Doctor showed up even with nurse practitioner. And normally the doctor talks to you, she examines you, explains things. And then normally the nurse practitioner fills up whatever they need to do in a database. And normally it's not distracting at all. It's all adequately it happens in the background, and you concentrate on the conversation with a doctor, and someone else is filling out all the paperwork. Something needs to be like sending the prescriptions to my pharmacy and setting up another test. Everything was done at the same time, but I don't feel it was destructive at all. It was good. [Patient 09]

Thus, to sum up, the health system elements impact patients' perception of technology use, trust in physicians, and satisfaction with care, which supports hypothesis 5.

Discussion

Principal Findings

In this study, we qualitatively explored the impact of work system elements on QOC and PCC and how PCC also impacts QOC among newly diagnosed patients with cancer in the first follow-up visits after the diagnosis. We found that newly diagnosed patients with cancer experience a high workload (mental, physical, temporal, effort based, performance based, and emotional) resulting from the frustrating diagnosis and the load of information that they receive in the first visits. This load impacted patients' trust in their physicians, satisfaction with care, and perception of technology use during the visits.

A diagnosis of cancer is a threat to one's sense of security, whereas feelings and emotions accompanying the disease uproot everyday existence [70]. Patients find themselves unpredictably facing a high emotional load and under the obligation to cope with the stress and anxiety caused by their diagnosis [70,71], which explains the high emotional and mental workload faced by our participants.

In addition to that, patients with cancer have to deal not only with the physical ailments resulting from the illness and its treatment but also with the thoughts of permanent health impairment, disability, fatigue, and pain that may result from their diagnosis [72], which correlates with our finding of high physical and effort-based workload perception among the participants. This may explain the dissatisfaction of patients with the quality of the care received. Emotional stress and mental problems can cause difficulties in everyday life, such as not being able to work, financial problems, and a lack of social support. This has been shown to impact quality of life perception among patients with cancer in other studies [73]. The literature also shows that patients with cancer can experience a variety of needs as each person reacts individually to the hardships of illness depending on their personality traits and understanding of their new situation [70]. With the substantial incoming flow of information, patients may find themselves unable to trust physicians and may consider technology as a distraction to their visits at that stage.

We also found that newly diagnosed patients with cancer can be very needy when it comes to communication with their physicians and that their communication with physicians impacts their perception of QOC. Communication is the cornerstone of the relationship with the patient in all medical settings, specifically chronic care, with the main aims of creating a good interpersonal relationship, exchanging information, and making treatment-related decisions [74]. Certain attitudes, behaviors, and skills (eg, ability to impart confidence, empathy, "human touch," relating on a personal level, being forthright, being respectful, and being thorough) are part of effective communication, which was validated by our findings in this study [74]. A poor physician-patient communication in cancer care negatively affects psychological well-being and patients' decisions and perceptions regarding treatments. This validates our findings of the impact of communication with physicians among newly diagnosed patients with cancer on their perception of technology use during visits and trust in physicians [75].

In addition, we found that the work system elements impact patients' workload, communication, and QOC perceptions. This correlates with the findings of other studies in which the environment design was shown to impact patients with cancer's perception of QOC. A recent review of evidence-based design also found that a conscious design adapted to patient needs had an impact on a decrease in infection spreading, length of stay, pharmacological needs, and perceived stress among patients [76]. Furthermore, symbolic objects found in the environment have been shown to impact patients' sense of self and well-being [76].

In addition, a recently published Cochrane review on environmental impact on health stressed the profound need for well-designed studies following intervention in health care environments [77]. This correlates with our finding that patients who liked the decoration of the hospital, the motivational signs, the colors, the cleanness, the organized processes, the lighting, and the care of the nurses were more satisfied with the QOC and felt less overwhelmed. These findings lead to the expectation that major considerations ought to be taken when designing health care environments to meet quality requirements while considering patients' needs and supporting patients' sense of control, autonomy, and independence.

Theoretical and Practical Implications of the Findings

In the previous section, we validated the preset hypotheses that correlate with the findings of the quantitative studies from the greater project. This framework can help inform patient-centered interventions that aim to provide newly diagnosed patients with cancer with the support needed and ensure their satisfaction with the QOC offered. More empathy and human bond links between physicians and patients should be considered as patients want to be treated in a more patient-centered way and to feel that they are not receiving the same care as everyone else in the same way.

Patients also want to have the chance to ask as many questions as possible and be given as many follow-up visits in the beginning as possible to receive comfort and reassurance that everything will be fine. Empowering workers (nurses and staff) to intervene in case of emergency would help patients trust the

health care organization. In addition, allowing patients to be accompanied by their family members would help them be emotionally comfortable. Another point to consider is to share a second screen with them in case a computer is used when the physician is communicating with them to comfort them regarding what the physicians are doing when they are not talking to them.

Pausing in the middle of the discussion to do other tasks would result in losing the patients' attention. Physicians should consider continuous communication where they pay as much attention as possible to the patients in a friendly way and where they listen to their concerns without rushing them even if there is a time limit as the time given can influence their decision-making process importantly.

This study's findings can also inform the organization's design. It should be considered that patients cannot move a lot between the laboratories and the visit rooms and it would be easier to assign them to rooms that are close to each other to minimize their physical effort during the visits. Better scheduling and allocation strategies should be considered to minimize the waiting time inside the hospital for each patient. Comforting colors, relaxing decoration, and motivational signs would help reassure patients while in the hospital. In addition, having any construction work when patients are coming in and out should be avoided as that can add more load to what they are already experiencing.

Limitations

Despite the useful insights garnered from this research, certain limitations must be addressed. First, the study's narrow geographic reach, which included only 1 cancer center, may limit the findings' generalizability to other cancer populations or health care settings. Patients' experiences and technology preferences in this facility may not represent those in other cancer centers or varied communities with different demographics or cultural backgrounds. Second, selection bias is possible as patients who chose to participate in the interviews may have different characteristics or opinions from those who declined or were unavailable. This may introduce bias in the findings and reduce the study's external validity. Furthermore, interviewing patients within a few visits following their initial

diagnosis may not completely capture the dynamic character of their technological choices, which may change over time as patients adjust to their diagnosis and treatment. The reliance on patients' recollection of their technology preferences at this early time point may also be subject to recall bias. Furthermore, contextual factors particular to the cancer center where the research was conducted, such as local health care policies and the availability and accessibility of technology, may not be applicable or may vary in different contexts. Finally, social desirability bias and interviewer prejudice throughout the data collection process may have an impact on the data's authenticity and veracity. Despite these limitations, the findings of this study provide valuable insights into the technology preferences of newly diagnosed patients with cancer, and additional research with larger and more diverse samples, longer follow-up periods, and considerations of contextual factors is required to strengthen the findings' generalizability and validity.

Conclusions

In this study, we suggested a framework called Effectiveness of Patient-Centered Cancer Care and tested its validity in cancer visits to support PCC among newly diagnosed patients with cancer using qualitative data. We found that workload and patient-centered communication impact QOC and that the work system elements impact the patient-centeredness (workload and communication) and QOC (trust in physicians, satisfaction with care, and perception of technology use). To improve patients' experiences in the first visits after diagnosis, more interest needs to be given to the design of the organization, the processes that the patients have to go through, and the collaboration among the different actors and providers. This study's findings can also inform the organization's design. It should be considered that patients cannot move a lot between the laboratories and the visit rooms and it would be easier to assign them to rooms that are close to each other to minimize their physical effort during the visits. Better scheduling and allocation strategies should be considered to minimize the waiting time inside the hospital for each patient. Comforting colors, relaxing decoration, and motivational signs would help reassure patients while in the hospital. In addition, having any construction work when patients are coming in and out should be avoided as that can add more load to what they are already experiencing.

Abstract

Background: Overdose Fatality Review (OFR) is an important public health tool for shaping overdose prevention strategies in communities. However, OFR teams review only a few cases at a time, which typically represent a small fraction of the total fatalities in their jurisdiction. Such limited review could result in a partial understanding of local overdose patterns, leading to policy recommendations that do not fully address the broader community needs.

Objective: This study explored the potential to enhance conventional OFRs with a data dashboard, incorporating visualizations of touchpoints—events that precede overdoses—to highlight prevention opportunities.

Methods: We conducted 2 focus groups and a survey of OFR experts to characterize their information needs and design a real-time dashboard that tracks and measures decedents' past interactions with services in Indiana. Experts (N=27) were engaged, yielding insights on essential data features to incorporate and providing feedback to guide the development of visualizations.

Results: The findings highlighted the importance of showing decedents' interactions with health services (emergency medical services) and the justice system (incarcerations). Emphasis was also placed on maintaining decedent anonymity, particularly in small communities, and the need for training OFR members in data interpretation. The developed dashboard summarizes key touchpoint metrics, including prevalence, interaction frequency, and time intervals between touchpoints and overdoses, with data viewable at the county and state levels. In an initial evaluation, the dashboard was well received for its comprehensive data coverage and its potential for enhancing OFR recommendations and case selection.

Conclusions: The Indiana touchpoints dashboard is the first to display real-time visualizations that link administrative and overdose mortality data across the state. This resource equips local health officials and OFRs with timely, quantitative, and spatiotemporal insights into overdose risk factors in their communities, facilitating data-driven interventions and policy changes. However, fully integrating the dashboard into OFR practices will likely require training teams in data interpretation and decision-making.

Introduction

Background

The escalating drug overdose epidemic in the United States continues to pose a major public health challenge. Previous research has identified general risk factors that are linked to increased overdose rates [1-3], including unstable housing [4,5], recent release from incarceration [6,7], and frequent visits to the emergency department (ED) [8-11]. However, overdose risk factors exhibit considerable variation across communities and are influenced heavily by geographic and demographic disparities, particularly in access to health care and prevention services [9,12]. Moreover, the evolving nature of the epidemic has led to shifting risk profiles among different subpopulations [13]. These disparities underscore the need for timely and data-driven interventions that are tailored to the specific needs and challenges of local communities.

One mechanism for implementing targeted, community-specific interventions is through local Overdose Fatality Reviews (OFRs). Modeled after child fatality reviews [14,15], OFR teams comprise reviewers from multiple agencies who conduct collaborative, in-depth reviews of case files for individuals who have died of overdose [16,17]. Through these detailed case reviews, OFRs identify service gaps and recommend strategies to prevent future overdoses in their communities. The use of OFRs has gained momentum, with teams operating across various US localities [18]. However, current OFR practices primarily focus on reviewing only a handful of cases, typically 2 to 5 monthly or quarterly [19]. These cases typically represent a small fraction of the total fatalities occurring in their jurisdiction. While informative, the emphasis on a few individual cases could skew the review process, leading to OFRs making recommendations that do not fully address broader overdose trends.

As local governments continue to collect data on overdose events, there is an opportunity to leverage these data to enhance the OFR process. Previous research demonstrates the value of linking administrative data sets routinely collected by state governments (eg, calls to emergency services and incarceration records) with overdose mortality data [20-24]. For example, cross-referencing the records of decedents who experienced overdoses from across various data sets allows for uncovering their “touchpoints”—interactions with health and social services and other local systems they had before their overdose. When brought to light, touchpoints offer key opportunities to engage at-risk individuals and connect them with prevention services and treatments [25-27]. Analyses to identify touchpoints have so far been performed manually by researchers. However, the process is amenable to automation, enabling continuous assessment of touchpoint characteristics. The results can then be communicated in real time to local OFRs through a dashboard, providing review teams with up-to-date, quantitative

information on the trajectories of decedents in their communities.

Dashboards have proven invaluable in public health settings [28,29] owing to their ability to visually summarize key metrics and statistics [30,31], thereby aiding surveillance and fostering evidence-based responses to emerging health threats [32,33]. Furthermore, dashboards are conducive to collaborative sense making among multiple individuals [34-36]. This feature makes them particularly suited to fatality review meetings, which are designed to be collaborative and deliberative in nature. Numerous dashboards have been developed to visualize drug overdose-related data [37-39]. However, existing solutions are primarily intended to surveil the level and distribution of overdoses as opposed to understanding events that *precede* them. Few of the earlier dashboards showcase touchpoints at the local level or update data in real time, making them less suited for understanding system-level gaps or for deriving prevention-oriented insights.

Aims

This study presents findings from human-centered research, design, development, and initial evaluation of a dashboard aimed at supporting OFR teams by visualizing overdose touchpoint statistics. The objective was to provide county-level OFR teams with timely and actionable data on events that consistently *precede* fatal overdoses in their communities. In doing so, we aimed to illuminate additional opportunities for interventions at the population level beyond what can be gleaned from individual fatality case reviews. The goal was to increase the chance of successful targeting and implementation of OFR recommendations. This stands to improve overdose prevention and reduce the number of preventable deaths.

Methods

Overview

To design a dashboard suitable for the needs of OFRs, we adopted a user-centered design framework [40,41] drawing on participatory methods to engage stakeholders in the process [42,43]. Specifically, we conducted focus groups with a panel of OFR experts to elicit perspectives on requirements and data needs, envision design possibilities, and document potential challenges. The elicited requirements were then used to develop exploratory visualizations of touchpoints data. The initial visualizations were further refined based on feedback from the expert panel. Subsequently, the revised visualizations were used to develop a web-based dashboard that is hosted by the Indiana state government.

Study Setting and Data Sources

We partnered with the state government of Indiana to prototype and develop the sought touchpoints dashboard. Indiana has a nationally recognized role in organizing and convening OFRs, with 28 active review teams organized at the county level and

supported by the Indiana Department of Health. Similar to many other states, Indiana maintains a comprehensive and up-to-date database of fatal overdoses. This database includes all suspected accidental poisonings (coded as X40-X44), intentional poisonings (X60-X64), assaults by drug (X85), and cases of undetermined intent (Y10-Y14) that occurred among Indiana residents. In addition to overdose data, the state maintains administrative data sets from various agencies, including incarceration records, emergency and medical service use, and prescription dispensation. Importantly, these administrative data sets are linkable to the overdose mortality records. The Indiana Management Performance Hub (MPH), a state-level agency, serves as a central repository for these data sets, which are gathered from the corresponding agencies.

To identify events that precede drug-related fatalities, overdose cases are linked to administrative data sets at the individual level. This linking procedure is performed by the MPH using a probabilistic matching algorithm that considers identifiers such as the decedent's name, date of birth, and social security number, among others. This process allows for the reconstruction of past interactions with various touchpoints for each identifiable decedent. Subsequently, deidentified statistics about these interactions are pushed to the dashboard for visualization. This linkage process is performed weekly, enabling (near) real-time updates of the visualizations.

User-Centered Design Process

To inform the design of the dashboard, we conducted 2 focus groups with a panel of OFR experts. We recruited participants via email, inviting experienced OFR practitioners and early developers from across the United States. Our goal in these focus groups was to understand OFR information needs and leverage the panel's experience in conceptualizing, co-designing, and refining visualizations. The focus groups took place virtually using Zoom videoconferencing software (Zoom Video Communications). A virtual whiteboard was used to place and arrange "Post-it"-style notes. Participating experts were recruited from the same pool, with later focus groups involving fewer participants to allow for convergence and facilitate more in-depth feedback. The focus groups were video recorded, transcribed, and analyzed using thematic analysis techniques [44].

The first focus group sought to uncover data access barriers and needs for OFR teams. A total of 13 experts participated in the discussion. Participants were first prompted to share challenges and "pain points" regarding access to data. In a second activity, participants were divided into 2 breakout groups to identify key data attributes essential for review teams. They also gave high-level design parameters for the dashboard. Finally, participants reflected on their hopes and concerns for the dashboard's integration into OFR processes, emphasizing potential positive outcomes and addressing apprehensions.

On the basis of the findings of the initial focus group, we created a series of 6 initial visualizations that illustrate overdose touchpoints using a static snapshot of the MPH-linked data set described previously. These initial visualizations served as the foundation for a second focus group with the participation of 6 experts. During this session, a facilitator presented each of the

6 visualizations and prompted participants for feedback. Specifically, participants were asked to evaluate the ease of understanding of these visualizations and their potential usefulness in the OFR process. We sought additional input by conducting a survey of 5 experts. The survey presented the same initial visualizations and requested open-ended comments on their intuitiveness and utility. Insights gathered from the survey along with feedback obtained during the second focus group were used to refine the visualizations and develop an interactive dashboard.

Dashboard Evaluation

To obtain feedback on the final dashboard, we conducted an initial assessment with 3 OFR experts. Participants were asked to perform a series of data extraction tasks (eg, identifying the touchpoint with the highest prevalence). In addition, they were prompted to make recommendations based on the observed touchpoint patterns, simulating the use of the dashboard within a typical OFR meeting.

Ethical Considerations

This human-centered research was reviewed and approved by the Indiana University institutional review board (approval 17809). Participants received an information sheet explaining the study goals and procedures before agreeing to take part. The analysis of state mortality and administrative data sets, while not considered human participant research, followed state legal and ethical procedures. The dashboard displays only aggregate, population-level visualizations. No individual records are released or displayed to preserve anonymity. Furthermore, special care was taken to minimize the risk of reidentification by withholding actual event counts and substituting with percentages. Participants received a US \$100 gift card as compensation.

Results

Overview

Participants highlighted barriers faced by OFRs in accessing and interpreting data within the context of fatality reviews. They also provided insights on what data attributes and features would be most useful for OFRs to look at. We report these findings and discuss how we incorporated them to create a real-time dashboard for visualizing overdose touchpoints.

Barriers to Accessing and Using Data

Data Accessibility

Several participants highlighted the lack of access to data as one of the major barriers in fatality reviews. Some of these barriers stem from challenges in sharing available data due to legal restrictions, data security, and privacy concerns:

Asking our state offices for data would result in, "Sorry, we can't share on the state level." There [needs to] be intergovernmental agreements between state police or our mental health or our human services or our health department. [P2]

[Gaining access] is always an issue, and especially without laws that allow for the OFRs to get this. I

know we had a lot of laws related to the child death review teams that I worked with that allowed us access to data, but it wasn't always the same for other death review teams. [P11]

While recognizing existing regulatory and logistical obstacles, participants anticipated that increasing data access could empower OFRs to make more informed decisions:

We're trying to drive positive change that could maybe be implemented statewide, and they just give us a little bit. It [data] would give us the power to make better decisions. [P2]

In addition to data access, the quality and accuracy of the data were also brought up as a prominent issue for OFRs, especially because of acknowledged variations in how data are coded and measured across different organizations. For example, 1 participant cited different standards for classifying services, noting that such inconsistencies could lead to misinterpretation:

When it's really law enforcement heavy, they're not understanding the public health ramifications of criminal justice involvement. It affects the lens from which data's being collected. So, when I go through the qualitative data...we've got people identifying jail substance use services as harm reduction, [and] you end up collecting some inaccurate data, which then misinforms the big picture. [P7]

Influx of Case-Specific Data

While obtaining population-level data in certain arenas proved challenging, another concern was the vast amount of case-specific data that OFRs must already contend with. Participants noted that review teams are increasingly tasked with handling large volumes of individual reports from multiple systems, which often need to be manually and qualitatively analyzed at considerable time and effort:

OFRs collect an enormous amount of data, but you really need a whole army of researchers to be able to analyze it, especially the qualitative data. When the teams are putting forth all of these recommendations, it's just so hard to go through all the information and make a meaningful plan of it. [P7]

Extensive data on individual death circumstances (as opposed to population-level statistics) reflect a conventional OFR focus on in-depth reviews of a few strategically selected cases. However, with the sheer number of overdose fatalities, it becomes difficult for OFRs to ensure that the selected cases represent the broader overdose patterns and risk factors prevalent in their community. One participant put it as follows:

[My experience] is that they would just randomly pick cases and then do a really deep dive into those cases, but you have no way to actually ensure that those are representative...And so, my hope had been that we would have certain [data] fields that we could have someone enter, and then that would allow us to do really large-scale analysis over the course of multiple years...[This] would have allowed us to really have

a good sense as it relates to a variety of factors, but there just wasn't capacity. So, then we're just picking cases that look good or meet some theme to be able to have a more robust conversation at any given meeting. But again, they're not necessarily representative and you don't end up having the whole picture. [P18]

Key Data Types and Attributes for the Dashboard

Participants identified key data attributes that they deemed essential for inclusion in a dashboard. We divided these attributes into 3 categories: touchpoints, social determinants of overdose risk, and case-specific data.

Touchpoints

Touchpoints represent interactions with systems and services before overdose. Thus, they serve as opportunities to connect people who use drugs with additional prevention services and treatments, potentially mitigating the risk of future overdoses. A frequently recurring set of touchpoints identified by experts was interaction with the justice system. For instance, the duration between a decedent's overdose and their last incarceration or residential treatment was cited as particularly important:

Were they justice involved or not at any point, but also the average distance in time from their last incarceration...So, to see were they in that window of high risk. And same if they were in residential treatments as average number of days. [P3]

Average days out from treatment and incarceration because I feel like those are solid spaces that action can be taken. [P5]

Several participants pointed to interactions with justice systems broadly as key touchpoints. Agencies such as county sheriffs, local police departments, and child protective services were thought to play a crucial role in an individual's risk of overdose both positively and negatively:

Justice systems can either be a force of treatment or a barrier to treatment. I think that involvement is really important...the extent of involvement can be really helpful to inform the justice system and the legislative changes that could help. [P4]

Participants noted that data on criminal justice touchpoints might reveal new prevention opportunities or support policy recommendations, such as facilitating continued treatment for institutionalized individuals:

...keep people engaged in treatment, [such that] we're not disrupting treatment by violating [ie, rearresting] people and incarcerating them...It's a fruitful area for policy change. Most of our policy changes and recommendations from our OFR have been in the justice space. [P3]

In addition to justice systems, participants noted interactions with health and medical facilities as crucial touchpoints. This included visits to the ED and emergency medical services (EMS):

Do we have one [attribute] here [on] the last date of medical intervention? Maybe like an ED visit or anything like that? [P4]

There's an ED and EMS interaction right at the center there. [P5]

Overall, three primary touchpoint categories emerged: (1) encounters with the justice system, such as incarceration; (2) engagement with health services, including ED and EMS interactions; and (3) involvement with residential treatment services. These touchpoints were recognized by participants as crucial opportunities for understanding risk factors and implementing services to close treatment gaps. Importantly, participants emphasized the typical interval between these touchpoints and overdose events as a critical feature to emphasize in the dashboard.

Social Determinants of Health

A second set of data attributes identified pertained to the social condition of the individuals themselves, which could shed light on factors that contribute to elevated overdose risk. For example, one of these factors was demographics:

Basic demographic information like poverty level, education level, homelessness. Anything that would affect those social determinants of health. [P4]

A second factor was individuals' access to harm reduction services, as the same participant noted:

I was going to add...access to harm reduction services. So, what an environmental scan of resources or access to naloxone, treatment centers, syringe service programs, all those different community level access points. [P4]

A third factor was housing, encompassing the shelter system and housing agencies:

Access to housing. Or maybe it's access to shelter because it could be both. There's housing policy, but then there's also the shelter systems. [P5]

A fourth factor was the availability of transportation, which, according to participants, could influence an individual's access to treatment and harm reduction services:

Transportation between places: how easy is it for someone to get from point A to point B? Even if there's a syringe service program down the street, can they get to it? That kind of thing. [P5]

Finally, participants also identified upstream social determinants such as adverse childhood experiences as potentially relevant factors in assessing overdose risk:

...and some of that I think would fall under ACEs too because even if they're an adult, finding out if they were involved in that system as a child, trying to make some of those associations maybe. [P5]

Case-Specific Data

Alongside touchpoints and social determinants of health, participants cited certain case-specific data, including toxicology reports, interviews with next of kin, and the decedent's

circumstances at the time of death (eg, their position and whether they were alone). While these attributes are relevant to reviewing individual cases, they were not considered for inclusion in the dashboard as our primary objective was to offer population-level data that complement rather than supplant the conventional OFR case review model.

Apprehensions and Foreseen Challenges

Although participants were positive about the potential of the dashboard to enhance the OFR process, there were a few apprehensions. A major concern was the risk of unintentional identification of decedents in smaller counties, where there are fewer overdose deaths:

I've been aware of a couple different cases in relatively small communities where all the data says one thing, and of course, as a small community, we know exactly who we're talking about. [P15]

I think one [concern] would be that the information might be too identifiable, especially for small communities. [P8]

Participants discussed the ethics of displaying data that might be inaccurate or that could be misused (eg, by law enforcement) to target at-risk individuals:

...that it has inaccurate and bad data. And that it is used for evil rather than for good...That it's not used for bad downstream consequences kind of thing. [P6]

Finally, participants raised the risk of misinterpreting data, noting that, while OFRs have expertise in studying individual histories of decedents to formulate recommendations, they are less familiar with analyzing population-level statistics. Some voiced reservations about OFR teams' data literacy and their ability to draw appropriate inferences from such quantitative data. For instance, 1 participant gave an example of how a decrease in emergency medical events could be erroneously interpreted as a reduction in overdoses when it might only reflect fewer 911 calls:

That [error] where you have a number and you think it means one thing, but it means another thing...You have measured something, but not the thing that you are taking that thing to be. [P1]

Others commented on the potential downstream consequences of misinterpreting data, which could manifest as inappropriate or even detrimental recommendations:

We've seen this trend in our data. That probably means X, Y, Z. And you might be right. You might be very wrong, and the data might be used to justify a policy or programmatic intervention that could in fact exacerbate it. [P17]

Helping users interpret data accurately was deemed by participants as a critical consideration for the dashboard. Equally important was not to inundate OFRs with even more (population-level) data that teams may lack the bandwidth or data literacy skills to act upon. These insights underscore the need to craft intuitive data visualizations that can be comprehended accurately with minimal effort. Moreover, such

displays should actively guide OFR teams into making valid inferences from the data presented.

