Detailed information regarding the sociodemographic and clinical backgrounds of these two participant groups can be found in [Table 1](#).

Table 1. Sociodemographic characteristics of participants.

Participants and characteristics	Values
HCPs^a (n=12)	
Age (y), mean (SD)	46 (5)
Sex, n (%)	
Male	3 (25)
Female	9 (75)
Job title, n (%)

^aHCP: health care professional.

User Operations and Usability Perception Interview Survey

Following user interaction with the system, we conducted one-on-one semistructured interviews to gather insights into operational experiences. The participants described any difficulties encountered as well as their feelings while executing the tasks. The entire interview process was recorded, transcribed verbatim, and then subjected to qualitative analysis using NVivo (version 12.0; Lumivero) for content analysis and synthesis.

Among the HCPs, 66% (8/12) acknowledged the need for a brief transitional period to familiarize themselves with the app interface and functionalities. During the transformation of data into graphical representations, more diverse visualizations were preferred. Specifically, 58% (7/12) expressed a preference for observing changes in heart rhythm and having graphical representations illustrating cyclic patterns to aid in explaining the progression of pulmonary function in patients.

Moreover, 84% (10/12) of the HCPs emphasized from the hospital's standpoint, the concern regarding inadequate self-health management in patients after discharge, especially considering that these patients belonged to a high-risk demographic and reported that prioritizing safety should be a top consideration. Therefore, it is recommended that the fundamental design of the app incorporate an emergency cessation mechanism or a real-time notification feature that activates upon detecting physiological abnormalities, aligning with the fundamental requisites for medical applications.

Within the patient participant group, 83% (15/18) of respondents reported a sense of complexity during their initial exposure to the app. Among them, 62% (11/18) indicated an inability to operate the app independently; this challenge was attributed to the age of the majority of participants (mean 66, SD 5 years) and their inherent skepticism regarding their operational capabilities. Despite the user interface of the patient-side app being menu-based and devoid of text input requirements, using tablets and apps as interactive media was still perceived as

challenging. Moreover, 45% (8/18) expressed difficulty in discerning or comprehending the information presented on the screen, contributing to feelings of unease and anxiety; 62% (11/18) believed that understanding the operational procedures of the app without guidance was challenging. Notably, the majority (12/18, 67%) of patients specifically highlighted the

difficulties encountered during the initial step of entering email and password information to log in to the system. Lastly, 39% (7/18) conveyed an inability to comprehend the numerical representations in the postexercise feedback reports, expressing curiosity or confusion regarding the meaning of the graphs. [Table 2](#) presents detailed feedback from participants.

Table 2. Operational challenges: findings from the semistructured interview.

Participant and participant's feedback	Pain points
HCPs^a	
<ul style="list-style-type: none"> “Um... Honestly, at first, without any instructions, I was a bit unsure where to start, but luckily, I quickly found the “+” sign to create an account.” [HCP 6] 	<ul style="list-style-type: none"> The “+” symbol for account creation might not be very clear, but fortunately, it was quickly resolved.
<ul style="list-style-type: none"> “I found it easy to fill in basic patient information, but prescribing medication is more challenging for me since I'm not a doctor.” [HCP 1] 	<ul style="list-style-type: none"> Different backgrounds may entail different responsibilities.
<ul style="list-style-type: none"> “I'm not sure if it's just me being unfamiliar with the system, but currently, while the screen displays patient heart rate and related data well, for clinical staff, besides linear charts illustrating historical backgrounds, it would be helpful to have icons indicating categories or different charts displaying changes in various physiological values for clarity.” [HCP 11] 	<ul style="list-style-type: none"> Clinical staff require more varied graphical representations or symbols to express the significance of diverse clinical data.
<ul style="list-style-type: none"> “I'm not sure if it's a network issue or a system problem, but I feel the screen updates a bit slowly.” [HCP 4] “Perhaps there's some network delay; when I modify prescriptions, the patient's screen doesn't always match what I intend to prescribe.” [HCP 12] 	<ul style="list-style-type: none"> It is essential to ensure data conversion speed and the ability to promptly provide accurate information.
<ul style="list-style-type: none"> “Hmm... Typically, it takes some time to accumulate clinical data to see the effectiveness. At this stage, although the feature exists, there might not be enough data to discern changes.” [HCP 1] 	<ul style="list-style-type: none"> A vast amount of data are required for clinical efficacy to be evident in the system.
<ul style="list-style-type: none"> “I'm afraid I might accidentally delete a patient's record.” [HCP 5] 	<ul style="list-style-type: none"> There is a lack of mechanism for recovery or error compensation.
Patients	
<ul style="list-style-type: none"> “I can't read, and I can't see what's written on the screen.” [Ps 8 and Ps 17] 	<ul style="list-style-type: none"> Patients who are older adults have lower levels of education or have poor vision and may not be comfortable with operating the app alone.
<ul style="list-style-type: none"> “I can use a tablet, but I don't know how to type.” [Ps 17] 	<ul style="list-style-type: none"> In addition to typing, other input functions and voice commands need to be added.
<ul style="list-style-type: none"> “I don't really understand what these numbers mean...And what is pairing connection...Do I just press it, or do I need to input something?” [Ps 5, Ps 9, and Ps 12] 	<ul style="list-style-type: none"> The connection mechanism poses a challenge for both the older adults and caregivers.
<ul style="list-style-type: none"> “I often accidentally press the pause button... I don't know how to get back to the exercise screen...It makes me very anxious.” [Ps 13] 	<ul style="list-style-type: none"> There are too many function keys on the screen, making it difficult for users to navigate.
<ul style="list-style-type: none"> “I see my heartbeat and heart rate...I don't quite understand them, so it would be better if there were colors or lines to remind me when to slow down.” [Ps 10] 	<ul style="list-style-type: none"> The interface should be more user-friendly to avoid excessive use of numbers and scientific charts and should make good use of patterns, icons, or voice commands.
<ul style="list-style-type: none"> “I received a message asking to connect and to input numbers. I find this very difficult.” [Ps 8] 	<ul style="list-style-type: none"> Text may be difficult to understand; replacing it with diagrams or call-in features might be easier to comprehend.
<ul style="list-style-type: none"> “This thing is too advanced; I can't figure it out.” [Ps 7] 	<ul style="list-style-type: none"> The digital divide is a significant barrier for many rural and older adult populations.

^aHCP: health care professional.

Evaluation of User Operational Difficulty

During the assessment of the usability of the app’s function, HCPs encountered minimal challenges in tasks, such as setting up user and patient accounts as well as modifying patient information using tablets. Specifically, 8 (67%) of the 12 participants rated these tasks as “very easy.” More than half (7/12, 58%) of the HCPs found it easy to set and transmit prescriptions to the patient’s end. In addition, the majority (9/12, 75%) found it relatively straightforward to access patient exercise histories and visualize health status charts, although some recommended potential enhancements.

Concerning the web-based monitoring of changes in patient physiological readings, the majority (9/12, 75%) of HCPs perceived the interface to be clear and easy to understand, with operations being very straightforward. However, when establishing connections, most (6/12, 50%) participants initially

found it somewhat difficult. Nevertheless, after becoming familiar with the process, they regarded it as relatively simple (8/12, 66%).

While tasks like adjusting web-based prescriptions and conducting remote consultations were found easy by most (9/12, 75%) HCPs, 7 (58%) of the 12 HCPs expressed that accessing patient information and engaging in web-based consultations were comparatively complex, requiring more time for comprehension.

Managing patient information was deemed straightforward by 10 (83%) of the 12 HCPs. They noted that the clear interface facilitated easy access to and deletion of information. Screen delays were reported by only 42% (5/12) of participants, classifying this issue as “moderate” (Table 3). Importantly, no task was rated as “difficult” or “too difficult.”

Table 3. Perceived difficulty of participant operations.

Participant and task	Very easy, n (%)	Easy, n (%)	Moderately difficult, n (%)	Difficult, n (%)	Very difficult, n (%)
HCPs^a (N=12)					
T1: Create an account	8 (67)	3 (25)	1 (8)	0 (0)	0 (0)
T2: Log in	8 (67)	3 (25)	1 (8)	0 (0)	0 (0)
T3: Patient information management	8 (67)	4 (33)	0 (0)	0 (0)	0 (0)
T4: Prescription management	4 (33)	7 (58)	1 (8)	0 (0)	0 (0)
T5: Record review and analysis	3 (25)	9 (75)	0 (0)	0 (0)	0 (0)
T6: Clinical monitoring	2 (17)	9 (75)	1 (8)	0 (0)	0 (0)
T7: Remote monitoring	2 (17)	8 (67)	2 (17)	0 (0)	0 (0)
T8: Consultation and reporting	3 (25)	9 (75)	0 (0)	0 (0)	0 (0)
T9: Prescription adjustment	3 (25)	4 (33)	5 (42)	0 (0)	0 (0)
T10: Record management	2 (17)	10 (83)	0 (0)	0 (0)	0 (0)
Patients (N=18)					
T1: Log in	4 (22)	8 (44)	1 (6)	5 (28)	0 (0)
T2: Viewing personal information	5 (28)	6 (33)	3 (17)	4 (22)	0 (0)
T3: Pairing for connection	4 (22)	3 (17)	5 (28)	6 (33)	0 (0)
T4: Retrieving exercise prescription	6 (33)	3 (17)	4 (22)	5 (28)	0 (0)
T5: Reviewing prescription details	6 (33)	11 (61)	1 (6)	0 (0)	0 (0)
T6: Viewing past exercise history	6 (33)	11 (61)	1 (6)	0 (0)	0 (0)
T7: Pausing exercise	12 (67)	6 (33)	0 (0)	0 (0)	0 (0)
T8: Examining cycle variations	5 (28)	7 (39)	4 (22)	2 (11)	0 (0)
T9: Requesting web-based consultations	1 (6)	2 (11)	7 (39)	8 (44)	0 (0)
T10: Completing questionnaires on the web	3 (17)	15 (83)	0 (0)	0 (0)	0 (0)

In contrast, the patient group experienced substantial challenges during system log-in. Most (6/18, 34 %) patients initially struggled to understand how to use the tablet. After reminders and demonstrations, 45% (8/18) of the patients eventually considered the log-in process as “easy,” while 28% (5/18) found it challenging. When viewing personal information, 34% (6/18)

individuals expressed that it was relatively simple, despite requiring some time for searching and consideration.

Regarding receiving pairing codes and connecting to the hospital end, most (7/18, 39%) patients could input the pairing code to establish a connection; however, 34% (6/18) still encountered difficulties due to a lack of familiarity and the absence of assistance from caregivers. Despite some (9/18, 50 %) patients

expressing confusion regarding the functionality on the screen to receive prescriptions from HCPs, 33% (6/18) and 17% (3/18) patients found it “very easy” and “easy,” respectively.

In addition, concerning viewing exercise prescriptions and accessing personal exercise history records (including visualized charts displaying clinical symptom trends), the majority (11/18, 61%) of patients considered these tasks relatively simple. When experiencing discomfort, 67% (12/18) knew which button to press to pause and considered this step as “very easy.”

Regarding viewing personal physiological information, 7 (39%) of the 18 patients found it relatively easy; however, 8 (44%) patients expressed uncertainty about how to initiate web-based consultations. Nonetheless, although participants within the patient group encountered operational difficulties, none described the tasks as “too difficult” in the questionnaire interviews (Table 3).

Usability Testing of System Task Accomplishment

In usability testing with HCPs, system tasks, such as setup, log-in, exercise prescription, and remote connectivity were assessed. None of the tasks were completely successful on the first attempt. However, log-in and clinical monitoring tasks showed a higher success rate, reaching 83% (10/12; Tables 4 and 5). In the testing process, each participant was given 5 opportunities for operation. The majority (8/12, 66%) of HCPs required some time to adapt to and familiarize themselves with the app features. About 42% (5/12) committed 1 to 2 errors during operations, while 25% (3/12) made 3 or more errors. Nevertheless, 58% (7/12) ultimately succeeded in completing the tasks within the specified time limit. The HCPs attributed these errors primarily to the unfamiliarity with the interface and the occasional accidental presses. However, they noted that the design of the system was not overly complex, and the inclusion of a “back” mechanism allowed for quick error correction.

Table 4. Success rates of participant actions (N=122).

Task	Success, n (%)	Failure, n (%)
T1: Create an account	9 (75)	3 (25)
T2: Log in	10 (83)	2 (17)
T3: Patient information management	8 (66)	4 (33)
T4: Prescription management	8 (66)	4 (33)
T5: Record review and analysis	9 (75)	3 (25)
T6: Clinical monitoring	10 (83)	2 (17)
T7: Remote monitoring	8 (66)	4 (33)
T8: Consultation and reporting	7 (58)	5 (42)
T9: Prescription adjustment	8 (66)	4 (33)
T10: Record management	9 (75)	3 (25)

Table 5. Success rates of participant (patient) actions (n=18).

Task	Success, n (%)	Failure, n (%)
T1: Logging in	8 (44)	10 (56)
T2: Viewing personal information	9 (50)	9 (50)
T3: Pairing for connection	6 (33)	12 (67)
T4: Retrieving exercise prescription	9 (50)	9 (50)
T5: Reviewing prescription details	11 (61)	7 (39)
T6: Viewing past exercise history	13 (72)	5 (28)
T7: Pausing exercise	16 (89)	2 (11)
T8: Examining cycle variations	10 (56)	8 (44)
T9: Requesting web-based consultations	4 (22)	14 (78)
T10: Completing questionnaires on the web	18 (100)	0 (0)

Conversely, the majority (12/18, 67%) of the patients were able to complete tasks with assistance. However, tasks such as “Pairing for connection” and “Request web-based consultations” remained challenging for many, with failure percentages of 67% (12/18) and 78% (14/18), respectively. Among these patients,

44% (8/18) made 1 to 2 mistakes, while 39% (7/18) made 3 or more errors on the test (Table 5).

During the study, the main reason for errors among the patients was the fact that they were older adults, which may have affected their ability to operate the tablet as we would have expected. Notably, the patients achieved a 100% success rate

in Task 10, "Completing questionnaires on the web," primarily because this functionality was operated by the HCPs at this stage, thereby encountering fewer issues in operation.

Moreover, the experiment was conducted in a medical setting; as a result, none of the participants in either group made critical mistakes.

Mobile App Satisfaction Survey

Regarding the satisfaction survey, over half (11/12, 91%) of the HCPs expressed satisfaction with the functionality design of the app, finding it relatively satisfactory with minimal operational issues. A substantial proportion, constituting 75% (9/12), perceived the app as highly user-friendly, and 66% (8/12) expressed considerable satisfaction with the design of the interface. Moreover, the HCPs could promptly access patients' physiological information in real time through the app, with 58% (7/12) indicating such capability. However, satisfaction levels slightly declined when monitoring patients' physiological conditions through web-based connectivity. Only 33% (4/12) perceived this function as comprehensive, while 17% (2/12) expressed concerns regarding the inability of the current connection quality to facilitate real-time monitoring. Furthermore, 25% (3/12) suggested that a more stable network connection would enhance safety. Finally, the extraction of information and the generation of graphical representations

were considered crucial by most (11/12, 91%) HCPs. In this study, 42% (5/12) and 33% (4/12) HCPs expressed extreme satisfaction and satisfaction, respectively, with the design of this app. Respondents anticipated that these functionalities would aid HCPs in assessing patients' physical conditions and prescribing medical treatments.

In the patient group, satisfaction with operational aspects notably lagged behind that of the HCPs across functions, such as operation, information retrieval, connectivity, and message access. Only 22% (4/18) of the patients perceived the interface design of the app as user-friendly, with nearly 33% (6/18) unable to provide a proper evaluation. This is attributed to the significant operational challenges faced by the patients, with 50% (9/18) of the users unable to comprehend each interface function (neutral 5/18, 28%, disagree 2/18, 11%, and strongly disagree 2/18, 11%). Moreover, a high percentage (13/18, 72%) were unaware of how to connect remotely, and 39% (7/18; neutral 2/18, 11%, disagree 4/18, 22%, and strongly disagree 1/18, 6%) were unsure of how to access historical rehabilitation exercise records. In addition, 61% (11/18) were uncertain about accessing personal messages, and over a quarter (5/18, 28%) expressed confusion about the significance of real-time values. Nonetheless, 61% (11/18; strongly agree 6/18, 34% and agree 5/18, 28%) expressed willingness to recommend and continue using the app (Table 6).

Table 6. App satisfaction survey.

Participant and task	Strongly agree, n (%)	Agree, n (%)	Neutral, n (%)	Disagree, n (%)	Strongly disagree, n (%)
HCPs^a (n=12)					
Easy to use	9 (75)	2 (17)	1 (8)	0 (0)	0 (0)
User-friendly interface	8 (67)	3 (25)	1 (8)	0 (0)	0 (0)
Well-designed patient information management	6 (50)	3 (25)	1 (8)	2 (17)	0 (0)
Effective real-time patient data access and analysis	7 (58)	4 (33)	1 (8)	0 (0)	0 (0)
Effective web-based health monitoring functionality	4 (33)	4 (33)	2 (17)	2 (17)	0 (0)
Clear medical information and graphics	5 (42)	4 (33)	1 (8)	2 (17)	0 (0)
Well-implemented connectivity features	4 (33)	4 (33)	1 (8)	3 (25)	0 (0)

Complete personal message records	3 (17)	4 (22)	6 (33)	4 (22)	1 (6)
Willingness to recommend this app	6 (33)	5 (28)	4 (22)	3 (17)	0 (0)

^aHCP: health care professional.

Discussion

Principal Findings

This study has revealed a dichotomy in app operation and satisfaction levels between the participating HCPs and patients. Both groups exhibited a demand for adapting to the app, with the majority (11/12, 91%) of the HCPs potentially acquiring app operation skills and understanding its functions through learning and adaptation. Conversely, some (9/18, 50%) participants in the patient group found it challenging to use tablets to assist them in rehabilitation programs. Overall, there exists a correlation between operational capability and satisfaction levels. Although both groups of participants provided suggestions for the app, they all recognized that the use of this app would contribute to personal health management and remote home health monitoring. In addition, the results of the usability tests and the suggestions provided will aid us in devising improvements to the design of the mobile app.

Considering Human Factors for Enhancing Health Care App Usability Design

Technological advancements offer various methods to enhance health care service quality. Despite the longstanding application of digital technology in medical facilities and home-based care, the practical implementation and user acceptance of eHealth tools remain limited [41]. A key reason is the absence of user-centric interface design [42]. A 2024 study highlights the importance of considering all stakeholders' perspectives and needs in product, system, and service design, identifying the significant challenge posed by the absence of such a focus on digital health care technology [32]. The study reveals that software usability directly impacts the smooth delivery of health care products and services and determines users' operational capability, acceptance, and satisfaction [43].

Our research indicated that the principle of user-centric design can be further refined to tailor designs to different stakeholders. Regarding the app interface proposed in this study, some HCPs required a short period to learn and adapt to the app to assess whether its functionalities met their needs or required improvement. Similarly, many patients appeared to lack the skills and abilities to sufficiently manage eHealth technology;

therefore, they were possibly unable to provide effective evaluations on functionality evaluations or suggestions for improvement or even determine the potential of the app for future home use. Previous research has emphasized that the challenges arising from implementing home-based care often stem from overly complex, expensive, or bulky equipment [44]. This study builds upon current literature and suggests that the technology used at home could pose challenges for patients who are older adults [44]. One challenge is attributed to issues with interface design between software and hardware, which negatively impact performance [45]. Thus, home-based care devices and equipment could be perceived as unhelpful and introducing such technology into patient rehabilitation at home could be rendered futile. Consequently, interface design should prioritize not only the capabilities and preferred modes of communication of app users but also how the information is transmitted and visually displayed. For instance, considering the educational levels of older adults and their unfamiliarity with consumer electronics, graphical representations should be favored over text and clickable options preferred over dropdown menus [46].

Feasibility of Digital Technology in Home Health Care

The benefits of digital technology alleviate the workload of clinical personnel in addition to providing more precise references for clinical decision-making [47]. An immediate assessment of patients' current physiological status and a prediction of their needs can be derived from the data generated by user interaction behavior [48]. However, effective information communication and exchange rely on the capabilities of caregiver and patients. Therefore, a well-designed user interface becomes a crucial element in message transmission and is also a reason for users to accept, trust, and rely on technology [49].

Or et al [50] explored technology acceptance among patients with early-stage disease, with a primary focus on factors relevant to older adult populations. The authors suggested that patients are more likely to adopt technologies if they perceive them as useful or are satisfied with the recommendations provided by HCPs through technological assistance. Conversely, users may reject or discontinue communication with HCPs when they fail to recognize the benefits of technology, struggle to understand its significance due to technological barriers, or experience negative emotions, such as increased anxiety, uncertainty, or fear.

The feasibility and acceptance of technology for managing chronic diseases among older adults entail key considerations, primarily due to potential limitations in perceptual abilities [51]. Factors such as diminished cognitive function, tactile sensitivity, and visual acuity may hinder the use of technology, consequently impacting the efficacy and acceptance of using mobile apps. Research findings indicate significant challenges among most older individuals in navigating touch-screen controls alongside difficulties in comprehending textual information displayed on screens. Hence, presenting relevant information through visual representations or incorporating voice prompts better caters to the needs of the older adults.

On the contrary, both patients and HCPs with higher education levels and tablet familiarity preferred using visual aids instead of text to illustrate patient recovery progress. In addition, they advocated for longer data cycles and considered them instrumental in enhancing the accuracy of medical decisions and influencing patient recovery results and timelines. As irreversible conditions, chronic lung diseases necessitate long-term monitoring and health management, making home rehabilitation and health management an inevitable trend among patients. The use of digital technology not only benefits HCPs but also closely relates to the health of patients with chronic disease. However, the benefits of digital technology can only be realized by leveraging its functional advantages, which allows all parties involved to benefit from and consequently accept eHealth tools. The usability tests conducted in this study revealed that despite numerous suggestions and challenges encountered by both groups of participants in using the app, there was still a high level of satisfaction with the intervention method. Importantly, most (11/18, 61%) participants expressed willingness to adopt this approach as a future method of health management.

Recommendations for App Design Based on the Results of Usability Testing

The usability study revealed challenges for older adults in using tablets or other touch-screen interfaces [52]. In addition to lower-than-expected tactile responses, their limited visual acuity and cognitive abilities may hinder their understanding of on-screen information [53]. Some studies have suggested that presenting information in visual formats is an effective method to alleviate communication barriers and enhance comprehension, particularly benefiting older adults [54]. Those with limited tactile perception may require additional aids such as auditory cues or styluses.

Both participant groups in this study recommended that designs be easily understandable and advocated for presenting clinically relevant graphical data in a simple and intuitive manner. Furthermore, during the trial period, some patients struggled with input commands (eg, drop-down menus) due to unfamiliarity with tablet touch-screen interfaces, leading to feelings of helplessness or confusion. Consequently, such input interfaces may not be suitable for older adults, and alternatives are required to meet their needs, for example, click-based interactions coupled with imagery, which are widely used pain assessment tools.

In terms of operational capability, most (11/12, 91%) HCPs encountered a few issues in tasks such as creating account, logging in, accessing patient information, managing or adjusting web-based prescriptions, and monitoring patient dynamics. However, some HCPs expressed concerns about the impact of connection quality on delivering medical services. Unstable connections could lead to message asynchrony as well as screen delays and lagging. While some HCPs considered this a normal occurrence due to data processing and screen updates, others believed that it might affect the effectiveness of medical services.

In contrast, patients could face more challenges in operation. Research observations have indicated that the primary reason

that most patients can operate technology smoothly is due to assistance from caregivers. However, as the interface of this app is primarily displayed in Chinese, caregivers whose native language is not Chinese likely require additional explanations and perhaps training to understand the app. To address this issue, future improvements could consider using icons to replace textual instructions for broader user adaptation.

To enhance patient privacy and security, the app implemented a bidirectional web-based consultation feature. However, this feature may not be user-friendly for patients, as many of them are unfamiliar with how to input pairing connection values via touch screens on tablets. Consequently, even if the hospital sends a request message, patients may struggle to comprehend or operate this feature. To address this issue, it is suggested that a simpler approach be adopted, such as using a basic incoming call icon as a prompt for physician calls or as a signal for connection.

Our findings demonstrate that placing human-centered design at the forefront is paramount. Considering the abilities, cognition, and perceptions of different stakeholders will aid in improving the design, usability, and acceptance of eHealth apps. Throughout the study period, no critical mistakes, such as incomplete tasks, were reported by the patients and the HCPs. Moreover, a high degree of satisfaction was expressed. Despite significant operational challenges faced by the patients, they indicated a willingness to learn to use the app and recommend it to others. This suggests that such a model has the potential to be used in home-based care settings; however, further considerations in design details are necessary.

This study involved 2 participant groups and aimed to assess the usability, cognition, and acceptance of eHealth interfaces from their perspectives. The study included a total of 30 participants, comprising 12 (40%) HCPs and 18 (60%) patients;

this met the required sample size for such studies. Nielsen [55] suggested that 5 participants are typically adequate to identify most issues; however, the actual sample size may vary depending on different categories, which has also been noted by numerous related studies. The findings of this study are consistent with those of other investigations evaluating the usability of eHealth technology tools. Nonetheless, there is a need for further refinement, particularly in simplifying the communication hardware and app interfaces used by patients. Tablets may not be the most suitable tools for older adults, and other alternative solutions such as voice calls instead of text input should be considered.

Conclusions

The survey results of this study indicated that most (11/12, 91%) HCPs found the app intuitive and easy to use, while most (5/18, 28%) older patients found it challenging to operate independently. Nevertheless, both groups of participants exhibited a high level of satisfaction in the usability satisfaction survey. It is imperative for us to focus more on discussing and addressing the difficulties and dissatisfactions encountered by participants during app use to enhance the potential for future home-based apps. By examining errors during actual operations, conducting usability satisfaction surveys, and analyzing qualitative data, we can gain a better understanding of the use of mobile health apps during testing. The results from user testing aided in comprehending the actual functioning of mobile apps and served as a basis for design modifications. Moreover, our usability tests underscore the importance of tailoring app designs to accommodate contextual factors and user characteristics, such as age, education, and functional conditions, especially in populations with chronic diseases like COPD. Addressing these variables is pivotal for ensuring the effective adoption and acceptance of digital technologies in health care settings.

Acknowledgments

This study received support from the National Science and Technology Council through grant 111-2222-E-182-02-MY2. The authors sincerely thank all the participants for their valuable contributions to this study. Special appreciation goes to the Respiratory Therapy Department at Chang Gung Memorial Hospital for their invaluable clinical support.

Data Availability

The datasets used in this study are not publicly accessible due to the need to safeguard participants' personal data. However, interested parties may obtain access to the datasets by contacting the corresponding author and making a reasonable request.

Abstract

Background: More clinical studies use social media to increase recruitment accrual. However, empirical analyses focusing on the ethical aspects pertinent when targeting patients with vulnerable characteristics are lacking.

Objective: This study aims to explore expert and patient perspectives on vulnerability in the context of social media recruitment and seeks to explore how social media can reduce or amplify vulnerabilities.

Methods: As part of an international consortium that tests a therapeutic vaccine against hepatitis B (TherVacB), we conducted 30 qualitative interviews with multidisciplinary experts in social media recruitment (from the fields of clinical research, public relations, psychology, ethics, philosophy, law, and social sciences) about the ethical, legal, and social challenges of social media recruitment. We triangulated the expert assessments with the perceptions of 6 patients with hepatitis B regarding social media usage and attitudes relative to their diagnosis.