Touchpoints Selection

Our observations point to a longstanding limitation of current OFR practices, which focus on reviewing a handful of overdose cases at every meeting. OFR experts appeared to recognize the shortcomings of this model when pitted against the sheer volume of overdoses. Simultaneously, participants expressed strong interest in accessing additional data sets that would paint a broader picture of overdose risk factors and touchpoints in their community, provided that these data were consistently coded, intuitively summarized, and presented in a manner that did not overburden review teams.

Among the data emphasized by participants, touchpoints emerged as particularly actionable as they represent system interactions preceding overdose events. For instance, the proportion of decedents who used various touchpoints offers predictive power to identify the most effective points within the system for targeting at-risk individuals with prevention services. Moreover, understanding the typical time window between a touchpoint and an overdose event, along with the frequency of touchpoint use, can assist in designing interventions, including their timing and regularity.

Drawing on the insights of the expert panel and data availability in Indiana, we incorporated 5 touchpoint types into the dashboard: jail bookings, prison releases, visits to the ED,

encounters with EMS, and prescriptions for controlled substances (eg, opioid analgesics). We excluded ED and EMS encounters occurring within a 24-hour window of death as those are likely to represent interactions directly related to the overdose event as opposed to potential touchpoints for prevention purposes. Interactions with both justice and medical systems were identified as key by the expert panel. Prescriptions for scheduled drugs, such as opioid analgesics, were included as touchpoints due to their established association with overdose risk [25]. We also included the dispensation of buprenorphine prescriptions as a touchpoint in the initial dashboard design. However, concerns were raised that singling medication for opioid use disorder as a separate touchpoint could cause it to be misconstrued as a causal risk factor for overdose. Consequently, buprenorphine data were merged and included among the general prescription dispensation touchpoint for scheduled drugs. [Table 1](#) provides a summary of these touchpoints as highlighted by participants and featured in the dashboard. Although interactions with residential treatment services were identified as an important touchpoint by participants, related data are not centrally tracked by the state and, hence, were not available for inclusion in the dashboard. Moreover, social determinants of health are not currently included despite their relevance as the dashboard was intended to prioritize opportunities for immediate as opposed to upstream prevention. Case-specific attributes were also not considered for inclusion because they would be redundant to the traditional OFR case review process.

Table 1. Data types and attributes as identified by experts and featured in the dashboard.

Data type and attribute	Identified by expert panel?	Included in dashboard?
Touchpoint		
Jail booking	No	Yes
Release from prison	Yes	Yes
Visit to the ED ^a	Yes	Yes
Encounter with EMS ^b	Yes	Yes
Interaction with residential treatment services	Yes	No
Prescription dispensation for scheduled drugs, including opioid analgesics and MOUD ^c	No	Yes
Social determinants		
Demographics	Yes	No
Educational level	Yes	No
Poverty	Yes	No
Access to harm reduction services	Yes	No
Housing	Yes	No
Access to transportation	Yes	No
Adverse childhood experiences	Yes	No
Case-specific attributes		
Toxicology report	Yes	No
Next-of-kin interviews	Yes	No
Circumstances of death (eg, body position and presence of witnesses)	Yes	No

^aED: emergency department.

^bEMS: emergency medical services.

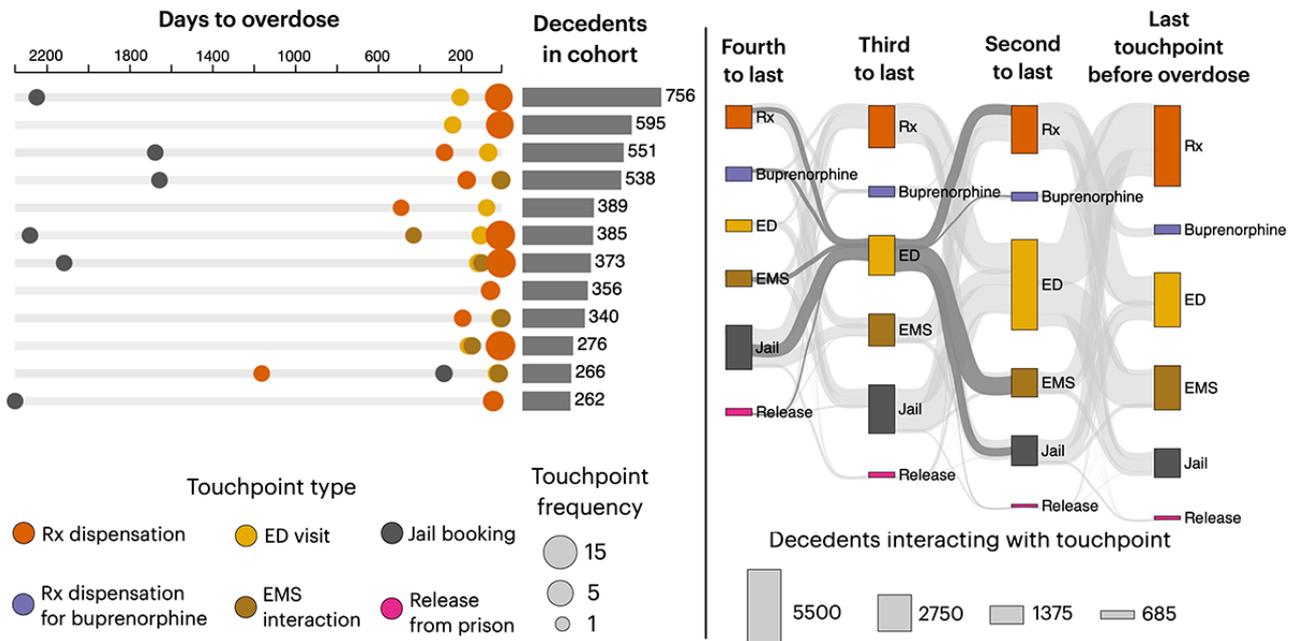

^cMOUD: medication for opioid use disorder.

Initial Visualization Attempts

Our initial visualization focused on timelines, illustrating cohorts of decedents who exhibited similar patterns of touchpoints before overdosing. For example, in [Figure 1](#) (left), each row represents hundreds of decedents who exhibited a similar touchpoint sequence (eg, jail booking followed by one or more ED visits and then a series of prescriptions). This particular

visualization was inspired by OFR teams' use of timelines to represent the histories of individuals discussed during case reviews. However, these initial visualizations received mixed reviews from the expert panel—while they were considered appealing and “interesting,” the focus on cohorts was seen as providing excessive detail for OFRs. This feedback was used to revise the visualizations and develop a final dashboard.

Figure 1. A total of 2 initial visual representations of touchpoints in Indiana (aggregate data from 2015 to 2022). On the left, a timeline-based visualization illustrates the cohorts of decedents with distinct sequences of touchpoints. The visualization depicts the average number of days to fatal overdose (circle position) and frequency of interaction with a touchpoint (circle diameter). For example, the first row shows 756 individuals who experienced a jail booking approximately 6 years before overdose, followed by a sequence of emergency department (ED) visits and medical prescription (Rx) dispensations, the last of which typically occurred approximately 200 and 90 days before overdose, respectively. A Sankey diagram (right) displays the temporal ordering of (up to 4) touchpoints but without showing durations. EMS: emergency medical services.

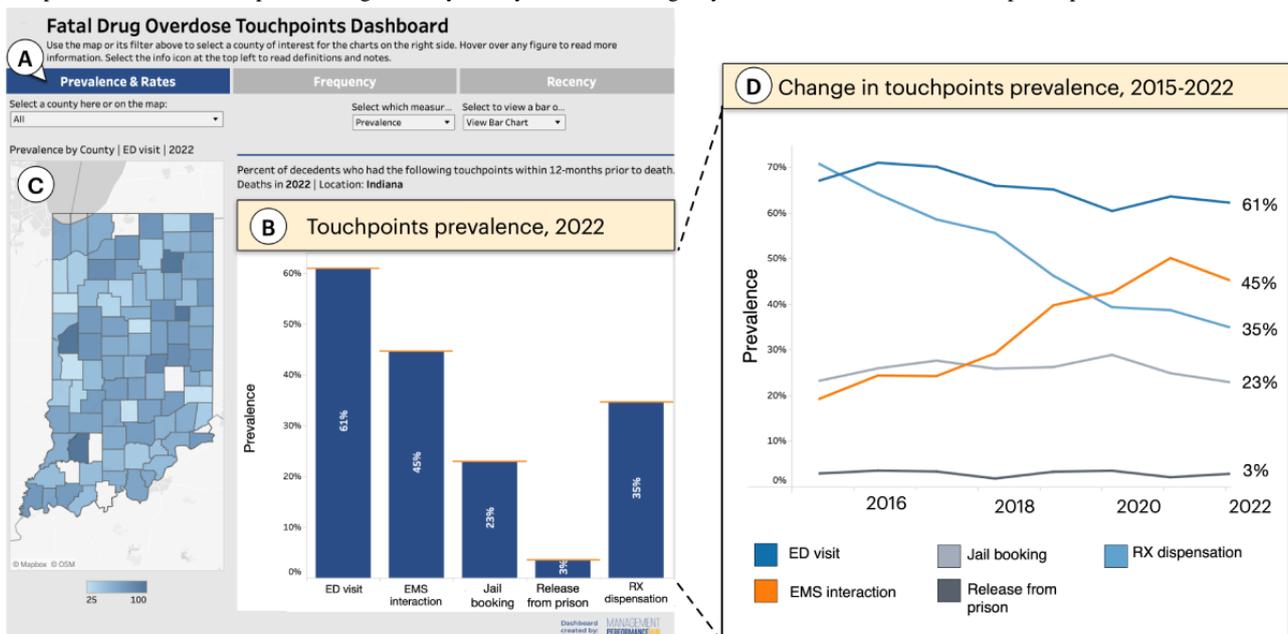

Final Dashboard

The dashboard consists of 3 primary displays (Figure 2A) showing the prevalence and rates, frequency, and recency for

the 5 touchpoints. The dashboard can be accessed at the MPH website [45].

Figure 2. The final dashboard showing overall touchpoints prevalence in Indiana. (A) Buttons enable the user to switch among 4 measures: prevalence, rates, frequency, and recency of touchpoints. (B) The selected measure is visualized here as a bar chart comparing touchpoint prevalence (ie, the percentage of decedents who used each of the 5 touchpoints). (C) A map shows touchpoint prevalence (in this case for emergency department [ED] visits) by county, where darker shades of blue indicate higher prevalence. (D) As an alternative to the bar chart, a line graph allows users to observe how the prevalence of the touchpoints changes from year to year. EMS: emergency medical services; Rx: medical prescription.

Prevalence and Rates

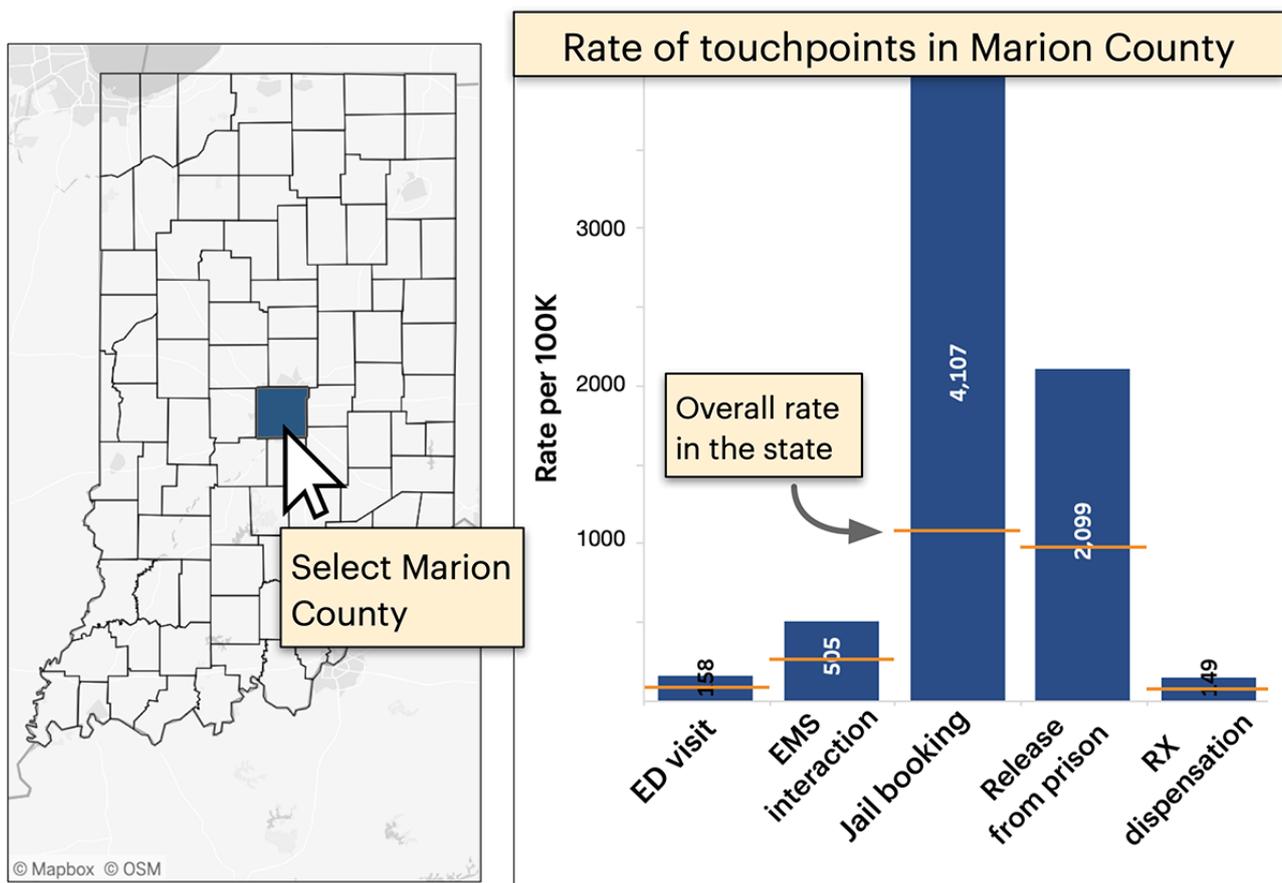

By default, the dashboard displays touchpoint prevalence, depicting the percentage of decedents who used various

touchpoints in the 12 months preceding overdose. For instance, in 2022, the highest-prevalence touchpoint was the ED, with 61% of individuals who overdosed in Indiana having visited the ED within a year before dying (Figure 2B). The user can

also see the change in prevalence over time. For example, the data show that the prevalence of ED visits decreased over time, whereas the proportion of decedents who use EMS increased >2 times between 2015 and 2022 (Figure 2D). In addition to showing state levels, the dashboard can break down the data by county. For instance, the user can see the prevalence of ED visits in different counties on a map (Figure 2C). Notably, the

map shows 4 counties in which practically all decedents had visited the ED a year before their overdose. The map can also be used to filter the bar or line graph displays. For example, clicking on Marion County, the most populous in Indiana, updates the display to show statistics for Marion only (Figure 3).

Figure 3. Rates showing the fraction of individuals who experienced a fatal overdose for every 100,000 people who use a touchpoint (right). A map allows the user to filter the data by county, in this example, to show rates for Marion County only. Orange dash marks depict the state average for context. ED: emergency department; EMS: emergency medical services; Rx: medical prescription.

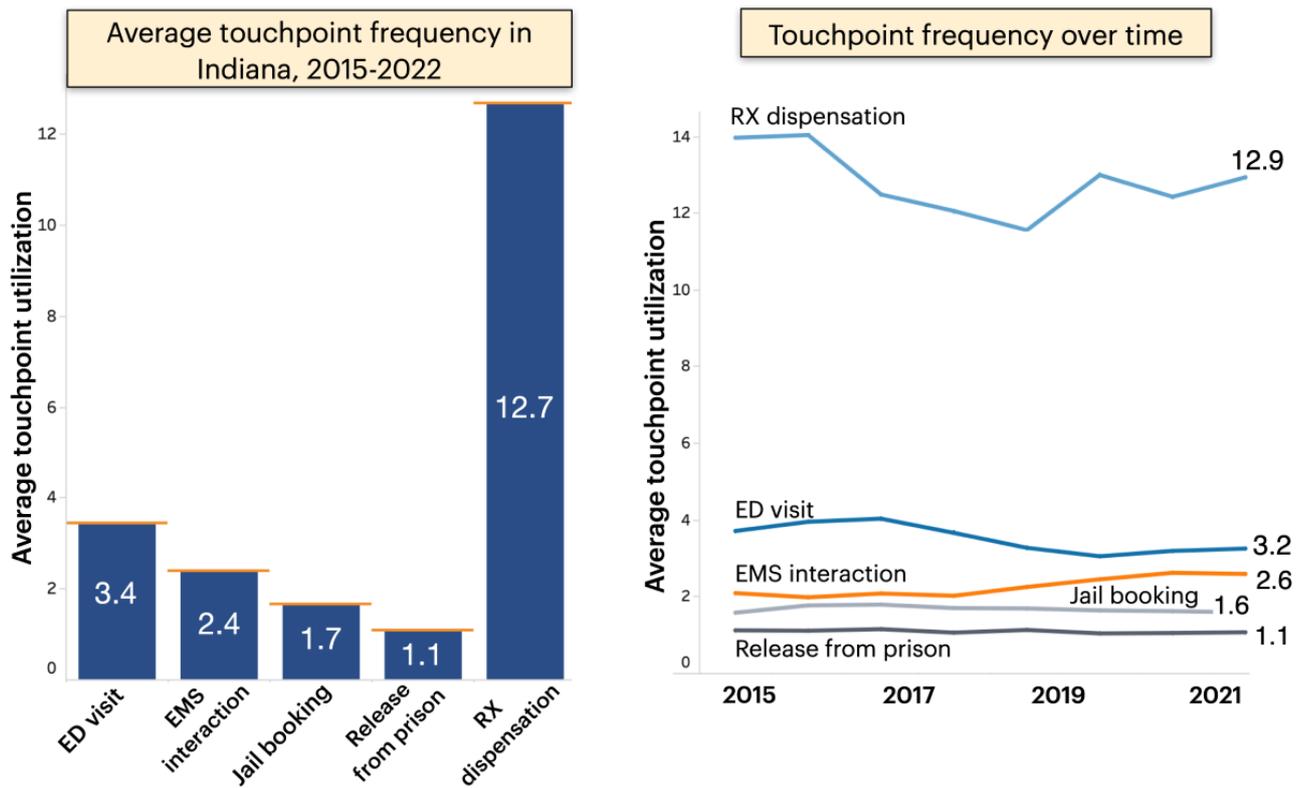

In addition to prevalence, the dashboard visualizes the *rate* of touchpoints among decedents. These rates depict the number of fatal overdose cases per 100,000 individuals who typically use services such as the ED. Unlike prevalence, which indicates the likelihood of a decedent using a touchpoint, rates reveal the probability of a fatal overdose after using 1 of the 5 legal or medical touchpoints included in the dashboard. Both measures are important for resource allocation—while prevalence helps users identify touchpoints with the broadest reach, rates can reveal more “efficient” touchpoints for targeted interventions. For example, consider jail bookings and releases from prison (Figure 3 [right]), which exhibit the highest rates among touchpoints in Marion County. This offers a high-specificity opportunity to focus on individuals at a greater risk of

overdosing despite these touchpoints exhibiting relatively moderate to low prevalence at the state level (23% and 3%, respectively, as depicted in Figure 2 [left]).

Touchpoint Frequency

The second display summarizes the average number of interactions a decedent had with a touchpoint in the year preceding their overdose (Figure 4). Notably, the most frequently used touchpoint in the state is medical prescription (Rx) dispensation for controlled substances, such as an opioid analgesic (12.7 events on average at the time of writing). The user can also see how this frequency changes yearly (Figure 4 [right]). The line graph shows relatively stable use for ED, EMS, and criminal justice services, with the average number of Rx dispensations trending down slightly.

Figure 4. Average number of interactions with the 5 touchpoints from 2015 to 2022 (left) alongside a year-by-year breakdown. ED: emergency department; EMS: emergency medical services; Rx: medical prescription.

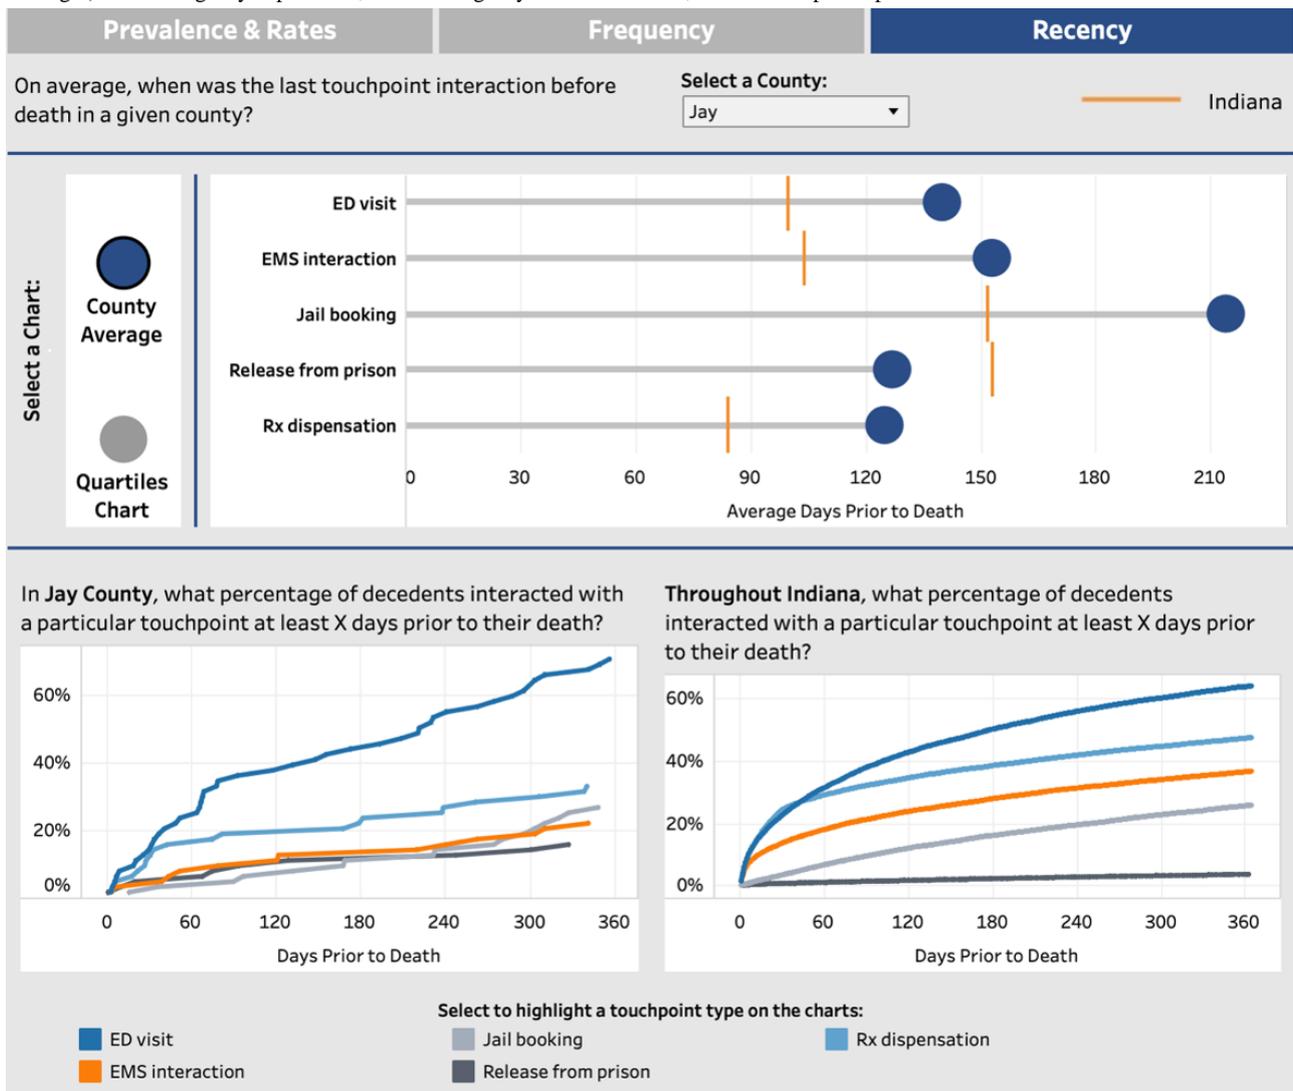

Recency

The timing of interaction with services was identified as a key factor for OFRs. Accordingly, the *recency* display illustrates the typical time intervals between final touchpoints and overdose events (Figure 5). The top features a “lollipop” chart depicting the number of days on average between the most recent interaction and the overdose (Figure 5 [top]). In this example, jail bookings in Jay County (selectable by the user) occur approximately 210 days on average before a fatal overdose

compared to approximately 150 days for the entirety of Indiana. Conversely, releases from prison tend to happen approximately 120 days before the overdose, closer relative to the state average. The bottom visualizations show a curve for each touchpoint representing the cumulative percentage of individuals who could have been engaged at various time points relative to their time of death. In this case, approximately 27% of decedents in Jay County could have been engaged through an Rx dispensation touchpoint 30 days before an overdose.

Figure 5. The average time gap between the final interaction and overdose events across different touchpoints (top). The lower section comprises 2 charts demonstrating the cumulative reach of touchpoints at varying time intervals, comparing the selected county (bottom left) with the state average (bottom right). ED: emergency department; EMS: emergency medical services; Rx: medical prescription.

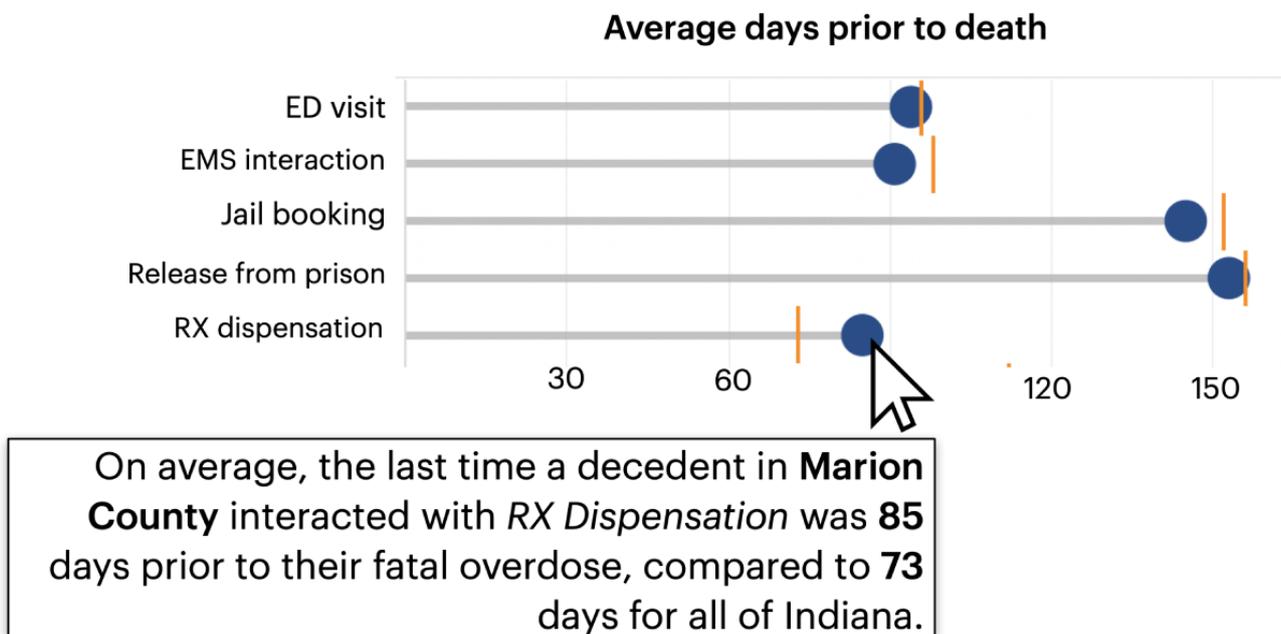

Aiding Data Interpretation

One concern that emerged during the focus groups regarded OFR teams’ ability to interpret population-level statistics. To aid users in making sense of these data, the dashboard provides

tooltips in the form of short text annotations that explain the interpretation of each visualization. For instance, in the recency chart, the text clarifies that the points depict the average number of days between a touchpoint and an overdose event (Figure 6).

Figure 6. Tooltips appear throughout the dashboard to promote accurate data interpretation. ED: emergency department; EMS: emergency medical services; Rx: medical prescription.

Initial Evaluation Results

We invited 3 OFR experts to review and provide feedback on the dashboard. They commented on features they thought were beneficial. They also provided suggestions on how to ensure dashboard integration into OFR practices. One of the notable strengths of the dashboard was its comprehensive data coverage, a feature that was highly appreciated by all participants. They specifically praised the breakdown of touchpoints on a county basis, a level of granularity that is often lacking in existing dashboards. The inclusion of small counties, the data on which can be especially difficult to obtain, was recognized as a significant advantage. Participants also appreciated the ability to compare different counties through the map, along with the ability to juxtapose county-specific data against state averages.

Among the various visualizations, the recency chart (referred to as the “timeline”) stood out for its depiction of events leading up to overdoses. Participants thought that these temporal data, which can be difficult to obtain at the population level, can help in tailoring interventions:

It is interesting to see this [chart], and to know what can be done with data. We can check the timeline and help implement a strategy. Through these strategies, we can outline short, medium, and long-term goals.

In thinking about how the dashboard might complement existing OFR practices, participants highlighted its usefulness in guiding case selection for review and helping OFRs build a representative case profile. One participant specifically noted the potential of the dashboard in conducting “community data review” to explore “what is going on in my community.” Moreover, the dashboard’s availability on a publicly accessible URL was lauded as “a wonderful resource,” extending its value to audiences beyond OFRs. The discussion opened the door for offering some form of training or educational support to OFR members, equipping review teams with skills to interpret

quantitative data. One participant suggested the addition of a “demo video to help interpret and apply the data.” Another suggested the need to specifically focus on OFR facilitators as crucial personnel for communicating data insights to review teams:

I don't think they [members of the review teams], will be able to fully understand the data, so training the facilitator will be key.

Discussion

Principal Findings

OFR teams are proliferating in the United States, becoming an important public health tool to combat the drug overdose crisis. Traditional fatality reviews, often limited to a few cases, do not fully capture the broader overdose trends, especially in communities with numerous drug-related fatalities. This research aimed to enhance OFR data use by addressing data access barriers, identifying information needs, and creating actionable visualizations of population-level overdose data.

Our findings shed light on challenges that OFR teams face in accessing timely data, frequently impeded by legal constraints. When available, these data can often be inconsistent, for example, in the coding of events and classification of services. Despite these challenges, OFR teams seemed keen on incorporating a wider range of data into their review to better understand the factors contributing to overdose risks in their communities. Notably, the expert panel highlighted several key touchpoints, including incarcerations, interactions with substance treatment services, and visits to medical facilities such as EDs.

Some of these touchpoints have been previously recognized as opportunities for delivering prevention services [25,46,47]. For example, the time window following a prison release has been identified as a particularly critical and risky period, making this touchpoint a highly specific and valuable opportunity for

administering prevention services [48-50]. However, effectively sharing these data insights with OFRs remains a challenge. Our findings suggest that a dashboard linking state administrative and mortality data could effectively provide local OFRs with insights on the timing and distribution of touchpoints. To explore this potential, we partnered with the Indiana state government and developed a dashboard that collates and visualizes data on 5 touchpoints at the county level, enabling OFR teams to see statistics and patterns on events that *precede* fatal overdoses in their community. To our knowledge, this is the first system to automatically analyze touchpoint characteristics and offer (near) real-time visualizations of their prevalence, frequency, and timing tailored to the local scale of OFR teams. In designing the dashboard, we specifically focused on this user group and prioritized actionable data that shed light on local prevention opportunities. The developed touchpoint dashboard stands in contrast to earlier dashboards for opioid prescription and overdose data, which are meant for the public or nonspecified stakeholders.

Our OFR expert panel suggested that one of the most crucial pieces of information is the timing of touchpoints—specifically, the average duration between an individual's last encounter and their overdose. The dashboard prominently features these data in a lollipop chart comparing the *recency* of various touchpoints. In addition, we incorporated displays of touchpoint prevalence and rates, providing insights into the reach of touchpoints and the specificity they afford for targeting individuals who are at high risk of overdose. The dashboard purposely uses familiar visualizations, including bar and line graphs and choropleth maps, to appeal to review teams who may be novice visualization users [51]. Importantly, the dashboard breaks down these statistics at the county level, aligning with how OFRs are organized in Indiana. By visualizing data “close to home,” we aimed to improve the actionability of the dashboard [52]. However, users can easily compare county data to state averages or those of other similar counties.

Our initial evaluations show promise for the dashboard's usefulness. However, successfully integrating the dashboard into OFR practices will likely require training for OFR members, many of whom lack expertise in data analysis—a point that was notably underscored by the expert panel. In particular, teams may need educational support in how to interpret population-level features, such as the difference between the prevalence and rates of touchpoints. Regular meetings with OFR users could also help uncover usability issues and gauge dashboard adoption by review teams.

While the dashboard offers detailed insights into community touchpoints, it omits data on social determinants such as race, educational level, and access to housing and harm reduction services. These factors can be important for understanding overdose risks, as per our expert panel and research findings [53,54]. Future versions of the dashboard could incorporate local statistics on these risk factors. Furthermore, it is possible to expand the current list of touchpoints to include specific events associated with social determinants, such as loss of housing or employment. These additional touchpoints could offer further intervention avenues to disrupt pathways from

marginalization to overdose [55]. Another limitation is that, while the dashboard includes critical touchpoints such as ED and EMS encounters, these events currently lack classification. Adding a breakdown of these touchpoints, for example, by distinguishing between substance-related versus other EMS encounters, could enable OFR teams to further tailor their recommendations.

The experts interviewed also sought demographic breakdowns of touchpoint data, in part to ensure that diverse populations would benefit from interventions at touchpoints. Unfortunately, this feature was not included in the current dashboard due to reidentification risks, particularly in rural areas that have fewer overdoses. In the future, the dashboard could be modified to provide a demographic breakdown of touchpoints at the aggregate (eg, state) level to substantially decrease the risk of reidentification instead of withholding these data altogether. To further protect individual confidentiality, which was a key concern of our expert panel, the dashboard presents data as percentages (eg, the proportion of decedents who were released from prison within a year before their overdose) and rates. Withholding the actual counts for events helps prevent the inference of individual identity in places where those counts are low. The dashboard provides a visual warning for statistics based on <20 cases, cautioning users against drawing strong conclusions from small samples. Future work could use more advanced privacy-preserving techniques [56,57], thus allowing for the display of a wider range of attributes without jeopardizing anonymity.

Although our dashboard is specific to Indiana, we believe that the approach could be adapted for other US states and localities. This expansion requires access to overdose mortality records that can be algorithmically cross-referenced with other administrative data sets. Many states already have data infrastructure for such linked analyses [58,59]. We estimate that the development and maintenance of the dashboard over 2 years will require approximately 350 personnel hours assuming the availability of data. The prevalence of overdose dashboards [39,60] indicates both the technical feasibility of creating such tools and the interest in them from the public health community. Our research demonstrates that dashboards can go beyond surveillance to directly visualize actionable prevention opportunities.

Conclusions

OFRs can play a crucial public health role in understanding overdose cases and recommending prevention strategies. This study explored the potential for enhancing these reviews with population-level data for broader, quantitative insights into risk factors. Following a user-centered design process, we developed a dashboard that tracks and visualizes decedents' encounters with medical and justice systems at the county level. Although initially designed for Indiana, the dashboard can be adapted to other localities, leveraging administrative and mortality data typically collected by local governments. Preliminary evaluation shows the potential utility of the dashboard for analysis and case selection but emphasizes the need for training OFR members in data interpretation and decision-making.

Acknowledgments

The authors thank the Indiana Department of Health; the Department of Homeland Security; the Indiana State Police; the Professional Licensing Agency; the Department of Correction; and the Governor's Drug Prevention, Treatment, and Enforcement Office for providing data for use in the dashboard and for feedback. This research was supported by the Helping to End Addiction Long-term Initiative through the Data 2 Action program (award R61DA057660). The work was also supported in part by Research Jam, the Indiana Clinical and Translational Sciences Institute Patient Engagement Core through an award from the National Institutes of Health, National Center for Advancing Translational Sciences Clinical and Translational Science Award (award UM1TR004402). The authors acknowledge Michelle Tran, BS, for her contributions to this work. Data Availability

The video recording data sets generated during and analyzed during this study are not publicly available to protect participants' confidentiality but are available from the corresponding author on reasonable request. The aggregate touchpoints data sets are available in the Management Performance Hub (MPH) data repository [61].

Authors' Contributions

AS and LAG analyzed the data and wrote the manuscript. BPC conducted the focus group and analyzed the data. SEW directed the human-centered research process and provided manuscript revisions. KC, JC, and TB developed the dashboard and the touchpoints data integration process. KS, ALD, BR, MCA, and KR edited and provided manuscript revisions. BR, MCA, and KR conceptualized the study and designed the research.

Conflicts of Interest

None declared.

Abstract

Background: While patient and public involvement and engagement (PPIE) is now seen as a cornerstone of mental health research, young people's involvement in PPIE faces limitations. Work and school demands and more limited independence can make it challenging for young people to engage with PPIE. Lack of ability or desire to attend face-to-face meetings or group discussions can further compound this difficulty. The VoiceIn app and digital platform were codeveloped by a multidisciplinary team of young people, mental health researchers, and software designers, and enables young people to engage directly with PPIE opportunities via a mobile app.

Objective: This paper aims to describe how VoiceIn was developed through a series of co-design workshops with relevant stakeholders, specifically (1) how the initial design of VoiceIn was informed and driven by focus groups with young people, mental health professionals, and PPIE leads; (2) how VoiceIn was refined through collaboration with the aforementioned stakeholders; (3) the priorities for an app to support PPIE; (4) the key features necessary in the PPIE app; and (5) the recommended next steps in testing and deploying the digital platform.

Methods: Initial co-design workshops took place with young people, mental health professionals, and PPIE leads to identify key features of an app to support PPIE. A series of VoiceIn design prototypes were developed and iterated based on the priorities and preferences of the stakeholders. The MoSCoW (must have, should have, could have, won't have) prioritization method was used throughout the process to identify priorities across the different stakeholder groups.

Results: Co-design with young people, mental health professionals, and PPIE leads supported the successful development and improvement of the VoiceIn app. As a result of this process, key features were identified, including allowing for various modes of providing feedback (eg, polls and comments), reviewing project updates, and expressing interest in categories of research. The researcher platform was developed to support multimedia uploads for project descriptions; a jargon detector; a dedicated section for providing project updates; and a visually appealing, user-friendly design. While all stakeholder groups emphasized the importance of allowing app users to engage with the app in various ways and for there to be ongoing progress updates, group differences were also noticed. Young people expressed a desire for incentives and rewards for engaging with the app (eg, to post on their public social media profiles), and mental health professionals and PPIE leads prioritized flexibility in describing the project and its PPIE needs.

Conclusions: A co-design approach was pivotal to the development of the VoiceIn app. This collaborative approach enabled the app to meet the divergent needs of young people, mental health professionals, and PPIE leads. This process mirrored the aspirations of PPIE initiatives by cocreating a digital health research tool with key stakeholders.

KEYWORDS

patient and public involvement and engagement; PPIE; digital mental health; young people; co-design; mental health

Introduction

Patient and public involvement and engagement (PPIE) has become a cornerstone of best practice in mental health research. PPIE is premised on the notion that research should be carried out “by” or “with” those who the research is intended to benefit, rather than “to” or “for” them [1]. At its core, PPIE values the primacy of subjective lived experience in knowledge construction and emphasizes a way of producing science where experts by experience are active co-designers and co-researchers through the entire research process [2,3]. PPIE provides valuable opportunities for addressing the democratic deficit and power imbalance that exist in much of health research by giving an equal voice to the intended beneficiaries of such research [4].

PPIE has numerous demonstrable benefits, including increasing the impact of research by homing in on the questions most relevant to stakeholders, designing more appropriate and targeted methodologies, addressing ethical tensions that exist between various stakeholder groups, and exploring novel ideas that may not have been generated by researchers alone [5-10]. By rooting findings and reports in user experience, outcomes are likely to be more relevant, relatable, and understandable to the public, thus enhancing both dissemination and implementation [6,7].

Young people can be valuable and engaged research partners. However, recent scoping research has demonstrated that young people’s expertise may be underused. A 2018 United Kingdom-based survey of public contributors to the National Institute for Health and Social Care Research found that only 2% of those involved were younger than 25 years [11]. Similarly, Rouncefield-Swales et al [12] found that where young people were involved in PPIE, their level of involvement was varied, the impact of their involvement was often unknown, and details of precisely how PPIE contributions were integrated into projects were lacking in written reports. However, in regions where a specific effort was made to include young people in PPIE, their involvement surpassed those of any other age group [13]. Given that the principle of young people’s involvement is clearly enshrined in international policy [14,15], there is a strong impetus to further develop ways in which young people can meaningfully engage with all stages of health research.

Involving young people in traditional, face-to-face PPIE can prove challenging. School and work commitments, limitations on independence and flexibility, resource and financial constraints, and rapid developmental and lifestyle changes can make it difficult for young people to engage with PPIE long-term [12,16,17]. Furthermore, meeting face-to-face with various stakeholders is not a suitable environment for all young people to feel comfortable and empowered to contribute. Consequently, researchers often struggle to recruit [18] and retain [19] young people to be involved in PPIE. Research projects may be further limited by recruiting young people from small geographic areas, thereby limiting the generalizability of research input and findings [20]. As a result, there is a clear

need to re-evaluate the current adult-centric modes of PPIE participation and spearhead innovative means of youth participation [21,22].

Shimmin et al [23] argue that many current PPIE practices are limited in their recognition of the real complexities of people’s lives. As a result, many individuals who carry the greatest burden of illness, particularly those with marginalized or excluded social identities and those experiencing various forms of systemic oppression, are less likely to have their voices heard in the sphere of PPIE. When looking at PPIE through the lens of health equity, there is a strong impetus to maximize diversity both in terms of social identity and in modes of meaningful participation.

Digital health technology provides a promising avenue for complementing existing PPIE methods by expanding participation opportunities to an audience that may not otherwise be reached. To our knowledge, there is currently no dedicated digital platform to provide PPIE opportunities to young people in real-time. To facilitate young people’s involvement in mental health research and to make PPIE opportunities more accessible and inclusive, we built the “VoiceIn” PPIE digital platform, which we introduce here. VoiceIn acts as a 2-way PPIE toolkit whereby researchers can solicit PPIE input from young people, and young people provide feedback in their own time via a mobile app.

VoiceIn is a digital platform aimed at enabling young people to contribute easily and quickly to PPIE activities. It particularly aims to support young people who may ordinarily be unable or unwilling to attend traditional, face-to-face PPIE groups or activities. VoiceIn has been specifically designed to be user-friendly, fun, and easy to fit into young people’s lifestyles. The app allows young people to give feedback on projects that align with their interests or lived experiences. Researchers can ask for specific input from PPIE participants on various aspects of the project, from the initial shaping of research topics and design to methodological feedback. Participants can provide feedback in the form of polls or free text. VoiceIn emphasizes ongoing collaboration between participants and researchers: researchers provide frequent updates to highlight the impact of PPIE on project development, and participants have the ability to track their contributions across various projects.

VoiceIn was co-designed with young people, mental health researchers, and leaders of community-based PPIE groups. The purpose of this paper is to detail (1) how the initial design of VoiceIn was informed and driven by focus groups with young people, mental health professionals, and PPIE leads; (2) how VoiceIn was refined through collaboration with the aforementioned stakeholders; (3) the central priorities for an app to support PPIE; (4) the key features necessary in the PPIE app; and (5) the recommended next steps in testing the digital platform.

Methods

Study Setting, Participants, and Recruitment

A convenience sampling approach was adopted for the phase 1 workshops, with participants recruited from established local young people’s advisory groups and through team networks. The phase 1 co-design workshops were run as exploratory patient and public involvement activities with locally established young people’s advisory groups, mental health staff, and PPIE leads. Convenience sampling was adopted at this stage to assess initial interest in the idea of the VoiceIn app and to determine high-level requirements. For the phase 2 co-design workshops, a purposive sampling approach was adopted. For phase 2, recruitment targeted individuals outside of immediate research team networks and aimed to reach people who were not previously involved in the project. The inclusion criterion for young people’s groups was a requirement to be older than 16 years with the capacity to consent. The inclusion criterion for mental health professionals was a requirement to be adult staff working in mental health services for children or young people.

For PPIE leads, the inclusion criterion was to have a role in running and coordinating PPIE activities for young people in a public sector or voluntary organization. Input from young people was seen as key to the development of a usable and engaging app, and for phase 2, we sought to increase the number of young people involved in the workshops (from 4 to 8). Around 8 people were deemed the maximum number we could support through a web-based workshop and sufficient for capturing ideas to progress the development of the app. Mental health professionals and PPIE leads for phase 2 were approached through national networks for mental health and PPIE. National organizations and third-sector or charitable organizations were approached by email at this stage.

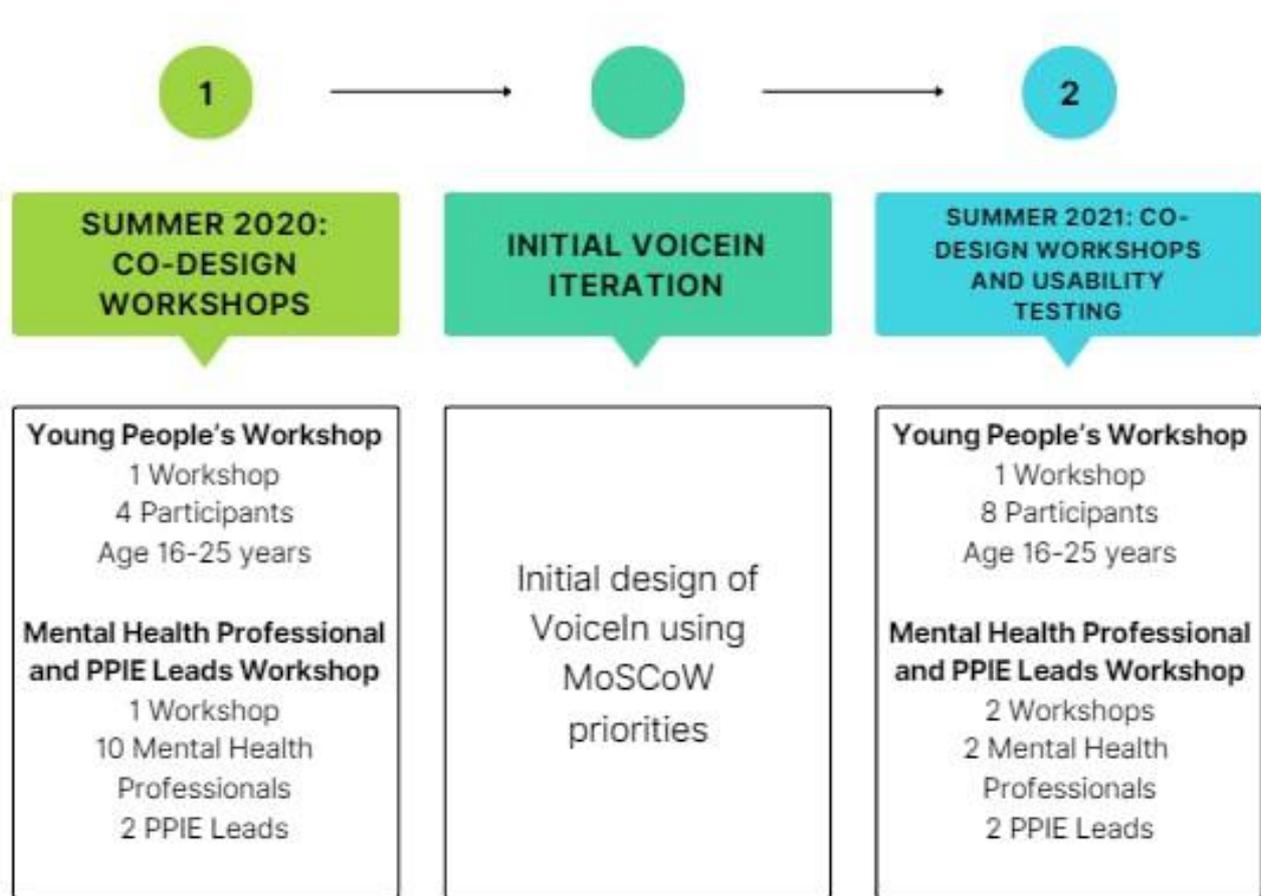

Co-Design Workshops

Overview

Between 2020 and 2021, a series of co-design workshops were conducted with young people, mental health professionals, and PPIE leads. An overview of the timeline of the workshops and their participants is outlined in Figure 1.

Figure 1. Co-design workshops timeline. MoSCoW: must have, should have, could have, won’t have; PPIE: patient and public involvement and engagement.

VoiceIn Project Phases

Workshops were held on Zoom and lasted 90 minutes. All workshops followed a similar structure: participants and the research team introduced themselves, participants were provided with an overview of the VoiceIn project, and the rest of the meeting was dedicated to exploring specific topics related to app co-design. The specific workshop structure is provided in Figures 2 and 3. For larger group sizes, participants were assigned to breakout rooms with 2 to 3 people and 1 member

of the research team. For smaller groups, a single group was maintained throughout. Topics of discussion were decided a priori and are described in Figure 4. Time was also allocated to allow for discussions of topics that arose organically during the meeting. The software collaboration tool Mural [24] was used in the young people’s workshop to enable participants to share their thoughts on a collaborative whiteboard.