Results: Experts perceived social media recruitment as beneficial for reaching hard-to-reach populations and preserving patient privacy. Features that may aggravate existing vulnerabilities are the acontextual point of contact, potential breaches of user privacy, biased algorithms disproportionately affecting disadvantaged groups, and technological barriers such as insufficient digital literacy skills and restricted access to relevant technology. We also report several practical recommendations from experts to navigate these triggering effects of social media recruitment, including transparent communication, addressing algorithm bias, privacy education, and multichannel recruitment.

Conclusions: Using social media for clinical study recruitment can mitigate and aggravate potential study participants' vulnerabilities. Researchers should anticipate and address the outlined triggering effects within this study's design and proactively define strategies to overcome them. We suggest practical recommendations to achieve this.

Introduction

Vulnerability, defined as “an increased likelihood of being wronged or of incurring additional harm,” [1] has been a topic of significant interest in research ethics. Types of vulnerability include cognitive, juridic, deferential, medical, allocational, and infrastructural vulnerability [2]. The Declaration of Helsinki underscores that vulnerable populations require heightened protection due to their increased risk of harm, stating that research involving them is only justified when it directly addresses their health needs and cannot be conducted with nonvulnerable groups [1]. Yet, labeling whole population groups

as vulnerable has been criticized as overly simplistic [3]. Accordingly, the revised Council for International Organizations of Medical Sciences guidelines from 2016 emphasize the importance of avoiding the exclusion of entire groups considered vulnerable from research participation under the guise of protecting their well-being, which has led to limited knowledge about diseases affecting these groups:

In the past, groups considered vulnerable were excluded from participation in research because it was considered the most expedient way of protecting those groups (for example, children, women of reproductive age, and pregnant women). As a

consequence of such exclusions, information about the diagnosis, prevention, and treatment of diseases that afflict such groups is limited. This has resulted in a serious injustice.... The need to redress these injustices by encouraging the participation of previously excluded groups in basic and applied biomedical research is widely recognized. [4]

To mitigate such effects, research ethicists suggested a more dynamic and context-dependent understanding of vulnerability. Luna [3] recognized that individuals may experience varying degrees of vulnerability and proposed that vulnerability is constituted by layers. Victor et al [5] emphasized the importance of identifying and addressing triggers that may exacerbate certain layers of vulnerability. Aggregating such layers of vulnerability might lead to cascading effects, a chain reaction of consequences that occur because of the activation of one vulnerability layer [5].

As such, these authors understand vulnerability as the sum of such layers (ie, personal characteristics or situational circumstances) that put a person at risk of being harmed or disadvantaged in specific contexts. An individual's vulnerability is shaped by a combination of factors (eg, social, economic, and health-related) that can influence one another in ways that heighten or reduce overall vulnerability.

One potential factor that might aggravate—or mitigate—vulnerability in the research context is using social media as a recruitment channel for research studies. On the one hand, social media recruitment allows for effective reaching of populations that are challenging to reach through other recruitment channels since social media have targeted advertising features that enable researchers to tailor recruitment efforts to specific characteristics, interests, and behaviors. The accessibility of social media allows individuals to participate in research studies from anywhere with an internet connection, removing barriers related to geographic location, mobility limitations, or time constraints [6]. Thus, in specific contexts, social media recruitment may achieve higher enrollment rates and be more cost-effective than other recruitment methods [7]. On the other hand, however, social media can also involve considerable risks for specific target groups, including potential privacy violations, the risk of stigmatization, and challenges in ensuring proper informed consent [8]. Thus, to ensure ethical recruitment strategies, it is essential to identify how social media recruitment might trigger or mitigate vulnerabilities, especially in the context of clinical studies, and examine ways to address these triggering effects.

Previous studies investigating the ethical benefits and challenges regarding social media recruitment found that ethical benefits primarily include reaching a broader and more diverse pool of participants, and cost-effectiveness and direct engagement with potential participants. However, challenges such as ensuring data privacy, navigating regulatory compliance, and managing the quality of information dissemination require careful attention to maintain ethical standards [7-10]. Key recommendations from these studies stress the importance of ensuring recruitment strategies adhere to relevant ethical norms and comply with federal and state laws. Transparency is also crucial for building

trust and upholding ethical standards throughout the recruitment process [10].

Despite these contributions, to our knowledge, no empirical studies specifically address vulnerability in the context of social media recruitment. For understanding the recruitment for clinical studies via social media as a “stimulus condition” [11] that potentially triggers or aggravates existing vulnerabilities, this paper aims to explore experts' perceptions of vulnerability and those of patients with hepatitis B in the context of social media recruitment. We asked multidisciplinary experts and patients diagnosed with hepatitis B about their experiences and perceptions of recruiting vulnerable people through social media. We addressed the following research questions: (1) How can social media recruitment mitigate existing vulnerabilities in the context of clinical study recruitment? (2) What social media features can trigger and exacerbate vulnerabilities and why? (3) How do interviewees suggest navigating these triggering effects?

Chronic hepatitis B infection serves as a use case for vulnerability, underscoring the interplay between medical and psychosocial vulnerabilities experienced by affected individuals. Hepatitis B, a viral liver infection caused by the hepatitis B virus, leads to chronic liver disease with severe complications such as cirrhosis and hepatocellular carcinoma, presenting a significant public health challenge worldwide [12]. Individuals with hepatitis B encounter medical vulnerability due to their medically exigent state, compounded by the absence of a curative treatment. This renders them susceptible to exploitation, as they may enroll in clinical trials with inflated hopes of accessing potentially effective treatment. Their vulnerability is underscored by a persistent but often misguided hope for a cure, leading them to enter studies with unrealistic expectations of success [13]. Beyond medical vulnerabilities, individuals living with hepatitis B also face profound psychosocial challenges. Stigma and discrimination persist in many societies, driven by misconceptions about transmission routes and fear of contagion. This stigma manifests in various parts of life, including employment, health care settings, and social interactions, resulting in feelings of shame, isolation, and psychological distress [14].

Methods

Study Design

As part of the international research consortium “TherVacB - A Therapeutic Vaccine to Cure Hepatitis B,” we conducted semistructured interviews with multidisciplinary experts and patients with hepatitis B to explore the ethical, social, and regulatory issues of social media recruitment for clinical studies. In this paper, the analysis focused especially on the aspects of vulnerability. We followed the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist to report on the research team, study design, and data analysis [15].

Ethical Considerations

Human Subject Ethics Review Approval

This study received approval from the Ethics Committee of the Technical University of Munich (431/20 S-KH).

Informed Consent

All participants were provided with an information sheet detailing the study's purpose and scope. Written informed consent was obtained from each participant before the interviews.

Privacy and Confidentiality

Interview transcripts were pseudonymized by replacing identifiable information with placeholders.

Compensation Details

Participants did not receive any financial compensation for their participation in the study.

Recruitment

Stakeholders with practical or theoretical experience in social media-based recruitment were eligible to participate. They were recruited via snowballing, convenient sampling through the TherVacB network, and screening the corresponding authors of relevant scientific publications in the field. The stepwise recruitment process was guided by considerations of theoretical saturation [16] and was stopped when additional interviews were not expected to reveal any relevant new findings based on the ongoing data analysis.

Moreover, we included patients with hepatitis B as an additional stakeholder group. Patients with hepatitis B aged 18 years and above with at least one social media account and English or German language skills were qualified to participate. They were recruited during regular hepatitis B-related check-ups at a German University Hospital. Due to the COVID-19 pandemic, patient recruitment was challenging. Therefore, no more than 6 patients with hepatitis B participated in this study. Consequently, theoretical saturation is limited for the patient population alone. We considered the insights from these interviews as an additional triangulation point to further substantiate our qualitative analysis.

Data Collection

TW and BMZ held the semistructured, qualitative interviews in German or English via phone or videoconferencing. We used separate interview guidelines for experts and patients with hepatitis B. The expert interview guide focused on the ethical, legal, social, and practical risks and benefits of social media recruitment. The patient interview guide included questions about their experiences with social media and their disease, drawing particular attention to the potential stigma and privacy issues as essential aspects of vulnerability in the context of hepatitis B and social media. Experts were also asked "The patients eligible for the TherVacB clinical trial often have particularly vulnerable characteristics (eg economic, social). What do you think is noteworthy to consider in this context?"

The interviews were conducted between August 2020 and September 2021. Each interview lasted between 25 and 60 minutes. Interviews were recorded and transcribed verbatim.

Data Analysis

The research team (BMZ; TW; Nina Goldman, PhD; and NM) transcribed audio recordings verbatim. Interview transcripts

were coded based on inductive thematic analysis [17,18], using Atlas.ti (version 9; Scientific Software Development GmbH) software. Interview transcripts were analyzed based on reflexive thematic analysis (see [Multimedia Appendix 1](#) for the final list of codes). Based on the first 6 expert interviews, BMZ and TW developed a preliminary coding scheme, which they applied to these 6 interviews. Then, they refined and reviewed the coding scheme in subsequent interviews until they identified no additional relevant codes. Next, the research team summarized the contents of each code across all interviews in analytical memos and related them to each other, with existing literature and theory. Thereby, we found vulnerability to be a central aspect of the interviews that warrants specific empirical and conceptual attention. In multiple rounds of discussion, NM, BMZ, and TW discussed aspects pertinent to the data inductively and refined them iteratively. Illustrative quotes in German were translated to English by NM and double-checked by BMZ.

Results

Overview

We conducted qualitative interviews with 6 patients with hepatitis B and 30 multidisciplinary experts from clinical research, public relations, psychology, ethics, philosophy, law, and social sciences. The patients resided in Germany; the experts were from Australia, Canada, Germany, Spain, Switzerland, and the United States. The findings from the qualitative analysis of these interviews are structured as follows: first, we outline how experts perceived social media recruitment to help mitigate pertinent vulnerabilities (eg, being affected by a stigmatized condition or belonging to historically disadvantaged populations) in the context of clinical study recruitment. Second, we present four features of social media that may trigger vulnerabilities. Third, we present experts' recommendations from the interviews on mitigating some of these triggering effects.

How Social Media Recruitment Can Help Mitigate Vulnerabilities

Reaching Hard-to-Reach Populations

Many experts have emphasized the potential of social media recruitment to reach traditionally disadvantaged hard-to-reach populations for research effectively. The paternalistic approach, often excluding these groups under the guise of protection, has led to a lack of research findings tailored to their specific needs and circumstances. An ethicist cautioned against such paternalistic views of vulnerability, underscoring the importance of respecting individuals' autonomy:

I believe that...it is important that the truly crucial concept of vulnerability is not used in an overly paternalistic way. To [avoid] thinking that anyone vulnerable is generally not autonomous. [Ethicist 1, Switzerland]

Achieving inclusivity in research necessitates shifting from paternalistic protectionism toward empowerment and collaboration with vulnerable populations. Meaningful inclusion entails valuing the autonomy of vulnerable individuals and actively involving them as partners in the research process while safeguarding their rights. Social media recruitment emerges as

a valuable tool in this context, enabling researchers to reach these hard-to-reach populations more effectively, thereby promoting inclusivity and equity in research participation. Another ethicist further stressed the tension between protecting and recruiting patients with vulnerable characteristics:

And maybe at some point, you can say, you know, you shouldn't even be using social media, at least maybe in certain ways to recruit those really kinds of stigmatized groups. Again, I think we have to keep the benefits in mind here due to our earlier discussion because some of these folks are going to be/ Maybe this is the only way you're going to reach them, right? Well, it's sort of/It's going to be the best way for you to reach them, so I guess I'm committed to kind of finding ways to do it sort of safely. [Ethicist 3, United States]

Consequently, several expert participants, especially ethicists, perceived social media as a helpful tool to reach underserved and hard-to-reach populations for research studies [19].

Preserving Patient Privacy

Despite some large social media platforms' reputation for having limited privacy standards [20], social media recruitment may, conversely, also preserve patient privacy. By using social media platforms, researchers can reach individuals experiencing stigmatized conditions or traits, such as hepatitis B, outside a personal, clinical setting. Social media users with stigmatized conditions or traits who view social media recruitment advertisements may, for instance, be more likely to participate in survey research that does not require direct contact with the research team. They may prefer online recruitment settings that offer increased discretion and anonymity.

In our case, and I'm thinking about the HIV study I'm involved in, we are trying very hard to reach people who may not be in healthcare. When we talk about putting flyers up around the hospital or an outpatient clinic we are already excluding people that don't have access to regular care. We may not want to show up at a venue known to be frequented for privacy purposes, so if someone is going through [inaudible] or dating website [inaudible] in a way that can protect their privacy while reaching them whenever they get a chance to see an ad. [Ethicist 2, United States]

As we will show below, however, the predominant view among interviewees was that social media recruitment infringed on user privacy. This indicates the importance of assessing recruitment strategies in a context-sensitive manner, particularly regarding data privacy. The context relevance of who exactly the target population is may determine the risks and benefits related to this privacy aspect.

Social Media Recruitment as a Trigger for Vulnerabilities

Overview

This section is structured along the features of social media that can trigger and exacerbate (existing) vulnerabilities in the

context of social media recruitment. The relative importance of vulnerabilities depends on this study's design and the target group of the social media recruitment strategy. Interviewees gave a range of examples of characteristics they considered making people vulnerable, including having sexually transmitted or infectious diseases (eg, hepatitis B), being affected by severe or untreatable conditions (eg, cancer), holding stigmatized traits (eg, sexual orientation or psychological conditions), or identifying with historically disadvantaged populations (eg, immigrants or people of color). If targeted for study recruitment via social media, these individuals may face various harms, including social exclusion, discrimination, and limited access to opportunities. For instance, those with sexually transmitted or infectious diseases may experience social exclusion and stigma. At the same time, individuals with severe illnesses may encounter financial burdens and emotional distress.

Similarly, individuals with stigmatized traits may confront prejudice, discrimination, and barriers to employment. Moreover, historically disadvantaged groups may encounter systemic inequalities, social injustices, and unequal access to employment and health care resources. While these risks of harm also exist beyond the context of clinical study participation, social media recruitment might trigger or exacerbate them.

Acontextual Point of Contact

When promoting studies via social media, individuals may encounter recruitment advertisements at unexpected moments. In the context of medical research, interviewees emphasized that learning about a clinical study outside a clinical setting might cause distress or exacerbate existing emotional challenges in participants' lives, triggering or aggravating existing vulnerabilities:

You don't know the timing of your reach out. You know, it could be something very disturbing. It could be not just inappropriate timing..., but just inappropriate in the context of a person's life.... So, there is this contextual aspect of...recruiting people on social media, which can be hugely problematic. [Ethicist 1, United States]

Relatedly, a communication specialist with practical expertise in social media recruitment deemed social media inappropriate for studies investigating severe, incurable diseases when social media content was usually about fun and happiness because this could be off-putting for those affected. He underscored the potential mismatch between the typically light-hearted nature of social media content and the serious nature of such health conditions:

I believe that certain studies should simply not be promoted on social media.... We have recently received a request regarding a blood cancer study it is about the fact that the patient cannot be helped.... I consider it very unethical to advertise such things on social media platforms like Facebook, Instagram, and TikTok, at least not to offer such advertising. [Communication specialist 3, Germany]

Moreover, it was mentioned that the acontextual and impersonal communication on social media increased the risk of therapeutic misconceptions and false hopes regarding receiving an effective or curative treatment through the clinical study. One interviewed patient with hepatitis B supported this by stating:

We are always told that there is never a chance for us to cure this disease,...and sometimes this thought overwhelms me. I want to search on social media to see what can be done in this regard. [Patient 2 with hepatitis B, Germany]

Thus, acontextual communication through social media might trigger both medical vulnerabilities that come with severe, untreatable, or otherwise burdensome conditions and cognitive vulnerabilities, such as insufficient health literacy.

Public Space

A second feature of social media is that at least some communication happens in public, where others can see and interact with the content. This feature can breach peoples' need for privacy and unwantedly expose the medical information of social media users, constituting a risk of discrimination and people's right to medical data privacy. A Canadian ethicist explained that patients might find it intrusive and irritating if they received targeted messages about their condition without actively seeking that information. When people publicly announce their illness, they may not expect that researchers looking for study participants with specific conditions could encounter their shared information. Thus, sensitivity is required in the initial engagement with potential study participants via social media, as receiving a targeted advertisement or private message based on this public disclosure may cause discomfort and feel like an intrusion into their privacy:

And so, I think the form of initial engagement has to be sensitive to the fact that people might not expect that they've made that information public to this particular audience when they made a public announcement. And so, if you're targeting a particular condition to sort of barge in and say, hey, so-and-so with condition X, that might be chilling to the person who's receiving that message. He might feel like, how do you know this? And that could be off-putting and change their experience. [Ethicist, Canada]

Several patients with hepatitis B confirmed the importance of privacy. They expressed fear of being exposed to their diagnosis on social media.

If I were to post something about my Hepatitis B to someone somewhere [on social media].... They would essentially have something in writing from me. And they could forward it or repost it at any time. [Patient 1 with hepatitis B, Germany]

Regarding stigmatized medical conditions, a communication expert raised concerns about hate speech and the potential for discriminatory comments on social media platforms, which can be off-putting for people, meaning that it could discourage them from participating in this study. The challenge is to create

recruitment posts that attract potential participants while avoiding harmful reactions in the comments section.

But how do you implement [social media recruitment ads] in a way that firstly appeals to the patients, and how do I also manage to avoid the hatred from healthy participants who have no understanding of what it means to have Parkinson's? Because if a person with Parkinson's reads something like this and is exposed to such advertisements, if they read those comments, what do you think will happen? They will not sign up for this study, and that's problematic. [Communication specialist 3, Germany]

Thus, the feature of many social media platforms to operate (partly) in a public communication sphere triggers vulnerability for people with high privacy needs, such as people with stigmatized traits who would not want to be exposed. Such privacy infringements can lead to cascading effects, making people with stigmatized traits or severe diseases more vulnerable due to unsettling comments from other users or risks of discrimination.

Biased Social Media Algorithms

A third feature of social media that might trigger vulnerabilities in the context of historical discrimination is biased algorithms on social media. Several participants mentioned the issue of social media algorithms being potentially biased and discriminatory toward disadvantaged social groups. Consequently, using such algorithms for clinical study recruitment could trigger vulnerabilities for these groups. For example, one US-based ethicist working for an institutional review board stated:

...we see a ton of social media, almost for every major clinical trial, from big industry sponsors like Novartis, and they almost always have some kind of social media outreach. I think there has been a growing desire to address potential inequities, so I know that Facebook has been criticized for, you know, when you run a clinical trial ad, who exactly is it going to reach? Is it going to reach people who are underserved and historically disadvantaged? There has been criticism of the algorithms they use to target people for clinical trial recruitment. And I think there is some desire amongst Facebook even to try and do better on that point. But I don't know/ I guess I haven't seen it slowing down. [Ethicist 3, United States]

While there is no right to participate in a clinical trial, the systematic neglect of research participants with certain traits might lead to lower health care standards. This occurs because clinical trials that lack diversity may produce results that are not generalizable to the entire population. For instance, if clinical trials primarily include participants from specific demographics, the findings may not accurately reflect how treatments affect other groups, such as those with different ages, genders, ethnic backgrounds, or health conditions. This can result in less effective treatments or unforeseen side effects in underrepresented groups, thereby lowering the overall quality and equity of health care. This issue is particularly relevant

because social media is often perceived as a means to reach populations that are otherwise hard to engage in research, such as minority communities, rural populations, or those with limited access to traditional health care settings. However, this perception does not always hold in practice, as algorithmic biases may limit the effectiveness of social media recruitment [21]. As a result, specific populations may remain underrepresented in clinical research, perpetuating the cycle of inequitable health care standards.

Technological Tool

Finally, social media, being technological tools, cause effects that might trigger existing vulnerabilities. Several interviewed ethicists pointed out that users needed “a certain technical expertise and familiarity in dealing with such media” (ethicist 2, Switzerland). Thus, some patients may be interested in clinical studies but lack the digital skills to access this information via social media. As one expert pointed out, this can be a matter of justice if individuals with insufficient digital literacy skills are excluded from clinical studies solely advertised on social media:

Especially with vulnerable groups, it is certainly an issue: Who doesn't even have the opportunity or the chance to either see or respond appropriately? In that sense, it is indeed a matter of justice, but it's probably not immediately apparent under the label of justice. It might be framed differently. [Clinical researcher 3, Germany]

In addition to insufficient literacy, restricted access to relevant technology can render those lacking this access as more vulnerable as they do not have the same access to information as others:

You need the hardware for it, internet access or a stable network, and so on. Many things are required, and by that, I may inadvertently exclude certain people who don't have access, who can't afford it, or who may be hesitant to engage or participate in something like this. And just like that, we have a selection bias again. I think we need to be careful here. It can even take on a discriminatory character if I only focus on such individuals. [Ethicist 2, Switzerland]

Because social media are technological tools that require skills and hardware, their use can systematically exclude specific populations from clinical studies. This may lead to lower health care quality and aggravate medical vulnerabilities because drugs might work less efficiently. In the following section, we will present experts' suggestions for mitigating these triggering effects of social media recruitment.

Mitigating Triggering Effects of Social Media Recruitment

Overview

The interviewed experts pointed to several practical recommendations that help mitigate the aforementioned triggering effects of social media recruitment.

Communicating Transparently

First, several experts pointed to the importance of transparency when communicating with potential research participants on social media. One ethicist referred to people with vulnerable characteristics as requiring a “higher standard of transparency and consent” (ethicist 1, United States). Investigators should, therefore, always be transparent about who they are and what they are contacting the person for, as a clinical researcher from the United States pointed out. To further support patient autonomy, researchers should make sure that patients can ask questions before consenting to this study:

...at least granting the opportunity to ask questions. What risks it would entail for me, for example? Even if it is formulated in writing, there might be instances where someone doesn't understand it or so.... So, providing information that is as comprehensible as possible, I believe that's what it is about. [Social scientist 1, Germany]

While transparency in research communication is a fundamental principle across all recruitment methods, it is particularly important in the context of social media recruitment, as users on social media platforms may receive numerous messages and requests. Transparency about the nature of the contact can help recipients differentiate legitimate research inquiries from spam or phishing attempts. This transparency helps establish trust and credibility with potential participants. By contrast, recruitment for clinical studies featured in newspapers or on the radio typically undergoes critical observation by the editorial teams beforehand. A clinical researcher from Germany also emphasized the need for personal interaction “to make sure that the patients understand that the information they are about to give you might contain personal health issues” (Clinical researcher 2, Germany).

Analyzing Algorithm Bias

To address the issue of biased algorithms, experts suggested researchers collaborate with ethicists and social media experts to review and assess the algorithms used for recruitment, identifying any potential biases and working toward mitigating them. Researchers should actively engage with Facebook and other social media platforms to understand how their algorithms work and to be aware of any changes or updates that may impact the fairness and inclusivity of their recruitment offers. Depending on the social media platform, this could be laborious, as this expert acknowledged:

But Facebook changes its rules every second day, and you have to have someone whose job it is to monitor those.... It's really, really hard from a privacy and confidentiality point of view because you're not in control of what Facebook does. [Social scientist 2, Australia]

Protecting Privacy

One ethicist from the United States emphasized the importance of raising awareness about the potential misuse of data on social media. He suggested that instead of solely focusing on finding ways to protect privacy, it would be beneficial to educate people about the challenges of maintaining privacy online:

I feel as though we need to be much more proactive about creating tools to protect all sorts of people in social media space from harm that may result from the misuse of their data. Rather than trying to figure out ways/I think it would be healthier if we educated people that they've given up a ton of privacy, and maintaining privacy by keeping your information inaccessible is hard in these spaces and that we need to create an environment that creates consequences for the misuse of people's information. So we shifted towards that sort of dynamic, maybe [inaudible] have a better understanding that but limited when you're participating in a lot of these spaces. [Ethicist 4, United States]

A clinical researcher with practical experience in social media recruitment explained that his research team did not allow comments on their Facebook page to prevent patients from sharing information “about their diagnosis status or ask[ing] questions about medication management” (clinical researcher 3, United States). To prevent patients from inadvertently disclosing personal health information, it is advisable not to specifically target individuals with a particular diagnosis in recruitment posts on social media. A US-based ethicist suggested making a disclaimer saying that users should not directly reply to study-related social media advertisements. Still, experts acknowledge the challenge of protecting patient privacy on social media because platforms may change their privacy policy anytime.

Using Multichannel Recruitment Approaches

Because not everybody has access to social media and might not see information regarding relevant clinical studies, one ethicist from the United States suggested that it may be necessary to use alternative offline strategies to reach populations with limited social media access:

Social media...may not be available to everyone.... So we have to sort of keep that in mind. There is a place where you might want to drive up and hand out flyers outside of a soup kitchen, depending on who you're trying to talk to. [Ethicist 2, United States]

Therefore, researchers should consider the possible drawbacks of relying solely on social media as a recruitment method and instead devise an approach that integrates various strategies (both online and offline) to promote inclusivity in clinical studies and increase the likelihood of reaching a more diverse and representative sample of participants. In addition, one expert suggested learning the target population's behavior to “track down what data is available in terms of what websites they are on” (ethicist, Canada). While the other presented strategies involve specific actions to mitigate the vulnerability-triggering effects of social media recruitment, multichannel recruitment consists of integrating online and offline recruitment methods to enhance inclusivity.

Discussion

Principal Findings

In many clinical studies, social media offer one of several ways to recruit potential study participants. Most often, participants are recruited within the clinical setting, through snowballing techniques, or via more traditional forms of advertisement such as billboards, newspaper advertisements, and community networks. Gelinas et al [10] argued for a nonexceptional approach to evaluating the ethical implications of social media recruitment because the same research ethics principles (respect for persons, justice, and beneficence) apply. Yet, as we delve into this discourse, we recognize the need for a deeper examination. In this context, we propose to extend Gelinas and colleagues' [10] recommendations. We offer the first empirical evidence of a more nuanced assessment of social media recruitment regarding participant vulnerability by showing features specific to social media that might mitigate or trigger vulnerabilities of potential study participants in the context of clinical study recruitment.

We will now discuss how the identified vulnerability triggers of social media recruitment are exclusive to social media. The vulnerabilities associated with social media recruitment are not mere extensions of issues seen in more traditional recruitment approaches. Instead, social media themselves shape vulnerabilities due to their unique characteristics. We argue that social media uniquely combines ethically relevant features of other recruitment channels and, thus, warrants special attention and ethical scrutiny. First, social media are unique because they operate in a semipublic sphere [22]: within this sphere, content can straddle the line between public and private, creating a complex web of accessibility. For the average user, determining who can access which specific activities and digital traces on social media is not trivial [23], particularly when considering the constantly changing terms of use imposed by social media platforms. Second, and this distinguishes social media recruitment from other online recruitment activities, is the deeply personal nature of these platforms. Social media platforms serve as more than just spaces for sharing information; they also collect vast amounts of data about individuals, including their preferences, behaviors, and interests.

Users recognize that the content they encounter on these platforms is tailor-made for them based on their previous interactions and the data collected about them. This personalization sets social media recruitment apart from traditional methods such as billboard advertisements, which are generally not personalized. This individual targeting might be off-putting for users because they may feel that their privacy is being invaded, which is not a concern with more traditional recruitment approaches. Finally, social media recruitment poses unique challenges related to privacy and algorithmic discrimination [20]. The power wielded by social media platforms in the digital realm is unprecedented, and their ability to shape the recruitment process is substantial. These platforms' algorithmic decisions can inadvertently contribute to inequalities in health care and research participation [21]. Thus, when researchers use nondisclosed social media algorithms for

recruitment, they may unintentionally exacerbate vulnerabilities for marginalized communities by targeting specific demographic groups and inadvertently excluding others, potentially exacerbating disparities in health care access and research participation. The use of such algorithms for clinical study recruitment has the potential to trigger vulnerabilities for marginalized groups. It is essential to consider the far-reaching impact of social media platforms and their algorithms on fairness in the recruitment process. As social media are used to recruit potential study participants, these risks of triggering or exacerbating vulnerabilities exist independent of actual research participation. Consequently, potential research participants could be harmed even without consenting to participate in a study, making it even more important to consider vulnerabilities in the context of social media recruitment carefully.

Particularly in Europe, privacy concerns and related legal uncertainty often cause researchers to refrain from using social media as a recruitment tool for clinical studies [9]. Yet, to not aggravate existing injustice, researchers and research ethics committees should not completely refrain from social media recruitment out of concern for vulnerability [24]. This should be especially considered in the context of historically underserved, hard-to-reach populations and people with stigmatized conditions, who may benefit from the platform's accessibility and reach. Consequently, we conclude from our findings neither promoting nor declining positions on the use of social media for clinical study recruitment. Instead, we highlight the importance of a context-sensitive assessment of study designs regarding the role of social media in triggering vulnerabilities and report on concrete ways researchers could develop appropriate safeguards tailored to address the specific types of vulnerability involved [2]. In developing such appropriate safeguards, assessing the risks and benefits of using social media recruitment regarding vulnerability is essential.

Limitations

The results of this study should be considered against the background of some methodological limitations. Due to limited access to patients during the COVID-19 pandemic, only 6 patients were recruited. While we found during the analysis that they represented a high variability in terms of age, digital literacy, and attitudes toward technology and social media, additional interviews might have revealed more nuanced patient

views. Additionally, this study's focus on patients with hepatitis B introduces another limitation. The vulnerability and ethical considerations related to social media recruitment can differ substantially across various diseases and patient populations, thus the findings may not be directly applicable to other medical conditions. Yet, this study provides relevant insights for future studies investigating vulnerability in the context of social media recruitment in the context of other disorders.

Another potential limitation is that some of the interviews were held via the phone. The absence of visual cues might have hurt the richness and quality of the empirical data compared to face-to-face interviews, particularly for patient interviews. Due to the COVID-19 pandemic, it was not possible to conduct these interviews face-to-face.

Finally, throughout the interview process, we did not provide a specific definition of social media to the participants. Instead, we asked them about their understanding of social media. As a result, the practical recommendations presented in this paper are expected to have a more universal scope rather than being tailored to specific social media platforms. Thus, the provided recommendations may depend on the particular social media platform being considered, the target population, the kind of study being conducted, and the envisaged study design [8].

Conclusions

The use of social media for clinical study recruitment can mitigate but also trigger or aggravate existing vulnerabilities. To avoid the systematic neglect of certain groups in research studies, vulnerability should be anticipated in the study design, and ways to mitigate them should be defined upfront. To facilitate this, we have reported a range of practical recommendations to address vulnerability and presented a practical case to do this. As such, social media recruitment should be designed and reviewed in a way to mitigate effects that render people more vulnerable. Our expert participants proposed that studies targeting people with stigmatized conditions or historically disadvantaged populations should make sure that the recruitment design allows for transparent communication and protection of privacy. Expertise in analyzing potential algorithm bias and using multichannel recruitment strategies are other practical recommendations for certain target populations.

Acknowledgments

We thank Nina Goldman, PhD, for data management and contributing to the initial analysis. The research for this paper received funding from the European Union's Horizon 2020 research and innovation program under grant agreement number 848223 (TherVacB). Abstract

Background: Image-driven specialisms such as radiology and pathology are at the forefront of medical artificial intelligence (AI) innovation. Many believe that AI will lead to significant shifts in professional roles, so it is vital to investigate how professionals view the pending changes that AI innovation will initiate and incorporate their views in ongoing AI developments.

Objective: Our study aimed to gain insights into the perspectives and wishes of radiologists and pathologists regarding the promise of AI.

Methods: We have conducted the first qualitative interview study investigating the perspectives of both radiologists and pathologists regarding the integration of AI in their fields. The study design is in accordance with the consolidated criteria for reporting qualitative research (COREQ).

Results: In total, 21 participants were interviewed for this study (7 pathologists, 10 radiologists, and 4 computer scientists). The interviews revealed a diverse range of perspectives on the impact of AI. Respondents discussed various task-specific benefits of AI; yet, both pathologists and radiologists agreed that AI had yet to live up to its hype. Overall, our study shows that AI could facilitate welcome changes in the workflows of image-driven professionals and eventually lead to better quality of care. At the same time, these professionals also admitted that many hopes and expectations for AI were unlikely to become a reality in the next decade.

Conclusions: This study points to the importance of maintaining a “healthy skepticism” on the promise of AI in imaging specialisms and argues for more structural and inclusive discussions about whether AI is the right technology to solve current problems encountered in daily clinical practice.

Introduction

Image-driven specialisms such as radiology and pathology are at the forefront of technological innovation in medicine, and many believe that artificial intelligence (AI) is the next innovation to reshape these fields [1-3]. AI refers to a broad range of machine-based systems designed to influence the environment by producing an output (predictions, recommendations, or decisions) for a given set of objectives [4]. AI is considered promising for image-driven medical fields because the work involves pattern recognition and is often digitalized, meaning rich datasets are available for AI training. Some have already argued that the professional roles of radiologists and pathologists will drastically change due to AI; they will become “information specialists” [5] or “imaging

consultants” [6] who seamlessly use AI to help interpret patient data. Jha and Topol [5] even speculate that the fields will most likely merge, leading to “a natural fusion of human talent and artificial intelligence. United, radiologists and pathologists can thrive with the rise of artificial intelligence.”

Despite the great promises for image-driven diagnostics and Dr Geoffrey Hinton’s prediction that radiology as a specialization would now be extinct, the implementation of AI in routine patient care is often lagging [7,8]. One cause is the lingering uncertainty among professionals about the added value for clinical practice. Another contributing factor is the large variance in acceptance and trust of direct and indirect adopters [9]. While fears about an upcoming “AI winter” [10] are likely unfounded, expectations must be tempered to prevent disillusionment. It is therefore relevant to consider “how to actually deploy AI in

clinical practice” and investigate whether the high expectations of AI in radiology and pathology require substantial changes in these fields—and in the current implementation approaches used by AI vendors [7].

Empirical studies have investigated how image-driven professionals view AI innovations. For example, professionals in radiology [9,11-14] and pathology [15-17] have a wide range of predominantly positive expectations for AI, yet they remain divided on the roles AI should have in their daily workflows. Studies have also called for a more thorough incorporation of medical professionals’ views in AI design and implementation [12,18]. This paper aims to add to the understanding of image-driven professionals’ views on the future of AI in radiology and pathology by highlighting how their views relate to current discussions on AI. As far as we are aware, this is the first qualitative interview study to combine views from both fields. By doing so, we hope to provide a more comprehensive perspective on AI’s influence on medical imaging. These insights are also intended to help inform the responsible integration of AI in image-driven medicine.

Methods

Overview

This study is part of a broader research project focusing on the ethical integration of AI in image-driven medicine, and the main research question is, “how should AI be responsibly integrated and used in image-driven medicine?” In order to answer this question, we use empirical research methods such as qualitative interviews and participant observations [19] to ground and inform our ethical analysis. The interview study design is in accordance with the consolidated criteria for reporting qualitative research (COREQ) [20]. In another publication, we reported the perspectives of pathologists, laboratory technicians, and computer scientists from 2 Dutch hospitals regarding the development and implementation of AI in pathology [15]. For the previous paper, we focused on the perceived roles and responsibilities of AI according to professionals working in pathology. In this paper, we compare and contrast the perspectives of professionals working in 2 departments—radiology and pathology—within 1 Dutch hospital and focus on the perceived promise of AI for image-driven medicine.

Research Design

To gain insight into the promise of AI for image-driven medicine, we conducted an inductive qualitative analysis of recorded conversations with radiologists, pathologists, and computer scientists [21-24]. The interviews with computer scientists have been used to contextualize and steer the interpretation of our findings.

Sampling in a High-Resource Context

Radiologists and pathologists working at 1 academic hospital in the Netherlands, the University Medical Center Utrecht

(UMCU), were invited to participate in this study via a department-wide call. Potential participants were also directly approached by the research team or a contact person at the department to reach a representative group of professionals. We personally approached radiologists and pathologists who were less involved in AI integration in these fields because we found it important to include their perspectives in the study. Computer scientists working with these departments were also asked to participate to provide additional context. For several reasons, we chose to focus on professionals from 1 innovation-driven medical center. First, these departments are relatively far along in their AI implementation processes compared with other Dutch hospitals. We hypothesized that this would correlate with a greater familiarity with AI, meaning respondents would be more likely to relate their opinions and expectations to practical encounters with AI. Second, we also recognize that context matters for AI integration and that it can be challenging to compare different medical contexts [25]. Focusing on radiologists and pathologists from 1 medical center enabled the comparison of perspectives on AI innovations between the departments, as, in general, the 2 departments function in the same context (eg, same region, managerial structures, and access to high-quality data), and both have access to internal computer science teams to support AI development and use. Nevertheless, we also recognized that conducting the study at 1 medical center would present a practical challenge. As there were a fixed number of radiologists and pathologists working at these sites, and we were dependent on their willingness to participate, the number of respondents for this study was finite. As our primary aim was to conduct a comprehensive exploration of perspectives on the promise of AI for image-driven medicine, we have focused on including a range of perspectives present in the departments to ensure broad representation instead of purely focusing on the sample size. This means we have taken meaning saturation into account in the analysis of the data to ensure that the quality of data is high and that the elicited views are representative of the perspectives present in the departments (except perhaps for those respondents who remained unwilling to discuss the potential of AI; see the Discussion section), but we mainly reflected on the information power in our in-depth interviews [26,27].

Data Collection and Analysis

Interviews were conducted between June 2020 and December 2021. Because of the pandemic, many of the conversations took place via the telephone; JD and MM conducted interviews individually and as a team. A semistructured topic list was used to guide the conversations (see Table 1 for sample questions). The recorded interviews were transcribed verbatim by a professional transcription service and checked for reliability by JD. The transcripts were then coded for confidentiality, and identifying information was removed. The interviews were conducted in Dutch and translated to English by JD and MM.

Table . Sample interview questions of semistructured topic list.

Designators	Questions
A. General questions about respondent's background	
A1	How long have you worked as a radiologist/pathologist?
A2	Why did you choose to specialize in the field?
A3	What technology developments did you encounter during the time you have worked as a radiologist/pathologist?
B. Question(s) on conceptualization of AI ^a	
B1	In your view, how would you define AI?
C. Questions about respondent's thoughts and opinions about AI: <i>What is the perceived effect of the introduction of AI in relation to ideas about professional identity and expertise?</i>	
C1	In general, what do you think AI could mean for radiology/pathology?
C2	To which extent are you involved in AI integration in your field?
C3	What kinds of AI applications would be most helpful or useful to you?
C4	In what ways do you think AI might impact your decision-making process?
C5	What (new) skill(s) or knowledge do you foresee yourself needing if AI becomes more prevalent?
C6	In the next 10 years, how do you expect AI to impact radiology/pathology?
D. Questions about desirable ethical guidance for AI in image-driven medicine	
D1	What ethical issues do you foresee with the increased use of AI in your work?
D2	Do you think special guidelines should be established for using AI? If so, what kinds of issues should be addressed?
E. Exit questions	
E1	Do you have any other thoughts or opinions about the use of AI in your department that you'd like to share with me?
E2	Is there anything you think we missed? Is there an important question I forgot to ask?

^aAI: artificial intelligence.

The data selection and analysis occurred inductively and iteratively [28] using constant comparison [29]. The software program NVivo (version 12; Lumivero) supported the data analysis. JD and MM read individual interview transcripts and independently identified conversation fragments or units of meaning [21-24] they considered relevant to the research question; they met regularly to compare their observations. They used the code tree from the analysis for the earlier publication [15] as a baseline, adapted the code tree to fit the new dataset, and supplemented it with new descriptive categories. JD and MM then sampled and independently coded 4 interviews, compared the results, and refined the code tree. JD then coded the remaining transcripts, adjusting the code tree when necessary. Finally, MM and JD performed an intercoder reliability check by recoding 2 interviews (1 pathologist and 1

radiologist) and comparing their results. Meaning saturation and information power were taken into account throughout this process [27,30]. During the analysis, JD, MM, and KJ kept track of new AI developments in radiology and pathology; in consultation with WV and SV, we evaluated the relevance of the data to current situations on the work floor and included current literature in the discussion.

Data Statement

The data have been presented by means of in-text illustrative quotes, carefully selected to represent the arguments presented in the interviews and do justice to the variety of perspectives captured in the interviews. We have considered whether the quotes could be understood without the context in which they were originally uttered. The complete datasets are not publicly

available because privacy of individual participants could be compromised. The individual privacy of the participants was particularly important as their statements included political opinions and philosophical beliefs regarding the ways in which AI should be adopted. These are deemed sensitive and, therefore, fall under the protection of the General Data Protection Regulation (GDPR: article 9).

Ethical Considerations

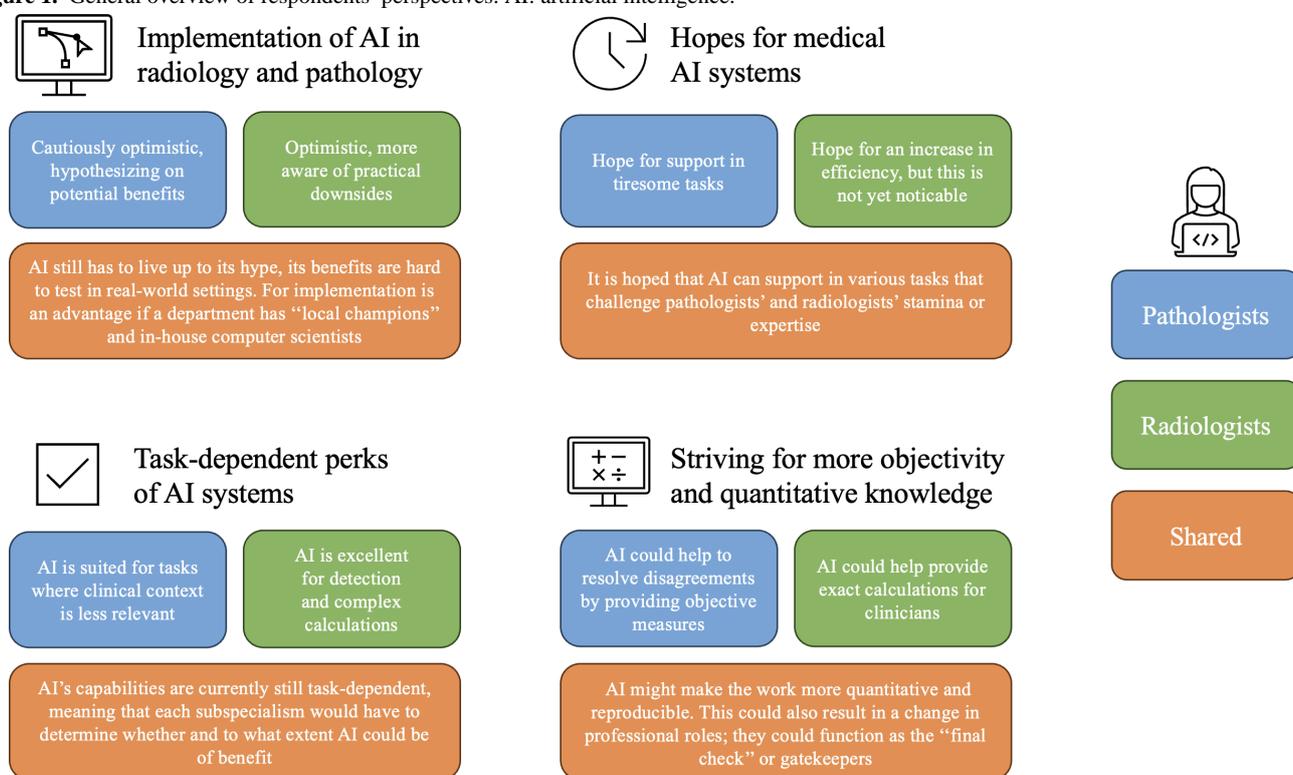

This study constitutes part of the Responsible Artificial Intelligence in clinical DecisIOn making (RAIDIO) study. Ethical approval for the RAIDIO study was obtained from the Medical Research Ethics Committee of the UMCU (WAG/mb/20/014090). The Medical Research Ethics Committee determined that this study was exempt from the Medical Research Involving Human Subjects Act. Written or oral

informed consent was obtained from all participating respondents. Data were deidentified through pseudonymization and stored in a protected digital environment of the UMCU. Participants of this study did not receive financial compensation.

Results

In total, 21 participants (7 pathologists, 10 radiologists, and 4 computer scientists) agreed to be interviewed, provided written or oral informed consent, and were included in this study. The following sections present how participants perceived current AI developments and AI’s promise for image-driven medicine; we pay special attention to similarities and differences between radiologists and pathologists (for an overview of respondents’ perspectives, see Figure 1).

Figure 1. General overview of respondents’ perspectives. AI: artificial intelligence.

Implementing AI in Radiology and Pathology

Respondents from both fields considered AI a novel technology. The extent to which participants could elaborate on technical or development issues of AI in their respective fields depended on their familiarity and previous experiences with these technologies. Nevertheless, it was striking that *all* respondents could refer to a landmark AI system as a point of reference; for the pathologists, this was a mitosis counting algorithm, and for the radiologists, it was a pulmonary embolism detection algorithm. To some extent, these 2 systems shaped the ways respondents envisioned future AI integrations in their departments. Because of the initial success of the mitosis counting algorithm, pathologists were cautiously optimistic about AI in their field. Many expected that other “simple” tasks could be supported or performed by an AI system, and some considered it a matter of time before applications for more

complex tasks would be developed. Most radiologists were also optimistic about AI systems, but multiple respondents referred to minor flaws in the pulmonary embolism detection algorithm when considering possible future AI applications. For example, although the accuracy of the detection tool was very high, they still had to actively verify the algorithm’s outcomes. Some also considered the notifications of possible pulmonary embolisms a disturbance to their workflow.

Both pathologists and radiologists, independent of their respective familiarity with AI, admitted that medical AI in practice had yet to live up to its hype. Besides the fact that it is technically complicated to integrate multiple AI systems into the workflow of professionals, another roadblock respondents mentioned was the difficulty in getting an AI system tested in real-world settings. As a pathologist (P7) described:

testing [the AI system] in the real world is something that is not standard practice, and you encounter all kinds of problems when you try to do it (...) [AI] functions suboptimally when employed outside the research setting.

Respondents mentioned that they were lucky to have computer scientists working in or with their departments who were available to help problem solve when integrating new AI systems into their daily practice. Respondents were aware that the close collaboration with data scientists made their departments unique. They considered their departments a “frontrunner” (P7) and example for other hospitals in regard to AI implementation. Both departments also had “local champions,” pathologists, or radiologists who were exceptionally knowledgeable about AI and could “speak the language” of medical specialists and computer scientists. These “local champions” helped accelerate the adoption of AI. As a radiologist (R8) described, AI implementation is site-specific:

In our hospital, some people are very invested in this topic. We probably encounter more changes than

other hospitals. It might go relatively quickly at our department.

For these reasons, the pathology and radiology departments of the UMCU may have a head start in working toward (more elaborate) AI implementation and are at a point in which they must decide how to proceed. In the following sections, we describe how pathologists and radiologists articulated the changes they were experiencing and how they envisioned AI’s impact on the future of their specialties.

Hopes for Medical AI

Most radiologists and pathologists in this study argued that AI could help improve medical care by supporting tasks that challenged their stamina or expertise. This is illustrated by an overview of AI systems that were present in the departments and which were referred to in the interviews (Table 2). These systems fall into one of three categories: (1) fixes for tiresome or time-consuming tasks, (2) support in cases where context and classification are challenging according to current standards, and (3) prognosis and therapeutic response (prediction) generators.

Table . Overview of AI^a systems at the radiology and pathology departments^b.

Field	Specific medical task	Potential role of AI algorithms	Relevant to which (sub)specialisms	Benefit mentioned by pathologists and radiologists	Level of risk involved	Stage of development
Pathology	Determining the aggressiveness of a tumor	Counting the number of mitoses on a digital slide Calculating the percentage of Ki67 positive tumor cells (proliferation index)	Pathology, medical oncology, pulmonary medicine, endocrinology, etc	Tiresome task, less subjectivity	Low—can be checked manually	Implemented
Pathology	Grading cancer; for instance, grading of breast and prostate cancer	For example, Bloom and Richardson grading score for breast cancer	Pathology, medical oncology, urology, etc	Tiresome task, less subjectivity	Low—can be checked manually	In development
Pathology	Analyzing the inflammatory response	Identifying as well as quantitative measurement of number and distribution of immune cells, for example, in/around tumors	Pathology, medical oncology, internal medicine, etc	Tiresome task, less subjectivity	Low—can be checked manually	In development
Pathology	Deciding whether to proceed to surgical (vs endoscopic) resection in case of early colon carcinoma	Analysis of tumor characteristics related to the patient's chance of developing (future) metastases of colon carcinoma	Pathology, gastroenterology, and surgery	Less invasive treatment for the patient, personalized medicine	High—not easy to check	Research phase
Pathology	Determining prognosis and treatment options for patients with cancer	Analysis of prognostic and (treatment) predictive tumor characteristics	Pathology, medical oncology, pulmonary medicine, etc	Less subjectivity, personalized medicine	High—not easy to check	Research phase
Pathology	Analyzing naevi and other melanocytic lesions on signs of malignancy	Analysis of characteristics associated with malignancy, providing reasons for why the sample is malignant or not, or calculate the risk of malignancy	Pathology, dermatology, and medical oncology	Less uncertainty about the diagnosis, learning from the algorithm	High—not easy to check	Research phase
Pathology	Generating the pathology report	Generating an initial pathology report for a pathologist to check	Pathology	Tiresome task, less variation in reporting style between pathologists	Low—can be checked and changed manually	Research phase
Pathology	Checking images on possible metastases in lymph nodes	Initial screening of lymph nodes on possible metastases	Pathology	Tiresome task	Low—can be checked	Research phase
Radiology	Confirm/rule out pulmonary embolism	Detect/rule out suspected pulmonary embolisms on dedicated CTPA ^c scans	Radiology, internal medicine, and cardiology	Faster diagnostic process in case of confirmed high accuracy	Low in terms of patient risk: dedicated CTPA are always checked for the primary rule out PE ^d question. But high level of trust required for benefit to be realized	Implemented

Field	Specific medical task	Potential role of AI algorithms	Relevant to which (sub)specialisms	Benefit mentioned by pathologists and radiologists	Level of risk involved	Stage of development
Radiology	Detect incidental pulmonary embolism	Detect incidental pulmonary embolism on CT ^e scans made for other indications	Radiology, oncology, trauma, internal medicine, cardiology, etc	Earlier detection of unsuspected PE in nonprioritized scans + increased detection rate of unsuspected incidental PE in general	Low—is primarily added value of current standard of care	Implemented
Radiology	Measure prostate in 3D and manually calculate both corresponding prostate volume estimate and its ratio with the plasma PSA ^f value to determine PSA density correlated with risk of prostate cancer being present	Measure actual prostate volume in 3D (+ provide PSA density)	Radiology, urology, oncology, and radiotherapy	Tedious and repetitive task	Low—volume calculation performed by AI and the corresponding segmentation on which the calculation depends is easily visually checked by the radiologist	Implemented
Radiology	Determine age of pediatric patient on the basis of hand x-ray	Independently perform the bone-age determination	Radiologists and pediatricians	Fully automated procedure	High—bone-age independently determined by AI—with only a visual check of the correctness of joint segmentation by the radiologist	Implemented
Radiology	Detecting and measuring lung nodules	Detecting lung nodules including quantitative 3D volumetry	Radiologists, pulmonologists, oncologists, etc	Tedious, repetitive task, and possible reduction in number of missed nodules	Intermediate—aids in detection, volume calculation more quantitative than radiologist, but correlation with prior scans (crucial for determining growths over time) still lacking in reliability and intuitiveness	Implemented
Radiology	Detecting cervical spine fractures	Detecting fractures in cervical vertebral bodies on CT scans that include the neck	Radiologists, trauma surgeons, orthopedic surgeons	Quicker diagnostic process—theoretically reduced number of missed fractures	Low—always checked	Implemented
Radiology	Quantify cerebral white matter disease	Quantifying the volume of white matter lesions on MRI ^g of the brain	Radiologists, neurologists	More quantitative and more reproducible measurements, including individualized comparison to reference standard	Low—correctness is easily and reliably visually verified	Research phase
Radiology	Working toward body composition–derived prognostication and personalized treatment	Quantifying the volume of multiple different muscle groups and of subcutaneous and visceral fat	Radiologists, any clinical profession ordering CT scans containing the abdomen	Impossible to perform by radiologists (far too time-consuming, would be hours of work per scan)	Low—with respect to the correctness of segmentations (important to understand that the prognostic application is not part of the AI output)	Actively used in research setting in clinical trials

Field	Specific medical task	Potential role of AI algorithms	Relevant to which (sub)specialisms	Benefit mentioned by pathologists and radiologists	Level of risk involved	Stage of development
Radiology	Working toward body composition for personalized drug dosing; from contrast agents to chemotherapeutics	Quantifying the volume of multiple different muscle groups and of subcutaneous and visceral fat	Radiologists, any clinical profession ordering CT scans containing the abdomen	Impossible to perform by radiologists (far too time-consuming, would be hours of work per scan)	High—while the segmentation is reliably verified, subsequent drug dose calculations require extensive validation	In development
Radiology	Segmenting the liver: both the organ and its internal liver segments for subsequent clinical and treatment calculation that depend on liver/segment volumetry	Segmentation of liver and liver segments	Radiologists, interventional radiologists, nuclear medicine, HPB ^h surgery, oncology	Time-consuming, tedious, task-automated, and made more reproducible	Intermediate—easily, visually checked, still requires some manual corrections	In development
Radiology	Working toward body composition for creatinine clearance calculations that are both more personalized and do not require 24-hour urine samples	Quantifying the volume of multiple different muscle groups and of subcutaneous and visceral fat	Radiologists, any clinical profession ordering CT scans containing the abdomen	Impossible to perform by radiologists (far too time-consuming, would be hours of work per scan)	High—while the segmentation is reliably verified, subsequent drug dose calculations require extensive validation	In development
Radiology	Deciding whether a patient undergoing a breast MRI for detection of breast cancer needs additional imaging or can exit the scanner	Triage of patients with and without possible breast cancer based upon the initial phases of enhancement directly after contrast injection	Radiologist, MRI technologist	Reducing examination time from ± 25 minutes to ± 5 minutes	High—not easy to check	In development

^aAI: artificial intelligence.

^bCheck for completeness by radiologists and pathologists working at the department.

^cCTPA: computed tomography pulmonary angiogram.

^dPE: pulmonary embolism.

^eCT: computed tomographic.

^fPSA: prostate-specific antigen density.

^gMRI: magnetic resonance imaging.

^hHPB: hepato-pancreato-biliary surgery.