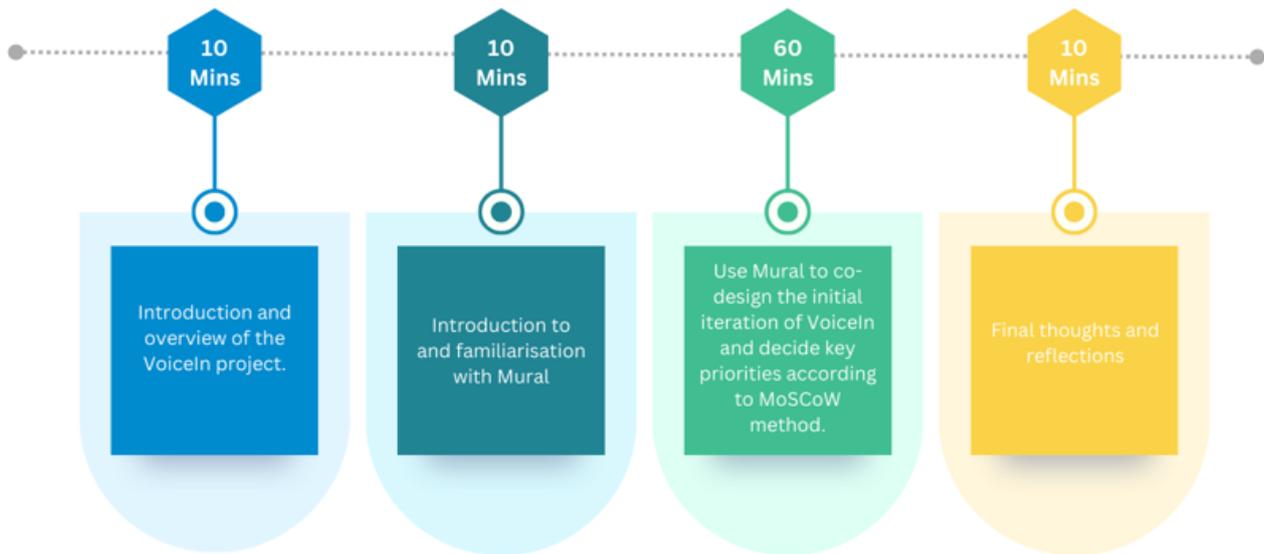

Figure 3. Structure of phase 2 co-design workshops. MoSCoW: must have, should have, could have, won’t have

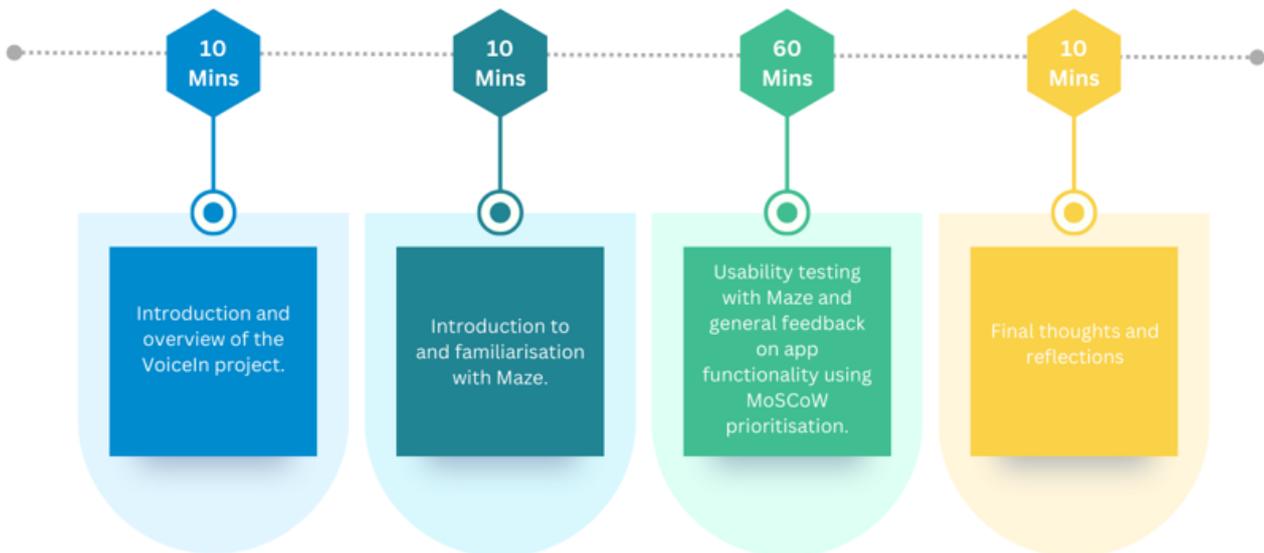

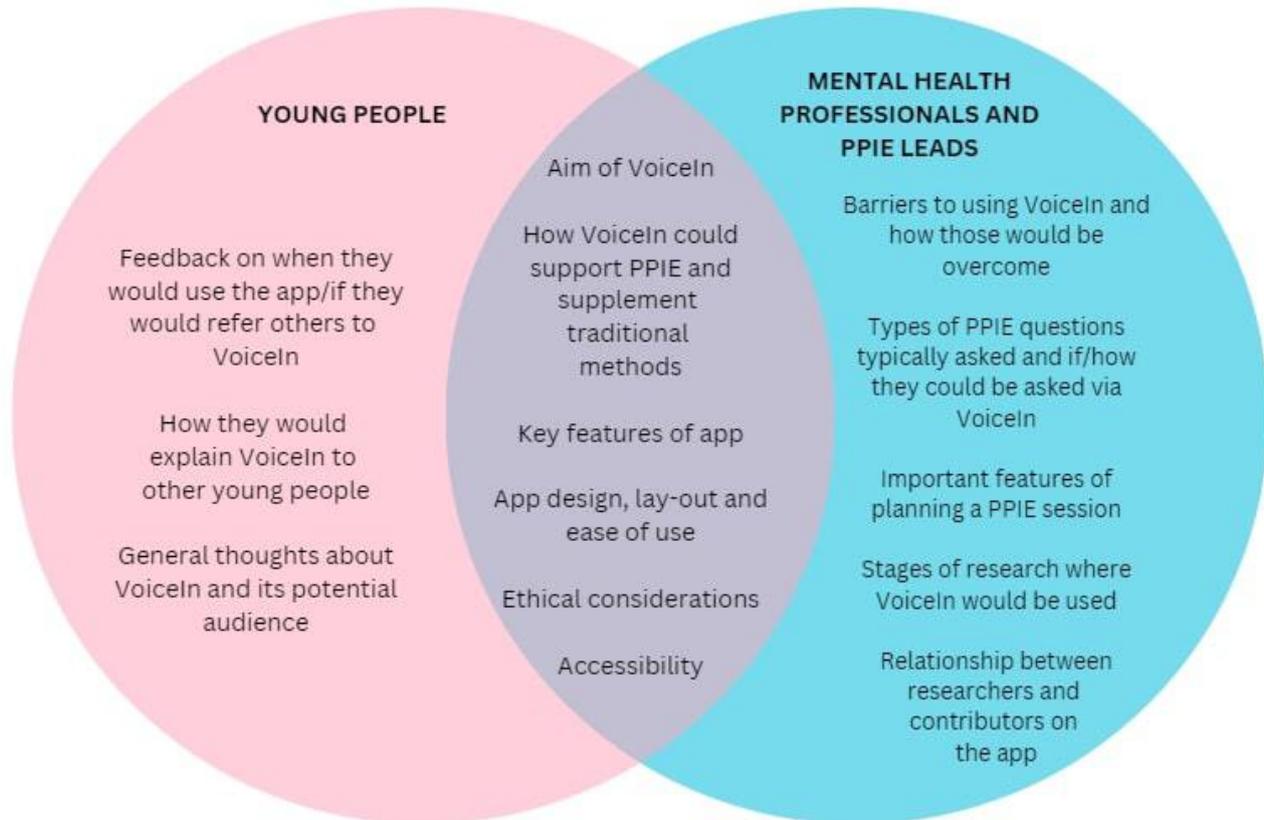

Figure 4. Topics discussed in co-design workshops. PPIE: patient and public involvement and engagement.

MoSCoW Prioritization

To enable the identification of priorities for the app, the MoSCoW (must have, should have, could have, won't have) prioritization method was used [25]. This method is an oft-used method in software project management to determine the most crucial deliverables across groups of stakeholders. In the MoSCoW approach, app features were ranked by each stakeholder group as “must have,” “should have,” “could have,” and “won't have.” “Must have” items were considered nonnegotiable by stakeholders; “should have” items were those considered to have significant value but would not affect the key functionality of the app; “could have” items were additional desirable features that were not necessarily related to the core goals of VoiceIn, while items classified as “won't have” were not priorities for the current VoiceIn release but may be considered for implementation in the future. Focus group facilitators supported discussion when different priorities were identified, aiming to arrive at a consensus decision. Where this was not possible, the majority of contributed opinions were used to determine the priority level assigned to each feature.

Agile Software Development

The software team adopted an Agile approach to software development, building the software iteratively and refining the platform based on feedback at the workshops. Following each co-design workshop, the software engineering team discussed the technical feasibility of identified requirements; some items were put on hold for implementation due to the complexity of the implementation involved and the time or budget constraints of the project. Software engineers then worked to incorporate

the features ranked “must have” and “should have” in the MoSCoW process into the next iteration of the app for presentation at the subsequent workshop.

App Technical Development

The VoiceIn app and digital platform were developed by the specialist Digital Health Software and Platforms team based at the University of Manchester [26]. The software team has expertise in developing digital health research technology. An Agile software development approach was adopted with the software team delivering the digital platform iteratively across a number of Agile sprint cycles. A hybrid app framework (Capacitor by Ionic) was used for ease of deployment to multiple devices and to align with expertise within the software team [27]. The web back end was supported by an open-source relational database (MySQL) [28] with a lightweight open-source framework Vue.js used for the front end [29].

Usability Tasks

In the phase 2 co-design workshops, participants were asked to complete a usability testing exercise on a platform called Maze [30]. Maze is a commercial product development platform that enables usability and prototype testing of new products, including web and mobile apps. Participants used their own devices to access Maze; Maze was accessible with all Android and iOS devices. In the young people's workshops, participants were asked to provide project feedback on a prototype of the app. In the mental health professionals and PPIE leads' workshops, participants were asked to create a mock project. After completing their respective task, participants were asked to rate the difficulty of the assignment and provide feedback

about what, if anything, they found difficult and if anything was missing.

Ethical Considerations

Informed consent was obtained from all workshop participants. Only participants older than 16 years with the capacity to consent were included in the workshops. Ethical approval for the phase 2 co-design workshops was granted by the University of Manchester Research Ethics Committee (REF 2021-10864-17849). Ground rules were established by the workshop facilitators at the start of each workshop to clarify the workshop's purpose and guide the conduct of the workshop.

Results

Phase 1 Co-Design Workshops: Young People

Preliminary co-design workshops with young people demonstrated a diverse array of preferences for engaging with the VoiceIn app. There was a general consensus that young people preferred to be involved throughout the entire research process, stating that PPIE should be the “driving force” behind research projects. Some participants felt it would be particularly interesting and rewarding to be involved in the design of research projects and identification of key research questions and priorities; others preferred more discrete and concrete tasks such as providing specific feedback on topic guides, picking questionnaires, and coproducing the terms of reference for ongoing PPIE support during projects. Participants highlighted the need for the app to fit into the day-to-day lives of young people, noting that quick responses such as polls and surveys should be included since some young people will not have the time or ability to review lengthy documents and give detailed feedback. Young people also suggested including rewards and incentives to encourage engagement with the app, considering ways for young people to engage with one another within the app, and including sections such as “meet the researcher” to make projects more contextualized and relational.

Young people identified a desire and need for training on research processes generally when long-term involvement PPIE involvement was necessary. Although this feedback fell outside the scope of the app (which was primarily intended to capture “quick” feedback on early-stage research ideas or short responses to specific questions during the lifetime of a project),

it was noted that a training module within the app describing the research life cycle and processes would be a useful addition to consider for future implementation. Additional training material (eg, a research handbook) has been developed as a result of these conversations, but likewise falls beyond the scope of what could be included in the app.

Phase 1 Co-Design Workshops: Mental Health Researchers and PPIE Leads

Similar to the young people, mental health researchers and PPIE leads aimed to seek ongoing PPIE input throughout the research process. In particular, they predicted using the app to explore possible areas of research and define research questions, seek comments on recruitment methods and data collection tools, and disseminate results through the co-development of communication plans. Researchers noted, however, that they would not use the app to seek PPIE input for determining specific outcome measures or data analysis, due to the specialist knowledge required for both tasks.

MoSCoW Prioritization and Initial VoiceIn Iteration

Overview

During both the phase 1 and phase 2 co-design workshops, participants were asked to rate different app features according to the MoSCoW prioritization method in order to determine their priority. Every effort was made to ensure that items ranked as “must have” and “should have” were included in the initial iteration of VoiceIn. Some items were deemed outside of scope for this version (due to time or budget limitations) but were noted for future iterations of the platform.

General Capabilities

A summary of stakeholders' priorities regarding the general capabilities of VoiceIn is described in [Table 1](#). Across stakeholder groups, providing project progress updates was identified as a clear priority; as such, VoiceIn was built to prompt mental health researchers to provide relevant updates, and a dedicated “project updates” section was built into the mobile app. Stakeholders likewise noted both global (eg, technical support section, terms of reference) and project-specific (eg, having the ability to decide on research questions and topics) as key priorities.

Table . MoSCoW^a general capabilities priorities for user-facing mobile app interface capabilities.

Description of general capabilities	Group			Included?	Reason for exclusion
	Young people	Mental health researchers	PPIE ^b leads		
Input to decide on research topics or questions	Must Have	Must Have	Should Have	Yes	— ^c
Information on the role of PPIE in shaping the research	Must Have	Must Have	—	Yes	—
Project progress updates	Must Have	Must Have	Must Have	Yes	—
Technical support section	Must Have	Must Have	—	Yes	—
Notifications for new research opportunities	Must Have	—	—	Yes	—
Ability to collect research data within the app	Must Have	—	Should Have	No	As the app is specifically to aid with PPIE, rather than carry out research procedures, this falls beyond the scope of the app
Contributor leader board to demonstrate users who have provided the most contributions	Must Have	Could Have	—	No	Leader board ultimately excluded to demonstrate that all contributions are valuable, regardless of the number of contributions per user
Credit or time-based rewards for contributions	Must Have	Must Have	—	No	Complexity of implementation and variety of reward types discussed precluded the provision of rewards in the initial version. Further discussion is required to scope the requirements, planned for the next phase
Recognition for user inputs	—	Should Have	—	No	PPIE contributions recognized on a project-by-project basis and therefore fall beyond the scope of the app
Terms of reference or expectations	—	Must Have	Must Have	Yes	—
Data access or GDPR ^d information	—	Must Have	—	Yes	—
Users to assist with publicizing study or helping with recruitment	Should Have	Must Have	Should Have	No	Formal recruitment activities are outside the current PPIE scope of VoiceIn but project information and contact details can be provided
Glossary of research terminology	—	Must Have	—	No	Resource limitations
Notice that content may cause distress	—	Must Have	—	Yes	—

Description of general capabilities	Group			Included?	Reason for exclusion
	Young people	Mental health researchers	PPIE ^b leads		
Project categories are lay-friendly and not diagnosis-based	—	Must Have	—	Yes	—
Notifications for researcher to put project updates on the app	—	Must Have	—	Yes	Researchers are reminded on login to the website
Payment policies	—	—	Must Have	No	This is actively under consideration of how to recognize contributions fairly and safely within the app
Contributions exportable to LinkedIn or CV ^e	Should Have	—	Must Have	No	Technical constraints limit the ability to create exportable contributions at this time. But under consideration for future
Reminders for research milestones and dates for feedback to be returned	Should Have	—	—	Yes	—
Ideas lab to generate novel research ideas	—	Should Have	—	No	Resource limitations, but under consideration for future iteration
Demonstrate impact of research projects	—	Should Have	Should Have	Yes	—
Create a database of people interested in research	—	—	Should Have	No	Data protection limitations prohibit the creation of this type of database
Hear about new funding and related work	Could Have	—	—	Yes	—
Certificates of involvement	Could Have	Could Have	—	No	Technical constraints prevent the creation of certificates within the app at this time
Questions to assess users' mood and offer support	—	Could Have	—	No	A support section is included in the app, but ongoing monitoring of users' moods is beyond the scope of the app and may not be acceptable for some users
Debrief area	—	Could Have	—	Yes	—
Area to share lessons learned	—	—	Could Have	No	Social features between researchers are not currently enabled

Description of general capabilities	Group				Reason for exclusion
	Young people	Mental health re-searchers	PPIE ^b leads	Included?	
Translation into other languages	—	—	Could Have	No	Current limitations on project resources prevent translating the app into other languages

^aMoSCoW: must have, should have, could have, won't have.

^bPPIE: patient and public involvement and engagement.

^cNot applicable.

^dGDPR: General Data Protection Regulation.

^eCV: curriculum vitae.

Project Details

There was no clear consensus across stakeholder groups on the priorities pertaining to study details; however, sharing

information about funding, including the project dates, and having the ability to upload documents were all identified as priorities among mental health researchers. Project detail priorities across stakeholder groups are outlined in [Table 2](#).

Table . MoSCoW^a project details priorities for user-facing mobile app interface capabilities.

Description of project details	Young people	Mental health re-searchers	PPIE ^b leads	Included?	Reason for exclusion
Information about funding	Could Have	Must Have	— ^c	Yes	—
Study date ranges as part of the project details	—	Must Have	—	Yes	—
Ability to upload documents	—	Must Have	Should Have	Yes	—
Addition of images/video/graphics to project description	—	Should Have	—	Yes	—
Researcher profile	—	—	Should Have	Yes	—
Flexible options for entering project details	—	Could Have	—	Yes	—
Addition of inclusion or exclusion criteria	—	Won't Have	—	No	Inclusion or exclusion criteria can be included as free text; there will not be a separate section to input these criteria. Participant recruitment is not the goal of the app

^aMoSCoW: must have, should have, could have, won't have.

^bPPIE: patient and public involvement and engagement.

^cNot applicable.

Project Feedback

Stakeholders agreed that it was vital for app users to provide quick feedback via polls and likewise indicated that having the

ability to give feedback on both participant and staff-facing material was a key priority. Project details priorities across stakeholders are outlined in [Table 3](#).

Table . MoSCoW^a project feedback priorities for user-facing mobile app interface capabilities.

Description of project feedback	Young people	Mental health re-searchers	PPIE ^b leads	Included?	Reason for exclusion
Ability to provide feedback via polls	Must Have	Must Have	— ^c	Yes	—
Sharing project materials (eg, PIS ^d , consent forms)	Must Have	—	—	Yes	This is possible but sharing lengthy documents via the app is discouraged as this is not the goal of the app
Providing feedback on project materials (eg, PIS, consent forms)	Must Have	—	Should Have	Yes	—
Method to select data collection tools	Should Have	—	Should Have	Yes	—
Area to review advertisements for staff, steering groups, etc	Should Have	—	Should Have	Yes	—
Area to analyze and interpret data	Should Have	—	—	Yes	—
Help provide feedback on qualitative interview questions	Should Have	—	—	Yes	—
Ability for users to pause and come back later to contribute	—	Should Have	—	—	—
Help decide who may be interested in hearing about the results	Could Have	—	—	Yes	—
Ways for contributors to share ideas (eg, recruitment, dissemination)	—	Could Have	—	Yes	—
Reviewing previous research	Won't Have	—	—	No	Not desired by young people

^aMoSCoW: must have, should have, could have, won't have.

^bPPIE: patient and public involvement and engagement.

^cNot applicable.

^dPIS: participant information sheet.

Training and External Links

Participants across stakeholder groups indicated a desire for the app to have the capability to both provide project-specific training and provide links to relevant resources and opportunities beyond the app. Resource limitations preclude maintaining a

comprehensive list of external training or providing internal training via the app. However, links to additional opportunities and resources can be provided on a project-specific level via the project updates page. Training and external links priorities across stakeholder groups are outlined in [Table 4](#).

Table . MoSCoW^a training and external links priorities for user-facing mobile app interface capabilities.

Description of training and external links	Young people	Mental health re-searchers	PPIE ^b leads	Included?	Reason for exclusion
Project-specific training	Must Have	— ^c	—	No	However, contextual background project information can be provided
Tailored training for participants and researchers	Should Have	—	Should Have	No	—
Hear about opportunities for future training or learning	Should Have	—	—	Yes	Can be supported per project updates
Job opportunities and information about other ways to be involved in research	Should Have	—	Could Have	Yes	Can be supported per project updates
Advertise internal or external development opportunities	Could Have	—	—	Yes	Can be supported per project updates
Training on research methodology	Won't Have	—	—	No	—
Information on meeting with peers and community groups	—	—	Should Have	No	—
Links to wider PPIE networks and opportunities	—	Could Have	Could Have	No	Planned for future iteration
Expand app to other audiences or ages	—	—	Must Have	Yes	—
Stakeholder consensus meeting	Won't Have	—	Must Have	No	—

^cNot applicable.

Social Features

The various stakeholder groups identified different priorities for social features within VoiceIn, with the “ability for users to connect with one another, the public and other researchers” being rated as the top priority. While resource limitations

preclude the ongoing monitoring necessary to enable social features, mental health researchers are encouraged to include information about the research team on the project details page, and provide ongoing updates to foster engagement with app users. Social features priorities across stakeholder groups are outlined in [Table 5](#).

Table . MoSCoW^a social features priorities for user-facing mobile app interface capabilities.

Description	Young people	Mental health re-searchers	PPIE ^b leads	Included?	Reason for exclusion
Social Features					Resource limitations preclude the ongoing monitoring necessary to enable social features
Ability for users to connect with one another, the public and other re-searchers	— ^c	Must Have	—	No	—
Private messages	—	Should Have	—	No	—
Area for users to share experiences, blogs, stories, etc	—	Should Have	—	No	—
Ability to have conversations between researchers and contributors	—	Should Have	—	No	—
Ability to share outside the platform	—	Should Have	—	No	—
Linkable to social media outcomes	—	—	Should Have	No	—
Area to share findings with the public	—	—	Should Have	No	—
Monitored chat-room for personal interaction	Could Have	—	—	No	—
Areas for more creative outputs	—	Could Have	—	No	—
Input to write blog articles	—	—	Could Have	No	—
Ability to connect with people with similar interests	—	—	Could Have	No	—

^bPPIE: patient and public involvement and engagement.

^cNot applicable.

Design Features

Participants emphasized that VoiceIn should have a visually appealing and easy-to-navigate design. Specific design feature priorities across stakeholder groups are outlined in [Table 6](#).

Table . MoSCoW^a design features priorities for user-facing mobile app interface capabilities.

Description of design features	Young people	Mental health re-searchers	PPIE ^b leads	Included?	Reason for exclusion
Customizable notifications	Must Have	— ^c	—	No	Considered for future iterations
Easy to navigate back to the home screen	—	Must Have	—	Yes	—
Academic diary	Should Have	Should Have	—	No	Falls beyond the scope of the app
Video guide on how to use app	—	—	Could Have	No	Resource limitations preclude the creation of a video guide

^aMoSCoW: must have, should have, could have, won't have.

^bPPIE: patient and public involvement and engagement.

^cNot applicable.

Mental Health Researchers' Priorities for App Functionality

Mental health researchers were also asked to rate their priorities for VoiceIn app functionality. The priorities are outlined in [Table 7](#).

Table . MoSCoW^a priorities for app functionality.

Feature	Mental health researchers	Included in the app?
Users can sign up on a mobile app	Must Have	Yes
Users have a password	Must Have	Yes
User selects interests from pre-populated list	Must Have	Yes
Users can view research projects added by re- search on the web interface in the app	Must Have	Yes
Easy to navigate back to the home screen	Must Have	Yes
Users can “like” or “dislike” project cards to ex- press interest	Must Have	Yes
Users can “like” a project to see more details	Must Have	Yes
Users who have “liked” a project and have cho- sen to contribute can respond to researcher polls & comments	Must Have	Yes
Users can view projects they have fed back on	Must have	Yes
Users contribute using both free text and polls	Must Have	Yes
Users can sign up using a handle of their choice	Should Have	No
User confirms birth year to verify age group	Should Have	Yes
Users can view progress on projects they have fed back on	Should Have	Yes
Users that have “liked” a project and have chosen to contribute can choose if they want to receive updates on the project.	Should Have	Yes
Users have an area where they can change pref- erences (topic interests)	Should Have	Yes
Users can choose to contribute anonymously (feedback does not have a user ID visible, but feedback can be seen by other users)	Could Have	Yes
Users can choose to contribute publicly (feedback has user ID visible)	Could Have	Not Yet
Users can change privacy preferences for visibil- ity	Could Have	Not Yet
Users that have “liked” a project and chosen to contribute can see other responses to researcher polls	Could Have	Not Yet
Users that have “liked” a project can save it for later	Could Have	Yes
Users that have “disliked” a project have it re- moved from their card stack and do not receive notifications about this project again	Could Have	Yes
Users that have “liked” a project then can choose not to contribute to the project; project will be removed from their card stack and they will not receive notifications	Could Have	Yes
Sign up requires identifiable information	Won't Have	No
Users can choose to contribute directly to the researcher (only researcher can see feedback; may or may not have user ID)	Won't Have	No

^aMoSCoW: must have, should have, could have, won't have.

Phase 2 Co-Design Workshops

The phase 2 workshops focused on asking participants to try out aspects of the tool and discuss the refined design prototypes. The prototypes showed how the mobile app and web-based researcher platform would look and function. In the workshops, participants were offered the opportunity to create a mock

VoiceIn project, provide feedback on the ease of use of the VoiceIn platform, and identify areas of improvement.

Results of written feedback on the ease of use and areas of improvement from the usability testing workshops are presented in [Table 8](#).

Table . Summary of usability feedback across stakeholder groups.

Feedback category	Young people	Mental health researchers	Changes incorporated
Ease of use	Easy to understand	First cohort rated the website as 5/5 in terms of ease of use	— ^a
Ease of use	Easy to engage with	Second cohort rated the website as 4.9/5 in terms of ease of use	—
Features that were good about the app or website	Use of videos in project descriptions	Clean and tidy design	—
Features that were good about the app or website	Choice about whether to contribute to each project	Straightforward to use	—
Features that were good about the app or website	“Quick and fun” to sort through project cards	Guides users through the process of setting up PPIE ^b events	—
Features that were good about the app or website	Project updates section	—	—
Features that were good about the app or website	Ability to save projects for later	—	—
Features that were missing from the app or website or could be improved	Include description along with title on the project cards	Funder details should be included	Description incorporated
Features that were missing from the app or website or could be improved	—	Project start or end dates	Project start or end dates added to project details page
Features that were missing from the app or website or could be improved	—	Inclusion and exclusion criteria as separate boxes	Can be defined on per project basis by the researcher
Features that were missing from the app or website or could be improved	—	Distress and debrief section	Support page added signposting users to mental health support
Features that were missing from the app or website or could be improved	—	Use service-user defined categories like “self-harm” and “low mood” instead of diagnostic labels like “depression” to categorize studies	Categories expanded to include nondiagnostic categories like “hearing voices” and “loneliness”
Features that were missing from the app or website or could be improved	—	Add “potential impact of project” section	Researchers have option to include this as part of the project description
Features that were missing from the app or website or could be improved	—	Section to outline expectation about time commitment and necessary skills	—
Features that were missing from the app or website or could be improved	—	More nuanced age range for study participants	—
Features that were missing from the app or website or could be improved	—	“Home” button that returns users to home screen	“Home” button added
Features that were missing from the app or website or could be improved	—	More colorful design	—
Additional suggestions	—	Flexible project details page so it is fit-for-purpose for each project	Flexible project description section which enables the use of additional headings, photos, and videos

^aNot applicable.