The hope that AI can support or take over time-consuming tasks was especially prominent in the interviews. Many respondents were concerned about the increased work pressure, as clinicians often depend on radiologists' and pathologists' knowledge to diagnose and treat patients. One respondent (R7) described their relationship with clinicians as follows:

There is almost no patient who (...) is treated without scans. We are constantly discussing patients with [other] medical disciplines. These meetings cost a terrible amount of time. Everyone wants you to be at their beck and call.

Respondents appreciated that their fields were seen as essential to the medical system and that their perspectives were valued. Still, many worried about the workload and the limited time to assess cases, write reports, and prepare for multidisciplinary meetings. Pathologists and radiologists were optimistic about

AI's future role in time-consuming activities, such as tissue or tumor segmentations, calculation of abnormalities such as deviations in heart function, and detection of the evolution of brain metastases or the presence of tumor cells in lymph nodes. In other words, by supporting these kinds of tasks, AI could help them refocus on the more "enjoyable" aspects of the job, such as diagnosing complex disease patterns. As a radiologist (R9) mentioned:

It would be fantastic if part of our routine work (...) could be taken over. I hope that this will be possible in the future, so we radiologists can again focus on the fun things.

Nevertheless, some also worried that AI applications would not increase efficiency and might even cost them extra time; as one respondent stated:

In the meantime, the amount of scans increases, and I'll also have to manage the AI. That's something to think about. Eventually, we'll just be doing our jobs. But hopefully, the quality will become a little bit better. [R10]

Respondents thus speculated about the impact of AI on the work pressure they experienced. This was particularly apparent for radiologists who noticed that the pulmonary embolism algorithm resulted in a quicker diagnostic process. Using the algorithm also meant that they had to recheck a patient's images when notified of a possible embolism.

Task-Dependent Perks

Notably, radiologists and pathologists put their hopes of AI in perspective by remarking that it is task-dependent, meaning that each subspecialism would have to determine whether and to what extent AI could benefit their work. Besides naming technical hurdles, many respondents noted that the amount of input needed to make a diagnosis or prognosis would likely determine whether AI would be suitable for their diagnostic process. For instance, respondents did not expect AI to be able to make complex integrations between different sources of knowledge or to prioritize information. As R7 argued, work in the field requires:

Integrating everything you've learned in your medical education and training as a radiologist, (...) I sometimes wonder how AI could help me with this. I think it will be useless on this front. AI (...) doesn't know how to search through old reports and gather the relevant information for my scans. I think this will remain—as I currently see it—a skill particular to medical experts.

As the quote illustrates, respondents questioned whether AI would be useful when a radiologist or a pathologist had to determine which information was relevant for interpreting a medical image, a common practice in all but the most straightforward cases. Although some respondents mentioned that AI could provide a differential diagnosis based on context-related information (eg, age, gender, or laboratory results), many doubted whether AI could prioritize or “weigh” this information in the same way they did. As one pathologist (P1) commented:

I think that context certainly matters. AI could go wrong because it insufficiently weighs the context. (...) Plus I also think a lot of histological images look similar. But the clinical context of one patient may be very different from another patient and will result in another diagnosis, even when the images look completely the same. (...) One histological image could indicate 20 different clinical diagnoses, especially if you're looking at images of inflammatory disease. This won't be easy for AI.

Radiologists and pathologists often viewed “real interpretation” (R3) as something exceeding the capabilities of AI. They mentioned that AI could be good at detecting certain things (such as lung nodules or other conspicuous manifestations of cancer) and might even gain an “associative capacity” (R1)

similar to their own, but that it would increase their workload if adopted in areas where they did not need it. Some respondents had not ruled out the possibility of AI becoming better at specific, well-defined “expert tasks” and found it an exciting thought that AI could become more competent than humans in the interpretation process. Nevertheless, respondents also stated that it would be hard for an algorithm to learn to independently evaluate pathological processes with respect to the clinical context, making many of the potential uses for AI more speculative than an inevitability.

Striving for More Objectivity and Quantitative Knowledge

Although there were varying views on the tasks best suited for AI, many radiologists and pathologists stated that AI could improve the quality of their work. This was often mentioned with the expectation that AI might make the work less “subjective” and more quantitative and reproducible. For instance, pathologists, in particular, talked about the possibility of AI (sometimes referred to as “the computer”) helping resolve disagreements in their fields by offering an additional, objective interpretation of medical images. As one pathologist (P5) stated:

If you have a tumor cell with a nucleus that is a little bit enlarged, one pathologist could say something like “alright, it's probably reactive,” and the other pathologist says “oh no, it is malignant.” But a computer could precisely measure the nucleus and determine “Okay, there is a lot of chromatin, it is irregular, this is the intensity of the chromatin.” These are all objective measures by which you could say whether it is benign, malignant or reactive.

Multiple respondents also discussed a potential beneficial characteristic of AI, namely, that it could keep track of minute details in medical images. It might, therefore, become better than humans at recalling and comparing image characteristics.

AI was also described as a tool to help radiologists and pathologists better understand the data by quantitatively measuring multiple aspects of medical conditions. AI systems have already been designed to compute a patient's fat and muscle mass, the amount of white matter in the brain, the volumes of various parts of the brain, and the histological parameters of a tumor. Some participants mentioned that these AI applications mirror a broader trend in radiology and pathology to approach medical findings in a more quantitative manner. A radiologist (R8) described this as an ongoing shift in the way medical images are used in the field, adding: “It's not just about the interpretation of images, but also the generation of scores and the production of numbers.” Some radiologists also referred to clinicians' wishes that they provide exact calculations. One radiologist (R5) even called this “the ultimate goal” of their specialism: to precisely identify a patient's condition for the clinician. Many respondents mentioned that such quantitative measures might also lead to more reliable and precise prognoses by giving the clinician more relevant information to determine a patient's treatment.

Both pathologists and radiologists also reflected broadly on how AI might change how they form medical judgments. While

some radiologists imagined that they would become “data specialists” (R8) or “translators” (R4) who would mainly check the algorithms’ reports, most radiologists and pathologists were inclined to describe themselves as the “final check” or gatekeeper. In other words, they were comfortable letting AI do some of the primary work but wanted the medical specialist to make the final judgment and bear the responsibility for the diagnosis. We observed some slight differences between radiologists and pathologists regarding the role of AI in their specialism. Radiologists seemed more inclined to describe specialism-wide changes initiated by AI and viewed AI as a more significant force that could become an integral part of their specialization. Pathologists primarily focused on AI as an innovation from which they could learn. Respondents from both fields indicated that they were unsure of the ultimate impact AI would have on their specialisms, and when asked for their expectations for the coming 10 years, most replied that they did not expect any fundamental changes to their professional roles or responsibilities.

Discussion

Principal Findings

This qualitative interview study investigated how professionals from the 2 most image-driven medical specialisms perceive the promise of AI for their respective fields. Overall, our analysis shows that pathologists and radiologists have comparable views on AI’s possible benefits and drawbacks. Differences between radiologists’ and pathologists’ perspectives were mostly a level of degree; for instance, the use of AI for quantification purposes seems to be somewhat more pronounced in radiology. One reason for this discrepancy might be that the radiology department in our study currently has more experience with implementing AI systems in practice.

The radiologists and pathologists in our study echoed some of the findings of earlier empirical studies concerning the potential of AI in these fields. Respondents in this study also argued that AI could provide them with quantitative data [11] and were interested in AI systems that could perform simple yet time-consuming and repetitive tasks [12]. However, they also worried that AI could result in more work [11] and hypothesized that AI would be less suitable for complex, variable, or intellectually challenging tasks [31]. Respondents from both disciplines (irrespective of their experience with AI) also cautioned about overstating the benefits of AI and tried to shift the focus to task-specific advantages. This resembles the results of the study by Hendrix et al [14], where respondents emphasized that AI-based decision support is contingent on its specific features and functionality. In our study, most respondents had a positive yet realistic view of AI, keeping in mind the current limits of AI and roadblocks for successful implementation.

As our findings reflect the unique combination of pathologists’ and radiologists’ perspectives from a technologically innovative academic medical center, the interview data can indicate how to proceed with the implementation of AI. In the following sections, we discuss the implications of our findings in relation

to broader questions about AI integration within image-driven medicine.

Will AI Reduce or Increase the Workload of Image-Driven Professionals?

Radiologists and pathologists in this study often mentioned that their workload had expanded over the last decades and that they increasingly participated in multidisciplinary meetings. Therefore, many respondents expressed the hope that AI would help them tackle their demanding workloads. This is consistent with other studies and literature, which point to the possibility of designing AI for the most tiresome and repetitive tasks in radiology and pathology [32-35]. Both radiologists and pathologists in this study mentioned that AI had already been developed for several time-consuming tasks in their departments, and some also hoped that AI would someday help them write their reports.

At the same time, many respondents questioned AI’s ability to contribute to increased efficiency. Many studies confirm that AI should not be considered an augmentation or support tool, not a direct replacement for pathologists or radiologists [36,37]. AI involvement would also result in new tasks for professionals, such as validating AI systems and checking outcomes. Professionals would also have to become more skilled in dealing with AI in their daily work. The amount of extra effort it costs to work with AI highly depends on the specific task and the trust radiologists and pathologists have in the algorithm’s functioning. This was illustrated by respondents’ emphasis that they wanted to remain involved in the final medical conclusion. A similar argument can be found, for example, in the study by Ranjan et al [37]. Literature on the successful adoption of AI in clinical workflows often stresses that physicians should have epistemic trust in AI functioning, adding that many open questions still exist on the level of control physicians should have over AI [38] and which kinds of outcomes physicians should trust [39,40].

The results of this study have highlighted the dichotomous role AI could play in the high workload of professionals working in image-driven fields; they also point to the importance of contemplating the amount of work AI could and should impose. Although AI could create welcome changes in the workflows of these professionals, it also has the potential to become another technology for them to manage and may not always be a legitimate aid to their already busy schedules.

What Will AI Mean for the Future of Radiology and Pathology?

Many authors contend that AI could lead to significant changes in the professional roles of radiologists and pathologists [6,41-43], and some have even argued that the fields will eventually merge to become the “information specialists” of the medical system [5]. In this study, participants shared the belief that AI could greatly impact how they perform their work and could change their professional roles. At the same time, they emphasized that many of these changes were speculative and unlikely to occur soon.

Because of the speculative nature of the grander promises of AI, Saboury et al [44] argue that “it is critical to improve our

understanding of the pitfalls of deep learning and maintain a healthy and constructive skepticism as we explore the tremendous potential of the technology.” Karhade and Schwab [45] also state that this kind of “healthy skepticism”—along with engagement and collaboration with technical experts—can support “the development of AI systems that complement and expand our abilities to diagnose, predict and operate,” help sustain informed dialogue, and ask the right questions concerning the use of AI in clinical practice. Therefore, it may be essential to focus on the actual impact AI can have on radiology and pathology and maintain a skeptical attitude in order to ultimately maximize the advantages of AI. For now, this could also mean focusing on AI’s task- and specialism-dependent benefits rather than its broader potential for integrating multiple medical specialisms—even though bridging disciplinary boundaries between radiology, pathology, and other medical fields may eventually benefit the quality of care [46,47].

How Can We Incorporate Critical Voices in AI Innovation?

There is currently a push toward AI in image-driven diagnostics, illustrated by assertions such as “radiologists who use AI will replace radiologists who don’t.” [48,49] Yet, the question is, who are the radiologists (and pathologists) who do not want to use AI? Who is going to be replaced? The positive voices about AI still outweigh the more critical voices in existing qualitative interview studies [50,51], and it is hard to find medical professionals who contest the possible advantages of using AI in image-driven medicine. Although those who refuse to work with AI altogether may be a relatively small group, we noticed in our recruitment process that professionals who were less convinced of the benefits of AI or were working in subspecialisms less suited to AI were more reluctant to participate in our study than individuals who were already involved in the validation and implementation of AI [9]. We successfully recruited some individuals with skeptical views but were unable to include those few radiologists and pathologists who remained unwilling to consider the potential of AI for radiology and pathology.

While not everyone has to participate in the debate about medical AI, it is important to be aware of the possibility of perpetuating existing bias in empirical studies about AI. Concerns about the issues that could arise by using AI (such as deskilling and the effects of changing practice patterns on AI) [52] persist; we, therefore, urge radiology and pathology

departments to create ways to include critical voices in the development of AI in their fields. Accelerating AI integration could force some professionals to use it even when they believe their field “is not ready for AI” [53]. Ideally, consideration should be paid to how *all* users respond to and can accept the involvement of AI in their workflows. As Krupinski [54] formulates:

Technology development and deployment are critical to improve patient care, health outcomes, and the efficacy and efficiency with which our health care systems achieve these goals, but it cannot take place without considering how it will be accepted and integrated in routine daily use by all stakeholders.

Although there may be practical roadblocks to ensuring all voices are represented, inclusive communication will help ensure that more specialists are familiar with specific AI systems; this will also ease the transition to using AI in their workflows. A broad representation of perspectives could also benefit developers by supporting them in detecting blind spots in the design and implementation of medical AI and might facilitate trust in the development process.

What Could Future Research on AI in Image-Driven Specialisms Focus on?

Besides the importance of maintaining healthy skepticism and focusing on the inclusion of critical voices, this study offers additional recommendations for future research. Future research could, for instance, repeat this study when (both) departments are further along in integrating AI into their workflows. Our study was limited in the sense that, although we selected departments that were relatively far along in implementing AI, the integration of AI in health care is generally still in its early phases. This meant that some questions were answered hypothetically. We expect that perspectives will become more concrete when AI becomes more thoroughly implemented into these specialisms. Another consideration for future research is that it is unclear whether the perspectives mentioned here would also apply to the implementation of AI in low-resource settings. We consciously focused on the integration of AI in 2 high-resource departments, which made the perspectives on AI between these departments more comparable and likely also with other high-resource settings. Yet, it is essential to state that the results of this study should not be taken at face value for low-resource deployment environments [25]. Further research is necessary to determine the extent to which the perspectives presented here are also mirrored in low-resource sites.

Acknowledgments

This study was funded by the Dutch Research Council (Nederlandse Organisatie voor Wetenschappelijk Onderzoek, NWO; project 406.DI.19.089). We extend our gratitude to our fellow RAIDIO project members, Sally Wyatt and Flora Lysen, for the valuable collaboration and insights that significantly supported writing this article.

Abstract

Background: General medical practitioners and other staff at primary care medical practices have an important role in facilitating patient access to online services in the National Health Service in England. These services range from online ordering of repeat prescriptions to conducting online consultations with health care professionals. We have defined "digital facilitation" as that range of processes, procedures, and personnel that seeks to support patients in their uptake and use of online services.

Objective: We report how we have synthesized the evidence from a mixed methods study of digital facilitation in primary care in England. The study's objectives were to identify, characterize, and explore the benefits and challenges of different models of digital facilitation in general medical practices in England and to design a framework for evaluation of the effectiveness and costs of digital facilitation interventions.

Methods: Our study comprised scoping review of literature, survey of staff in general practices, survey of patients, and ethnography at case study practices plus stakeholder interviews. We compiled a triangulation matrix of the findings from individual work packages through an iterative process whereby each work package's results were first analyzed separately and were then cumulatively combined across work packages in 3 successive workshops. From the resulting matrix, we developed a program theory and an implementation theory and constructed a framework for evaluations of digital facilitation in primary care. The final step of the synthesis process was to discuss the results with national and regional National Health Service stakeholders.

Results: Triangulation yielded a combined set of findings summarized within 11 thematic groupings: 3 setting the scene within which digital facilitation takes place, and 8 related to different types of digital facilitation, their implementation, and effectiveness. Some thematic groupings were evident in the findings of all 4 of the research work packages; others were not addressed in all the work packages but were evident from those where they were addressed. Throughout the synthesis, there were no instances where findings from one work package contradicted the findings of another. Findings either reinforced each other or offered complementary or additional insights. The discussion at the stakeholder meeting held at the end of the study resulted in the research team clarifying some findings but not changing any of them.

Conclusions: Digital facilitation can take many forms, though much of what is currently done in primary care practices in England is reactive and passive. Clear lines of responsibility, digital tools and platforms that work well for patients and practice staff, and investment in staff time and training are all needed if digital facilitation is to deliver on its promise. We propose a framework for future evaluations of the effectiveness and costs of digital facilitation interventions.

Introduction

The National Health Service (NHS) offers all UK residents primary care physician services delivered by general medical practitioners (GPs). GPs work in local practices in multidisciplinary teams with nurses and other health care professionals such as health care assistants, pharmacists, and paramedics, all supported by staff and administrative and reception staff. Each individual patient registers with a GP practice of their choice, usually near to where they live, and the practice is funded via a capitation fee and other payments from the NHS; GP services are free of charge to patients. That practice is responsible for their registered patients' care. GPs and other primary care staff consequently have an important role in facilitating access to the growing range of digital NHS services. It is crucial to note that colloquially within the health service in England, patient-facing services that use the web are known as "online services" [1] but that at policy level and in the academic literature, these services are among what are referred to as "digital" services [2], with digital used as an umbrella term. As a consequence, we use the 2 terms within this paper applying the term "online" when referring to the use of services within general practice in the NHS in England, and "digital" to refer to the wider context.

This paper reports how we synthesized the evidence from multiple parts of a mixed methods study of such "digital facilitation" in NHS primary care in 4 regions of England [3] and the overall findings of that synthesis.

Health care policy in England, in common with many other countries, highlights the role and potential of digital services for patients. There have been increasing contractual requirements for GPs to offer and promote a range of online services following the publication of the NHS Long Term Plan [4] and associated 5-year framework for GP contract reform [5] in 2019. Online services in primary care range from ordering repeat prescriptions, viewing test results, and booking appointments with primary care professionals, to online consultations between patients and doctors. There is considerable diversity in the online services offered across more than 6000 general practices in England. The move to increase reliance on online means of accessing services stems from assumptions that they improve choice, convenience, and ease of access for users; improve triage systems; and streamline service delivery [6-8]. The exigencies of the COVID-19 pandemic from March 2020 onward reinforced and accelerated this initiative [9]. Increased emphasis on many types of digital services has occurred in many jurisdictions [10], associated with the development of policy responses to support the continuing use and growth of such services. In New Zealand, for example, there has been recognition that a longer-term strategy is needed to provide comprehensive and less fragmented digital services in primary care [11].

Offering digital services is not enough to ensure that people use them. Patients may need encouragement and help engage with and use digital services. Our research addresses the experience and future potential of digital facilitation by GPs and other practice staff (ie, providers of primary care). We have defined

"digital facilitation" as that range of processes, procedures, and personnel, which seeks to support patients in their uptake and use of online services. This is a pragmatic definition intended to include actions that specifically support patients to take up and use online services already available within the NHS. Although our study focuses on primary care in England, it has relevance for any health care system offering digital services to patients. A scoping literature review undertaken as the first stage of our research found international evidence that digital facilitation can be effective [12].

Our research had 2 principal aims overall: first, to identify, characterize, and explore the potential benefits and challenges of different models of digital facilitation in use in NHS primary care practices in England; and second, to design a framework for future evaluations of the effectiveness and costs of such interventions.

Methods

Overview

We conducted four main, interrelated research work packages over the period 2020 - 2022: (1) a scoping review of literature [12] to determine the types of digital facilitation relevant to primary care, their effectiveness, and cost-effectiveness; (2) a survey of staff in 156 general practices in 4 regions of England: East of England and North London, North-West, South-West, and West Midlands; (3) a survey of 3051 patients from a sample of general practices in East of England and North London, South-West, and West Midlands; and (4) qualitative exploration, based on rapid ethnography undertaken at 8 case study practices and 19 additional interviews with senior stakeholders, to understand in-depth and from the perspective of staff, patients, and other stakeholders the benefits and challenges of different models of digital facilitation. Full details of the methods and findings of each work package are presented elsewhere [3]. This paper focuses on how we have synthesized the evidence from the 4 work packages and the implications of that synthesis.

We have used as our theoretical framework Weiss's approach to theory-based evaluation [13]. The essence of our approach was to compile a triangulation matrix [14] of the findings from individual work packages. The matrix was developed in an iterative process that exploited the staggered completion of the different work packages. First, the researchers for each work package analyzed their findings. The work package findings were then brought together and analyzed cumulatively in a series of 3 half-day workshop meetings of researchers from the relevant work packages and members of the public. Two of the researchers who participated in all 3 workshops were part-time staff in general practices, 1 as a GP (JC) and 1 as an administrator (RW). Among the other participants were members of the patient advisory group established for the research project. Briefing material was circulated to all participants in advance and plenty of time was allowed at the start of each workshop for discussion and clarification of that material. In each workshop the participants identified themes arising from the developing data set and discussed how different sources of evidence reinforced, added to, or differed from one another in their findings.

The first synthesis workshop took place online in November 2021. Nine researchers and 3 patient advisory group members analyzed the findings from the practice survey and the scoping literature review. At the second synthesis workshop in July 2022, also online, 12 researchers and 3 patient advisory group members added the emerging findings from the qualitative research. The final synthesis workshop was held in-person in September 2022 and involved 15 researchers and 3 patient advisory group members, bringing together the entire evidence set from all work packages. The output from the third workshop was an agreed set of 11 thematic groupings identified from the evidence.

Following Weiss's approach [13], we used this knowledge to develop a "program theory," which specifies the mechanism of change, and an "implementation theory" of how digital facilitation is operationalized and what facilitates or hinders its implementation. From the 11 thematic groupings, the program theory and implementation theory, and with reference to UK Medical Research Council guidance on evaluating complex interventions [15], we then constructed a framework for future evaluations of digital facilitation approaches in primary care.

The final step of the synthesis process was to discuss the themes, program and implementation theories, and evaluation framework at an online meeting in December 2022 with representatives of NHS stakeholders at national and regional levels. The participants were from the national body responsible for the operation of the NHS in England (NHS England); the national body specifically responsible for implementation of digital health care services (a part of NHS England); and one of the 42 integrated care boards, which are NHS bodies responsible for commissioning and coordinating health services at a regional level. We shared findings and invited the challenge and review of participants, considering whether change in findings, interpretation, or emphases was warranted.

Ethical Considerations

Ethics approval was obtained for the patient survey and ethnographic case studies within the research project from the North East—Newcastle and North Tyneside 2 Research Ethics Committee on April 27, 2021. Health Research Authority approval was obtained in July 2021 (IRAS number 289425, protocol number L01886). All methods were carried out within the ethical and data governance guidance overseeing this project. This research was carried out in compliance with the World Medical Association Declaration of Helsinki. Ethics approval was not required for the practice survey element (as advised by the Health Research Authority) because the survey did not intend to change practice or patient care. Patients were deemed to have consented to participate in the patient survey if they returned a questionnaire either by post or online (implied consent). The research team did not ask for any personal data from survey participants, although participants could provide their contact details (which were kept separate from other survey data) if they wished to take part in the prize draw. Information on processing of personal data on the participant information sheet provided an explanation of our approach to handling personal data. Practices responding to the practice survey were entered into a prize draw for 1 of 10 £250 (US \$316) vouchers. A

voluntary prize draw for 1 of 10 £25 (US \$32) vouchers was offered as an incentive for patients participating in the patients survey. Potential patient survey respondents were informed that consent would be assumed upon return of a questionnaire either by post or online. Analysis of General Practice Patient Survey data was deemed service evaluation not requiring ethics approval.

Results

Themes

Overview

The detailed results from the literature review, practice survey, patient survey, and qualitative research are reported elsewhere [3,12]. Triangulation of the results from these sources yielded a combined set of findings summarized within 11 thematic groupings: 3 of them setting the scene within which digital facilitation takes place and 8 related to different types of digital facilitation, their implementation, and their effectiveness. Some of the themes (we use this shorter notation from here on) were evident in the findings of all 4 of the research work packages. Other themes were not addressed in all the work packages but were evident from 1, 2, or 3 of them. Throughout the synthesis work, there were no instances where findings from one work package contradicted the findings of another. Findings either reinforced each other or offered complementary or additional insights. The discussion at the stakeholder meeting at the end of the study resulted in the research team clarifying some of its findings but not changing any of them.

The 11 themes are described in turn in the following paragraphs. We first present the 3 scene-setting themes. These were identified from the qualitative exploration. Thus, they emerged from the discussion in the second synthesis workshop—when the emerging results of the qualitative exploration were added into the evidence synthesis process. The third scene-setting scene, related to COVID-19, had also been implicit in some of the practice survey data that reflected the major changes that primary care underwent in response to the pandemic, including reductions in face-to-face consultations and increased reliance on remote methods of ordering prescriptions, for example. The sources that led to the generation of the other themes are explained for each theme in turn.

Theme 1 (Scene Setting)

The *value and purpose of digital services* determines the usefulness of facilitating use of those services. Our qualitative research found that the value of some digital services, and what they are expected to achieve, is not always clear to primary care staff or patients and views and understanding about the value and purpose of such services may differ.

Theme 2 (Scene Setting)

"Digital" conflates online with other routes to access primary care. The qualitative research showed that while patients are greatly interested in navigating the system to gain access to health care, the distinction between "online services" and other access routes may not be important to them. Indeed, any way

of accessing primary care remotely is sometimes seen by patients as “digital,” including telephone consultations.

Theme 3 (Scene Setting)

Our survey of GP practices confirmed that the *COVID-19* pandemic and the measures taken in response to it had led to major changes in primary care, including much-increased reliance on remote ordering of prescriptions as well as remote consultations. The qualitative research at case study sites found that at the same time as the need for digital facilitation increased, the pandemic led to the cessation of some digital facilitation initiatives (such as using tablet computers to sign patients up to online services while they sat in the practice waiting room).

Theme 4

Defining and identifying digital facilitation: at the beginning of the study, the research team had defined “digital facilitation” as stated earlier and based the literature review on this, but practice staff may have different definitions. The practice survey, considered with the literature review findings at the first synthesis workshop, revealed that in some practices ad hoc facilitation efforts, such as receptionists answering queries from patients about using online services, would not be seen as digital facilitation but in other practices they would be. The patient survey and the qualitative research then added to this theme by showing that patients may not be aware of digital facilitation per se.

Theme 5

Types of digital facilitation can be active or passive, reactive, or proactive. This was already clear after the literature review and hence the range of types of digital facilitation was already an emergent theme at the first of the 3 synthesis workshops. We revisited the typology at each subsequent synthesis workshop. An example of active digital facilitation is a member of a practice’s staff recommending to a patient that they use an online service and showing them how to do that. A poster in a waiting room, or a message played to callers to the practice’s telephone line, is passive facilitation. Helping patients only when they ask for assistance is reactive, whereas offering help before it is sought is proactive. Our literature review found that most published studies concern active digital facilitation, while respondents to our survey of GP practices more commonly reported passive and reactive approaches rather than active and proactive, and this was borne out by the qualitative study. The survey of patients demonstrated low awareness of any type of digital facilitation taking place, alongside an often-unfulfilled wish for proactive support to use online services.

Theme 6

Supporting *initial sign-up to online services versus sustained use* thereafter: the literature we reviewed implies that most digital facilitation is focused on achieving initial patient sign-up, rather than supporting sustained use thereafter. The questions we asked in the practice survey were about digital facilitation in general and did not ask separately about support for ongoing use of online services as compared with supporting initial registration to use those services. Our qualitative research findings, added at the second synthesis workshop and confirmed at the third, are consistent with this: digital facilitation by

primary care practices more often concerns getting people signed up rather than providing ongoing support to patients subsequently. The patient survey results, discussed at the third synthesis workshop, showed that initial registration for an online service in general practice can be a hurdle for patients.