^bPPIE: patient and public involvement and engagement.

In the phase 2 workshops, participants were also invited to give general feedback about the app and its potential use. A summary

of this discussion and the changes incorporated in subsequent iterations of the app are described in [Figures 5-7](#).

Figure 5. Summary of young people’s feedback on VoiceIn and its potential use. PPIE: patient and public involvement and engagement.

Figure 6. Summary of mental health researchers’ feedback on VoiceIn and its potential use. PPIE: patient and public involvement and engagement.

Figure 7. Summary of PPIE leads' feedback about VoiceIn and its potential use. CV: curriculum vitae; PPIE: patient and public involvement and engagement.

Final VoiceIn Iteration

VoiceIn Mobile App

The final iteration of the VoiceIn mobile app allows users to choose their research interests from a range of categories (eg, mental health and public health). Users are then brought to the home screen, in which relevant projects appear and users choose whether they are interested in finding out more about the project.

When a user indicates they are interested in a project, they are shown the project description and asked if they would like to provide feedback on the project. Users then have the ability to answer questions (both poll and free text) and view project updates. In instances where feedback was provided via a poll, users will have the opportunity to see the distribution of responses. Interests and privacy settings can be changed by the user at any point. Sample images of the VoiceIn app are displayed in [Figures 8-11](#).

Figure 8. VoiceIn home screen where participants can view all projects.

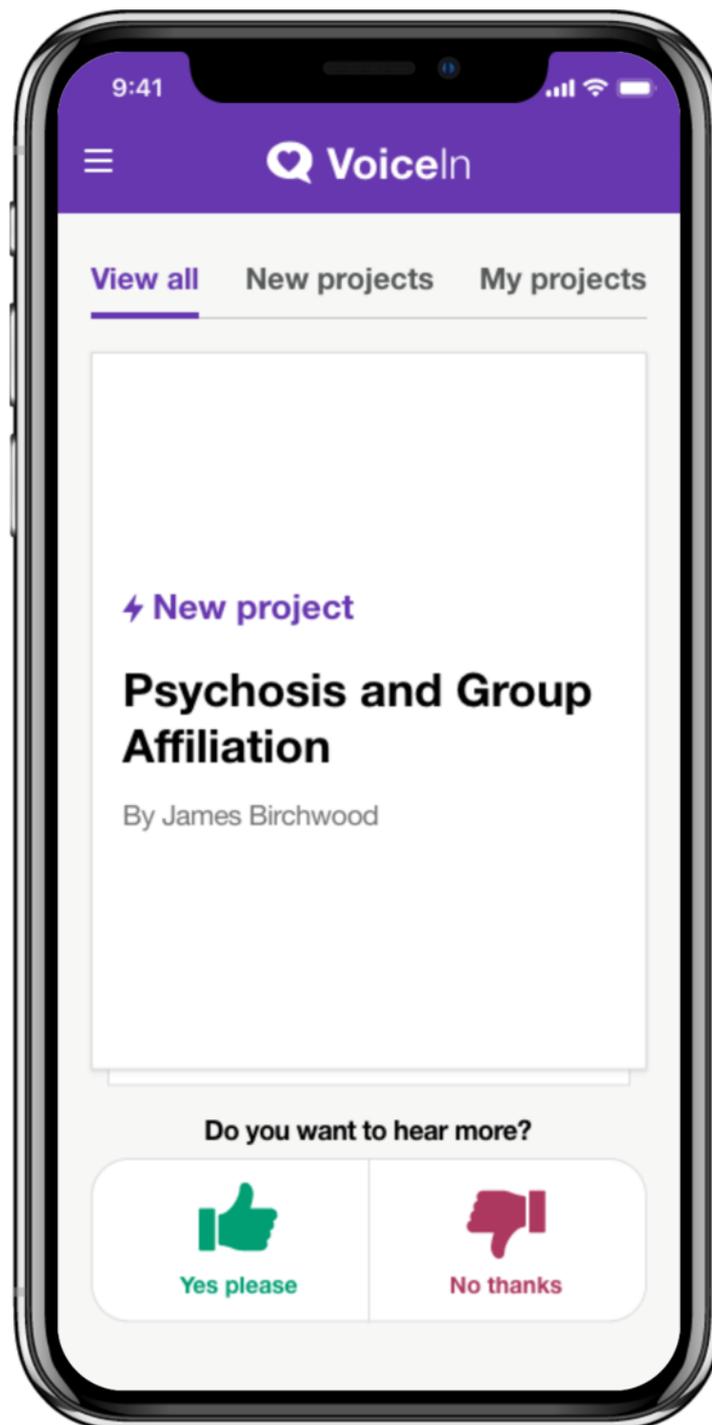

Figure 9. "My projects" page.

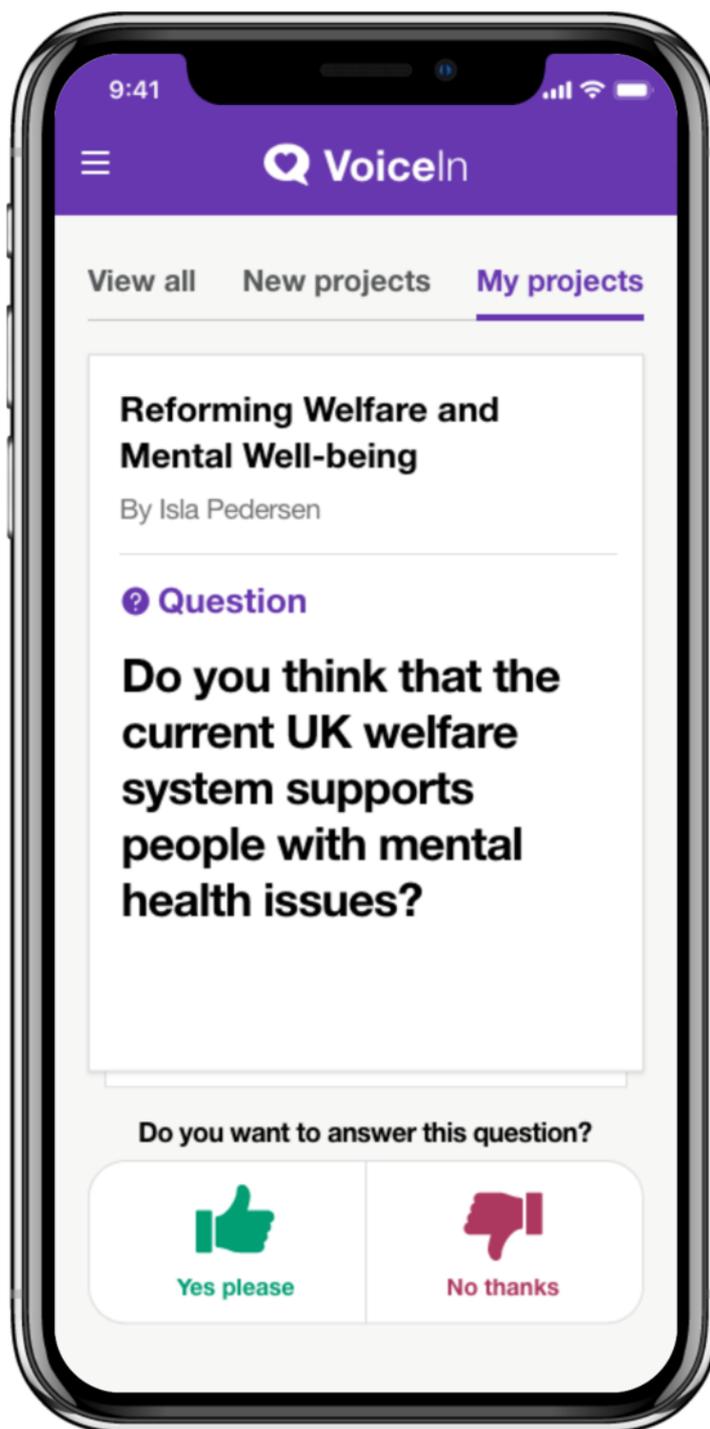

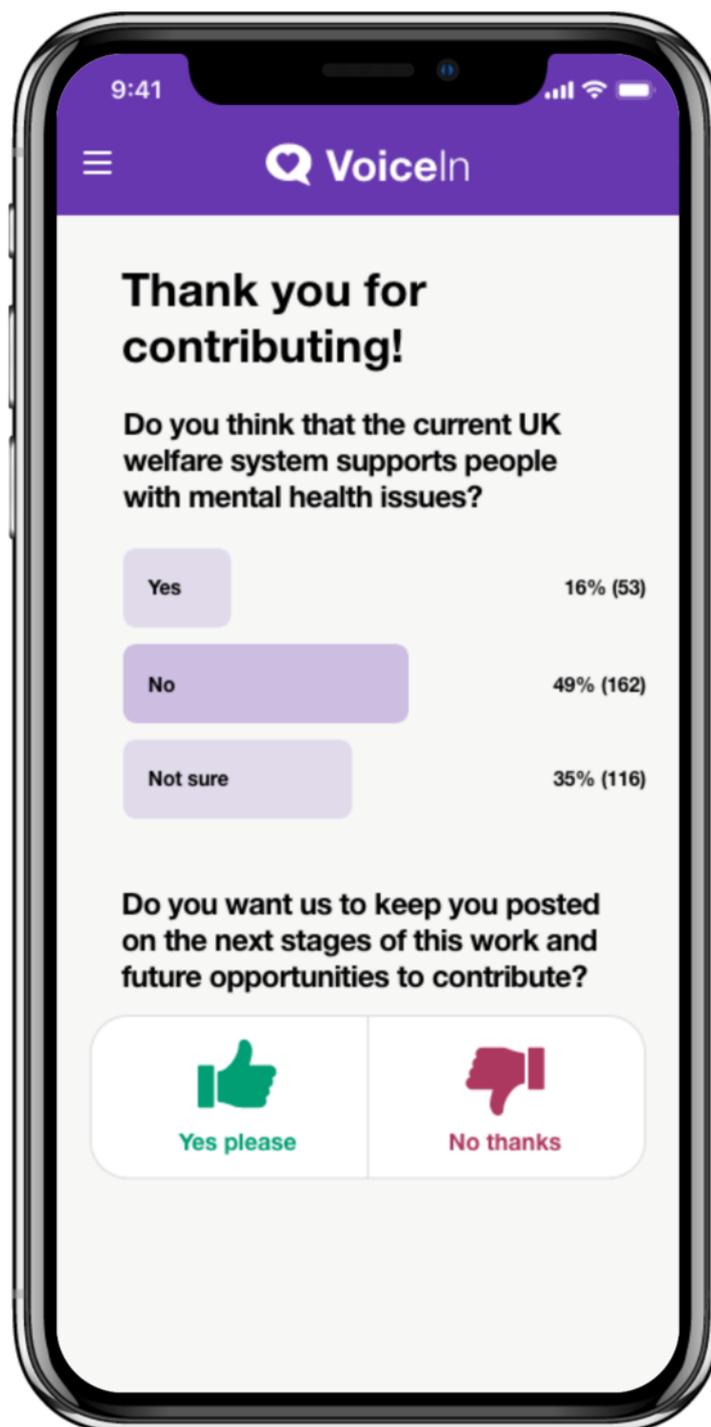

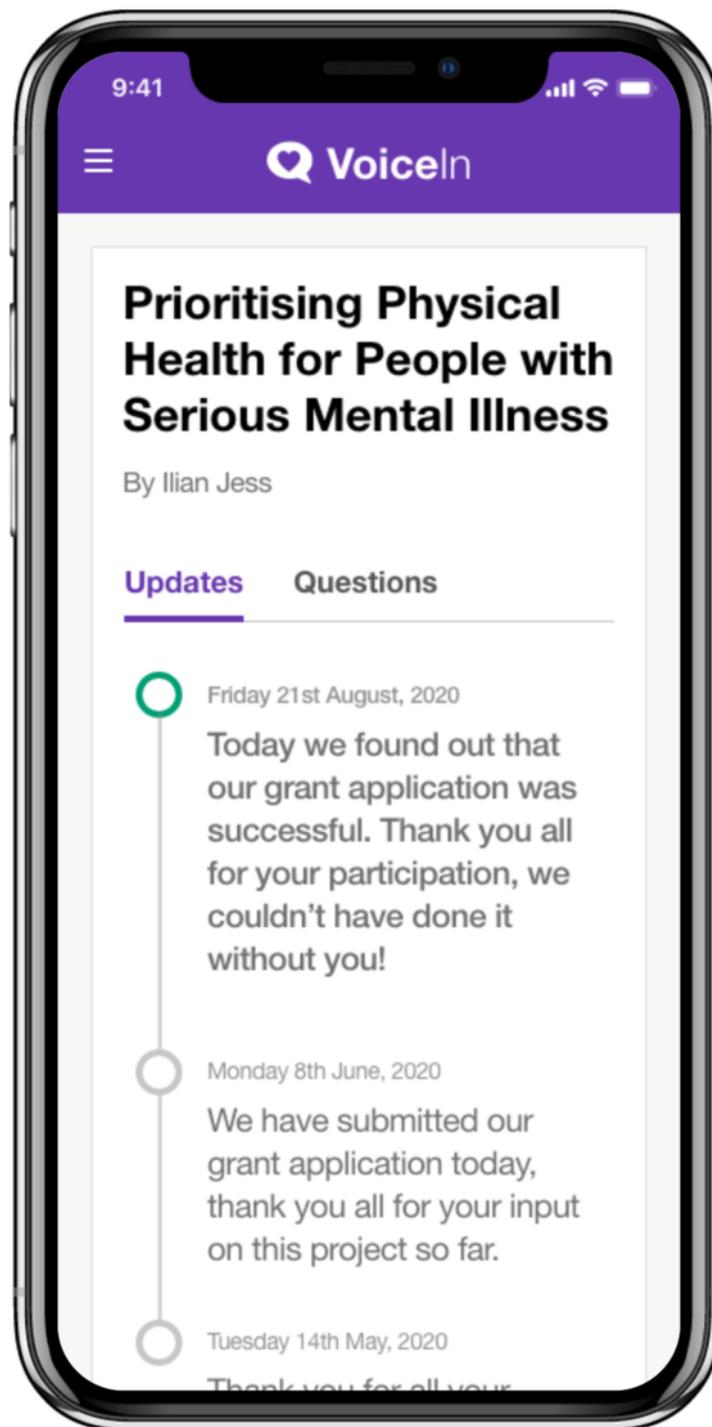

Figure 10. Sample distribution of responses to a poll.

Figure 11. Sample “project updates” page.

Researcher-Facing Web Platform

VoiceIn was designed to enable researchers to have flexibility with how they present and elicit feedback for their projects. The home screen displays all of a researcher’s active projects and the amount of feedback received per project. When creating a new project, researchers insert a project title and indicate the intended audience (eg, age and interest), start and end dates, and terms of reference for the project. Project details can be

displayed in the form of text, images, or videos; feedback can be requested as a poll or free text; and additional study documents can be uploaded. Once responses have been collected, researchers can view the demographic breakdown of participants, as well as see the poll and free text responses. Throughout the project, researchers can ask new questions, provide project updates, and review feedback to be displayed publicly on the app. Sample images of the web interface are displayed in [Figures 12 and 13](#).

Demographics

The public engagement (people who have either chosen to read more about your project, or not read more about your project) break down into the following demographics.

Discussion

Principal Findings

This paper outlines the process of co-designing the first digital tool to our knowledge that has been developed to enable real-time digital PPIE in mental health research. It likewise details the features that were identified as most important for young people, mental health professionals, and PPIE leads alike. Across stakeholder groups, participants highlighted that the VoiceIn app needed to be accessible, flexible, and easy to fit into the lives of young people. The key features that were included in the app were a flexible description of the research project, which can include the use of images and videos; numerous ways of engaging with the app and providing feedback on projects, including polls and free-text response options; and progress updates so that users can see how their input impacted the project and hear about how the research is making a difference in the world.

Co-designing the app with key stakeholders enabled the team to explore unique perspectives on developing a purely digital

form of PPIE. The co-design process supported the development of an app that responded to the needs of our target user groups. It identified key features of the platform that were required for a usable and useful experience; supported feedback on the design and layout of the mobile app and web-based platform; established how a digital form could both supplant and supplement face-to-face PPIE activities; and highlighted the necessity of face-to-face modes of PPIE for in-depth discussion and exploration. It identified the potential for a mobile app that is accessible 24/7, and without geographical or spatial boundaries, to reach audiences often not represented in face-to-face activities.

The use of Agile software development methods enabled iterative versions of the app to be taken to app co-design workshops. This allowed end users to see the development of the app and the integration of features and changes that had been requested at previous workshops. Working iteratively with the software and research team, the Agile approach supported an ongoing process of iterative refinements and integration of feedback from the groups.

Time and budget inevitably constrained the breadth and depth of requirements that the software team was able to implement. Difficult choices on which features and functions to include in the app had to be made to ensure that the project met key milestones for delivery. Moreover, the co-design workshops, which were run by videoconference, encountered some of the problems that the VoiceIn app is designed to tackle. The co-design workshops required a reasonably long time commitment from people (90 mins); PPIE was conducted in a shared group space, which we recognize some may find challenging; and the research team struggled in some instances to recruit participants from diverse backgrounds. In the future, traditional modes of requesting co-design input could be supplemented by using the VoiceIn app to request feedback on itself by polling users.

Some challenges described during the co-design workshops were difficult to fully resolve and may require further iteration after live deployment. The challenge of remuneration of public users or contributors was difficult to resolve. Unlike traditional PPIE where fixed fees are usually paid for attending PPIE sessions, the groups suggested that payment for short contributions via the app was difficult to cost and to administer. Future versions of VoiceIn will consider remuneration in light of the philosophies of both PPIE, which promotes deep involvement in research, and citizen science, which may privilege rapid feedback [31]. VoiceIn will be more easily harmonized with rapid feedback models, many of which rely on voluntary involvement and nonmonetary incentives for involvement.

Next Steps

The potential of the app to support PPIE for mental health research has not yet been tested. The next phase of the project is to test the app. User needs will continue to be identified as the app is rolled out and piloted in the United Kingdom. The co-design and stakeholder involvement will continue to capture user needs after the app is in real-world use. A benefit of VoiceIn is that we can use the app to capture feedback in real-time, as well as track data analytics on how people use the app. Real-time feedback and analytics allow researchers to respond to problems or improvements identified. At the time of writing, we believe this is a world-first platform for digital

PPIE; the potential for VoiceIn to reach a wider audience for PPIE than more traditional or face-to-face methods and to develop a learning health system for PPIE remains to be tested.

Our overarching goal is for VoiceIn to support PPIE activities for anyone, anywhere who would find it helpful. Our initial aim is for the platform to be widely used across the United Kingdom to support PPIE in health research broadly. Ultimately, we aim to scale the platform to support global research studies.

Conclusion

VoiceIn can support PPIE by providing an easy-to-use, digital interface that enables public contributors to share ideas and feedback on research projects from the comfort of their smartphone, at times that are convenient to them. For researchers, VoiceIn offers a new way to engage public contributors who otherwise may be difficult to access or who may not like to participate in face-to-face PPIE activities.

VoiceIn is not a solution for all PPIE needs and activities. There remains an important need for traditional and face-to-face ways of involving and engaging public contributors that can support sustained and meaningful conversations and more detailed exploration and discussion of ideas. Digital inequalities, such as lack of access to technology and lack of skills or confidence to use digital technology, also mean that VoiceIn is not an accessible solution for all. However, for VoiceIn's target audience of young people aged 16 - 25 years, providing an option to contribute to research via their smartphone was seen as convenient and appealing.

While VoiceIn was initially developed for mental health research, it has now been adapted to accommodate health research more broadly. The next phase of the project involves releasing the VoiceIn app onto the public app marketplace and enrolling research projects onto the platform. Our co-design work indicates that there is both a need and an appetite for this digital mode for PPIE. However, it remains to be seen if VoiceIn will be widely used by researchers and public contributors. The potential for VoiceIn to revolutionize PPIE by enabling individuals and groups who may have previously felt excluded from face-to-face or traditional PPIE activities and by supporting researchers to reach a wider public audience now needs to be tested.

Acknowledgments

Vocal, hosted by Manchester University NHS Foundation Trust in partnership with the University of Manchester, offers support to bring people and researchers together to connect with health research. We would like to extend our thanks to both Vocal and the GM Digital Young People's Digital Advisory Group for their participation in our co-design workshops and for offering invaluable feedback on all iterations of the app. This paper presents research funded by the National Institute for Health and Care Research (NIHR) Applied Research Collaboration Greater Manchester (ARC-GM). The views expressed are those of the authors and not necessarily those of the NIHR or the Department of Health and Social Care.

Authors' Contributions

PB and KL conceived of the idea, which was developed further in discussion with PW and SB. SF designed the VoiceIn app. PW led the technical development and design of the app and led all co-design and usability activities. AB collated workshop findings and wrote the first draft of the manuscript. All authors critically reviewed the manuscript and approved the final draft for publication.

Conflicts of Interest

PW is a director and shareholder of a for-profit digital mental health company, CareLoop Health Ltd, and a director and shareholder of Prism Life Ltd, a small consultancy company. SB is a director and shareholder of CareLoop Health Ltd.

In “An Artificial Therapist (Manage Your Life Online) to Support the Mental Health of Youth: Co-Design and Case Series” (*JMIR Hum Factors* 2023;10:e46849) the authors noted an error.

In the Results section of the text, a variable was wrongly described as the number of words typed by users, instead of the number of characters typed by users. Therefore, all mention of this variable has been revised.

The following sentence:

The word count of these conversations ranged from 58 to 2104 words and participants sent 2 to 20 texts.

has been revised to:

The character count of these conversations ranged from 58 to 2104 characters including spaces and participants sent 2 to 20 texts.

The following sentence:

As shown in Figure 3, in total 100% of the conversations 1000 words were rated as helpful, and all the remaining conversations 1000 words were rated as either unhelpful or neither.

has been revised to:

As shown in Figure 3, in total 100% of the conversations in which participants typed over 1000 characters were rated as helpful, and the remaining conversations were rated as either unhelpful or neither.

The caption and axis title of [Figure 3](#) have also been revised from:

Figure 3. Number of participant-generated words in each conversation and overall helpfulness rating.

to:

Figure 3. Number of participant-generated characters in each conversation and overall helpfulness rating.

In the discussion section the following sentence:

We identified a potential threshold of 1000 words for a conversation with MYLO to be rated as helpful, as opposed to unhelpful or “neither.”

has been revised to:

We identified a potential threshold of 1000 characters for a conversation with MYLO to be rated as helpful, as opposed to unhelpful or “neither.”

The correction will appear in the online version of the paper on the JMIR Publications website on December 16, 2024, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Abstract

Background: Dementia management presents a significant challenge for individuals affected by dementia, as well as their families, caregivers, and health care providers. Digital applications may support those living with dementia; however only a few dementia-friendly applications exist.

Objective: This paper emphasizes the necessity of considering multiple perspectives to ensure the high-quality development of supportive health care applications. The findings underscore the importance of incorporating input from stakeholders and the needs of affected families into application development.

Method: A qualitative approach was chosen, consisting of three interviews and an expert workshop. The interviews and the workshop were recorded and transcribed, and qualitative content analysis was carried out according to the methodology described by Kuckartz with the support of MAXQDA.

Results: During the development phases of the application, team meetings and discussions took place. We found that general practitioners and family caregivers play pivotal roles in the treatment and care of people with dementia, often expressing specific preferences and suggestions regarding supportive and assistive technologies. Moreover, the successful development of a useful tablet application requires robust scientific and multidisciplinary discussions and teamwork within the health care community.

Conclusion: This paper underscores the necessity of including multiple scientific, clinical, and technical perspectives to ensure the high-quality development of supportive health care applications. Furthermore, adopting a spiral development approach inclusive of feedback loops is imperative for iterative refinement and enhancement of the application.

dementia; tablet application development; multidisciplinary health care; feasibility study; general practitioners; digital health care

Introduction

Dementia and Health Care

Dementia impacts approximately 47 million individuals globally, with nearly 10 million new cases emerging each year [1]. In Germany, around 1.6 million people live with dementia [2], posing a significant challenge not only for those affected but also for their families, caregivers, and health care providers. Dementia is characterized as “a syndrome resulting from mostly chronic or progressive brain disease, disrupting various higher cortical functions, including memory, cognition, orientation,

perception, arithmetic, learning capacity, language, and judgment. Consciousness remains unaffected. Cognitive impairments often coincide with changes in emotional control, social behavior, or motivation...” [3]. These extensive symptoms coincide with a gradual decline in the ability to independently perform daily activities. Consequently, there are physical, psychological, social, and economic effects, leading to disability and dependence among affected individuals [1]. The substantial burden on caregivers, including family, has been widely recognized [1,4,5]. The majority of dementia caregivers are family members of people with dementia, who experience

physical and psychological strain due to the declining health status and increasing health needs of the person with dementia [2,6]. For instance, the German College of General Practitioners and Family Physicians [5] provides a brief overview of various health issues faced by caregivers, such as physical health problems (eg, back injuries), mental health issues (eg, depression), and a constant feeling of being overwhelmed. Moreover, previous research has revealed that family caregivers also grapple with challenging behaviors from people with dementia [7].

Information and communication technologies (ICTs) may represent a promising approach to improve dementia treatment, especially for people with dementia that live at home. A systematic review of ICT studies by D'Onofrio et al [8] showed that ICTs can support several daily life activities for people with dementia, allow people with dementia to remain in their own home, increase the quality of life of their caregivers, and decrease health care costs. Evidence-based guidelines and training for general practitioners (GPs) [9] regarding treatment pathways and communication [10], as well as a multiprofessional team approach [11], may represent helpful mechanisms to support GPs.