Theme 7

Who delivers the digital facilitation was not a focus of the literature found in our review. However, the examples in the literature mostly refer to primary care physicians and nurses helping with digital facilitation. Our survey of practices found that GPs and practice staff view the responsibility for digital facilitation as shared between practices and other parts of the NHS regionally and nationally, and that within practices it is the administrative staff who provide most support. Our qualitative research, discussed at the second and third synthesis workshops, found a “bystander effect”: different staff groups, patients, and other stakeholders identify other groups as being responsible for digital facilitation. NHS stakeholders at national and regional levels placed responsibility with clinicians and other practice staff. Primary care clinicians seem to place responsibility on practice reception staff (and on patients to sort themselves out); patients viewed it as the responsibility of the NHS more widely.

Theme 8

Enablers of digital facilitation were referred to in many papers in the literature we reviewed. Enablers include staff and patients’ perceptions of the usefulness of the online services, along with the user-friendliness of the digital platforms that patients are to use. The practice survey results, discussed at the first synthesis, found that the majority of practices had positive perceptions of online services (that they lead to operational efficiencies). The qualitative exploration found other enablers of digital facilitation, all also mentioned in the literature, including funding or paid time for staff to deliver the facilitation, expectation that an online service will be useful to patients or bring operational efficiencies for the practice or both, the existence of guidelines, 1 or more of the practice staff having specific responsibility for digital facilitation, and patients’ trust in practice staff. The patient survey found that only 13% (392/2935) of patients reported having been given help to use online services but also yielded suggestions for enabling digital facilitation.

Theme 9

Barriers to digital facilitation can include staff attitudes toward online services and stereotyped assumptions about the capabilities of some patients, such as the elderly. The multiplicity of different platforms for online services makes digital facilitation more difficult. The literature review highlighted the need for staff time and capacity to deliver digital facilitation, and the practice survey found that most practices consider that they lack the staff time and ability to sufficiently support patients in using online services. Our qualitative research confirmed the existence of all these barriers and also found that digital facilitation can be a low priority for practice staff. The patient survey found that some patients are unaware of online services and others are unhappy about them and resist using the services regardless of facilitation efforts.

Theme 10

Inequalities in digital access and digital facilitation between subgroups in the population: we found little information in the literature about how well digital facilitation works for different population subgroups, although some literature pointed out the risk of practice staff concentrating on the most digitally literate patients and neglecting others who might be in more need of support. In our practice survey, we asked whether digital facilitation was particularly focused on any subgroups of the population. Practices responding frequently reported targeting digital facilitation at older adults. The qualitative research reinforced that a patient's age may be assumed (not necessarily correctly) by staff to be an indicator of digital competence. But many practices also reported "targeting" all the other patient subgroups suggested in the questionnaire, which calls into question what such "targeting" amounts to. The patient survey found that older patients were less likely to be aware of or use digital facilitation.

Theme 11

Effectiveness of digital facilitation: the literature review revealed examples of where digital facilitation had successfully encouraged initial registration with online services, including when GPs and other practice staff personally recommend online services and when practices run introductory sessions for patients. Ongoing guidance and support that is delivered within primary care consultations may be effective not only in increasing initial registration with online services but also in sustaining their subsequent use [12]. We did not address this theme in our survey of practices, which was more concerned to identify the extent and type of digital facilitation activities being undertaken, and enablers and barriers for such activities. The qualitative exploration, discussed at the second synthesis workshop, found that some practices highlight how many patients sign up to online services as evidence of effectiveness—but without knowing the contribution to that of digital facilitation efforts. Our patient survey findings, discussed at the third (final) synthesis workshop, suggest that practices that report using displays, social media, workshops, or events for digital facilitation were more likely to have patients who are aware of and use digital facilitation. We found no such difference, however, for practices that use leaflets, text messages (or emails), or online approaches to digital facilitation for use of online services. Practices that use a "practice champion" for online services have more patients who report being told about such services than other practices.

Program Theory

From the findings of our research as captured in the 11 themes, we developed the program theory using a realist approach to describe provision of digital facilitation in terms of the context in which it takes place, the flow of activities comprising the intervention, and the theory and assumptions underlying the intervention, including the intended outcomes.

Digital facilitation in primary care in England takes place in a context of NHS policy to encourage greater use of digital services, which are seen as a way to improve patients' access to care, improve triage systems, and streamline service delivery. But our research found that practice staff and patients do not

always share this view of the value of online services, which makes it challenging to facilitate their use. The context of digital facilitation is also characterized by a multiplicity of platforms for delivering online services. Individual GP practices choose which to use, and the result is a patchwork of different systems and approaches. The COVID-19 pandemic and the measures taken in response greatly accelerated the introduction and use of online services. Our qualitative research found that at the same time some practices stopped providing digital facilitation activities during the pandemic and did not resume them.

The activities that could comprise digital facilitation are varied. Active forms of facilitation include practice champions, training, and workshops. Passive forms include informational leaflets, text messages, and recorded messages on practices' telephone lines. We found that most facilitation is reactive, relying on the digital skills of practice staff—especially reception and administrative staff—to respond to a patient's immediate needs, rather than forming part of a wider effort to enable participation in a health service that increasingly relies on online services. There is evidently some confusion over who has responsibility for supporting patients to use online services. Although practice staff are largely undertaking the digital facilitation that is taking place, they and patients saw a role also for other parts of the NHS at regional and national levels, for example, to tackle the need for wider efforts to educate patients about the benefits of booking appointments online.

Digital facilitation can help patients both directly—to access services such as ordering repeat prescriptions online—and indirectly—by making them more confident users of online services. Our research has shown that the pathways linking digital facilitation to expected beneficial outcomes can be complex. Patients want help to access care and not necessarily help with online services. It is, therefore, unsurprising that we found that digital facilitation is frequently just responding to immediate issues of patient access rather than being aimed at building patients' capacity to access and continue to use online services generally. The path from digital facilitation to its hoped-for benefits requires not only that patients sign up to online services but also that they continue to use them thereafter. Digital facilitation needs to be focused on the latter rather more than is currently the case. Digital facilitation could also be more responsive to inequalities in accessing NHS online services. Our survey showed that practices are aware of the need particularly to support older age groups, non-White ethnicities, lower socioeconomic groups, those in poorer health, and those in rural settings, who may struggle to access digital services. But it was unclear in what ways digital facilitation was being tailored for such patients. Our survey of patients found that ethnic minorities and those for whom English is not a first language are more likely to be aware of and use digital facilitation. However, we also found that older patients are less likely than others to be aware of, or make use of, digital facilitation and (with assumptions made by staff about the impact of older age) are less likely to be told about digital services or helped to use them.

Implementation Theory

Implementation of digital facilitation varies across general practices, both in the capacity to provide it and in the types of facilitation used. Practice populations also differ—for example, in health needs, age structure, and ethnicity—and hence have varying needs for digital facilitation. Within themes 8 and 9 we describe the range of enablers of, and barriers to, implementing digital facilitation. The staff time and resources available to a practice clearly are a major constraint. Most practices we surveyed felt that they had insufficient capacity to provide digital facilitation to the extent they would like. Reactive and passive approaches are more commonly used and they require less staff time (at least in the short term) than more active approaches.

The quality and usefulness of online services as perceived by practice staff and patients affect how, and how far, digital facilitation is implemented. Online services that are easy to use and with clearly apparent benefits require less facilitation effort. For example, repeat prescription ordering online was found in our patient survey and qualitative case studies to be relatively well used. Our qualitative research indicated that issues with more difficult to use services are seen by staff as not their responsibility to resolve. The diverse and changing mix of online services not only presents challenges to patients in understanding what is available and with what support but can also create issues for staff in maintaining knowledge of the online services and the requisite skills to provide facilitation.

Unclear lines of responsibility can also hinder implementation. Practice staff, patients, and other stakeholders (suppliers of digital technology; other parts of the NHS) may each assume that some responsibility for digital facilitation lies with other parties. When no one considers it their responsibility to support patients with broader issues of digital access such as digital literacy and confidence, then these aspects are likely to be neglected. In general, implementation would be aided by all members of staff in a general practice having a clear, shared understanding of what digital facilitation its patients need and how to deliver that.

Evaluation Framework

One aim of our research was to design a framework for future evaluations of the effectiveness and costs of digital facilitation interventions. Based on our synthesis of the findings from all 4 work packages, we propose an evaluation framework consisting of 4 aspects. The high-level nature of the proposed framework reflects what we have learned about the awareness and extent of digital facilitation in the NHS in England. The implementation of future evaluations will require engagement with all stakeholders and with policy makers. Within the bounds of timescales and funding available, an iterative approach to evaluation, with progressive and cumulative learning, is, as ever, desirable.

1. Digital facilitation as an intervention: digital facilitation may be defined as support to enable patients to achieve access to care services digitally. Many types of digital facilitation interventions are possible, are not mutually exclusive, and are often complex [15].

2. Responsibility for digital facilitation: clarity about who is responsible for (which) digital facilitation is key to it happening: which practice staff are responsible and how this fits with their role; what is expected of patients; are any third parties (eg, technology suppliers and charities working with patients) involved in delivering or supporting digital facilitation and how do they interface with practice staff and patients; and how does digital facilitation fit into the wider health care community beyond general practice?
3. Patient groups and potential for inequalities: for which groups of patients is digital facilitation most needed; do such groups differ in the extent to which they would benefit from, or be burdened by, online services and will they have different views of the importance of online services; and which types of facilitation are most effective for which groups?
4. Outcome and cost measures: Potential measures of outcomes (intended and unintended) include the following and should be collected in a way that permits determination of inequalities between subgroups in the population: patient awareness of, registration with, and sustained use over time of digital services; measures of access to GP services and rates of digital access within that; patient-reported experiences of engaging with facilitation and of the online services used; practice staff-reported experiences with facilitation (ease of delivery, impact on workload, and views on whether it is working); costs to general practices of digital facilitation (training, staff time, materials, and equipment); costs or savings to practices from changed use of online services by patients; costs or savings to the rest of the health care system; and costs or savings (money and time) to patients from using online services. Within the bounds of feasibility and funding, the longer the period over which outcome and cost data can be collected the more complete will be the understanding of longer-term impacts.

Discussion

Principal Findings

To the research team's knowledge, our research is the first to explore the range and extent of digital facilitation in primary care in a health care system. We have found that the digital facilitation being provided by general practices varies from place to place but is often passive and reactive, rather than active or proactive, and is focused on immediate difficulties rather than on broader and longer-term support for patients generally to use online primary care services. By identifying themes emerging from our findings when taken together, we have developed a program theory and an implementation theory of digital facilitation in primary care, which in turn have enabled us to construct a framework for future evaluations. These lead collectively to the following implications for policy, practice, and research.

Implications for Policy

A range of policy implications is evident and may well apply in many other countries than just England. Digital facilitation has a role in achieving the move to greater use of digital services in health care. But there is a disconnect between policy makers'

expectations about what use of online services might achieve and the limited efforts at digital facilitation that are occurring at general practice level. A first step for policy makers is to recognize the existence of this disconnect. Rectifying it implies a need to better articulate to service users and practice staff the hoped-for benefits of the online services. To deliver digital facilitation requires investment in staff time and training. It also requires clarity about how the responsibility for supporting patients to use online services is distributed across different parties. Although some responsibility for digital facilitation falls on practice staff, there is a role for complementary support from health service organizations nationally or regionally [16], and this needs to be recognized and acted upon. An additional option is for the providers of online service platforms to be encouraged, or mandated, to offer support to patients either directly or by helping general practice staff to deliver digital facilitation (see, for example, eConsult [17]).

Implications for Practice

There is clear potential for digital facilitation to help patients and practices use online services. Realizing this potential requires investment in, as well as by, general practices. It also requires clear, shared understanding of which staff are responsible for doing what [18]. Practice leaders and managers need to take responsibility for their practice's digital facilitation strategy and associated training and resources being provided for those staff tasked to deliver facilitation activities [19]. There exists a wide range of facilitation types and it is likely that a combination of approaches would be appropriate. Attention needs to be paid to the likely differing digital facilitation needs of subgroups of the patient population, rather than assuming that a generic approach will suffice. Getting patients signed up with online services is a necessary but insufficient condition for realizing the benefits of the services. Monitoring and support for continued use after initial sign-up are also needed but appear to receive insufficient attention currently. Finally, it is inevitable that some patients will never be able or willing to use some (or any) online services; hence adequate, equitable, and nondigital access to care will need to remain an option however good digital facilitation becomes.

Implications for Research

There is great scope for useful research around digital facilitation. There is a need to explore the association between patients' awareness of online services and their use of them, and how different digital facilitation approaches affect that. Measuring the effectiveness of digital facilitation efforts requires a holistic approach in line with guidance on complex interventions, which suggests that evaluation goes beyond whether an intervention works [15]. Our research suggests several areas for future evaluation of digital facilitation, where current evidence is lacking, including:

- the extent of patient demand for online services to access general practice, and how this varies between population subgroups,

- the level and mix of digital facilitation interventions needed,
- the role of general practice administrative staff in supporting online services,
- the relative effectiveness and costs of different approaches to digital facilitation,
- how different approaches to digital facilitation work for different population subgroups, and
- focusing on supporting sustained patient use of online services, not just initial registration.

Strengths and Limitations

A strength of the research project was the collection of evidence from 4 main sources and the triangulation between them that enabled. The 4 work packages were deliberately staggered and yielded results at different times. We exploited that through a cumulative design of the evidence synthesis, comprising 3 workshops (as successive work packages yielded findings) and a final stakeholder challenge meeting, which took place at intervals over 13 months. This design was chosen to ensure a thorough, effective, and efficient process with time for detailed challenge and discussion. Members of the public were actively involved throughout, including at the 3 synthesis workshops, and they were supported throughout by a researcher in our team specializing in that role. The public participants made pertinent challenges and shared experiences in each workshop leading to clearer thinking about the context and meaning of the research findings.

The principal limitation of the synthesis reported here is that it is based on evidence gathered during a period of great change in primary care in the United Kingdom (as elsewhere): 2020 - 2022. The COVID-19 pandemic prompted great and sudden changes in the practice of primary care, with much greater emphasis on providing services remotely rather than in person. The full implications of those changes are not yet wholly apparent. We have noted their importance and taken them into account to the extent possible so far.

Conclusions

Digital facilitation is important in the context of increasing opportunities for online access to services in primary care. It can take many forms, though much of what is currently done in GP practices in England is reactive and passive. There is scope to develop an approach to facilitation that more actively engages patients. There seems to be a disconnect between stakeholders' expectations and perceptions of how digital facilitation could help and the reality seen in everyday practice. Digital facilitation requires staff time and resources, along with clarity over responsibilities. The establishment of clear lines of responsibility, the development of digital tools and platforms that work well for patients and practice staff, and investment in staff time and training will all be needed if digital facilitation is to deliver on its promise. Based on synthesis of the findings from our research, we propose a framework for future evaluations of the effectiveness and costs of digital facilitation interventions.

Acknowledgments

This study was funded by the National Institute for Health and Care Research (NIHR) Health and Social Care Delivery Research Programme 128268. Abstract

Background: Pain and its adequate treatment are an issue in hospitals and emergency departments (EDs). A virtual reality (VR) tool to manage pain could act as a valuable complement to common pharmaceutical analgesics. While efficacy could be shown in previous studies, this does not assure clinical adoption in EDs.

Objective: The main aim of this study was to investigate which factors affect the adoption and potential reimbursement of a VR tool for pain management in the ED of a Swiss university hospital.

Methods: Key informant interviews were conducted using in-depth semistructured interviews with 11 participants reflecting the perspectives of all the relevant stakeholder groups, including physicians, nurses, patients, health technology providers, and health insurance and reimbursement experts. The interviews were recorded and transcribed, and the extracted data were systematically analyzed using a thematic analysis and narrative synthesis of emergent themes. A consolidated framework for eHealth adoption was used to enable a systematic investigation of the topic and help determine which adoption factors are considered as facilitators or barriers or as not particularly relevant for the tool subject of this study.

Results: According to the participants, the three key facilitators are (1) organizational environment; (2) tension for change, ease of use, and demonstrability; and (3) employee engagement. Further, the three key barriers to adoption are (1) workload, (2) changes in clinical workflow and habit, and (3) reimbursement.

Conclusions: This study concludes that the adoption of a VR tool for pain management in the ED of the hospital subject of this study, although benefiting from a high tension for change in pain and workload management, is highly dependent on the respective organizational environment, engagement of the clinical staff, and reimbursement considerations. While tailored incentive structures and ambassador roles could benefit initial adoption, a change in the reimbursement landscape and further investigation of the positive effects on workflow effectiveness are required to drive long-term adoption.

Introduction

Background

Pain management in emergency departments (EDs) has been shown to be a challenge, with oligoanalgesia, the undertreatment of pain, being a major issue [1], leading to inadequate treatment of pain [2]. According to the European Society for Emergency Medicine, effective pain relief, whether through nondrug methods or medication, involves several key steps: consistently

assessing pain levels, using age-appropriate pain management techniques, selecting suitable pain relief medications, understanding potential side effects, and regularly reevaluating both the patient's pain and their pain management plan to adjust as needed [3]. This implies that addressing acute pain in emergency situations necessitates a personalized approach, taking into account the specific characteristics of each pain management method [4].

Within EDs, pain treatment is impaired by the fact that pain is highly individual, knowledge and education are often scarce, the individual expression of pain is culturally dependent and the workload in EDs is high [1]. While this issue may be addressed through specific education and guidelines on pain treatment [2], tools such as virtual reality (VR) could support clinicians as a complementary pain management option to common pharmaceutical analgesics [5,6]. VR is generally defined as “the use of computer modeling and simulation that enables a person to interact with an artificial 3D visual or other sensory environment. VR applications immerse the user in a computer-generated environment that simulates reality through the use of interactive devices, which send and receive information and are worn as goggles, headsets, gloves, or bodysuits” [7].

VR interventions have emerged as a promising nonpharmacological treatment option for managing pain in patients. Multiple benefits have been demonstrated including decreasing pain intensity perceived, anxiety, unpleasantness, and the time spent thinking about pain during medical procedures [8,9]. Hoffman et al [10] showed that the use of VR tools can result in pain alleviation comparable to a moderate opioid dose, and that it can be an effective complement to common analgesics. As a complementary pain management practice, VR has shown potential for both acute and chronic pain conditions [11]. However, as this study focused on an ED setting, it is centered around acute pain interventions.

The use of VR in pain management is based on the concept of providing immersive, multimodal stimuli to engage the patient, thus distracting patients from their pain [12]. These stimuli may include, but are not limited to, a device, projecting visuals (eg, in the form of a head-mounted display), earphones (potentially noise canceling), and handheld steering devices [12]. The resulting multimodal sensory inputs are an important differentiating factor to passive diversion such as watching television, as the stimuli provide the patient the illusion of being in a different environment [12].

Researchers studying VR as a tool to attenuate pain explain that the underlying methodology of immersive distraction has been identified as a main factor contributing to a reduction in the experienced pain of patients [11]. Hoffman et al [13] argued that VR is redirecting the limited attentional capacity of humans. Thereby, VR treatments would leave less attention available to process and direct input from pain receptors. Strong et al [14] found a similar neuronal explanation, reasoning that neural pathways are not available for transmitting pain signals while occupied with VR input. Gupta et al [11] argue that while there is evidence on VR affecting pain beyond distraction, the respective research is focused on chronic rather than acute pain.

Objectives

This study investigates the adoption of a VR simulation for pain and anxiety at a Swiss university hospital ED. The VR tool, called Healthymind (HEALTHY MIND), is a patented, CE (conformité européenne) marked, International Organization for Standardization 13485 certified, and registered Class I medical device that is commercially available [15]. The intervention consisted of the application of the Healthymind

VR simulation, using a Pico G2 4 K VR headset (Pico Interactive Inc) with a resolution of 1920×2160 pixels and a diagonal field of view of 101 degrees and Bose Quiet Comfort 35 II noise-canceling headphones (Bose Corporation) as an adjunct to usual care in the ED.

The ED team in the hospital subject of this study has conducted an initial research about Virtual Reality for Pain Relief in the Emergency Room to investigate the feasibility of deployment of a VR simulation in the busy setting of the ED for an adult population presenting with traumatic or nontraumatic pain, and the effectiveness of the VR simulation in pain and anxiety control. This work builds on and complements this initial study that was published earlier [5], and TCS shares coauthorship of both papers.

While the tool was introduced with intense training and the highly engaged VR tool advocates pushing adoption, its use has not yet set into clinical routine. Therefore, the key objectives of this work were to assess what factors impact the adoption of the VR tool in question, and whether they act as barriers or facilitators. Furthermore, potential solutions for the identified barriers were also investigated. The authors were guided in their thinking by the consolidated framework for eHealth adoption by Jacob et al [16]. The consolidated framework, informed by the sociotechnical theory [17], categorizes adoption factors in three key clusters: (1) organizational and policy, (2) technical and material, (3) social and personal factors.

Methods

Study Design

The qualitative paradigm was chosen due to its emphasis on prioritizing “the voices of participants” and the rich insights it offers [18]. Qualitative methods allow for a deeper understanding of the participants’ individual perceptions in ways that cannot always be attained through quantitative approaches [19].

Data Collection

Data were gathered through in-depth, semistructured interviews, all held digitally. Additionally, physical artifacts such as screenshots of the VR tool, compatible devices, and examples of user feedback were collected to provide a comprehensive assessment of the tool under study (Healthymind) [20]. The data collection period spanned from March to June 2023, during which a total of 11 interviews were conducted (out of 62 individuals contacted). The interviews were conducted and recorded in German by the first author (JL), with durations ranging from 15 to 60 minutes depending on the participant’s depth of perspective. The interview topic guide is available in [Multimedia Appendix 1](#). Research themes and questions were developed in accordance with Jacob et al’s [16] consolidated framework of the factors impacting eHealth adoption. As per this framework, themes in the interview guide were categorized into three groups: social, organizational, and technical. Data collection continued until a satisfactory level of saturation was achieved, indicating that new data no longer yielded novel insights [19].

Sampling Techniques and Participant Profiles

Considering the specific expertise required for this research, purposive sampling was used, in which potential participants were selected based on their ability to provide rich and in-depth information about the topic. We used a purposive sampling method, selecting participants based on their capacity to provide detailed and comprehensive information about the app and its use [18,21]. Initially, key informants within the Swiss university hospital ED were approached, and subsequently, snowball sampling was used to identify suitable participants. The primary selection criteria included participants being key stakeholders in the Swiss health care system and in the adoption discussion around VR tools. A “stakeholder” is defined by Effective Health Care Program as a person or group with a vested interest in a

particular clinical decision and the evidence that supports that decision [22]; in the context of this study, this includes physicians, nurses, patients, health insurance professionals, policy experts, and employees of the hospital provider of the VR tool and experts of the Swiss Federal Office of Public Health as well as of the cantonal health department. Thereby, this research is incorporating insights from various points of views in the Swiss health care context to portray an inclusive picture on the current situation. Participant recruitment was conducted through tailored LinkedIn and email outreaches, including a detailed study information sheet as shown in [Multimedia Appendix 2](#). [Table 1](#) lists the participant profiles showing their diverse angles that represent the different stakeholders in the Swiss health care ecosystem.

Table . Participant profiles.

Participant ID	Participant perspective	Organization
P1	Policy expert	Hospital subject of this study
P2	Physician	Hospital subject of this study
P3	Physician	Hospital subject of this study
P4	Nurse	Hospital subject of this study
P5	Technology provider	Provider of the virtual reality tool subject of this study
P6	National policy expert	Member of the Eidgenössischen Kommission für Leistungen und Grundsatzfragen, which translates to Federal Commission for Benefits and Policy Issues
P7	Reimbursement expert	Mandatory insurance provider
P8	National policy expert	From the Federal Office of Public Health
P9	Cantonal policy expert	From the canton where the hospital subject of this study operates
P10	Nurse	Hospital subject of this study
P11	Patient	Hospital subject of this study

Data Analysis

Thematic analysis was used to identify and extract relevant themes, as well as to interpret their potential meanings and interrelationships [21,23]. For data coding, computer-assisted qualitative data analysis software, specifically Atlas.ti (Lumivero and ATLAS.ti Scientific Software Development GmbH), was used. Excerpts were selected to construct a narrative for each theme, aiding in enhancing comprehension of the analysis. The primary author (JL) conducted the interviews and the analysis

and coding. CJ reviewed the coding, and any instances of disagreement were resolved through discussion with the third author (TCS).

The deductive themes were predefined according to the consolidated framework for eHealth adoption by Jacob et al [16]. [Figure 1](#) shows the deductive themes that served as the starting point for the thematic analysis; the inductive themes emerged from the data as some factors were marked as facilitators, barriers, or not particularly relevant for the case subject of this study.

Figure 1. Deductive themes according the consolidated framework for eHealth adoption by Jacob et al [16].

Ethical Considerations

All participants signed an informed consent form prior to the qualitative interview. This research was part of an overarching study approved by the local ethics institutional review board Kantonale Ethikkommission Bern (Req-2020 - 01,266). All participants were briefed about the research background and signed a consent form agreeing to participate. Participants did not receive any payment for their participation.

Results

Overview

Based on the interview analyses, this section synthesizes which factors are currently supporting or inhibiting the adoption of the VR tool for pain management in the ED setting of the Swiss university hospital subject of this study. [Multimedia Appendix 3](#) includes direct quotes from the participants supporting the narrative synthesis of the different themes reported below.

Organizational and Policy-Related Adoption Factors

Organizational Factors

The interview analysis confirms that the overall organizational environment is a critical facilitating factor for adoption. A policy expert within the hospital pointed that the organizational circumstances are indeed beneficial for the adoption of such a technology, as the innovational spirit in a university hospital is high. The physician's perspective underscores the advantage of university settings in fostering early adoption of new technologies or approaches. Since these environments are often research-focused, financial concerns can take a back seat during pilot phases. This allows for a more exploratory and experimental approach without immediate financial pressures, thus facilitating innovation and the testing of new methods or technologies.

A factor that was unanimously mentioned as a strong facilitator is the inner setting and strong focus around training and education within the hospital, particularly on innovative treatment methods. Physicians and nurses appreciate the promotion of tools such as VR within the hospital and the general focus on new technologies. Specifically, the teaching assignment of the university hospital promotes the adoption of new tools by not merely offering the option to use the device, but by carefully introducing it to the relevant personnel. Therefore, the importance of proper training and the effort required for it were emphasized.

Leadership commitment and management support regarding this and similar projects that go in the direction of digital solutions were explicitly mentioned as a facilitator. Furthermore, participants noted that the VR tool might act as a unique selling point of the organization and its ED in clinician recruitment efforts, which could act as a component reinforcing implementation, especially in the context of a hospital engaging in education.

Lastly, the organizational factor of "tension for change" and the current trend toward such interventions can create traction, as innovations in this direction are anticipated. Additionally, pain management in the ED was confirmed as a pressing

concern; having an additional option to alleviate patient pain will facilitate adoption.

Workflow-Related Factors

The analysis of workflow-related factors revealed that changes to clinical workflow, workflow fit, resources, and workload are highly interrelated. The required changes in clinical work to implement VR were brought up as a barrier. Workload was mentioned frequently as a main barrier to adoption into the clinical workflow and routine, as time is scarce in the ED.

While VR adoption requires habituation and adaptation, and pharmacological options might initially be faster, a clinician believed that VR may lead to time savings in the long run, benefiting the organization. Although nurses did not explicitly confirm this efficiency gain, the tool could allow them to allocate their time more effectively by distracting patients in pain before further attention is needed. Additionally, the tool's adoption may support the transformation away from purely pharmacological pain management, which was mentioned as a positive change of clinical care.

Regarding compatibility and adaptability, the provider of the tool emphasized that trials on further adaptation of the software to specific environments or medical uses did not yield better results. That is why they provide environments which are applicable to as many use cases as possible. However, within the possible simulation environments that the provider supplies, customization is possible in a sense of selection of the preferred environment through the patient, which is a facilitating factor.

Although the potential threat of new technologies for clinicians was mentioned during interviews, this does not seem applicable to the VR case at the hospital studied. On the contrary, especially for nurses, this tool is seen as an opportunity to expand their capabilities and skill sets. Additionally, it is beneficial that nurses can decide to use the VR tool without needing to escalate up the hospital hierarchy or require a physician's prescription.

Policy and Regulations

Since the tool is already approved and certified, research participants did not perceive regulatory approval as a barrier, as is often the case in similar studies. During discussions on "policy and regulations," participants did not raise this point; instead, the focus was on reimbursement aspects, particularly in the context of Swiss health care. From a health insurance perspective, participants emphasized that the Swiss insurance system operates on a fee-for-service payment model, where reimbursement is based on the volume of care services provided. This model incentivizes providers to perform more services, such as filling hospital beds and conducting procedures. Therefore, a solution adds the most value if it increases efficiency, allowing more patients to be seen and generating more billing revenue. This could act as a barrier to adoption for digital health interventions such as the VR tool studied, which focus more on quality and patient experience improvements rather than increasing service volume.

The overarching concern was how the VR application could be funded for patients in pain in the ED. Reimbursement may happen via the mandatory insurance or through a supplementary

route. One suggestion for reimbursement through the mandatory health insurance was via the so-called MiGeL (German: *mittel und gegenständeiste* which translates to *means and object list*; Nova Cantica). This exhaustive list for reimbursable tools for the use outside the hospital, was proposed by the federal ministry of health. However, as the VR tool subject of this study is applied inside the hospital, the MiGeL-related reimbursement is not applicable. Instead, reimbursement would happen via TARMED, the current Swiss tariff system for outpatients in hospitals, as the VR tool is to be categorized as a mandatory service provided in the hospital. Such a categorization is not substantiated on an exhaustive list, but by a so-called principle of trust, an assumption that medical insurers reimburse all performed examinations and treatments if they are appropriate according to the WZW criteria (in German: *wirksamkeit, zweckmässigkeit, und wirtschaftlichkeit*; translates to *effectiveness, expediency, and efficiency*). As the categorization as a mandatory service is not currently doubted or questioned by insurers or other parties, reimbursement of mandatory health insurers would be expected. However, the categorization as a mandatory service cannot definitely be confirmed according to the policy experts participating in this study. This categorization would rule out options of reimbursement through complementary insurances, which was the initial reimbursement method suggested by clinicians and payers. Further it rules out self-payment of patients, as mandatory services fall under a so-called tariff protection.

For the categorization as a mandatory service the WZW criteria must be fulfilled. The service provider, in this case the hospital subject of this study and its physicians, must determine whether the WZW criteria are fulfilled by the tool, by demonstrating effectiveness, appropriateness, and economic efficiency. If this can be confirmed, reimbursement within the mandatory health insurance could be given. However, the categorization as a mandatory service through the fulfillment of the criteria above, does neither automatically lead to a cost-covering reimbursement amount, nor does it create tariff positions in the TARMED system for “standard” reimbursement, as TARMED is not kept up to date anymore because it will be replaced in the upcoming years.

Reimbursement could also be pursued through individual case invoices, where a physician would need to justify the necessity and appropriateness of the tool to the insurer. However, this approach is resource-intensive and not advisable in this case. Instead, other short-term solutions should be explored, such as assessing whether the tool’s adoption offers economic advantages, making it attractive even without immediate reimbursement. In the long-term, participating policy experts strongly recommend that the hospital engage in advocacy and help shape the new outpatient tariff system. This would ensure that VR for pain management and other digital tools have an appropriate category within the new system, allowing for seamless reimbursement if categorized as a mandatory service.

Patient-Related Factors

Patient access to care was not a concern for the participants, due to the fact that the Swiss EDs are open to all citizens, thanks to compulsory health insurance, anyone living in Switzerland

has access to medical care [24]. Similarly, patient safety was not a major concern as the VR tool subject of this study does not prompt any known safety risks according to this study’s participants. However, patient condition and engagement were discussed.

Patient condition was mentioned in the context that the severity of the patients’ pain may impact the tools’ effectiveness, as the necessary immersion may be harder to achieve. While this can have a negative impact on adoption, the general difficulty to appropriately treat the condition “pain” in the ED, including the reluctance for the use of opioids, can be seen as a facilitator, as another treatment option expands the clinicians’ toolkit according to this study’s participants.

The nurses in this study highlighted that patient education requires significant time and effort, which might not always be available. The participating patient confirmed the time taken to inform them and noted their high involvement in deciding whether to use the VR tool. This process substantially increased patient engagement and their willingness to use the tool.

User Engagement

Participating physicians emphasized that nurses may perceive the tool as an expansion of their capabilities, which may have a positive effect on their feelings about their job. Confirming this perspective, the interviewed nurses expressed excitement about the application of the new tool. Furthermore, the clinicians explained that fostered engagement may positively affect adoption through the enhancement of employee engagement and other factors such as habit. However, the nurse view also revealed that different nurse team members and physicians individually vary in their perception, which affects teamwork and adoption.

Technical and Material Adoption Factors

Usefulness

The tool’s usefulness was of high relevance for all participants. User perception was generally positive, and the participating clinicians highlighted the great potential of VR for pain management. As for efficiency of care, the picture is more complex. This is as installing and applying the tool takes about 20 minutes, which the care professionals must integrate into their already busy schedule. However, it may be argued that while the patient is occupied with the tool for 20 minutes, the care team may take advantage of this time more efficiently. Therefore, the factor efficiency can be seen as a barrier at a first glance, but it can also be perceived as a facilitator.

Communication was also discussed, with the care team noting that explaining the function and usefulness of the device could take significant time, depending on the patient’s prior knowledge. However, this effort can enhance the patient experience. Both patients and clinicians confirmed that positive stories about the tool increase patients’ willingness to try it. Therefore, clear guidelines on how to effectively present the tool to patients may facilitate its adoption.

IT Capability and Capacity

Although IT capability and capacity can affect adoption for certain tools, it was not perceived as of relevance for the VR tool subject of this study as it does not require any additional infrastructure and does not necessitate any integration with other IT systems in the hospital. Even though the hospital subject of this study was going through a major IT transformation at the time of this research, this did not seem to impact use or adoption, which may be due to the tool lacking the need for system integration.

Data-Related Factors

Data-related factors were also mentioned as a general challenge for eHealth adoption but were not particularly relevant for the tool subject of the case study, as it does not generate health data. While data quality, exchange, and storage were general considerations shared by policy experts, these were mostly not applicable to the VR tool in question.

User Experience

Regarding the design content and quality for patients, the participating nurses highlighted recent software updates of the visual simulation, which made the VR environments more realistic and thereby more immersive and enjoyable. The option to select specific scenarios based on personal preferences was especially appreciated by patients. User experience was generally positive, which suggests good content design and quality. This was further emphasized by the tool's developer, who shared insights into their design testing and optimization for ideal immersion. One negative aspect which the participating patient brought up, is that certain medical conditions impacting the mobility of the neck, may not be suitable for the application of VR in a lying position, as putting on the headset was experienced as uncomfortable.

Ease of Use

High design quality, especially regarding user guidance was indicated by the developer, as they specifically referred to user-centered design and how users are guided through the application step by step on the tablet steering the VR simulation. It was specified that even without training, a person less familiar with technology can handle the device. However, this is partially contradicted by the nurse perspective, which revealed that although the tool was perceived as intuitively usable by some, others had issues using the tool, especially in connection with their personal innovativeness. Specifically, the lack of technical affinity is mentioned to affect ease-of-use on a personal level.

The physician perspective on habit was discussed in relation to using VR tools with patients. The lack of a routine in using VR tools was attributed to workload and time constraints, as conventional medication procedures are habitual and potentially quicker. This issue could be generalized for other innovative treatments. However, the intuitive nature of the VR tool's handling suggests that it may not pose a significant barrier. From the clinician's viewpoint, the importance of external encouragement in breaking previous habits and adopting the tool was highlighted, though it was noted that this transition might require ongoing effort.

Monetary Factors

While reimbursement potentially finances the use of the device through clinicians and possibly amortizes the equipment costs over time, the initial cost and affordability of the device are not considered, neither are the maintenance and software updates costs. With the limited information at hand, the analysis remains inconclusive whether this factor may act as a barrier, especially as it is highly interrelated with reimbursement considerations.

Social and Personal Adoption Factors

Personal Characteristics

Personal characteristics were indicated to play a relevant role in successful adoption. Participating clinicians explained that patients' awareness and personal attitudes could be affected through persistent and educative communication. Comfort and acceptance were reported to be positively related to technical skills and experience, and are highly personal. Overall, personal characteristics can therefore be a barrier or a facilitator, depending on the user in question.

Social and Cultural Factors

Clinicians' endorsement is key for the acceptance of the tool and may positively influence individual decisions. The power of endorsement was highlighted by the technology provider and clinicians. It was emphasized that even only one promoting individual physician serving as a VR tool advocate can socially influence others to adopt VR as a tool for patients in pain, especially connected with a push toward a change of habits. Further, the importance of the team was highlighted regarding social influence. When no other team member uses the device, that may therefore inhibit adoption. Conversely, the participating patient voiced that they did not feel impacted by culture or their environment in their decision to use VR for pain management.

Moderating Factors

The moderating effects of gender and age were brought up by several participants, implying that younger age was frequently associated with higher comfort and acceptability as well as skills and attitude toward novel technologies. The participating nurses also confirmed that older patients generally require more on-boarding time. Additionally, male gender was associated with a higher openness to try VR for pain management, potentially due to personal experience of gaming and leisure time with VR applications.

Discussion

Most Prominent Barriers and Facilitators

Overview

The analysis showed that some factors had a more prominent facilitating or inhibiting impact on user adoption than others that had limited relevance for the VR tool subject of this case study. Therefore, the focus of the discussion will be the factors that had a clear impact in this specific case and their respective potential implications for practice.

Facilitator 1—Organizational Environment

The organizational environment in which the tool is implemented is considered a critical facilitator to eHealth adoption according to several published studies [25-28], a finding that was confirmed by the outcomes of this research. The participants acknowledged that the environment in the ED of the hospital under study was conducive to adoption. The overall culture of openness to innovation within the hospital was seen as a facilitator, particularly in terms of leadership commitment and the emphasis on training and educating staff in the use of new devices, consistent with findings from similar research [29,30].

Facilitator 2—Tension for Change, Ease of Use, and Demonstrability

This study's participants emphasized that a high tension for change toward more efficient ways of working and pain management is perceived as a facilitator, especially when the adoption of the VR tool allows nurses to focus on other tasks while the patient is immersed in VR and, at the same time, shows clinical effectiveness to reduce pain. Similar studies correspondingly suggested that this demonstrability of the tool's usefulness, especially in combination with ease of use may indeed positively impact adoption [25,26,31]. Technical affinity has been discussed in relation to the tool's ease of use; in alignment with similar studies, the easier a technology is perceived in use, the less technical affinity is required [32,33]. In this context, the ease of use of the VR tool under study has been perceived as a facilitator. Furthermore, immediate positive effects on patients after the application regarding anxiety and pain levels could be observed by clinical personnel and could also be proven by the hospital subject of this study [5]. This high level of demonstrability may be used to convince clinicians and patients alike that the VR tool is a valuable, easy-to-use option, especially as the tension for change in pain management within EDs is rising.

Facilitator 3—Employee Engagement

The clinicians participating in this study emphasized that employee engagement, particularly because the VR tool is primarily administered by the care team, is a crucial facilitator. Analysis of the interviews suggested that the new tool could have a positive impact on nurses' attitudes toward their profession by enriching their jobs. This finding aligns with other studies indicating that eHealth tools may empower and expand the roles of health care professionals in certain cases [34,35]. However, further insights revealed that as initial excitement for a technology subsides, this engagement may decrease if not actively managed.

Barrier 1—Workload

The first important adoption barrier according to this study's participants is the experienced workload, especially among nurses that administer the VR tool. As suggested by the literature, workload is a general concern in the health care sector [36,37], and at the same time, health care professionals are expected to increase their work quality and efficiency. This was confirmed by the interviewees to be an inhibiting factor of the implementation of a new tool such as VR for patients in pain.

Especially since the tool is currently perceived as an additional task that consumes more time rather than saves time through the set-up of the patient, but especially given the patient education required to ensure willingness to use and overall satisfaction by the patient.

Barrier 2—Changes in Clinical Workflow and Habit

A further important barrier that could be observed is the required change in clinical work and therefore in the work habits of nurses and physicians, in alignment with previous studies that emphasized the workflow changes associated with eHealth use as a potential adoption challenge [38,39]. Changing the clinical workflow from the current standard of care's medication-only approach toward the usage of an additional, complementary tool, requires a substantial adjustment of the standard workflow and work habits of clinicians.

Barrier 3—Reimbursement

Finally, the current reimbursement situation in Switzerland is a very important potential barrier for the VR tool's adoption. The analysis of Swiss reimbursement structures in the outpatient setting of the ED showed that even if the tool fulfills the relevant WZW criteria for reimbursement and is therefore considered a mandatory service under the mandatory health insurance, it could currently not be efficiently reimbursed, given the lack of an appropriate position in TAR MED [40]. This is primarily due to the current billing system not being properly maintained as it is to be discontinued [41]. Reimbursing through supplementary insurance is an option, but it would demand significant resources to establish agreements with various commercial insurance companies and would only reach a limited number of potential patients. Moreover, categorizing the tool as a noncompulsory treatment would impede reimbursement through mandatory health insurance in the future, as transitioning from noncompulsory to mandatory service is challenging.

Practical Implications

The analysis revealed a nuanced perspective for some factors, as they may act both as facilitators as well as barriers, depending on the specific circumstances such as personal characteristics of the user (patient and nurse) and future reimbursement landscape. This study's participants helped us identify three key facilitators and three key barriers. To enhance the impact of the key facilitators and mitigate the effects of the main barriers observed, four measures are proposed as visualized in Figure 2 and explained in the subsequent paragraphs. The numbers on the figure represent the four measures proposed to tackle the corresponding barriers and facilitators.

To foster the beneficial organizational impact, an incentive structure within the ED to drive the adoption of new tools, such as VR for pain management, allows for an external push toward adoption. The introduction of a specific ambassador role is proposed, as a further extrinsic push factor. The ambassador could capitalize on the high tension for change, the ease-of-use of the tool, and the demonstrability as arguments to remind the clinical staff of the valuable option of VR as a complementary pain management option. Moreover, the ambassador could demonstrate and accompany its use to increase employee engagement. Ambassadors could thereby also mitigate the

barrier combination of workflow and habit, as their continuous efforts could promote clinical adoption.

To tackle the key barrier of workload, further investigation is proposed in the direction of the potential of the VR tool to support clinical staff in allocating their time as effectively as possible, thereby potentially changing the perception of the tool as additional workload. As patients are immersed in VR, this could potentially lead to less simultaneous attention requirements of the nurse, who is then able to focus on the remaining patients and tasks. Simultaneously, the application could lead to higher patient satisfaction.

Since it is unlikely that reimbursement will improve soon, it is recommended to explore how hospitals can financially benefit

from adopting these tools. This could involve assessing their impact on workflow efficiency to see if they reduce workload barriers. This argument suggests that the hospital currently cannot bill the VR service to the patient’s health insurances to achieve reimbursement, but by increasing the effectiveness of the workflows in the ED, the hospital may eventually yield a positive return on investment. However, in the long term, investment in advocacy work by the hospital is suggested to shape the upcoming revision of the Swiss tariff system for outpatient treatment to enable adequate reimbursement of such mHealth tools in the future and have clear positions in the tariff system for VR tools in pain management.

Figure 2. Key facilitators, barriers, and proposed measures. VR: virtual reality.

Key Facilitators		Measures
Key Facilitators	Details	
Organizational environment	Innovation endorsing environment creating facilitating conditions for adoption	→ 1. Adoption incentives for external push toward clinical adoption
Tension for change, ease of use, and demonstrability	Issues in pain management and workload could be mitigated with an easy to use tool with high demonstrability	→ 2. Introduction of new role as ambassador of specific tools to ensure continuous efforts
Employee engagement	VR tool may elevate employee engagement as it represents additional responsibilities and requires competencies	
Key Barriers		
Key Barriers	Details	
Change in clinical workflow and habit	A new tool requires changes in the clinical workflow which is negatively affected by habit of personnel	→ 3. Investigation in and potential repositioning of VR as a tool for a more efficient time distribution of personnel
Workload	The generally high workload affects negatively as the VR tool is currently perceived as additional work	→ 4. Short-term: research in the direction of the third measure (evidence generation for efficiency gains) to justify use Long-term: advocacy work for the new tariff system
Reimbursement	Reimbursement in the current tariff system is highly unlikely although the tool should fulfil the necessary conditions	

Limitations and Recommendations for Future Research

This study has some limitations worth noting. We focused on a specific VR tool in one Swiss hospital during a set period of time, so it is hard to generalize our findings to other contexts that might have different characteristics, such as a different regulatory landscape. Although the target was to cover all relevant stakeholder perspectives on the matter, the recruitment of insurance professionals and patients for their perspectives was especially challenging, leading to only one interview for each of those stakeholder types. To minimize the selection bias that can be introduced by purposive sampling, we used snowballing; this involved asking participants to suggest other colleagues who were willing to participate. Lastly, while this research used the comprehensive list of factors in the

consolidated framework for eHealth adoption by Jacob et al [16] as a basis for the interview guide and subsequent analysis, it observed connections between factors and disclaimed them when applicable. More research on their interrelatability may be useful when developing measures to address barriers and facilitators. Future studies could explore other tools in different settings to overcome some of these limitations.

Conclusions

Key facilitators and barriers identified in this study and the respective suggested measures may help improve adoption of the VR tool in the hospital subject of this study. Key facilitators include the supportive atmosphere in settings such as the hospital subject of this case study, which encourages VR adoption and is backed by leadership commitment and training; high demand for change in pain management and VR’s effectiveness and

usability, which promote its adoption; and continuous support, which is crucial to sustain user engagement over time.

Key barriers include nurses' perception that the VR tool is adding to their workload, particularly in patient education and setup; incorporating the VR tool requires the staff to adapt their standard workflows, posing challenges; and the current reimbursement systems lack appropriate codes for VR services, hindering financial incentives.

To address these factors, some measures are recommended: establishing proper incentive structures can encourage VR adoption, ambassador roles can offer ongoing support and advocacy, further research into VR's impact on workflow efficiency is necessary, and advocacy efforts are needed to influence reimbursement system revisions. By leveraging facilitators and mitigating barriers, hospitals can optimize VR's benefits in pain management and enhance patient care.

Acknowledgments

The authors would like to express their gratitude to Mayella Favre (MAS in health economics and management) and Ulla Strobel (CAS in digital health) for generously sharing their in-depth expertise of the Swiss reimbursement system with the research team.

Abstract

Background: Low-income pregnant patients are at high risk of postpartum depression (PPD). Mothers and Babies (MB) is a cognitive behavioral therapy–based program that prevents up to 50% of de novo PPD when provided in person to low-income Spanish- and English-speaking people who are pregnant without depression. MB is limited by the need for trained personnel to support it. Transforming MB into a smartphone app may mitigate this key barrier.

Objective: We aimed to use qualitative data from target end users to create and optimize MBapp, a novel app centered on the MB program.

Methods: Draft wireframes of MBapp were created in English and Spanish with cognitive behavioral therapy–based modules adapted from MB. These wireframes included several features shown previously to sustain app engagement: (1) push notifications delivered at participant-preferred times; (2) text-, graphic-, and video-based content; and (3) gamification with digital rewards for app engagement. English- or Spanish-speaking individuals with public health insurance who were between 32 weeks gestation and 6 months post partum and owned smartphones were eligible to consent for individual in-depth interviews. Individuals with prior or current depression were excluded. Interviews were recorded, transcribed, and analyzed using deductive and inductive codes to characterize opinions about MBapp and perceptions of challenges and facilitators of use of MBapp or other perinatal or mental health apps. End user feedback led to major modifications to the wireframes. Each of these changes was categorized according to the FRAME (Framework for Modification and Adaptation), an established method of systematically reporting adaptations and modifications to evidence-based interventions via end user feedback. Recruitment ceased with content saturation, defined as 3 successive participants providing only positive feedback on MBapp’s wireframe, without further suggestions for improvement.

Results: A total of 25 interviews were completed. Participants were racially and ethnically diverse, generally representing our target end user population, and 48% (n=12) of interviews were conducted in Spanish. Participants’ suggestions to improve MBapp were categorized within the FRAME as adaptations that improved either content or context to optimize reach, retention, engagement, and fit for end users. Specifically, the following features were added to MBapp secondary to end user feedback: (1) audio narration; (2) “ask a clinician” nonurgent questions; (3) on-demand module summaries accessible upon module completion; and (4) choice to defer assessments and start the next module. Participants also provided insights into features of perinatal or mental health apps they found appealing or unappealing to understand preferences, challenges, and negotiables or nonnegotiables for MBapp.

Conclusions: Adapting MBapp to incorporate end users’ perspectives optimized our digital PPD prevention intervention, ideally increasing its appeal to future users. Our team’s next steps will confirm that MBapp is a feasible, acceptable intervention among English- and Spanish-speaking perinatal people at risk of PPD.

Introduction

Approximately 15% of all pregnant women in the United States develop postpartum depression (PPD) [1-6], and more than 95% of people with PPD have persistent symptoms [7]. The reasons for such a high burden of persistent symptomatic burden from PPD are complex but include the following barriers: (1) obstetric providers who are not trained to care for psychiatric conditions and who do not routinely screen and treat for mental health conditions such as PPD; (2) a shortage of trained mental health providers to care for those who screen positive; and (3) stigma of receiving in-person mental health care, which prevents those with PPD from receiving effective treatment [8-14].

Thus, preventing PPD from occurring is crucial, particularly among individuals with unmet social needs such as financial stress or food insecurity that place them at higher risk for this condition than those without unmet social needs [1-6]. The US Preventive Services Task Force recommends that women at risk for PPD participate in 1 of 2 evidence-based psychotherapy programs shown to effectively prevent PPD from developing [15,16]. One of these programs is an in-person cognitive behavioral therapy (CBT)-based program, Mothers and Babies (MB) [17-19]. MB was created to prevent PPD among low-income English- or Spanish-speaking pregnant women and has been shown to be effective in diverse communities of low-income perinatal patients [17-19]. Though MB has been adapted to an asynchronous online intervention [18,20], access to the program generally remains limited to people who receive prenatal care in clinical settings affiliated with MB-trained providers, reducing MB's dissemination potential.

App-provided mental health care has dramatically expanded access to mental health services through their ability to be scaled without reducing fidelity and their ability to reduce barriers and potentially stigma related to receiving in-person mental health care [8,21]. In addition, app-provided mental health care has been shown to effectively treat depressive symptoms and is commonly used in pregnancy (the majority of people who are pregnant download apps regardless of income) [22-24]. From a perinatal patient perspective, engaging with an app to improve somatic and mental health symptoms has become commonplace [25,26]. However, most mental health apps do not contain evidence-based psychotherapy [27,28], and, of the apps that do contain CBT elements, most do not contain content that has been specifically created for peripartum people [29]. For these reasons, we aimed to adapt the evidence-based MB course, ultimately creating a 9-module, app-based intervention, entitled MBapp, from the original 6-session in-person group intervention. In this paper, we present findings from individual in-depth interviews with pregnant or postpartum individuals regarding optimal perinatal or mental health apps. We also use an established method of systematic reporting of adaptations and modifications to evidence-based interventions via end user feedback to describe how incorporating end users' suggestions optimized MBapp for future pregnant or postpartum users. To

our knowledge, this study represents the first to systematically report the process of adapting an existing in-person curriculum to a perinatal mental health app before the intervention was deployed.

Methods

Creating MBapp Draft Wireframe

MB materials are publicly available [30]. Once downloaded, MB's curriculum for course leaders and the participant workbook served as the starting point for MBapp. The draft wireframe was created by this study's principal investigator (AKL), who was supported by his coauthors—a multidisciplinary team with expertise in perinatal mental health, digital health interventions, and qualitative research methods. To create the draft wireframe, MB's curriculum was first adapted to be delivered asynchronously on a smartphone app. Prior digital adaptations of MB reported that end users requested additional alterations to the digital draft content by further simplifying language and adding more visuals [20,31,32]. Thus, in MBapp's initial draft wireframe, paragraphs of text or worksheets in MB were re-structured to include short, direct phrases, colorful graphics (some from the MB curriculum), and pictures of pregnant and postpartum people and young infants. Some of MB's videos were included within MBapp to allow users to learn the curriculum via a combination of text, graphics, and videos. The draft wireframe also contained ecological momentary assessments and gamification, features that have been shown in other perinatal mental health apps to increase the likelihood of sustained user engagement [33-35]. Specifically, MBapp included daily push notifications at users' preferred times that prompt them to complete a mood scale. Their scores on this scale send them to pertinent content within the app. In terms of gamification, responding to at least 3 of the 7 daily ecological momentary assessment requests to complete the mood scale generated a digital reward, which can be visualized in a digital trophy case. Original MB creators confirmed the draft wireframe was adherent to CBT principles and retained fidelity to MB. Once the draft wireframe was completed, qualitative feedback was obtained from target end users to further adapt the intervention.

Study Population

Participants were recruited from among those receiving perinatal care at a clinic that exclusively serves patients with government pregnancy-related health insurance (Medicaid), as having perinatal Medicaid insurance is only available for low-income patients who are pregnant in our state (Rhode Island, United States) [36]. To be eligible for this study, participants were English- or Spanish-speaking, aged at least 18 years, owned a smartphone, and were either in the third trimester of pregnancy or had an infant that was born within the prior 6 months. As MB prevents—but does not treat—PPD, volunteers were excluded if they reported prepregnancy or current anxiety or depression, an active (or within last 5 years) prescription for

psychotropic medications, active engagement in psychotherapy, untreated substance use disorder, or if they were unable to consent. Potential participants were approached in person during routine antenatal or postpartum care visits. Those interested, who remained eligible after screening, provided written informed consent in person before the interview was scheduled. Participants who did not complete their interview after 3 no-shows at interview appointments were not rescheduled.

Data Collection

Individual in-depth interviews were all conducted via video teleconferencing at the participant's preferred schedule and in their preferred language (English or Spanish). Each interview was conducted by the same investigator (AKL), who followed a semistructured interview agenda that divided the interview into two components. First, the interview discussed the participant's personal experiences, preferences, and challenges with apps, particularly those that focus on perinatal or mental health. Then, the investigator shared his computer screen to review distinct components of MBapp's wireframe with the participant and obtain page-by-page feedback. All interviews were audio-recorded, transcribed by a professional transcription service, and reviewed for accuracy with identifiers redacted. Participants were asked their race and ethnicity.