GPs play a pivotal role in providing health care for people with dementia. Bohlken and Kostev [12] demonstrated that in 2015, GPs treated an average of 29.9 people with dementia, marking a 40% increase compared to 2005 (21.3 people with dementia). However, the role of GPs in diagnosing and treating dementia is subject to debate. Despite their commitment to holistic care and long-term relationships [13], there are significant challenges, including knowledge gaps, reluctance to diagnose, and cost concerns [14], alongside differing care priorities and limitations within the health care system [13]. For instance, in terms of communication, GPs' decisions to disclose a dementia diagnosis to a patient or their families are influenced by personal beliefs, patient circumstances, systemic care factors, and cultural norms [9]. Additionally, euphemistic terms like "memory problems" are often used instead of medical terminology to describe dementia [9]. Wangler and Jansky [10] observed that GPs' distant or negative attitudes, as well as their reluctance toward dementia testing and diagnoses, directly impact practical diagnostic outcomes. As a result, GPs may deny responsibility, fear stigmatization of their patients, and avoid confrontations with patients, citing concerns over the effectiveness of interventions, low compensation, and lack of recognition [10]. In summary, existing literature recognizes the indispensable role of GPs in caring for people with dementia and highlights the need to improve primary dementia care.

Digitization and Technologies

In Germany, current political initiatives aim to expedite the digitalization of the health care system, such as the Digital Act, with the goal of enhancing health care [15]. However, for these efforts to be successful, the technical solutions must align with the needs of the target group. Developing and evaluating assistive technologies necessitates an understanding of the diverse interactions between technology, users, and the contextual environment, as well as knowledge translation [16]. Dugstad et al [17] highlight crucial aspects for the successful

implementation of digital technology in dementia care, emphasizing the involvement of key stakeholders from the very beginning, allowing time for exchanges and participation during the initial stages, and advocating for iterative refinement and skill development. Particularly in the development of assistive technologies for individuals with dementia, given their complex circumstances and requirements, extensive collaborative and transdisciplinary engagement is essential, as demonstrated by Boger et al [16].

The research project DemTab (tablet-based outpatient care for people with dementia) aimed to develop and evaluate a tablet-based intervention to enhance treatment for people with dementia in primary care by promoting guideline-based treatment [18,19]. To achieve this goal, a tablet-based intervention was created within the research project. The project was a collaboration between the Institute of Medical Sociology and Rehabilitation Science (ISMR) at Charité-Universitätsmedizin Berlin and the Quality and Usability Lab (QULab) at Technische Universität Berlin. Additionally, a cluster-randomized controlled trial was conducted to investigate the impact of this tablet-based intervention on guideline adherence (primary outcome) and various health-related outcomes for patients and caregivers (secondary outcomes). The tablet-based intervention offers several key functions for people with dementia and their informal caregivers [18]. The final application version contained serious games and included cognitive training games (eg, quizzes), activities focusing on daily living skills, an interactive music program, and a picture gallery for biography work. These tools were designed to engage and stimulate users and enrich their daily lives. Interactive location services provided by the Federal Ministry for Family Affairs, Senior Citizens, Women and Youth highlighted nearby consulting and support services for people with dementia, such as dementia-specific occupational therapy and daycare facilities, as well as resources for informal caregivers like support networks, counseling points, and self-help groups [20]. The communication platform allows for both indirect and direct communication with the GP through health information documentation and messaging, respectively. The care plan developed in collaboration with the GP can be accessed on the tablet by both the person with dementia and their caregivers and provides regular notifications and reminders (eg, for medication intake). Finally, a guided audio-relaxation program, which can be used by both people with dementia and their caregivers, supported relaxation and stress management.

The following functions were designed to support GPs in providing comprehensive, guideline-based care and improving communication with patients and caregivers [18]: (1) a checklist for guideline-based treatment based on the German Dementia Guideline [13]; (2) a prescription support function for antedementia drugs providing guideline-driven treatment recommendations, including automatic reminders for correct medication intake and adjustments; (3) a care development plan that assisted in creating a care plan and determining treatment plans and aims; (4) health information recorded by people with dementia and caregivers displayed on the GPs device, such as general condition or blood pressure values and direct messaging between GPs, people with dementia, and caregivers to enhance

communication and action, such as adjusting medication or scheduling appointments; and (5) access to educational material on dementia and dementia care. This also included access for GPs to an electronic version of the German Dementia Guideline [13] and additional information about outpatient dementia care. People with different stages of dementia were included in the study. The application should therefore contain offers for these different stages of the disease. However, the majority (87.9%) of participants in this study had a mild to moderate dementia [19]. For more comprehensive information about the DemTab study, its participants, interventions, and expected outcomes, we refer to the study protocol [18].

Aim of This Study

This study focused on the initial phase of the DemTab study: the development of a tablet application designed for people with dementia, their caregivers, and GPs in Berlin and the surrounding regions. The objective was to outline the development process of the application within the framework of a feasibility study. The primary aim was to illustrate how health care providers (GPs and experts from supportive organizations in dementia care) contributed to the content development process and how collaborative and interdisciplinary research efforts between the ISMR and the QULab led to the cocreation of a functional health care application. A key objective was to ensure the incorporation of diverse perspectives and professional insights, as well as to facilitate a continuous and iterative research process through feedback loops and team discussions.

Methods

Ethical Considerations

Ethical approval was obtained by the ethics committee of the Charité–Universitätsmedizin Berlin (EA1/085/19). Written informed consent was obtained from all participants or legal guardians prior to data collection. All participants had the opportunity to drop out at any time. All data from the interviewees and workshop participants were pseudonymized. The list of reidentifying data was stored separately from the analyzed data, and only authorized individuals have access to them. A data protection concept and a data protection impact assessment were created for the entire project. No compensation was paid for the interviews and the workshop. At the end of the workshop, there was a small buffet lunch for all participants. No one was paid for the pretest application testing in the day clinic or the general practice.

Research Process and the International Organization for Standardization Standards

Our methodological approach adheres to the International Organization for Standardization (ISO) 9241 - 210 standard, titled “Ergonomics of human-system interaction—Part 210: Human-centered design for interactive systems” [21]. The ISO has devised a framework aimed at ensuring systems are both usable and useful, with a focus on users and their needs and requirements, by leveraging human factors, ergonomics, and usability knowledge and techniques [21]. Similarly, the user-centered design (UCD) framework provides a structured

methodology for translating ideas into products, prioritizing user preferences and interactions with the final product [22]. The process aims to facilitate natural interactions without altering user behavior or expectations. UCD methodologies are rooted in the ISO 13.180 for ergonomic standards, with the standard 9241 - 210 playing a central role in the UCD framework [21]. Our approach to developing the DemTab application aligns with the 4 general phases of the UCD process.

First, we delineated the application’s context, identifying primary user groups and their typical environments based on the method outlined by the International Organization for Standardization [21]. Second, we identified the requirements that our solution must fulfill, encompassing content, usability, and regulatory compliance such as adherence to the General Data Protection Regulation principles [23]. Third, we formulated concepts and prototypes based on the identified requirements, marking the starting point of the design and development phase. Last, we concurrently and continually evaluated our prototype through expert interviews and usability tests with the target user group. This iterative process provided feedback that we could incorporate into subsequent iterations of the development process. Following the process [21], we provided a detailed account of the feedback activities that took place. Additionally, this process exhibits a resemblance to the widely recognized qualitative circular research process, which permits some degree of flexibility and refers back to previous research steps, as it embodies a more dialogical approach [24].

Process and Data Collection

The DemTab project and the application development process were based on the foundation laid by the previous project PflegeTab. PflegeTab was a tablet-based intervention designed to engage nursing home residents with dementia, with the aim of enhancing quality of life and addressing behavioral symptoms [25]. PflegeTab consisted of various adaptive tablet applications tailored to the participants’ cognitive, functional, and emotional self-regulation abilities. Based on this previous work, the main goal of the DemTab project was to extend this application and create a comprehensive platform for outpatient dementia care. In addition to the existing functionalities for people with dementia, the DemTab application also included additional functionalities developed specifically for GPs and informal caregivers [18,26].

In the initial phase of application development, two GPs from Berlin with experience in dementia primary care were interviewed (step 1): one with expertise in technological approaches in primary care and the other operating in rural areas. Another interview was conducted with a psychologist who worked as a leading manager for the National Dementia Association and was responsible for providing consultations and support to people with dementia and their relatives. These participants were selected based on their valuable expertise and were directly approached by the researchers. A semistructured interview guide was collaboratively developed by the research team. The interviewees were prompted to discuss key aspects of medical and social needs for people with dementia and their informal caregivers, as well as the role of technical support systems in practice. The objective was to gain a deeper

understanding of the potential benefits of a tablet-based application for people with dementia, their caregivers, and GPs. The interviews were fully transcribed, and a content analysis was conducted following the methodology outlined by Kuckartz [27], using the MAXQDA 2018 software (VERBI Software) for data analysis.

For the expert workshop (step 1), the researchers extended invitations to two practicing GPs in Berlin, one researcher from the Institute of General Medicine at Charité–Universitätsmedizin Berlin, and two people in managing positions from a support organization based in Berlin that offers voluntary assistance for people with dementia. The workshop was held in September 2018, with participants selected based on their expertise, and they were directly approached by the researchers. While three GPs were initially invited, one was unable to attend. The workshop commenced with a presentation outlining the DemTab study, followed by participants testing version 0.5 of the application and engaging in a focus group discussion. This discussion included a presentation of the results pertaining to the 4 application functions: dementia guidelines, data representation, messaging, and games. Additionally, all workshop attendees completed a questionnaire detailing their personal information and their respective contexts of working with people with dementia and informal caregivers. Following the workshop, members of the research team also completed a brief written survey to capture immediate reflections. The survey comprised of 3 questions including:

- How did you perceive the workshop?
- Which application features or discussion topics were quickly dismissed?
- What topics were extensively discussed?

Team talks and discussions, as well as mutual agreements between researchers from the ISMR and the QULab, were integral (step 2). Biweekly team meetings were held throughout the development period, following a structured procedure. First, the QULab presented new feature additions, then the ISMR researchers tested and evaluated them, then all team members engaged in discussions regarding the user-friendliness of the tool, and finally potential changes and additions informed by insights from interviews and the expert workshop were instituted. The central questions of this study included:

- What valuable knowledge from the previous project PflgeTab should inform our approach?
- What insights from qualitative interviews and workshops should shape specific application functions?
- How can we enhance the implementation of the application in real-world settings?
- What technical features can feasibly be implemented within the timeframe and how?

Additionally, a pretest (step 4) of the DemTab application (version 0.5) was conducted in a geriatric day clinic in Berlin, where people with dementia and staff used the application for 7 days. Furthermore, the application was tested once by a GP who provided feedback and recommendations on content and visualization.

Results

The main results are presented following the steps explained in this section.

First Step: Preparation—Interviews and Workshop Findings

General Practitioners

Through the interviews and workshop, it became evident that GPs play a crucial role in the comprehensive care of individuals living with dementia and their families. Serving as primary care providers, they are trusted figures who facilitate communication and act as mediators. GP offices also serve as hubs for interdisciplinary and intersectoral communication. It was emphasized that collegial exchanges with specialists and collaboration with family members are vital for ensuring comprehensive home-based care. Moreover, there was a call for increased usage of dementia-specific advisory and support services. One GP highlighted the need for quick access to reliable information, noting the impracticality of consulting extensive guidelines on short notice. Describing the factors influencing care, one GP stated, “Accessing fast, secure information is essential; however, it’s impractical to review all the extensive guidelines on short notice” (Interviewee 1, passage 205).

Technology

GPs emphasized the importance of having concise, practical, and filtered information to ensure guideline-oriented treatment and cooperative specialist care. They suggested that data collected by the application should be prioritized and presented graphically to improve comprehension. GPs stressed the significance of choice and self-determination in using the tablet, as well as decisions regarding its functionality. They also advocated for greater integration and networking to facilitate the sharing of information on available assistance and support services. Additionally, there were concerns about the potential for relatives to overload the technical application, particularly with communication functions, which could inadvertently burden GPs. This was discussed critically along with the advantages of video consultations, but they were ultimately rejected by the participating GPs. One GP also commented on potential future technologies stating, “The advantage of video calling is being able to see the person; that adds a different level compared to just talking” (Interviewee 2, passage 130).

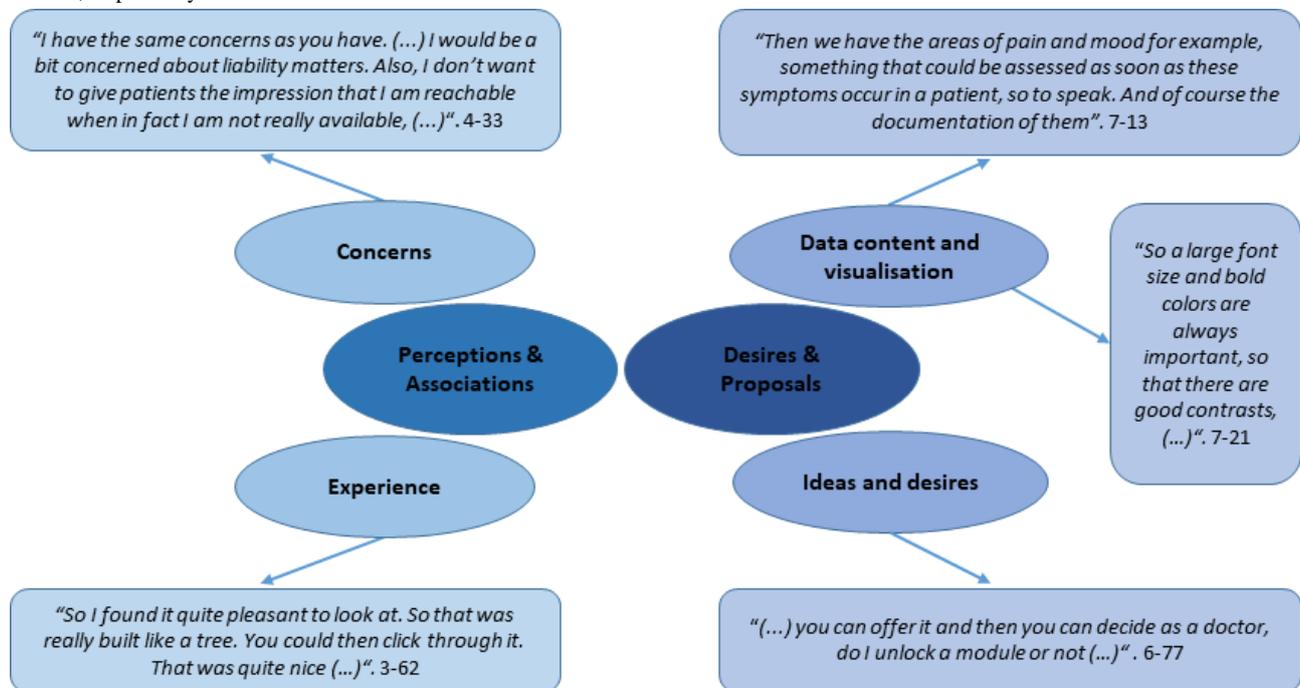

Relatives and Caregivers

Relatives and caregivers play a significant and multifaceted role in the care of people with dementia at home. Family caregiving occurs under diverse circumstances and can be accompanied by significant stress. Consequently, family members of people with dementia require guidance on medical, psychosocial, and legal matters, as well as access to support services aimed at alleviating stress and fostering social connections tailored to their individual situations and needs. Empowering individuals to help themselves and enhancing their ability to act independently were recognized as crucial objectives. This is illustrated by the following quote stating, “The psychosocial

counseling of relatives, aiming to empower them to help themselves and to raise awareness of their own competencies” (Interviewee 8, passage 15). Conclusively, caregivers should be actively engaged in diagnostic and therapeutic processes.

The workshop results encompassed information within two primary categories: perceptions and associations, which encompassed experiences and concerns, as well as desires and proposals, which included considerations regarding data content, visualization, and innovative ideas. The principal findings and examples are detailed in Figure 1.

Figure 1. Main categories and subcategories of the workshop with examples. Interviewee ID and passage number for each quote are presented in parentheses, respectively.

Second and Third Step: Application Development—Accompanying Team Talks and Discussions

The outcomes of the second step represent the culmination of frequent interdisciplinary team discussions and represent the core of application development. During these team deliberations, in conjunction with the findings of qualitative content analyses, the team concentrated on the study interests and objectives, feasibility, implementation of content, and presentation styles, taking into consideration time and resource constraints. The discussions were marked by their vibrant and emotionally charged nature, especially when deliberating the development of the application's features. This negotiation of feature development emerged as the primary focus within the team and was carried out in an interdisciplinary manner. For instance, decisions regarding medical content originated from the ISMR, while those concerning technical aspects were made by the QULab.

A substantial portion of the discussions drew upon insights gathered from the interviews and workshop. Based on these insights, the team opted to incorporate ten questions related to the state of health that people with dementia, with or without the assistance of their caregivers, should respond to at least weekly. These questions centered on daily activities such as well-being, hydration, and sleep patterns. Formulated by the ISMR team, these questions aimed to provide GPs with valuable health information and were crafted to be easily accessible by

participating individuals. Further, the interdisciplinary discussions with GPs and caregiving experts led to several critical modifications in the application's design and functionality, including:

- An emergency disclaimer in the chat: A disclaimer was included in the chat function to inform users that the application is not intended for emergencies and that emergency services should be contacted in case of an emergency, with the appropriate emergency number prominently displayed.
- Patient records: The application was updated to include detailed patient profiles, allowing health care providers to access comprehensive patient information quickly and efficiently.
- A single patient view interface: The application's interface was redesigned to enable a single patient view, where selecting a patient displays all relevant data across various application functions, streamlining the process for health care providers.
- Checklist integration: Based on medical guidelines for dementia care, a checklist feature was added. This checklist allows items to be checked off as completed, with the system automatically resetting the item after three months to ensure regular follow-ups as per the guidelines.
- User interface enhancements: Various suggestions were incorporated to improve the application's usability and accessibility, ensuring it was intuitive and user-friendly for all health care providers.

Fourth Step: Application Testing—Feedback and Finalization

The pretest occurred in a geriatric day clinic, involving people with dementia, a social worker, physicians, and one GP who had previously participated in interviews. They provided comprehensive feedback on individual subapplications, focusing on aspects such as user-friendliness, effects on people with dementia and themselves, identification of missing or redundant content, and suggestions for useful additions. Given the time constraints of the project schedule and limited financial resources, discussions on prioritization and timelines were impactful. Throughout the development process, there was a consistent emphasis on ensuring good usability and an appealing presentation style.

Discussion

The findings of this study indicate that GPs and relatives bear the primary responsibility for the treatment and care of people with dementia, and they harbor specific desires and proposals concerning supportive and assistive technologies. Interdisciplinary discussions are essential to address these needs and develop a practical tablet application. The primary objective of this study was to delineate a multidisciplinary and interdisciplinary approach to the development of an application aimed at enhancing primary care for people with dementia and their caregivers. People with dementia and their caregivers should be supported in their daily lives and disease management, and GPs should be provided with support for their health care. The application should support the joint and interlocking care of those involved.

In conclusion, this study yields various results and implications. First, the study highlights the significant contribution of individuals with diverse disciplinary and professional backgrounds in the development of supportive technical health care applications. In addition to researchers, professionals working in different areas of dementia care provided invaluable insights into care aspects for people with dementia and their family caregivers. These experts should be integrated into the development process as specialists, as they possess implicit knowledge and contributory expertise [28], and experts in local knowledge should be included to leverage the potentials and mitigate the risks of such a study [29]. It is essential for potential users and beneficiaries of the application to be involved from the outset of the development process [21].

We chose to interview employees of the Alzheimer's Association instead of individuals with dementia and their caregivers. While this approach does not replace the deep, individual perceptions and experiences of affected individuals and their caregivers, it allowed us to gather consolidated information and comprehensive insights accumulated over years of work. Moreover, factors such as time constraints, personal resources, and the challenges of accessing interviewees influenced this decision. While much is known about the progressive and multifaceted challenges and needs of people with dementia, the health care system, professional care institutions, and society still fall short in providing full-time emotional and practical support for them, their caregivers, and

their GPs [1]. Additionally, there remains ambiguity surrounding technical solutions [8]. The participation of GPs and employees from the Alzheimer's Association provided practical insights from health care providers engaged in daily interactions with people with dementia and their caregivers. They shared professional experiences and highlighted daily challenges and needs for improvement. This collaborative process can enhance the acceptance and usage of the application [21].

Our interdisciplinary approach not only facilitated a comprehensive understanding of the needs of GPs and caregivers but also directly influenced the application's development. The inclusion of features such as the emergency button, patient records, and a checklist system were direct results of feedback from health care professionals. These features were critical in ensuring that the application provided practical, guideline-oriented support in real-world health care settings. Moreover, the interface redesign to include a single patient view and other usability improvements underscored the importance of integrating diverse perspectives to create a tool that is both functional and user-friendly.

Second, the process of developing a health application necessitated multidisciplinary and interdisciplinary teamwork. It is crucial to differentiate between intermittent multidisciplinary teamwork, characterized by juxtaposed disciplinary work, and interdisciplinary teamwork, which entails proactive and interactive collaboration [30]. However, both multidisciplinary and interdisciplinary teamwork are circular scientific endeavors in social care research and involve a process of social negotiation. Effective collaboration involves not only managing coworking due to separate work locations, formal team meetings, and the exchange of information and data but also engaging in discussions and informal team meetings to address preferences, relevancies, and disagreements. Given that each scientific discipline possesses its own specific domain, concepts, and methodologies, multiple constraints and barriers between different disciplines must be dismantled and integrated [31]. Successful multidisciplinary and interdisciplinary teamwork necessitates openness to the knowledge, structures, and practices of other disciplines [32] while consistently advocating for one's own discipline. Continuous communication and compromise are essential requirements for effective collaboration [21].

Third, future generations are expected to rely more heavily on technical applications for various aspects of life, including health care [33]. Therefore, it is crucial to examine and delve into the development of technical tools, even though the current older generation may not be as technologically savvy as today's adults and youth. However, it is anticipated that the usage and acceptance of digital technologies will grow in the future [33].

Overall, this study underscores the necessity of multiple scientific, clinical, and technical perspectives to ensure the high-quality development of supportive health care applications. The content and design of such applications for GPs, people with dementia, and their caregivers must be informed by the expertise and experiences of various professional disciplines involved in health care provisions and the usage of such applications in real health care settings. Therefore,

multidisciplinary and interdisciplinary collaboration is indispensable in the realm of health care—supporting applications. The development of this dementia care application exemplifies the importance of an interdisciplinary approach in health care technology. The modifications made based on feedback from GPs and other caregiving experts, such as the emergency button, patient profiles, and the checklist feature, highlight how diverse professional insights can lead to a more effective and user-centered design. These changes not only improved the application's functionality but also enhanced its acceptance and usability among health care providers. The

overarching goal is to systematically improve health care for those affected and those involved in their care. Everyday life and care for people with dementia should be supported. Medical disciplines, social sciences, technical expertise, and supporting organizations are all essential to integrate relevant knowledge and competencies into the design and development of useful products, as well as facilitating daily use and active support for health care needs. Furthermore, such development processes require a spiral approach and feedback loops, as well as critical professional and emotional discussions, to reach a consensus and make informed decisions.

Acknowledgments

The authors would like to express their special appreciation to Sebastian Möller and Adelheid Kuhlmeier for their support in the application process of the DemTab study, as well as to all workshop participants, employees of the day clinic, and all study participants. We used the generative artificial intelligence tool ChatGPT 3.5 (OpenAI) to correct and improve the English language. The original ChatGPT transcripts are provided as [Multimedia Appendix 1](#). The research is funded by the Innovation Fund of the Federal Joint Committee (G-BA), (Grant Project “DemTab” Grant-Number 01VVF17039).

Data Availability

Data are stored in a nonpublicly available repository. Data are available from the corresponding author upon request.

Authors' Contributions

J Supplieth was the primary contributor to data analysis, data interpretation, and manuscript drafting. SL, JLOS, JNVA, and RS assisted with writing and interpreting findings. J Schuster and JNVA designed and led the DemTab study in which this study was embedded. All authors contributed to this study and critically revised and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Artificial intelligence (AI) chatbots have the potential to assist individuals with chronic health conditions by providing tailored information, monitoring symptoms, and offering mental health support. Despite their potential benefits, research on public attitudes toward health care chatbots is still limited. To effectively support individuals with long-term health conditions like long COVID (or post-COVID-19 condition), it is crucial to understand their perspectives and preferences regarding the use of AI chatbots.

Objective: This study has two main objectives: (1) provide insights into AI chatbot acceptance among people with chronic health conditions, particularly adults older than 55 years and (2) explore the perceptions of using AI chatbots for health self-management and long COVID support.

Methods: A web-based survey study was conducted between January and March 2023, specifically targeting individuals with diabetes and other chronic conditions. This particular population was chosen due to their potential awareness and ability to self-manage their condition. The survey aimed to capture data at multiple intervals, taking into consideration the public launch of ChatGPT, which could have potentially impacted public opinions during the project timeline. The survey received 1310 clicks and garnered 900 responses, resulting in a total of 888 usable data points.

Results: Although past experience with chatbots ($P < .001$, 95% CI .110-.302) and online information seeking ($P < .001$, 95% CI .039-.084) are strong indicators of respondents' future adoption of health chatbots, they are in general skeptical or unsure about the use of AI chatbots for health care purposes. Less than one-third of the respondents ($n=203$, 30.1%) indicated that they were likely to use a health chatbot in the next 12 months if available. Most were uncertain about a chatbot's capability to provide accurate medical advice. However, people seemed more receptive to using voice-based chatbots for mental well-being, health data collection, and analysis. Half of the respondents with long COVID showed interest in using emotionally intelligent chatbots.

Conclusions: AI hesitancy is not uniform across all health domains and user groups. Despite persistent AI hesitancy, there are promising opportunities for chatbots to offer support for chronic conditions in areas of lifestyle enhancement and mental well-being, potentially through voice-based user interfaces.

(JMIR Hum Factors 2024;11:e51086) doi:[10.2196/51086](https://doi.org/10.2196/51086)

KEYWORDS

AI hesitancy; chatbot; long COVID; diabetes; chronic disease management; technology acceptance; post-COVID-19 condition; artificial intelligence

Introduction

Artificial intelligence (AI) chatbots are programs designed to simulate human conversations and provide tailored responses to users' questions and concerns. Chatbots can provide a range

of services, including appointment scheduling, medication reminders, and various types of health support. AI chatbots have the potential to support individuals with chronic health conditions by providing tailored information and resources, monitoring symptoms, and offering emotional support [1]. While

there are some limitations to chatbots' use, they could be a valuable tool for individuals with long-term conditions such as long COVID (or post-COVID-19 condition) [2] and those living in remote or rural areas [3,4].

Researchers have long investigated the use of chatbots in managing various chronic illnesses. For example, past studies have documented how chatbots improved medication adherence rates of patients with breast cancer [5]; enhanced the quality of life for people with type 2 diabetes [6]; reduced the severity of panic disorder symptoms [7]; and helped health care professionals, patients with asthma, and their family members build collaborative relationships [8]. Several systematic literature reviews on the topic suggest that conversational agents are generally effective in supporting the self-management of chronic conditions, particularly for mental health [9-11]. Hence, "empathic" chatbots that demonstrate "emotional intelligence" seem particularly relevant and useful. Although some researchers use the term emotional intelligence to denote a chatbot's ability to express a full range of human sentiments (positive and negative) [12], in the health care context, an emotionally intelligent chatbot usually refers to a conversational agent being able to recognize and respond to emotions a user expresses in their interaction and that "uses evidence-based self-help practices such as CBT, DBT, motivational interviewing, positive behavior support, behavioral reinforcement, mindfulness, and guided microactions and tools to encourage users to build emotional resilience skills" [13].

Despite the potential benefits of AI chatbots in health care, empirical research on public attitudes toward health care chatbots is still in its early stages [14]. Some early studies have suggested that users are generally positive about the use of AI chatbots [15]. For example, Bickmore et al [16] found that participants were generally satisfied with a health care chatbot that provided them with medication reminders and lifestyle advice. Similarly, a study by Crutzen et al [17] found that a health promotion chatbot targeting adolescents was used intensively and evaluated positively, especially in comparison with information lines and search engines. However, recent research has also highlighted many challenges associated with the use of AI chatbots in health care. There are concerns about the ability of chatbots to understand complex medical issues and provide accurate advice [11,18]. Patients and medical researchers alike were skeptical about the use of chatbots for mental health support, citing concerns about the lack of empathetic communication and the potential for the chatbot to misunderstand their emotional states [18,19].

Research on voice-based chatbots for health management is also in its infancy. Medical professionals' views on voice-based chatbots echo views on text-based chatbots in terms of the technology's potential and limitations. A 2-round Delphi study [20] surveying experts on the future of voice-controlled AI agents in health care anticipates significant technological development and increased user trust. The study focused on how voice-controlled agents could support health care professionals through applications like remote real-time interviews with patients, hands-free instructions for medical staff, and communication between staff and patients. However, the authors concluded that chatbots are not expected to

outperform or replace human health care workers despite a more intuitive speech interaction.

A systematic review conducted in 2020 examining the literature on voice-based conversational agents for chronic health conditions only found 12 papers [21]. In another scoping review conducted in 2021, only 4 studies among 32 reviewed focused on voice-based chatbots in health care [11]. The consensus in the literature seems to be that the technology shows feasibility and acceptability for managing chronic diseases, but more research is still needed on their real-world efficacy. Importantly, these literature reviews highlight several limitations in the literature such as small sample sizes, questionable sample compositions (healthy or convenience samples instead of samples of patient groups), and not controlling for participants' previous experience with voice-based intelligent agents.

In summary, AI chatbots have the potential to provide targeted support and improve the management of various chronic diseases, but only if they are designed to meet the specific needs and preferences of their users. It is essential to understand target users' perspectives, preferences, and experiences of using chatbots for health purposes so that chatbot solutions address the needs of their intended users. Individuals with long-term health conditions often face complex challenges that require ongoing tailored support, while the extant research on using chatbots for health care support provides limited insights into the acceptance (or resistance) among people with chronic conditions. To address the limitations identified in previous studies [11,21], this study gathered a large sample of people with chronic conditions and delved into their past experiences of and future preferences for interacting with AI chatbots.

Methods

Overview

A web-based survey study was conducted between January 1 and March 31, 2023, targeting the diabetes.co.uk user population. The site is the largest web-based community of people with diabetes in Europe with hundreds of thousands of registered users [22]. We chose to target this population because our previous research collaborations showed the community's wide awareness and practice of using technological solutions to self-manage their long-term health conditions (people with diabetes often experience other chronic conditions) [23,24]. For the survey, we defined AI chatbots broadly as computer programs designed to interact in humanlike conversation, and referred to Alexa and Siri on smart devices as examples of AI chatbots. As ChatGPT was launched on November 30, 2022, and quickly gained popularity, public understanding and opinions of chatbots might have changed during our project timeline. Hence, we aimed to capture the survey responses at multiple intervals. Several social media advertisements with the survey link were posted in January, February, and March 2023 on the Facebook page for diabetes.co.uk and clicked on by 1310 people.

As part of a research project funded by an Innovate UK grant, the survey was administered through the Qualtrics software by the digital health company leading the project. The purpose of

the study and a consent form were presented on the landing page of the web survey. After the survey was closed, we exported response data from Qualtrics to SPSS v.28 (IBM Corp) for a quality check, data recoding, and variable labeling. We carefully examined the initial data set to remove duplicate records (mainly generated in the survey setup and testing process) and poor-quality responses such as those who completed (or abandoned) the survey in less than 120 seconds. The final data set for analysis contained 888 records. We also used SPSS to assign numeric values to all the nominal variables in the survey (eg, 1=male, 2=female). After the data set was cleaned, we exported it as a .csv file to R version 4.2.3 (The R Foundation for Statistical Computing) for frequency, crosstabulation, and regression tests.

The survey contained 30 questions: 24 closed questions, 2 open questions, and 4 demographic questions. Participant consent was provided at the start of the survey before completion. Quantitative information (closed and multiple-choice questions) was collected on four topic areas: (1) demographic characteristics; (2) long COVID symptoms and clinical diagnoses; (3) health apps, websites, and chatbot use; and (4) opinions about chatbots. The majority of the questions were adapted from the digital health literature (eg, [14,25]). To address the two research objectives, we first asked questions on general attitude and acceptance toward chatbots, such as “How familiar are you with AI chatbots?” and “How likely are you to use a health chatbot within the next 12 months if available?”; then we focus on questions on using chatbots in specific health management scenarios, such as “Do you think chatbots have the capability of delivering accurate medical advice?” and “Would you like a chatbot to understand your stress levels and emotional states?” We also included questions on widely cited factors in the literature that might affect chatbot adoption such as trust and privacy.

Ethical Considerations

The survey instrument, along with other details of the methodology, was approved by the Royal Holloway, University

of London (Full-Review-3509-2022-11-18-13-35-UATM024). The participants were presented with a consent page before starting the web-based questionnaire. The purpose and the method of the research were briefly explained, along with an informed consent form asking participants to confirm that they were 18 years or older and that they were voluntarily taking part in the study. The survey did not collect personally identifiable information. The IP addresses were monitored to prevent multiple entries from the same computer. However, all IP addresses were removed from the data when the survey closed. Each survey response was assigned a unique ID, and the encrypted data were stored in the United Kingdom on Microsoft Azure servers. No compensation was provided to participants for completing the survey.

Results

Demographic Characteristics

Of the 888 individuals who started the survey, 729 (82.1%) responded to the sex question, of which 471 (64.6%) were female, 252 (34.6%) were male, and the remaining 6 (0.8%) were nonbinary/third sex or “prefer not to say.” Of the 741 respondents who provided their age, 556 (75%) were 55 years or older, with a median age of 63 (IQR 55-70) years. The sample consisted predominantly of White (n=466, 64.2%) individuals; other ethnicities were represented in smaller percentages and scattered across different categories of ethnicity (eg, Indian and Pakistani: n=25, 3.5%; Black n=7, 1.2%).

In relation to chronic health conditions, almost half of the 888 respondents reported having type 2 diabetes (n=437, 49.2%). [Table 1](#) provides an overview of the top 10 chronic conditions identified in the survey responses, plus long COVID. Of the 740 individuals who responded to the question “Would you describe yourself as having Long COVID?” 170 (23%) answered yes. While a majority of the respondents utilized health apps (n=500, 73.5%), a much smaller portion (n=259, 38.1%) made use of voice-assisted apps or devices like Amazon Alexa.

Table 1. Most common chronic health conditions (n=888).

Frequency rank	Condition	Frequency, n (%)
1	Type 2 diabetes	437 (49.2)
2	High blood pressure/hypertension	330 (37.2)
3	Alzheimer’s disease	240 (27.0)
4	Long COVID	170 (19.1)
5	Arthritis	195 (22.0)
6	Allergies	187 (21.1)
7	Anxiety	157 (17.7)
8	Depression	137 (15.4)
9	Asthma	114 (12.8)
10	Type 1 diabetes	106 (11.9)
11	Chronic pain	102 (11.5)

Attitudes Toward Health Chatbots

Although the survey was conducted at a time when ChatGPT was beginning to receive wide public attention, a significant number of respondents were “not familiar at all” (n=272, 40.5%) or only “slightly familiar” (n=175, 26%) with AI chatbots. There was an overall hesitancy about using a health chatbot, with less than one-third of respondents (n=203, 30.1%) indicating that they were “somewhat likely” or “very likely” to use a health chatbot in the next 12 months if available.

However, a deeper dive into the survey data reveals a more nuanced picture. There seems to be a great deal of uncertainty among people about AI chatbots’ capability of providing accurate medical advice. When asked if they believe chatbots

have the capability of providing accurate medical advice, 396 of 677 (58.5%) respondents answered “unsure,” while only 77 (11.4%) answered “yes” and 204 (30.1%) chose “no.”

On the other hand, people seem to be more open to the idea of chatbots supporting mental well-being: 272 (40.2%) would like a chatbot to understand their stress levels and emotional states, 211 (31.2%) were unsure, and 194 (28.7%) indicated no interest.

A further cross-tabulation and χ^2 analysis using the chisq function in R suggests that people with long COVID in our sample were more likely to be interested in an emotionally intelligent chatbot than those without long COVID (n=673; $\chi^2_2=13.73$; $P=.001$), although nearly one-third of the former group were still “unsure” (Table 2).

Table . Cross-tabulation: long COVID chatbot understands stress and emotion.

	Long COVID?		Total (n=673)
	Yes (n=162)	No (n=511)	
Would you like a chatbot to understand your stress and emotional states?			
Yes	81 (50.0)	190 (37.2)	271 (40.3)
No	29 (17.9)	164 (32.1)	193 (28.7)
Unsure	52 (32.1)	157 (30.7)	209 (31.1)
Did not respond	— ^a	—	215 (24.2 ^b)

^aNot applicable.

^bPercentage based on the 888 total respondents.

This “chatbot hesitancy” is also evident when comparing people’s preferences of a bot and a real person in various health scenarios. Overall, our survey respondents overwhelmingly prefer to speak to a real person rather than a bot about physical

and mental health. However, people seem to not mind speaking with a bot about nutrition and sleep as much or letting it collect symptom data and conduct some preliminary analysis as indicated in Table 3.

Table . People’s preferences of a bot and a real person in various health scenarios.

Would you prefer a bot or a real person when...	Bot, n (%)	Person, n (%)	Don’t mind, n (%)	Did not respond, n (%) ^a
Speaking about general health (n=600)	18 (3.0)	484 (80.7)	98 (16.3)	288 (32.4)
Speaking about mental health (n=596)	26 (4.4)	483 (81.0)	87 (14.6)	292 (32.9)
Speaking about sleep (n=595)	46 (7.7)	370 (62.2)	179 (30.1)	293 (33.0)
Speaking about nutrition (n=599)	64 (10.7)	343 (57.3)	192 (32.1)	289 (32.5)
Collecting symptoms (n=590)	63 (10.7)	270 (45.8)	257 (43.6)	298 (33.6)
Conducting preliminary analysis (n=596)	72 (12.1)	314 (52.7)	210 (35.2)	292 (32.9)

^aPercentages in this column are based on the total 888 respondents.

Consistent with the observations above, an encouraging sign for health chatbot developers is that people are willing to try voice-based health chatbots despite the overwhelming hesitance toward bots. Of 679 respondents, 309 (45.5%) expressed willingness to use a voice-based chatbot to record their health

symptoms on a mobile device, and 278 (41.1%) would let their voice be analyzed to diagnose health problems. When asked if they would like to trial a voice-based health chatbot that the research team is developing, 364 of 560 (65%) respondents answered “yes,” as illustrated in Table 4.

Table . Attitude toward voice-based health chatbot.

	Yes, n (%)	No, n (%)	Unsure, n (%)	Didn't respond, n (% ^a)
Would you use your voice to record health symptoms on a mobile device? (n=679)	309 (45.5)	182 (26.8)	188 (27.7)	209 (23.5)
Would you use an app that analyzes your voice to diagnose potential health problems? (n=679)	278 (41.1)	158 (23.3)	241 (35.6)	209 (23.5)
Would you like to trial the voice-based health chatbot we are developing? (n=560)	364 (65.0)	196 (35.0)	— ^b	328 (36.9)

^aPercentages in this column are based on the total 888 respondents.

Factors Predicting Health Chatbot Adoption

We ran linear regression analyses in R to explore factors that could predict individuals' likelihood to use a health chatbot in

the next 12 months. We categorized the variables into three groups: demographic, experience, and attitudinal. [Table 5](#) presents our findings.

Table . Predictors analysis using regression. Likelihood of adopting a health chatbot in the next 12 months (n=485).^a

	β	SE	<i>P</i> value	95% CI
Demographic				
Age	-.075	.005	.06	-.021 to .000
Sex	.078 ^b	.097	.03	.039 to .460
Long COVID?	-.064	.115	.08	-.428 to .023
Experience				
Familiarity with AI ^c chatbot	.169	.048	<.001	.110 to .302
Frequency of online health information seeking	.198	.012	<.001	.039 to .084
Attitudinal				
Comfortable with reporting symptoms to health chatbot	.228	.060	<.001	.142 to .377
Worry about privacy using health chatbot	-.032	.042	.40	-.128 to .042
Trust health chatbot	.255	.069	<.001	.219 to .489

^aLikelihood of adoption was measured on a 5-point Likert scale (1=extremely unlikely and 5=extremely likely). $R^2=0.388$.

^bItalics indicate statistical significance.

^cAI: artificial intelligence.

We considered P values $<.05$ as statistically significant in our regression analysis results. The results showed that age ($\beta=-.075$; $P=.06$) and long COVID status ($\beta=-.064$; $P=.08$) have little to do with participants' tendency to use a health chatbot. Sex, dummy-coded as male=1 and female=2 with other sex categories excluded from this analysis due to a small number in each of the categories, seems to have a marginal effect ($\beta=.078$; $P=.03$), with female respondents potentially being more inclined to adopt a health chatbot than male respondents. Past experience with an AI chatbot ("familiarity with AI chatbots"; $\beta=.169$; $P<.001$) and online health

information-seeking frequency (aggregated frequencies across Google, social media, and professional health sites; $\beta=.198$; $P<.001$) show strong associations with chatbot adoption likelihood. Similarly, two attitudinal items measuring a person's comfort in outlining symptoms to a health chatbot ($\beta=.228$; $P<.001$) and their trust in a chatbot for advice ($\beta=.255$; $P<.001$) also strongly predicted their likelihood of adopting a health chatbot. Interestingly, privacy concerns, despite being widely reported in the academic literature as a deterrent to chatbot or virtual assistant adoption [20,26], did not seem to affect the

likelihood of survey respondents adopting a health chatbot ($\beta = -.032$; $P = .40$).

Discussion

Principal Findings

The survey results summarized above present a nuanced portrayal of public attitudes toward health care chatbots. The findings indicate that trust continues to be a crucial element in predicting people's inclination to embrace health chatbots, aligning with prior research on user acceptance of digital health technologies [11,27,28]. It seems that for our sample of predominantly female adults older than 55 years, most of them do not trust a chatbot to provide accurate diagnosis and professional medical advice. This echoes findings in previous studies [11,29] that while patients were generally receptive to the use of AI chatbots in health care, they had concerns about the accuracy of information provided and the ability of chatbots to understand complex medical issues. Although past experience with chatbots and online information seeking are strong indicators of respondents' future adoption of health chatbots, they are in general skeptical or unsure about the use of AI chatbots for health care purposes. Because of this "AI hesitancy" [14], it is unsurprising that most people show an overall preference for a real person (clinician) over a chatbot in health care encounters.

On the other hand, this study contributes fresh insights into overcoming AI hesitancy and the potential use of AI chatbots in supporting long-term health conditions like long COVID. A key finding from the survey is that AI hesitancy is not uniform across all health domains and user groups. A significant proportion of survey respondents expressed willingness to engage with a health chatbot regarding nutrition and sleep, as well as allowing it to collect symptom data. Furthermore, although doubts about the medical capabilities of AI chatbots persist, people are more receptive to utilizing them for stress detection and emotional enhancement. Notably, individuals with long COVID in our sample exhibited a particular interest in emotionally intelligent chatbots, highlighting the mental health needs of those with long COVID and the potential of using conversational agents as an intervention [30]. It is also surprising that privacy concerns did not correlate with the likelihood of health chatbot adoption in our study, a finding contrary to conclusions in many previous studies [20,31]. Leveraging these positive attitudes toward AI chatbots could enhance public familiarity and increase the likelihood of chatbot adoption for health care purposes, as evidenced by our regression analysis. For instance, an AI chatbot focusing on lifestyle or emotional well-being could pave the way for broader acceptance of health chatbots that are reliable and highly personalized [32].

This research also provides preliminary insights into the potential of voice-based interaction with health chatbots. Despite the popularity of voice-based AI agents such as Siri and Alexa on smart devices, there are only a handful of academic studies on the public's attitude toward an alternative voice-based interface for health chatbots [11,21]. Traditional text-based chatbots on mobile phones present challenges to older adults

in terms of vision and dexterity, as typing on a smartphone can be difficult and the screen size is often too small for them [33]. From the technology acceptance research, we understand that the usability of a health chatbot plays a role in its perceived usefulness [32]. Therefore, the relatively high acceptability and enthusiasm toward voice-based health chatbots expressed in our survey responses indicate a potential avenue for reaching a wider, often neglected population of adults older than 55 years. In addition to the usability benefits, voice input can be captured and analyzed for symptom tracking and medical diagnosis [34], complementing other data inputs to enable a more accurate assessment of the user's health.

Limitations

It is noteworthy that this study had several limitations. The use of a web-based survey for the empirical study introduces the potential for response bias. The sample primarily consisted of female adults older than 55 years with diabetes and other long-term health conditions, rather than representing the general population. As this population may have been more attuned to ongoing health concerns, they might have been more prone to reporting long COVID symptoms, potentially explaining the significantly higher proportion of those with long COVID in our sample compared to the national data from the National Health Service. The UK COVID-19 Infection National Survey (monthly, terminated in March 2023) reported that around 3% of the UK population were experiencing symptoms 4 weeks after they first had COVID-19 [35].

As cross-sectional survey research, this study is unable to provide a deep understanding of attitudes and opinions. For example, we do not know exactly why people are more receptive to voice-based AI chatbots aside from an educated guess that a voice interface may be easier to use and more natural than typed text for adults older than 55 years. Future research based on in-depth interviews or experimental methods might help unpack these user attitudes reported in the survey and identify possible causal factors.

Conclusion

With the rapid development of AI and chatbot technologies, the utilization of chatbots in health care is primed for substantial expansion in the forthcoming years. The potential benefits offered by these technologies, such as enhanced health care accessibility [4,36], cost reduction [15], and improved patient outcomes [37], are too substantial to disregard. However, health care providers and technology developers must acknowledge AI hesitancy [14] among patients and ensure the inclusive and effective utilization of AI chatbots.

This study contributes valuable insights into the acceptability of health chatbots among a population identified as requiring continuous long-term health care support, such as individuals at high risk for conditions like long COVID [38]. First, we augment the evidence in the literature that there exists a general skepticism toward health chatbots among people with chronic diseases. Second, notwithstanding this persistent AI hesitancy, we found that individuals are more receptive toward chatbots supporting lifestyle enhancement than those aiding disease diagnosis and health care management. Third, compared to other

subgroups in the study, those with long COVID were more amenable to using chatbots for emotional support. Lastly, while popular AI chatbots on the market are text-based, this study demonstrates that individuals with chronic conditions exhibit a high interest in voice-based conversational agents despite their

general AI hesitancy. Moving forward, it is paramount to continue exploring the potential applications of health chatbots in addressing the unique needs of specific patient populations, including those with chronic health conditions.

Abstract

Background: Out-of-hospital cardiac arrest (OHCA) is a leading cause of mortality in the developed world. Timely detection of cardiac arrest and prompt activation of emergency medical services (EMS) are essential, yet challenging. Automated cardiac arrest detection using sensor signals from smartwatches has the potential to shorten the interval between cardiac arrest and activation of EMS, thereby increasing the likelihood of survival.

Objective: This cross-sectional survey study aims to investigate users' perspectives on aspects of continuous monitoring such as privacy and data protection, as well as other implications, and to collect insights into their attitudes toward the technology.

Methods: We conducted a cross-sectional web-based survey in the Netherlands among 2 groups of potential users of automated cardiac arrest technology: consumers who already own a smartwatch and patients at risk of cardiac arrest. Surveys primarily consisted of closed-ended questions with some additional open-ended questions to provide supplementary insight. The quantitative data were analyzed descriptively, and a content analysis of the open-ended questions was conducted.

Results: In the consumer group (n=1005), 90.2% (n=906; 95% CI 88.1%-91.9%) of participants expressed an interest in the technology, and 89% (n=1196; 95% CI 87.3%-90.7%) of the patient group (n=1344) showed interest. More than 75% (consumer group: n= 756; patient group: n=1004) of the participants in both groups indicated they were willing to use the technology. The main concerns raised by participants regarding the technology included privacy, data protection, reliability, and accessibility.

Conclusions: The vast majority of potential users expressed a strong interest in and positive attitude toward automated cardiac arrest detection using smartwatch technology. However, a number of concerns were identified, which should be addressed in the development and implementation process to optimize acceptance and effectiveness of the technology.

Introduction

Out-of-hospital cardiac arrest (OHCA) is a leading cause of mortality in the developed world [1,2]. The chain of survival after OHCA starts with timely detection of the cardiac arrest and prompt activation of emergency medical services (EMS)

[3,4]. While this step is crucial to prevent the death of the patient, it is also the most fragile link in the chain of survival because it requires the presence of a witness. Reliance on bystander activation often introduces a significant delay that markedly reduces the chances of survival [5-7].

Several research groups, including our own, are developing a possible technical solution to automatically detect OHCA and to automate the activation of EMS using wearables and smart devices [8-10]. Smartwatches are computing devices that resemble wristwatches, with functionalities comparable to smartphones. Smartwatches are one of the most prevalent wearable technologies [11] and incorporate a wide array of sensors. Among these sensors are GPS and photoplethysmography (PPG). GPS is a global navigation satellite system that provides location, velocity, and time. This could potentially be used to track the location of patients experiencing cardiac arrest. PPG is used to detect changes in light absorption due to pulsatile blood flow [12] and hence can be used to measure the heartbeat, allowing smartwatches to accurately detect cardiac arrhythmias [13-15]. PPG and other sensors integrated in smartwatches could also potentially be used to detect cardiac arrest by measuring the cessation of pulsatile blood flow.

Such a technical solution, which is currently being developed, should be well aligned with the needs of its potential users in order to enable successful implementation [8]. We therefore aim to investigate users' perspectives on aspects of continuous monitoring such as privacy and data protection, as well as other implications, and to collect insights into their attitude toward the technology.

Methods

Study Design

We conducted a cross-sectional web-based survey aiming to investigate the perceptions and attitudes of potential users toward automated cardiac arrest diagnosis using smartwatches. We identified 2 groups of potential users: the first was consumers who already own a smartwatch (the consumer group), as these individuals could instantly make use of this technology as soon as it becomes available. The second was patients at increased risk of experiencing cardiac arrest (the patient group), as these individuals can potentially benefit the most from using this technology. A survey was deployed among both groups as described below, and participants had up to 4 weeks to respond. Data were collected between October 27, 2022, and March 17, 2023.

Ethical Considerations

The study was assessed by the Medical Ethics Review Committee of VU University Medical Center (2022.0544), which declared on November 29, 2022, that the study was not subject to the Medical Research Involving Human Subjects Act (WMO), such that formal approval was not required. Participants received written information about the purpose of the research and consented to the use of their provided answers for research purposes. Participants in the consumer group were compensated with €0.30 to €0.50 (US \$0.32 to \$0.53) for their participation. Participants in the patient group did not receive any compensation. The data collected from both groups were completely anonymous.

Participant Recruitment

Consumer Group

The consumers were recruited by a leading Dutch market research agency, Markteffect. This agency has several panels comprising approximately 225,000 consumers from different sectors in the Netherlands. For our survey, we recruited consumers who were aged 18 years or older and owned a smartwatch.