Using an Evidence-Based Framework to Determine Sample Size

Similar to other web-based digital adaptations of MB [18,20], a human-centered design approach was used to optimize MBapp based on end user feedback about the intervention itself and other, optimal perinatal or mental health apps. We recorded MBapp's evolution according to the FRAME (Framework for Modification and Adaptation) [37], an established method of systematic reporting adaptations and modifications to evidence-based interventions via end user feedback. The FRAME provides insight about when MBapp's wireframe was modified during the development process and the reason for the modification. Feedback on MBapp's themes, content, and function were extracted from the data and, after 5 to 7 interviews, the draft wireframes were revised to incorporate this feedback. The new iteration of the wireframe was then presented to subsequent participants to allow revisions suggested by earlier participants to be seen and commented on by subsequent participants. We anticipated recruiting up to 36 participants and planned to cease recruitment with content saturation, defined as 3 successive participants providing only positive feedback on MBapp's wireframe, without further suggestions for improvement.

Data Analysis

Authors AKL, MG, and KMG generated a preliminary codebook for the interviews based on the semistructured interview agenda.

This initial version of the codebook was limited to deductive codes. Authors AKL, MG, KU, RB, and LL then collaborated via consensus coding in stages. First, two transcripts were coded collaboratively, and additional codes were added inductively to the codebook. Some of these codes were added de novo whereas other inductive codes were based on deductive codes that were reorganized to better capture data. Second, each of these authors independently coded a third transcript, and the authors met as a group to reconcile coding discrepancies. In this manner, consensus coding was achieved and a codebook comprising deductive and inductive codes was finalized. Then, all transcripts—including those that had already been reviewed—were coded independently by two authors (AKL and either KU, RB, or LL). A third coauthor reviewed transcripts and codes when coding disagreements could not be resolved (MG). All coding was then inputted into NVivo (Lumivero), and coded excerpts were organized and synthesized into thematic memos and discussed by the coding team. This study was reviewed and approved by Women & Infant's Hospital of Rhode Island's institutional review board prior to the consenting of the first participant.

Ethical Considerations

This study was approved by the institutional review board of Women & Infants Hospital of Rhode Island (submission WIH 21-0021; approved on September 7, 2021). All participants were assigned a study identification number, which was stored on a password protected file and was only utilized to coordinate the \$50 electronic gift card, which was provided to each participant after the study interview was completed. Otherwise, all data generated during the interview was deidentified and stored in a password protected computer network.

Results

Characteristics of Study Participants

From August 2022 to August 2023, a total of 33 patients were consented, and 25 individual in-depth interviews were conducted. There were no differences in language of scheduled interview, patient-reported race, or parity between those who consented and did versus did not complete the interview. The sociodemographic and obstetric characteristics of participants who completed their interviews are described in Table 1. In brief, 24% of participants were aged 35 years or older, 24% self-reported as White, and nearly half (n=12, 48%) of interviews were conducted in Spanish. Approximately the same proportion of participants were pregnant versus post partum, and over half of participants were first-time parents (ie, either about to deliver or had recently birthed their first child).

Table . Sociodemographic and obstetric characteristics of study participants (N=25).

Characteristic	Value
Age (years)	
Median (IQR)	29 (24-35)
Minimum, Maximum	20, 43
Advanced maternal age (35 years or older at time of delivery), n (%)	6 (24)
Race, n (%)	
American Indian or Alaska Native	3 (12)
Asian	2 (8)
Black	5 (20)
White	6 (24)
Other ^a	9 (36)
Ethnicity, n (%)	
Hispanic	13 (52)
Language of interview ^b , n (%)	
English	13 (52)
Spanish	12 (48)
Primiparous (pregnant with first child or recently delivered first child), n (%)	13 (52)
Pregnancy status, n (%)	
Pregnant	13 (52)
Postpartum	12 (48)

^aOther: multiracial (White and Black): 4; multiracial (White and American Indian or Alaska Native): 3; multiracial (Black and American Indian or Alaska Native): 2.

^bFour participants spoke a combination of English and Spanish. Their interview language was categorized as the language that most of the interview was conducted in.

Perspectives on Optimal Features Within Perinatal or Mental Health Apps

Twenty-one of the 25 participants reported using at least one pregnancy-related app, and 2 of the 25 participants accessed a mental health related app during the perinatal period. The general consensus among perinatal app users was they were more likely to engage with an app if it provided pertinent, updated, and easy-to-understand text and video education either via a push notification or an email and contained digital rewards or games. Many perinatal app users noted that they turned to apps to receive perinatal education between prenatal care appointments or to supplement perinatal education received during these appointments:

The doctor focuses on talking about the pregnancy, focuses on the baby or they just look at your vagina and then [participant waves arms to mimic dismissing someone, as if doctor had instructed her to leave the room]. It was not much about me... [My app] helped me learn about what I wanted to know [Postpartum, English-speaking, first-time mother]

Another consistent theme that emerged was that many participants engaged with perinatal apps to learn from people

similar to them (those who were pregnant or had recently given birth):

[After my baby was born] they would call me, maybe it was a doctor or nurse, and they would ask me questions, but it's not the same. I can't explain it. It's not the same as seeing a mom that is the same as me [who] is saying, "Look, do this. No, do this. Look," and they show me with their own baby. [Pregnant, Spanish-speaking mother with prior children]

Though apps were consistently described as useful throughout the perinatal period, the majority of users who had delivered at least one child at the time of the interview noted that apps were particularly helpful after delivery. The need for perinatal apps in the postpartum period was described in language suggesting that apps help fill the gap between in-person medical care from birth until 6 weeks after delivery. The long interval between medical appointments left participants feeling unsupported by their prenatal care team, and apps helped to provide support:

[When I left the hospital] they did give me a pamphlet that had some...breastfeeding classes and stuff like that [but] I lost the paper...Now I have questions [on breastfeeding] and don't have anywhere to go, but wait for the next doctor appointment... [My app] gives

an idea of how much milk I should give him. Super helpful. [Postpartum, English-speaking first-time mother]

While prenatal apps were often used for additional perinatal education, there was a recurrent theme that these apps—such as prenatal care—focus more on the baby than on the mother:

Apps for mother and baby focus more on the baby than the mother...[just like in real life]. An example, when the mother gives birth to the baby, everyone is concerned about the baby. Hardly anybody worries about the mother, but the mothers go through a difficult process. [Pregnant, Spanish-speaking mother with prior children]

Participants in this sample were much less likely to use mental health apps than perinatal apps. Mostly, participants attributed this difference to a lack of knowledge that such resources were available, not due to lack of interest in perinatal mental health apps. For example, one participant shared that she had depressive symptoms after delivery and informed her midwife of these symptoms at her postpartum visit:

She told me it was normal. She [gave] me a sheet of paper to...see if I had suicidal thoughts, if the depression was severe...and things like that. [Then] she told me to find a counselor. That I needed one. I started to look for a counselor...I wish she had told me about this [mental health apps]. I would have used one and found it useful. [Postpartum, Spanish-speaking first-time mother]

Once the interview shifted toward talking about how MBapp aimed to provide app-based mental health support for perinatal people, the majority of participants responded very favorably, even before viewing any of MBapp's wireframe:

I feel like an app that talks about mental health and they make it fun with the game and the video and the colors and everything, I think it could be useful. I would've liked something like that—or even now, I would like it. [Pregnant, English-speaking first-time mother]

Adapting the MBapp Wireframe

The MBapp wireframe was adapted in multiple ways through end user feedback. Participants were asked about specific

features in perinatal or mental health apps, and whether each feature was appealing (or not) and useful (or not). In addition, each participant viewed at least two distinct sections of MBapp's wireframe and provided direct feedback on the appearance, appeal, content, and usability of each page. This feedback led to minor changes in MBapp's font size or color scheme. Each participant also was asked general questions on how MBapp should be modified to encourage initial and sustained user engagement from the third trimester until 6 months post partum. All feedback from participants was considered by the study team and adaptations were incorporated into MBapp's wireframe. [Table 2](#) highlights the major adaptations made to MBapp's wireframe during qualitative interviews and categorizes these changes according to the FRAME [37]. Of note, participant feedback resulted in both significant and nuanced changes to MBapp but did not alter MBapp's core CBT content; thus, these adaptations did not affect MBapp's fidelity to the evidence-based MB curriculum.

MBapp's wireframe was originally created to mirror MB's programmatic structure, in which a module on parenting education and infant care occurred midway through the curriculum and participants were instructed to complete daily mood scales between each in-person session, regardless of content. Based on end user feedback, MBapp was restructured such that the parenting module was first. We also edited the wireframe to provide users with the option to proceed with the daily mood scales for one week before accessing the next module or to defer these assessments in lieu of moving on immediately to the next module.

Participants recommended adding multiple new features to increase the likelihood of sustained engagement. These included modest financial reimbursement tied to responding to the daily mood scale and the option for audio narration, as well as an "ask a clinician" feature in which users can ask a nonurgent question to a member of the MBapp clinical team, who would respond through the platform. End users also desired short module summaries to be added after each module so they could review high-yield content without repeating the entire module. Module summaries now appear automatically on a digital bookshelf upon completion of each module. [Figure 1](#) provides an example of how MBapp's wireframe was adapted from the initial to final versions.

Table . Major end user-requested adaptations to MBapp's wireframe, categorized according to the FRAME^a [37].

MB ^b feature	MBapp adaptation	Classification ^c	Reasons ^c	Nature of the content modification ^c	Timing of change implementation	Participant recommendation addressed
Not in MB	"Ask a clinician" nonurgent questions	Content: adding elements	Recipient: access to resources	Improve fit with recipients	After interview #16	Resource for perinatal or mental health advice, support, or education
Not in MB	Audio narration, to be turned on or off on each page	Context: adding elements	Recipient: first or spoken languages	Improve fit with recipients	After interview #11	Increase engagement with MBapp via additional method to deliver content
Mood assessments given between in-person classes	Choice to defer week of mood assessments and pass immediately to next module	Context: format	Recipient: cognitive capacity	Increase retention	After interview #11	Flexible schedule
Parenting education module in middle of curriculum	MBapp module order restructuring, with parenting module in the beginning	Content: reordering of intervention modules or segments	Recipient: cognitive capacity	Improve fit with recipients	After interview #6	Optimize MBapp flow by removing parenting education from middle of curriculum
Not in MB	Module summaries to access high-yield content after module is completed	Content: adding elements	Recipient: cognitive capacity	Increase retention	After interview #6	Practical, high-yield content for fast review
Not in MB	Small financial reimbursement based on number of responses to ecological momentary assessment prompts	Content: tailoring, tweaking, and refining	Recipient: motivation and readiness	Increase reach or engagement	After interview #21	Increase meaningful engagement with MBapp via gamification

^aFRAME: Framework for Reporting Adaptations and Modifications.

^bMB: Mothers and Babies.

^cAs defined by FRAME [37].

Figure 1. Visual representation of major adaptations to MBapp's draft wireframe (left) and final wireframe (right), using the digital trophy case as an example. In MBapp's draft wireframe (left), the graphic was smaller; the digital rewards were trophies; and the icons in the header (which appear on every page) were limited to the table of contents, the digital reward icon, and the bookshelf (from left to right). Also, modules 4 and 5 were mislabeled. The final wireframe (right) represents adaptations to MBapp due to end user feedback, which included larger graphic size, medals as digital rewards, more text description for each module, less text description on the page itself (the text is spread over to two pages), and additional icons in the header (audio feature is in the middle, and the question mark icon is how users ask a provider a nonurgent question). The updated header appears on every page.

Discussion

Principal Findings

To our knowledge, this study represents the first to systematically report the process of adapting an in-person curriculum to a perinatal mental health app before the intervention was deployed. Indeed, this paper presents qualitative data from 25 diverse pregnant or postpartum perinatal patients with Medicaid insurance, describing their perspectives on perinatal or mental health apps and design recommendations for MBapp, a novel app based on an in-person CBT program shown to effectively prevent PPD among low-income patients [15,16]. The majority of participants used perinatal apps to receive on-demand pregnancy or postpartum education, and many preferred learning from others with similar experiences. Comparatively, mental health app use was less common, but this lack of uptake was attributed to lack of awareness, not disinterest.

Participants' perspectives and recommendations were incorporated into MBapp's wireframe, which led to minor adjustments in MBapp's aesthetics and major adaptations to

MBapp's structure and features. All major adaptations were categorized according to the FRAME [37]. As each modification was derived directly from qualitative feedback from individual end users, incorporating minor and major adaptations to MBapp's appearance, structure, and features should increase its appeal to future users.

Comparison With Prior Work

MB was originally created as 6 in-person 2-hour group sessions [17] and has been implemented successfully in nontrial, community settings [38]. Since its inception, MB has been adapted into multiple formats. For example, 1 in-person MB curriculum comprises 10 individual sessions occurring during prenatal visits or at home [19] and can include supplemental text messages to participants [32]. There are also two asynchronous, online adaptations of MB, one for perinatal women and one for pregnant adolescents at risk for PPD [20]. Each digital adaptation of MB (text-based or online) included mixed methods research to optimize the intervention according to end user perspectives, and this feedback led to simplified language and more visuals in the final digital MB intervention [20,31,32]. Based on prior investigators' experience with adapting MB to a digital intervention, we assumed that adapting

MBapp would also need to include simplified and direct language and visual engagement via graphics and pictures of perinatal individuals and infants. The initial wireframe was developed with these features. Thus, all participants could provide granular feedback on features that were included or should be added to MBapp to encourage engagement, instead of focusing on giving the investigative team feedback on reducing the amount of text or adding visual appeal to the wireframe. It is important to note that only the online MB program for high-risk perinatal adolescents used formative qualitative interviews to adapt MB via a structured framework such as the FRAME, as is described in this paper. Incorporating this evidence-based approach ensured that all major MBapp modifications were well-justified and provided transparency to inform how future data on MBapp's effectiveness may be interpreted.

Strengths and Limitations

Our study had many strengths. Each aspect of intervention creation and adaptation was grounded in evidence-based practices: (1) MBapp's core content was derived from an in-person CBT curriculum known to be highly effective for PPD prevention [17-19]; (2) the individual in-depth interviews were performed according to established and recommended qualitative research practices as described by coauthors of our paper [39-41]; and (3) MBapp was adapted using a standard, commonly used framework for modifying established interventions [37]. In addition, our participants were diverse in terms of race, ethnicity, language, and parity, helping to ensure that different perspectives and opinions were included in our digital perinatal mental health intervention. Lastly, MBapp was created with a multidisciplinary team with expertise in perinatal mental health, digital health, and qualitative research, ensuring the digital health intervention was created via best practices.

Nevertheless, our study is not without limitations. First, our study population was comprised of 25 participants. Though a

standard sample for a qualitative research study, this study population cannot possibly represent all opinions and perspectives of perinatal patients. Second, recruitment was limited to one obstetric clinic, which may reduce transferability of findings to individuals within different types of clinics (eg, academic vs community-based obstetric clinics). Third, MBapp will be a fully functional native app available on iTunes (Apple Inc) and Google Play (Google LLC). Compared to a web-based intervention that can be easily and cheaply modified after creation, native apps such as MBapp incur significant software developer costs for any modifications postcoding. Though we cannot alter MBapp postproduction as has been carried out in web-based perinatal mental health interventions [42], we are optimistic that using the FRAME and end user feedback has optimized MBapp's wireframe to the point that additional edits are unnecessary. Lastly, though MBapp was deemed to have preserved fidelity to MB's curriculum by MB's original creators, it remains an empirical question whether an asynchronous digital education delivered via smartphone app is comparable to a 12-hour in-person group education led by a trained facilitator. Thus, the effect of MBapp on PPD will need to be explicitly and intentionally tested in future randomized trials.

Conclusions

In conclusion, the majority of our participants—pregnant or postpartum individuals with public health insurance—used apps to obtain on-demand perinatal education, and this expertise was leveraged to update and enhance a novel smartphone adaptation of MB. MBapp's wireframe was tailored to the unique needs of app-based interventions and to feedback from target end users, which may result in sustained user engagement once the app is deployed. Our team's next steps will be to confirm that MBapp is a feasible, acceptable intervention among English- or Spanish-speaking pregnant and postpartum people at risk of PPD through a pilot randomized trial. Ultimately, we aim to demonstrate that MBapp is an effective, scalable intervention that can prevent PPD on a population level.

Abstract

Background: Emergency nurses actively manage the flow of patients through emergency departments. Patient flow management is complex, cognitively demanding work that shapes the timeliness, efficiency, and safety of patient care. Research exploring nursing patient flow management is limited. A comprehensive analysis of emergency nursing work systems is needed to improve patient flow work processes.

Objective: The aim of this paper is to describe the work system factors that impact emergency nurse patient flow management using the System Engineering Initiative for Patient Safety model.

Methods: This study used grounded theory methodologies. Data were collected through multiple rounds of focus groups and interviews with 27 emergency nurse participants and 64 hours of participant observation across 4 emergency departments between August 2022 and February 2023. Data were analyzed using coding, constant comparative analysis, and memo-writing. Emergent themes were organized according to the first component of the System Engineering Initiative for Patient Safety model, the work system.

Results: Patient flow management is impacted by diverse factors, including personal nursing characteristics; tools and technology; external factors; and the emergency department's physical and socio-organizational environment. Participants raised concerns about the available technology's functionality, usability, and accessibility; departmental capacity and layout; resource levels across the health care system; and interdepartmental teamwork. Other noteworthy findings include obscurity and variability across departments' staff roles titles, functions, and norms; the degree of provider involvement in patient flow management decisions; and management's enforcement of timing metrics.

Conclusions: There are significant barriers to the work of emergency patient flow management. More research is needed to measure the impact of these human factors on patient flow outcomes. Collaboration between health care administrators, human factors engineers, and nurses is needed to improve emergency nurse work systems.

Introduction

Background

Emergency department crowding poses a grave threat to global health [1]. Hospitals face high patient volumes and acuity, limited bed capacity, staffing shortages, and financial constraints [1,2]. These issues necessitate an urgent optimization of patient flow to provide timely, efficient, high-quality care [2,3].

Emergency nurses play a central role in effective patient flow management, but their work is poorly understood [4-6]. This paper describes the human factors that impact the work of emergency nurse patient flow management.

Patient Flow Management

Patient flow analysis is the study of progressive patient movement through a unit, hospital, and wider health care system [6,7]. Research analyzing patient flow has grown over the last

2 decades to address patient crowding and limited health care resources [1,2]. The study of patient flow is especially important within emergency departments, where overcrowding and access block pose great dangers to patient safety [1]. Significant contributions from patient flow research include the identification of strategies to reduce demand for emergency services, improve hospitalwide management of system capacity, and expedite emergency throughput through process improvements such as patient streaming, point of care laboratory tests, fast-track treatment zones, and short stay observation units [1,2,6].

Throughout this research, emergency patient flow has been widely conceptualized using linear models that illustrate patient transitions into, through, and out of the emergency department [1,8]. However, studies that represent patient flow as a simplified sequential process may fail to account for the impact of the human agents who actively manage patient flow [9-12]. Research that does not adequately consider human factors has been criticized for poorly capturing the complexity of real-world systems, lacking generalizability across emergency departments, and failing to provide a deeper understanding of how and why patient flow interventions succeed or fail [4,6,13,14]. Emergency nurses are autonomous decision makers who exert active agency over care processes and have a demonstrated impact on patient flow outcomes [5,10,15]. Nevertheless, few scholars have investigated this aspect of nursing work [5,15].

To respond to this gap in knowledge, this paper is the second in a series that describes emergency nurse patient flow management. For the purposes of this research, “emergency nurses” describes registered nurses employed in hospital-based or freestanding emergency departments. The first paper described how emergency nurses conceptualize patient flow management as the balancing practice of optimizing patient care without exhausting department resources [16]. This balance is guided by the primary goal of patient safety [12,16]. Patient flow management encompasses five critical tasks: (1) information gathering, (2) continuous triage, (3) resource management, (4) throughput management, and (5) care oversight [16]. By engaging in these tasks, emergency nurses monitor fluctuating resources and patient care needs and aim to ethically allocate limited resources to the right patient. Emergency nurses also manage a tension between the desire to expedite patient throughput and the desire to provide care that comprehensively meets patient needs [16].

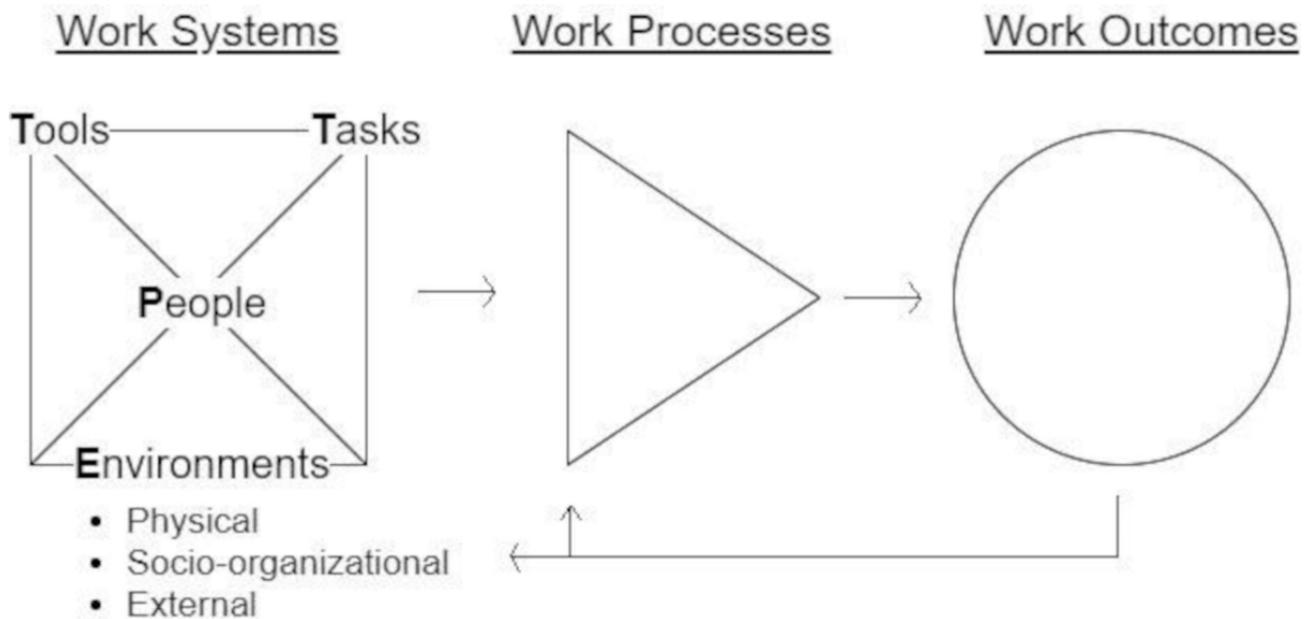

More specifically, nurses manage the flow of patients by making real-time, frontline decisions to shape patient care [12,16]. Nurses are often responsible for triaging patients and determining the order of bedding assignments, placing patients in appropriate treatment spaces, choosing which patients receive limited department resources such as cardiac monitors and specialized treatment rooms, and managing the size and acuity of nursing assignments [16-18]. Nurses also influence the timeliness and order of patients to receive treatment, diagnostic testing, inpatient bed assignment, and discharge or transfer [16-18]. Patient flow management is understood to be complex, dynamic, and cognitively demanding [6,12,15]. This paper adds to previous descriptions of emergency patient flow management by analyzing the factors that shape nursing work systems.

Human Factors and the Systems Engineering Initiative for Patient Safety Model

A purposeful investigation of interactions between humans, processes, and their environment is needed to effectively design systems, promote worker well-being, and understand and improve worker performance [19]. However, human factors methods have been underutilized in emergency medicine, and the organizational, cultural, and interpersonal factors that impact emergency patient care have yet to be fully explored [20-22]. Barriers to applying human factors approaches within emergency medicine include a lack of resources within hospitals to conduct human factors research, policies that impede human factors experts from accessing clinical settings, and limited dissemination of published examples [20].

The Systems Engineering Initiative for Patient Safety (SEIPS) model provides a human factors-based framework to investigate health care work [23]. The SEIPS model was first proposed in 2006 and has been refined several times, including the recently simplified SEIPS 101 model (Figure 1) [23-26]. SEIPS builds upon Donabedian’s classic System-Process-Outcomes model [27] to further explicate the elements of work systems, work processes, and work outcomes [23]. Within emergency health care research, this model has been successfully used to investigate physician documentation practices, physician disposition decision-making, and the transitions of older adult patients back home [28-30]. Within nursing, the SEIPS model has been used to better understand the work systems factors that impact nursing medication errors in critical care units, cardiac nursing workflow, and endotracheal cuff pressure management [31-33].

Figure 1. SEIPS 101 model by Holden and Carayon [26], published under Creative Commons Attribution-Noncommercial 4.0 International License [34]. SEIPS: Systems Engineering Initiative for Patient Safety.

This manuscript focuses on the work system, which is the first element of the SEIPS model [26] (Figure 1). The work system comprises 6 interconnected components: people, tasks, tools, physical environment, socio-organizational environment, and the external environment. These elements interact to form the work processes that directly impact outcomes such as health care quality, safety, and worker well-being [23].

Methods

Study Design

This study employed constructivist and situational analysis grounded theory methodologies, as articulated by Kathy Charmaz and Adele Clarke. Each methodology involves inductive, qualitative analysis [35,36]. Constructivist grounded theory focuses on exploring social processes [36], while situational analysis supports analysis of the disparate, nonhuman elements that shape situations [35]. To minimize bias and preconceptions, grounded theorists may postpone formal literature reviews until after data collection and analysis [36]. Therefore, this study started with the broad question, “How do emergency nurses perform patient flow management?”

Data Collection

Data collection strategies included individual interviews, focus groups, and observations across 4 emergency departments. Interview and focus group participants were recruited using purposeful and snowball sampling through email and social media platforms. Participation inclusion criteria were the following: English-speaking, over the age of 18 years, and registered nurses with at least 90 days of experience working in an emergency department. Initial interviews and focus groups lasted approximately 60 minutes and were guided by broad interview guides. Meetings were held remotely over Zoom and were audio/video recorded and transcribed with manual verification.

After initial rounds of focus groups and interviews, theoretical sampling was used to recruit existing participants for additional rounds of follow-up and think-aloud scenario interviews. Think-aloud scenario interviews [37] prompted participants to verbalize their patient flow management considerations when presented with a mock, simulated emergency department tracking board. These subsequent interviews were conducted individually, lasted between 30 - 60 minutes, and were used to support and further develop coding categories. In all, a total of 5 focus groups and 24 interviews were conducted across 27 participants.

Participant observations were concurrently conducted at 4 emergency departments in the northeastern United States. Departments had varying community settings, sizes, trauma designations, and annual patient visit volumes. The researcher recorded handwritten narrative field notes to describe the departments and staff behavior. Field notes also described brief interactions with staff that were used to clarify their actions and decision-making strategies. Observations were conducted in 4-hour blocks at variable times throughout a 24-hour period, for a total of 64 hours of observation.

Data Analysis

Data analysis occurred simultaneously with data collection and continued until saturation was reached. Data analysis relied on coding in NVivo 12 Plus (Lumivero) and constant comparative analysis. Line-by-line in vivo and gerund coding were used for initial coding [36]. As data analysis progressed, incident-by-incident coding was also used to code larger segments of data [36]. Constant comparative analysis is a method of qualitative analysis where coding of incidents and categories are compared to previous analysis to clarify emerging themes, inform additional data collection, and generate a theory [38]. Memo-writing was used to investigate coding categories, clarify theory development, and prompt reflexivity. Data collection and analysis were performed by a researcher experienced in emergency nursing; thus, reflexivity was an

active process of investigating assumptions and personal experiences, as well as reflecting upon potential biases [36].

After emergent themes were developed, a review of the literature was performed, and study findings were found to closely align

with the SEIPS model (Table 1). Emergent themes were then recategorized according to the SEIPS framework. As Carayon et al state, the SEIPS model can be applied during data analysis even if it was not used to guide data collection [24].

Table 1. Emergent theme and corresponding SEIPS component.^a

Grounded theory emergent theme	Corresponding SEIPS component
Tasks of patient flow management	Tasks
Factors that impact patient flow management	
Individual nursing factors	Person factors
Departmental factors (structural: resources, technology, physical layout; interpersonal: communication, staff roles and norms, department culture)	Technology and tools, and physical and socio-organizational environment factors
Interdepartmental factors	External environment factors

Trustworthiness

Strategies to increase study trustworthiness included prolonged engagement with data, negative case analysis, triangulation of participant samples and data collection strategies, and use of an audit trail. Three formal member checking interviews were performed and affirmed study findings. Study design, data analysis, and theory generation were informed by consultation with methodology and subject matter experts.

Ethical Considerations

This study was approved by the institutional review boards of the participating health care system and the University of Massachusetts Amherst (number 017066 - 00002). A Certificate of Confidentiality from the National Institutes of Health was obtained to increase participant confidentiality. Informed consent was obtained from focus group and interview participants using

Qualtrics surveys. Observed participants were informed of the study using an information sheet and interactions were guided by an oral script with verbal confirmation of participation. Focus group and interview participants were compensated at a rate of US \$35/hour using Amazon gift cards.

Results

Overview

Study findings are categorized according to elements of the SEIPS work system: person, technology and tools, socio-organizational environment, physical environment, and external environment (Figure 2). Participant demographics, emergency department setting characteristics, and patient flow management tasks are described in detail elsewhere [16]. Table 2 summarizes supporting evidence.

Figure 2. A SEIPS model of emergency nurse patient flow management. SEIPS: Systems Engineering Initiative for Patient Safety.

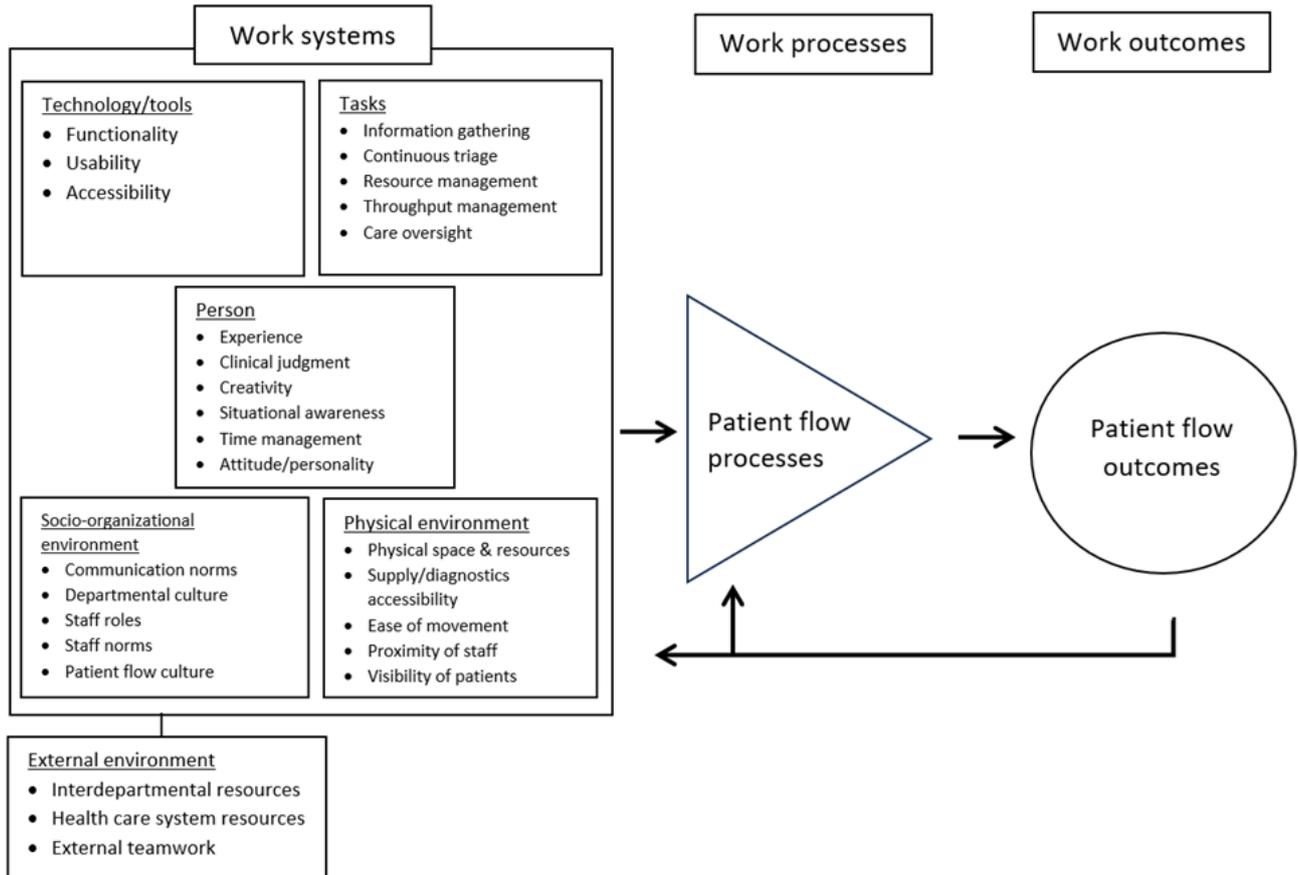

Table . Summary of findings with supporting evidence.

Work system element, major theme, and minor theme	Supporting quotes
Person	
<i>Experience</i>	
Emergency department	It's taking him a long time to adjust to this environment...in the ICU, "patients are there for so long, their plan of care is established." (RN2) – Field Note 14
Overcrowding experience	Community hospitals have a harder time dealing with stress influxes on patient resource management, while larger hospitals are used to being consistently stressed... and handle that patient flow management under stress a little bit better. (Int5)
Experience in specialized flow roles	When you're able to take those experiences, it opens your eyes up to the bigger picture...of patient flow. (Int11)
Clinical judgment	It has to be somebody with...that has a good core knowledge as a base. (Int6)
Creativity	Part of the charge nurse's job is to be really creative... you have to be innovative. (FG5)
<i>Time management</i>	
Correct prioritization of tasks	So I guess prioritizing...having a great awareness of prioritizing what is important at the time. (Int7)
Ability to multitask	I think that's where a lot of nurses really get caught up, is they don't have the ability to effectively multi-task and remember the 7 different directions that they need to go at once. (Int10)
Situational awareness	Our charge nurses, I think of them as up in the balcony, watching the orchestra play. They're imperative to the functioning of the team, but they've gotta be up a level so that they can actually see what's going on, and so they've got that complete view that isn't skewed because they're, you know, sinking in the quicksand with everybody else. (Int1)
<i>Attitude</i>	
Sense of accountability to department	The nurses are wrapped up in their own little section, and they don't want more because they're overwhelmed. (FG3)
Degree of motivation	And then you have bedside nurses who will sit on patients, sit on orders, to hold on to as many patients as they can, so that they don't have openings and flow. (FG5)
Level of burnout	I've never seen nurses this exhausted, physically and emotionally. (Int6)

Work system element, major theme, and minor theme	Supporting quotes
<p style="text-align: center;"><i>Personality</i></p> <p style="text-align: center;">Compassion for patients and colleagues</p> <p style="text-align: center;">Adaptability</p>	<p>I think they're good people... it's definitely a personality thing. They're friendlier, more socially aware of other people's struggles, and they care about it. I think other nurses don't give a shit. (Int9)</p> <p>There's some people that they're like 'Chicken Little the sky is falling' all the time, and it's like, 'Take a deep breath. It's gonna be okay.' (Int2)</p>
<p>Technology and tools</p>	
<p style="text-align: center;">Functionality</p>	<p>We all have the computers on wheels and they're just all over the place...and you know, of course, half of them don't work. (Int8)</p>
<p style="text-align: center;">Usability</p>	<p>I was trying to login so I could get report, and it pops up, 'Your patient is overdue for a bath.' It's like, 'Why, why?!'...and you can't get out of the screen unless you chart something, and if you chart "not responsible," it tries to prompt you as to why?... and then it's, you're clicking out of the boxes... it's alarm fatigue, but for the charting side. It's charting fatigue. (Int15)</p>
<p style="text-align: center;">Information accessibility</p>	<p>So when an ambulance comes in, I don't like to be like, 'Oh, hold on let me change my screen.' I just wanna know, visually, like what I have available, and who has what, and that kind of thing, at all times. (Int7)</p>
<p>Physical environment</p>	
<p style="text-align: center;">Physical capacity and resources</p>	<p>There's just no space, no room. Even if we try to bring them back, there's just nowhere to put them. (FG12)</p>
<p style="text-align: center;">Access to supplies and diagnostics</p>	<p>Our isolation room has a little ante-room...we were kind of using it for storage, and we would just shove stuff in there, all kinds of stuff. And a lot of equipment has to be plugged in all the time, so their solution was to mount an extension cord strip type thing to the wall... so all that equipment is just right there, to get to sterile gloves, I have to move things out of the way. (Int8)</p>
<p style="text-align: center;">Ease of movement</p>	<p>There wasn't even a hallway space to put the patient in. It was like, 'Okay, I have 14 inches here in a hallway.' Everybody just turned sideways to go around this trauma patient. (FG11)</p>
<p style="text-align: center;">Proximity of staff</p>	<p>Just having everybody kind of close to the nurses' station just really helps communication. (Int7)</p>

Work system element, major theme, and minor theme	Supporting quotes
Visibility of patients	The worst setup that we did was fast-track. They were made all private rooms, and you couldn't see the patients 'cause they were behind a closed door. (Int6)
Socio-organizational environment	
Communication norms	If you have [staff that] don't openly communicate, you are going to have significant delays in your patient flow management. (Int5)
Staff roles	There was no flow coordinator. I had never heard of that until my friend was talking about their flow coordinator, I'm like, 'Who is that?' (Int15)
Staff norms	
Role flexibility	If I'm lead that day, like, I have my plan... I have my system. And if people do try to help ...I think it adds to the chaos. (Int7)
Role preference	That's a bad job by the charge person, because you've got all your buddies doing all the fun jobs for the day, and then everyone else has to do the other ones. And if you don't think they notice that, you're out of your mind. So that's a cultural problem that will slow things down. (Int9)
Role hierarchy	Good patient flow has to be somebody who's willing to not sit in the White Tower... or 'I'm gonna sit in the pod chair and get 'charge butt' and never move.' You have to move. (Int3)
Departmental culture	
Teamwork and camaraderie	They would step over your quivering body on the floor to get to where they're going, instead of picking you up or helping you. (Int9)
Respect between providers and nurses	If they walk up to a doctor, whether it's a third or fourth year resident or an attending, and they say 'You need to come right now and see this patient.' That doctor will stop what they're doing and they will go see their patient. (Int6)
Relationship between staff and administration	It's so frustrating, 'cause this is the 6th hospital I've worked in, and they're all the same. They're greedy, greedy corporations and they don't care about patients. (RN6)
Capacity for change	RN2 tells me some of the older nurses are "stuck in the old ways" when they only saw 5 patients in their whole shift and they've had trouble adjusting. — Field Note 11
Patient flow culture	

Work system element, major theme, and minor theme	Supporting quotes
Perception of provider incentives	I'll have a patient come in from the waiting room and they're already admitted. And it's for bullshit reasons...They need to look at what they're admitting and send more people home. (RN7)
Provider-driven versus nurse-driven flow	So now, it's interesting for me to come back and see this clash between what the doctors are used to. They're used to nurses running things, and the nurses are used to doctors running things. (Int12)
Role of patient flow metrics	Like door-to-doc time less than 20 minutes, discharge time less than 7 minutes...it was engraved in everybody's head. As soon as that manager left—we just got a new manager—and there's no real guidance for this new manager. (Int7)
External environment	
Interdepartmental resources	That's our biggest pushback... we've had a CT scanner down and they're understaffed right now, and we had a 4-hour delay in CTs yesterday. (Int2)
Health care system resources	There's this backlog... when patients haven't been efficiently discharged from upstairs, and there's a delay to the folks who have been admitted. And then, obviously, it's probably the same thing that's happening in the bigger hospitals, so there's no transfers available. (FG5)
External teamwork	But the house supervisor will come and help—sometimes they'll send...a nurse over here, who comes in kicking and screaming. (Int8)

Person

Emergency patient flow management relies on nurses' individual characteristics, including their level of experience, cognitive skills, and personal attributes. In addition to overall years of nursing experience, participants emphasized a need for experience working specifically in emergency settings. Emergency departments have their own unique rhythm and pace of care. In observations, this was exemplified by a senior intensive care unit (ICU) nurse who struggled with the speed and turnover of emergency patients.

RN2 has significant ICU experience, including 8 years working in a MICU, SICU, NICU [medical, surgical, neonatal ICU]. "It's a totally different environment and flow than I'm used to." [Field Note 14]

Emergency department experience is also needed to gain knowledge of emergency medical treatment and care processes. Strong patient assessment skills, critical thinking, and knowledge of emergency patient care are perceived as the "core knowledge" (Int6) of emergency patient flow management. Notably, patient flow management is viewed as work that nurses learn after they

master these fundamentals of emergency nursing. As one participant stated, "a new nurse is just trying not to kill a patient. And not miss anything" (RN3).

Grounded in clinical judgment, patient flow management also relies on nurses' creativity, time management, and situational awareness. To successfully manage flow, nurses must think on their feet and creatively problem-solve in real time, while simultaneously managing multiple, urgent patient care priorities. This creativity is fostered by experience in overcrowded settings, where nurses learn to "think outside the box" (Int1) and develop a repertoire of innovative strategies.

Above all, participants emphasized the need for situational awareness. Situational awareness was described as the ability to maintain a holistic perspective of fluctuating patients, care needs, staff, and resources. Nurses with strong situational awareness are knowledgeable about the entire emergency department within its wider contexts of the hospital, emergency medical system, and surrounding health care system.

So you need to be able to look at the big picture, not just your one team of patients, or even your one ER.

You have to be able to look and see globally what's going on. [Int4]

The cognitive skills required to manage patient flow are strengthened through experience in specialized flow roles. Nurses in lead, float, flow coordinator, journey navigator, resource, or charge roles are immersed in the work of managing patient flow across an entire pod, zone, or department. As one participant described, these roles “open your eyes up to the bigger picture of patient flow” (Int11) and provide nurses with a deeper knowledge of the policies, organizational procedures, and internal politics of their institution.

Patient flow management is also impacted by nurses' attitudes and personalities. Nurses engage more in patient flow management when they have a sense of accountability to the wider department. Nurses who focus more narrowly on their own patients often lack an awareness of the department's patient volume, the number of waiting patients, or of coworkers struggling with heavy assignments.

They're just focused on their assignment...they work on their own pace and are in their own bubble. They're not hustling as much as the charge nurse would be, or somebody who's trying to make room for other folks. [FG5]

Nurses' engagement in patient flow management also varies according to their level of motivation. Many nurses demonstrate a sense of urgency to expedite patient throughput. Other nurses are described as “unmotivated, complacent, or lazy.” Burnout was seen as an especially common barrier to patient flow management engagement. Participants reported widespread physical, mental, and emotional exhaustion among emergency staff. For disengaged nurses, expediting patient flow is undesirable because it leads to new patients and additional work. As one participant summarized, “the more you kick in quicksand, the faster you sink” (FG3).

Well, the faster I get this out, the faster you're just gonna give me something new, and this never gonna end, so why should I hurry? [FG4]

Regarding personality, patient flow management is impacted by nurses' level of compassion and adaptability. Nurses are perceived as more highly engaged when they hold deep compassion for their patients and colleagues that drives a desire to help and provide better care. Effective patient flow management also relies on the ability to remain calm and level-headed under pressure.

None of my nurses really spin, you know, they don't get caught up and start freaking out about things. My team is so tight...we just don't get that excited over stuff. [Int10]

To summarize the personal factors, patient flow management appears to be facilitated by highly engaged nurses who are experienced in emergency department care, have deep clinical and institutional knowledge, and have the cognitive capacity to perform creative, complex, dynamic work.

Technology and Tools

Technology was found to significantly shape emergency nurse patient flow management. Access to Pyxis medication dispensers, portable computers, pneumatic tube systems, portable communication devices, and online applications that provide pharmacy or education support were observed to impact nurse workflows. Health information systems, including emergency tracking boards, electronic medical records, bed tracking systems, and ambulance tracking systems, appear to be especially consequential to patient flow management because they shape emergency nurses' ability to gather information about department resources and patient care.

When describing technology, participants reported concerns with functionality, usability, and information accessibility. Inconsistent access to functioning technology is a common and time-consuming barrier to patient flow management. Participants frequently dealt with failures and breakdowns such as broken medication scanners, computer downtimes, stalled pneumatic tube systems, and challenges with portable communication devices.

Nothing is working...yawn...the computers aren't working. (RN3) [Field Note 11]

Participants also struggled with technology usability, often lacking a full understanding of how to operate and troubleshoot devices or make sense of presented information. Emergency nurses heavily rely on emergency tracking boards, which present a departmentwide overview of patient assignments and care progress. Multiple participants acknowledged uncertainty in the meaning of the icons, symbols, and colors displayed on the emergency tracking board.

... the stars indicate if an order is late by 15 minutes or 30 minutes. They both laugh, “See? I didn't even know that.” (RN3) [Field Note 8]

Although some participants reported satisfaction with their health information systems, many described information platforms that were overwhelming, contained burdensome alert functions, and had poorly designed interfaces.

I ask about their experience using [product]. “It's overwhelming,” “Way too much on the eyes. I don't know how pod leads can look at this board.” (RN10) [Field Note 8]

Last, information accessibility appears to be impacted by the number of different health information systems required to access patient information and the transparency between different systems. Participants reported outdated programs, the need to navigate several different interfaces, and time-consuming workarounds.

To look up the actual lab numbers you have to go to [a] different screen, to look up radiology results you have to go to [a] different program, and so there's a lot of minimizing, you know, getting to this screen, or that screen, or this screen, or that screen, to figure out what needs to be done. [Int8]

Socio-Organizational Environment

Patient flow management is impacted by the social and organizational characteristics that influence how nurses communicate and work together. First, participants emphasized the importance of clear, closed-loop, and frequent communication to keep one another apprised of department resources and patient care. Observations revealed that, in practice, nurses often rely on indirect strategies, such as writing updates on the emergency tracking board, to communicate changes in patient locations. Communication failures were especially common during handover with prehospital personnel, during bedding assignments, and when calling patient report to inpatient units.

“Do you have that guy?” (RN5) “Oh, so I probably have that guy. I don’t know, I just came out and my name was on them. Alright, I guess I’ll go see him.” (RN4) The patient they’re talking about has been in the department for 2 hours. [Field Note 3]

Patient flow management is also shaped by the culture of emergency staff, providers, and administration. Departments with high levels of teamwork and camaraderie are able to work together toward common patient flow goals. Participants described respect between providers and nurses as the foundation for patient safety and optimized flow. Without a sense of mutual respect, nurses report a reluctance to ask questions, raise concerns, and share their opinions. Whereas nurses praised departmental cultures where staff and providers were a unified team, participants often expressed a disdain or distrust of hospital administrators. Nurses’ suspicion of administrators’ intentions can exacerbate a reluctance to embrace change or engage in patient flow improvement initiatives.

With this model and this process that they want to try—that was directed by our medical director, who is not a nurse, and he doesn’t push for us to get these patients out like he should, or stand up to the people with the dollars and the pulling of strings. [Int14]

Staff roles were found to vary widely between departments, encompassing a broad array of role titles and job functions. Responsibility for patient flow management decisions may be held by staff nurses, charge nurses, or by a variety of specialized flow roles such as flow coordinators, triage nurses, navigator nurses, pivot nurses, pod leads, float nurses, streamer nurses, or bed czars. Individual roles fluctuate according to staffing levels, such that one staff member may have to take on the duties of several roles during periods of poor staffing. Patient flow management is also shaped by the presence of other staff and provider roles, such as technicians, medical assistants, paramedics, orderlies, transporters, and medical residents.

And then the roles within the department, your typical staff nurse—clinical nurse, but we also have a resource nurse, which is just a charge nurse. We also have a flow nurse and then triage nurses as well. [FG17]

In addition to differing staff role titles and functions, departments vary in their role norms. Some departments demonstrate high levels of flexibility in responsibility for patient

flow management decisions, while others have more rigid role expectations. For example, in some departments, the responsibilities of answering the ambulance radio, assigning patients to emergency rooms, or shuffling patient locations are strictly held by a charge or flow coordinator nurse. In other departments, nurses in bedside roles readily take on these tasks when they see an opportunity to help. Departmental norms further impact the desirability of certain roles and role hierarchy. High degrees of hierarchy that create distance between the charge nurse or flow coordinators and the patients’ bedside may impede that nurse’s familiarity with direct patient care and create animosity between staff.

I feel like when some people level-up they forget how it is to be in an assignment. And then they’re in an assignment and they’re drowning and they’re asking you for your help. [RN4]

Role norms also impact whether patient flow management is perceived as primarily provider- or nurse-driven. Departments perceived to be more “doctor-driven” were described as those where the providers more closely monitor the waiting room patients and voice their opinions about who should be assigned emergency beds, and where providers delegate frequently and engage less in collaborative decision-making.

RN2 said that post-COVID, with all the newer nurses, that patient care is more “micromanaged” by the doctors. “It never used to be like that.” (RN2) [Field Note 8]

Finally, patient flow management is influenced by the incentives provided to physicians and nurses. Participants criticized the perception that providers may be incentivized to empty the waiting room, perform excessive diagnostic imaging, and admit high proportions of emergency patients as especially impactful on patient flow management.

Our doctors... hate waiting room times. So at (hospital), what I appreciated was it was okay to have a waiting room. That’s what the waiting room is for. [FG17]

Emergency departments vary in the extent to which management has established clear incentives to meet patient flow metric goals. These metric goals might include specifications for the length of time that patients should wait to be assessed or transported to an assigned bed. Nurses differ in their opinions of these patient flow standards. Although some participants felt that strict timing expectations were helpful to increase staff engagement, others felt that they compromised nursing judgment and patient care.

It made it harder to be really thorough. Like you’d think ‘Hmm, I can either do a really thorough assessment, or I can meet my time.’ [RN2]

Physical Environment

Participants perceive access to resources to be the single most important factor influencing patient flow management. Patient flow management is impeded by insufficient beds, rooms, equipment and supplies, and inadequate staffing.

The halls are narrow, especially when we have the hallway beds in there. So, you know, when you're pushing a gurney through there, you're kind of having to wiggle a little bit, make sure you don't hit somebody. [Int8]

In addition to its physical capacity, the layout of a department impacts nurses' access to supplies and diagnostic testing, physical movement, the proximity of staff, and visibility of patients. These characteristics impact the efficiency and ease of emergency nurses' work. In observations, departments were found to be cluttered, cramped, disorganized, and lacking sufficient capacity for patients, medical equipment, and supplies.

So layout is important...because there are rooms where you're kind of isolated, and it's hard because they don't hear the doctors talking, or updates on patients, so that has an impact on patient flow. [Int7]

External Environment

Last, emergency patient flow management is shaped by factors external to the work system of the department. Interdepartmental resources—including staffing levels of diagnostic departments, environmental services, transport services, and inpatient units—impact the efficiency of patient care and movement out of the department. Participants also acutely felt the consequences of working within an overburdened health care system that limits their ability to successfully transfer and discharge patients. Nurses emphasized a frustration with the lack of adequate ambulance transportation.

Our EMS service's so short-staffed, they can hardly handle the 9-1-1 calls, let alone handling the transports out. Like, how do we get these people out? [FG4]

Teamwork between the emergency department and other hospital departments impacts the ability to coordinate and advance patient care processes. Tension and pushback from inpatient floors during reports from the emergency department to floors is a common experience. Participants reported that inpatient nurses are often unavailable to take report, reluctant to accept patients, and engage in delaying tactics. This pushback from the floor results in challenges transporting emergency patients out of the department.

It's been like hand-to-hand combat with the floors, trying to get patients upstairs. [Int10]

Discussion

Principal Findings

This is the first paper, to our knowledge, to comprehensively describe the work system of emergency nurse patient flow management. Using this approach, we have framed patient flow processes around the work processes of nurses rather than sequential patient transitions. The articulation of 5 discrete patient flow management tasks is described more thoroughly in the first paper in this series [16]. Conceptualizing patient flow management as a balance of tasks offers a new framework for improving patient flow by supporting the nursing work of

information gathering, continuous triage, resource management, throughput management, and care oversight.

The SEIPS model places a “person” at the heart of the work system. This human-centric approach theoretically links nurses' individual characteristics to patient flow outcomes. Study results propose that patient flow outcomes are influenced by emergency nurses' attitude, personality, experience level, and cognitive abilities. Collectively, these findings emphasize the importance of strengthening nurse training, retention, and support. Developing nurse patient flow management training has been proposed as a potentially cost-effective approach to improve patient flow [15]. The current lack of training may be due, in part, to a limited understanding of needed skills and traits [39]. Nursing education also predominately focuses on individual, patient-centered care rather than collective decision-making across multiple patients [16,40]. This study has clarified that clinical judgment, time management, and situational awareness are essential for patient flow management and should be a priority for training efforts. In addition to training support, findings suggest that hospitals may consider investing in nurse retention and well-being as a patient flow intervention.

Patient flow management depends on several structural factors, including department technology, physical capacity, layout, and internal and external resources. These elements impact the speed and ease of nursing work, including the ability to gather information, access needed supplies, collaborate with peers, and visualize patients. Broadly, participants described emergency departments as ill-suited to support the work of patient flow management. Nurses criticized the accessibility, functionality, and usability of health information systems, and physical work environments were found to be cramped, cluttered, and lacking adequate supply and staffing resources. Although the physical capabilities and resource levels of emergency departments are often challenging to change, there is potential to better support patient flow managers by redesigning health information systems [41]. Notably, a recent systematic review found that, despite their importance to patient flow, how and why health information systems impact patient flow processes remain poorly understood [42], re-emphasizing the need to better understand emergency nursing work processes.

Finally, patient flow management is shaped by social and organizational factors. Although the importance of departmental communication and culture to promote patient flow are apparent, the variability of staff roles, staff norms, and patient flow incentives are noteworthy findings. Patient flow management roles, norms, and incentives were found to be highly inconsistent, context dependent, and largely informal. Staff roles and norms lack uniformity between departments and fluctuate as staffing levels, individual staff members' preferences, and levels of expertise change. Departments also vary in the degree to which patient flow management is perceived to be doctor- or nurse-driven, and these expectations are unwritten and obscure. Unclear responsibility for patient flow management decision-making is further complicated in departments with high role flexibility, where flow decisions are made on an ad hoc basis by available or nearby nurses. Other scholars have noted this ambiguity and blurring of emergency

department flow management roles and have called for greater clarity in staff responsibilities [43-45].

Further, findings suggest a great disparity between departments' enforcement of patient flow metric expectations. Some nurse participants described working in environments with highly stringent timing guidelines, while other nurses were unsure if their hospitals had any timing expectations at all. The impact of these patient flow incentives is unclear. Scholars have recognized an inherent tension between quality and speed of care in the work of patient flow management [9,16,45], but research is needed to understand how emergency nurses manage this balance. Overall, strategies to clarify and promote consistency between patient flow management roles, norms, and incentives may benefit emergency nursing work.

Implications and Applications