Patient Group

The at-risk patients were recruited through the health panel of the Netherlands Patient Federation (NPF). This health panel comprises approximately 23,000 individuals from different patient associations. All patients had to be aged at least 18 years and at increased risk for cardiac arrest based on self-reported medical history and comorbidities. Patients were considered at increased risk of cardiac arrest if they had 1 or more of the following: cardiovascular disease (eg, hypertension, heart failure, angina pectoris, myocardial infarction), severe renal insufficiencies, diabetes mellitus, cerebrovascular accident, or severe pulmonary disease (eg, chronic obstructive pulmonary disease or lung emphysema).

Sample Size Considerations

An a priori sample size analysis revealed that a minimum sample size of 385 participants would be needed to attain a margin of error of no more than 5% at a 95% confidence level. To attain an even higher precision while still allowing for dropouts and subgroup analyses, we targeted approximately 1000 participants per user group.

Survey Development and Data Collection

The surveys were developed by WMFvdB and PS in collaboration with the research experts from Markteffect and the NPF. Both surveys underwent a comprehensive review and testing by members of our research group and Markteffect or the NPF, respectively, and the surveys can be found in [Multimedia Appendix 1](#). Both surveys largely comprised the same introductory text and questions, but slight modifications were made to tailor the surveys to each group. The surveys included an introductory text explaining the prevalence of witnessed and unwitnessed OHCA in the Netherlands, emphasizing the need for an alerting system to ensure prompt intervention in case of cardiac arrest. We explained that we are currently developing a novel technology that could potentially address this issue, as it is capable of automatically diagnosing cardiac arrest using smartwatches. We underscored our interest in obtaining their opinions and perspectives on this technology. If participants agreed to participate by continuing to the online survey, we would proceed to ask questions regarding automated cardiac arrest diagnosis using smartwatches. In addition, we asked questions about gender, age, income, and other demographic characteristics. The questions primarily consisted of closed-ended questions and included 5-point Likert-scale questions to assess their agreement with specific aspects of the technology. Limited open-ended questions were provided to enable supplementary insights. Markteffect hosted and distributed the online survey to the consumer group using Collecthor (Collecthor BV). The online survey sent to the patient

group was created and hosted Castor Electronic Data Capture (Ciwit BV). The NPF distributed the survey to the patients who were at increased risk of cardiac arrest and had indicated interest to participate in the survey.

Data Screening and Statistical Analysis

Markteffect cleaned the consumer data set, removing surveys with any of the following characteristics, according to their internal standard operating procedures: (1) speeders—surveys that were completed within an exceptionally implausibly fast timeframe; (2) double respondents—multiple surveys submitted by the same individual; (3) straight liners—participants who consistently selected the same answer choice (eg, always chose a neutral response or always chose the first option) or did not answer the questions; and (4) surveys with consistent unintelligible language. The cleaned data set was provided for further analysis. The data from at-risk patients were cleaned by removing completely empty surveys, speeders, and surveys in which less than 50% of the questions were completed.

Quantitative data were analyzed descriptively. Measures of central tendency, measures of variation, and measures of distribution were calculated [16]. The analyses were performed using R (version 4.2.1) and RStudio (version 2022.2.3.492; R Foundation for Statistical Computing).

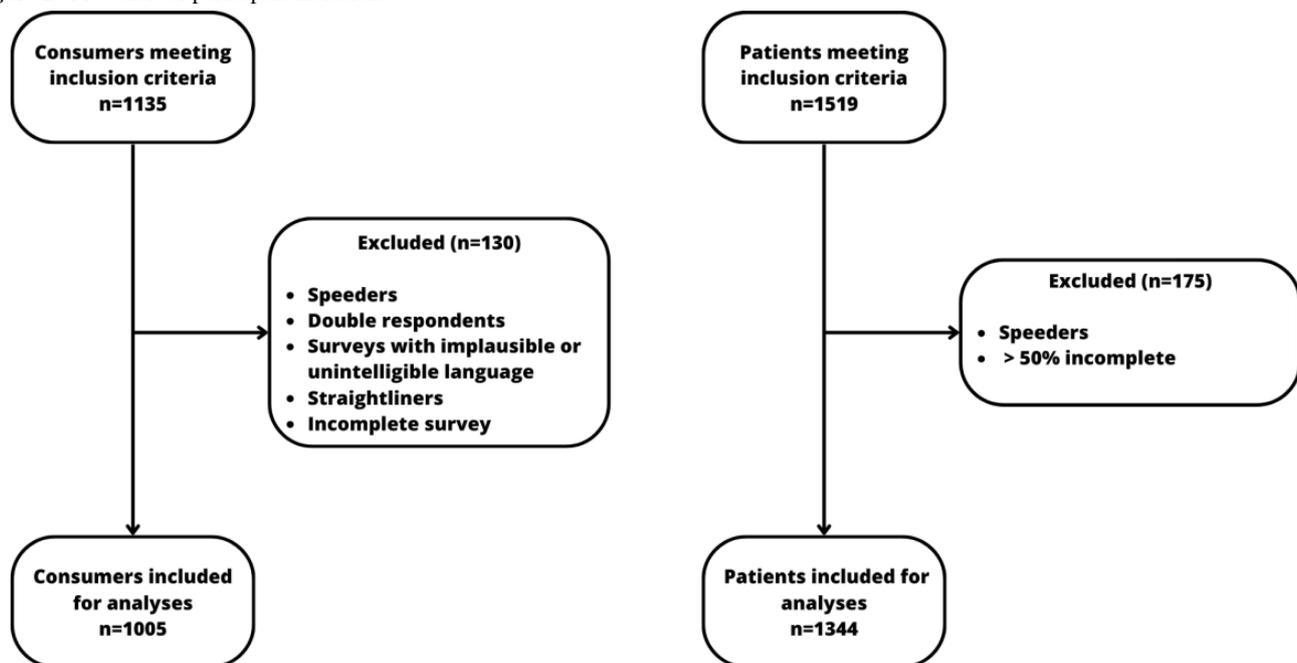

A content analysis of the open-ended questions was conducted to provide deeper insights into the participants' perspectives. WMFvdB created a coding framework consisting of inductive and deductive codes. The coding was reviewed by PS and any disagreements were resolved in consensus. The codes were categorized to identify emerging themes. The content analysis was performed using MAXQDA 2022 (VERBI Software).

Results

Quantitative Analyses

In the consumer group and the patient group, 1135 and 1519 participants, respectively, met the inclusion criteria. In both groups, 88.5% (n=1005 and n=1344, respectively) of the participants were included for analysis (Figure 1).

Figure 1. Flowchart of participant inclusion.

The mean age in the consumer group was 48.6 (SD 13.2) years, and 48.7% (n=489) of the population was male. In the patient group, the mean age was 67.7 (SD 10.0) years, and 56.4% (n=750) of the population was male. Regarding level of education, smartwatch preference, and ethnic background, both groups followed a similar pattern. In the consumer and patient

groups, 58.5% (n=588) and 56.1% (n=731), respectively, had a higher level of education. Apple and Samsung smartwatches were most prevalent, and the majority of the population had a Dutch background (Table 1). Both groups had a similar geographical distribution throughout the Netherlands as the general Dutch population (Figure 2).

Table . Population characteristics.

	Consumers (n=1005)	Patients (n=1344)	Dutch population ^a (n=17,475,415)
Age (years), mean (SD)	48.6 (13.2)	67.7 (10.0)	42.3 (N/A ^b)

^aData from 2021, acquired from the Central Bureau of Statistics (CBS) in the Netherlands [17,18].

^bN/A: not applicable.

^cIn 2021, according to CBS, the median primary income of a household in the Netherlands was €3525 per month [19]. An exchange rate of €1=US \$1.06054 applied at the time of the study.

Figure 2. Population density in percentages. Data for the Dutch population for 2021 comes from the Central Bureau of Statistics [18].

Both groups expressed interest in the technology; 90.2% (n=906; 95% CI 88.1%-91.9%) of the consumer group and 89% (n=1196; 95% CI 87.3%-90.7%) of the patient group considered the technology as “interesting” or “very interesting” (Figure 3). Moreover, 75.2% (n=756; 95% CI 72.5%-77.9%) of the participants in the consumer group and 77.6% (n=1004; 95% CI 75.3%-79.8%) of the patient group indicated their willingness to use the technology (Figure 4). The most frequently cited reason for abstaining from or expressing uncertainty about

adopting the technology in both groups was “not wanting to be resuscitated.” The second most common reason given by the consumers was cultural or religious objections, whereas none of the patients provided this as a reason for expressing uncertainty or abstaining from using the technology. In the patient group, 31.7% (n=92) of participants who had indicated abstaining from or expressed uncertainty about adopting the technology stated not wanting to use a smartwatch as a reason (Figure 5).

Figure 3. Participants’ interest in the technology according to a 5-point Likert scale.

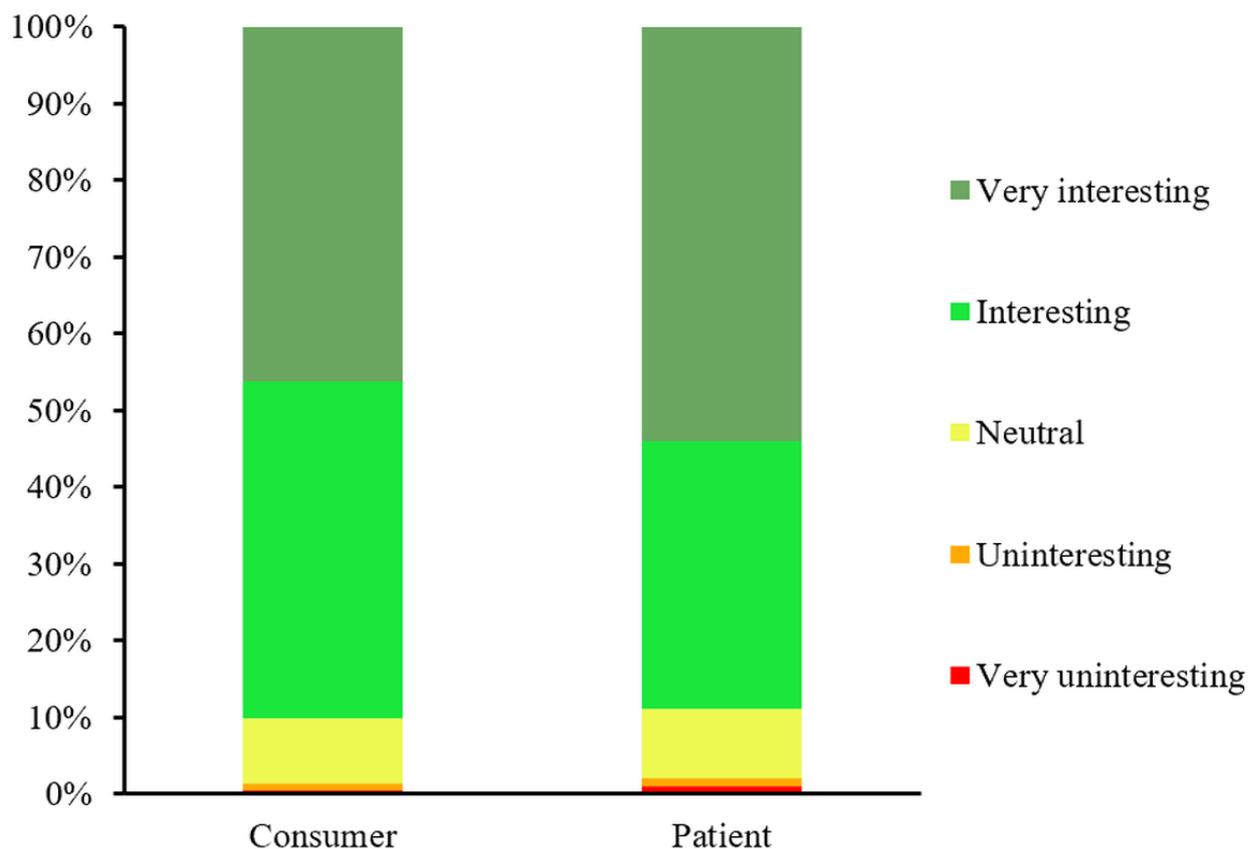

Figure 4. Participants' willingness to use the technology. Error bars represent 95% CIs. Consumer group n=1005, patient group n=1294.

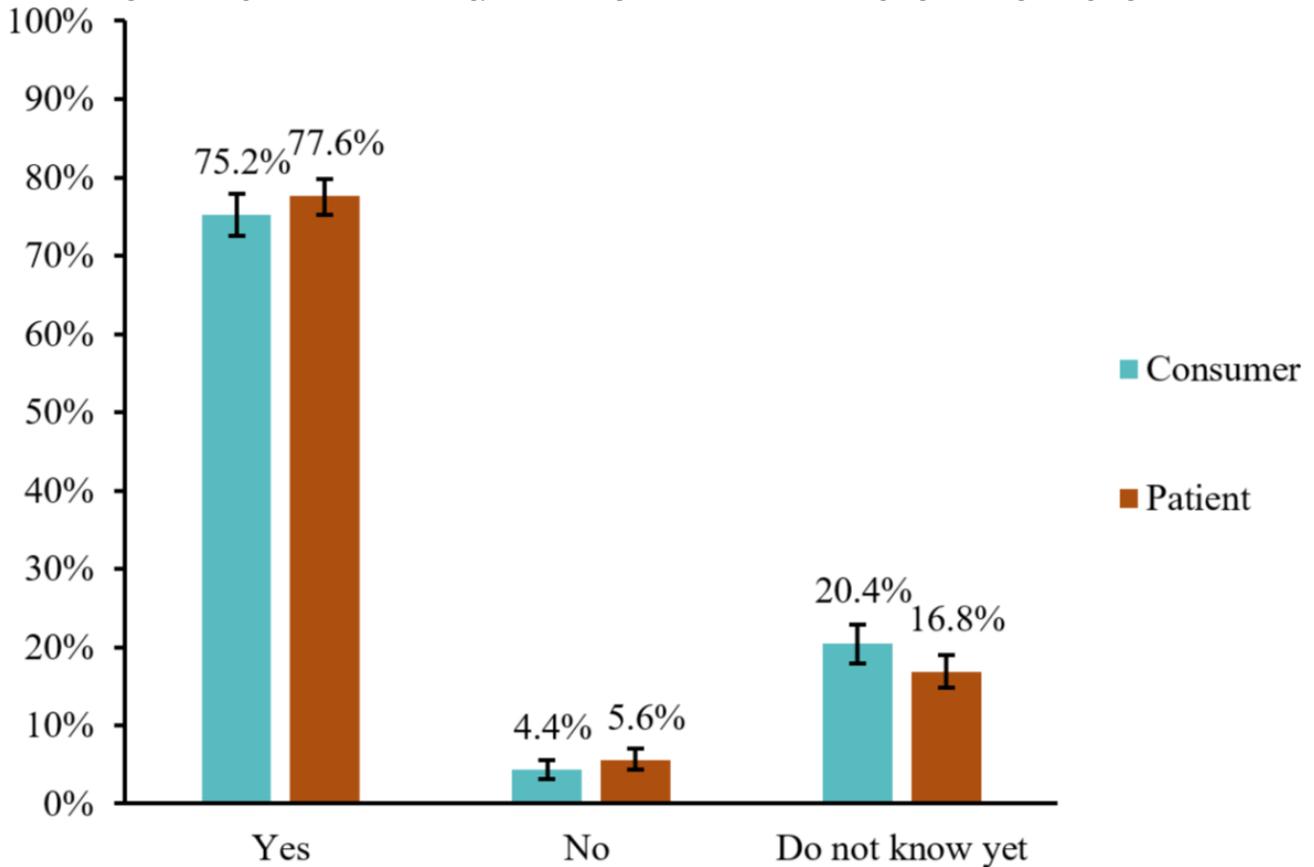

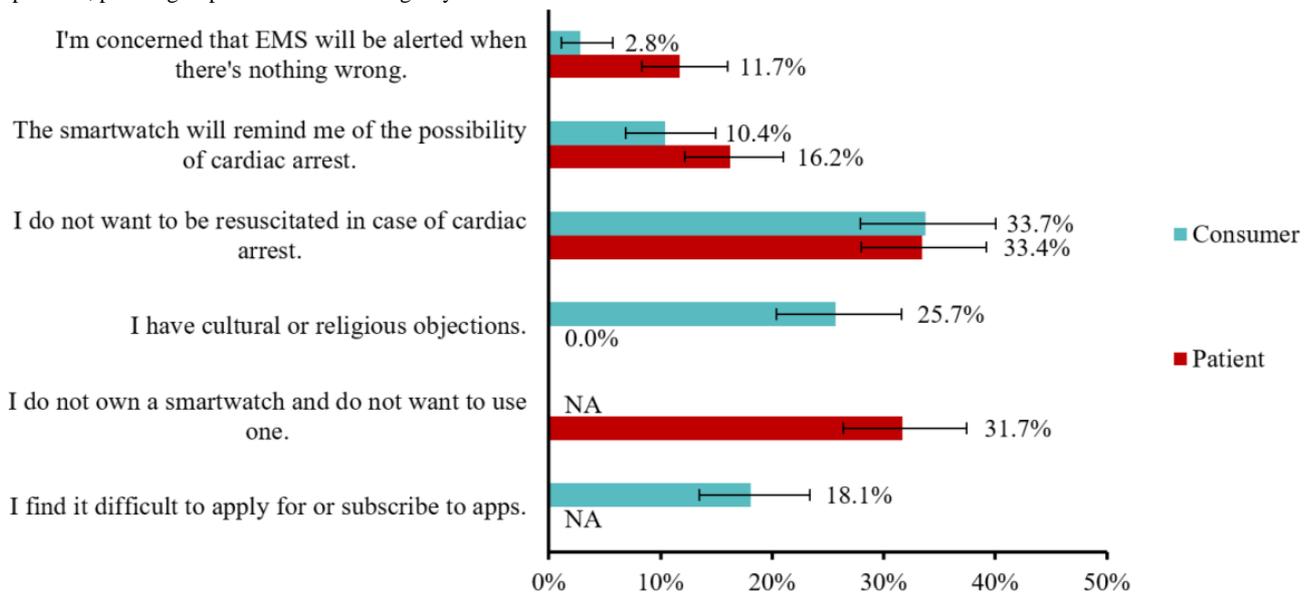

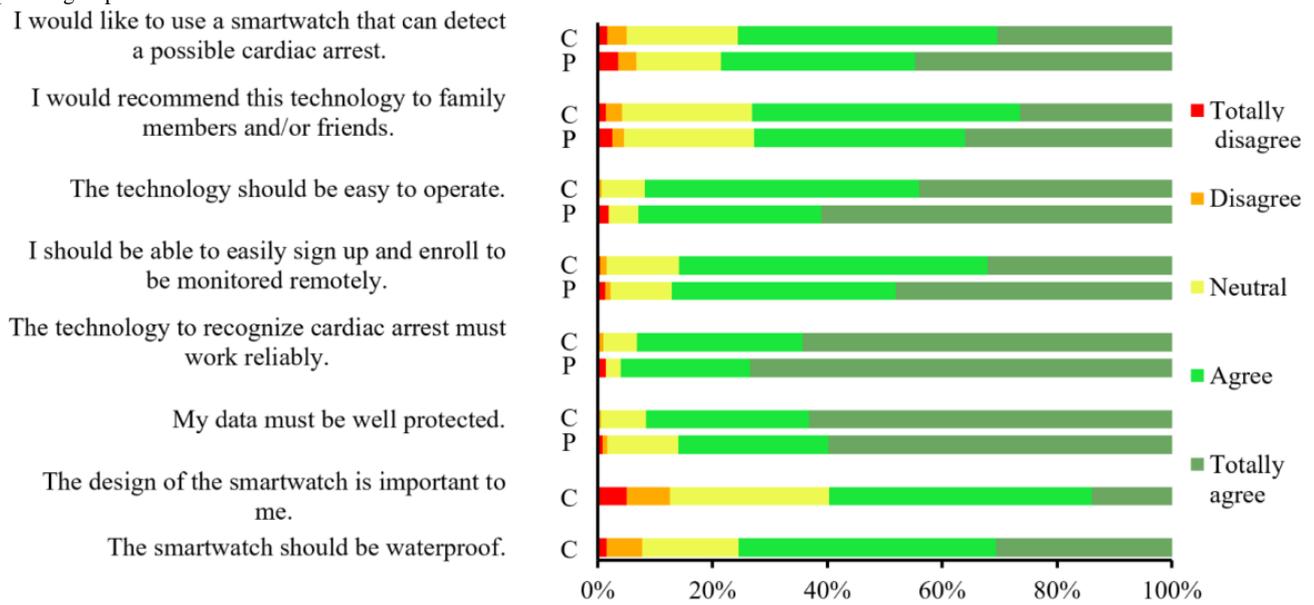

Figure 5. Most cited reasons for abstaining from or expressing uncertainty about adopting the technology. Error bars represent 95% CIs. Consumer group n=249, patient group n=290. EMS: emergency medical services.

In both groups, around 75% (consumer group: n=760; patient group: n=1045) agreed that they would like to use a smartwatch that can be used to detect cardiac arrests, about 72% (consumer group: n=735; patient group: n=964) agreed they would recommend the technology to family and friends, and around 86% (consumer group: n=863; patient group: n=1116) agreed that it should be easy to sign up to use the technology. Both

groups agreed (>93%) that the technology should be reliable (consumer group: n=936; patient group: n=1204), and agreed (around 92%) that the technology should be easy to operate (consumer group: n= 923; patient group: n=1223). The consumer group felt a little more strongly that data should be well protected; 91.6% (n=920) agreed compared to 86% (n=1071) in the patient group (Figure 6).

Figure 6. Participants' agreement with general statements regarding the technology, ranked according to a 5-point Likert scale. C: consumer group; P: patient group.

Participants were also surveyed regarding their willingness to make monthly payments for the technology, expressed in euros. The median amount the consumer group and patient group were willing to allocate, given they indicated that they would use the technology, was €5.0 (IQR €2.0 - €10.0) and €10.0 (IQR

€5.0 - €20.0), respectively, per month (an exchange rate of €1 = US \$1.06054 applied at the time of the study).

Content Analyses

The open-ended questions were categorized into the most prevalent themes, as summarized below. Table 2 provides a quantitative overview of the content analysis.

Table . Content analysis.^a

Themes and subthemes	Consumers, n	Patients, n	Total, n
Life-saving potential			
Overall	278	402	680
Time	107	257	364
Experience/medical history	72	195	267
Peace of mind			
Overall	49	72	121
Reduce stress	39	59	98
Induce stress	10	13	23
Prevention	48	92	140
Affordability and accessibility			
Overall	96	145	241
Health inequity	22	53	75
Ease of use	30	44	74
Accuracy and reliability	55	59	114
Data and privacy protection	24	11	35

^aParticipants could give answers that were applicable to multiple themes and subthemes. The table shows the number of individuals that mentioned the specific theme in the open-ended questions.

Life-Saving Potential

Both groups acknowledged the potential life-saving capabilities of the technology; this was mentioned by 680 participants. Participants underscored the importance of swift intervention

during critical events such as cardiac arrest and expressed that this technology could help shorten the time to resuscitation by EMS; 364 participants mentioned this. They acknowledged that rapid intervention is associated with increased survival and

recognized the potential benefit from using automated cardiac arrest detection.

In total, 267 participants mentioned their personal experiences or medical history. Some shared accounts of friends or family members who experienced cardiac arrest, some of whom did not survive. These experiences influenced their favorable perception toward automated cardiac arrest diagnosis. Additionally, participants, especially in the patient group, often referred to their own medical history, noting their increased risk of cardiac arrest. They expressed a strong desire to use every tool available to enhance their chances of survival in such an event.

Peace of Mind

A total of 98 participants mentioned that the technology could also provide peace of mind for users, offering the assurance that EMS will be alerted in the event of cardiac arrest, even if no witnesses are present. Potential users mentioned an increased feeling of security and confidence if such a technology were available, potentially leading to greater physical activity. However, 23 individuals also expressed concerns that this technology could serve as a constant reminder of the possibility of cardiac arrest, potentially leading to stress.

Prevention

A total of 140 respondents also mentioned that such a technology could potentially be used for preventive purposes, such as detecting a cardiac problem before it manifests in cardiac arrest. Participants also indicated that using this technology may raise awareness for heart problems and may also promote a healthier lifestyle.

Affordability and Accessibility

A total of 241 individuals expressed concerns about, or mentioned the importance of, the accessibility and affordability of the technology. Among them, 75 highlighted that disparities in access could potentially lead to or exacerbate health care inequities. The participants indicated that researchers and product manufacturers should identify solutions for widespread accessibility.

Moreover, participants mentioned the importance of integrating the technology into standard health insurance as an option to enhance accessibility. Finally, to increase accessibility, the technology should be intuitive, simple, and easy to use. This was emphasized by 74 individuals. This is especially important when making the technology accessible for users with a low level of technical proficiency.

Accuracy and Reliability

A total of 114 participants expressed concerns regarding the accuracy and reliability of the technology. They emphasized that thorough testing is needed to minimize false alarms. False alarms could potentially strain the existing health care system, induce anxiety, and erode trust in the technology.

Data and Privacy Protection

Another concern raised by 35 participants was related to data collection and the secure handling of medical and personal data. Mainly, the consumers placed significant emphasis on

safeguarding their data and privacy and the need to obtain consent regarding data collection while ensuring that only essential data are collected. Some participants expressed reservations about the involvement of smartwatch companies in managing medical data.

Discussion

Principal Findings

We assessed attitudes and perceptions of potential users toward automated cardiac arrest detection using smartwatch sensor data. We found that the vast majority of the participants expressed their willingness to adopt this innovative technology. However, 1 of 20 individuals indicated that they did not want to adopt this technology, and a considerable number of individuals were yet undecided. Our findings revealed several barriers and concerns that warrant careful consideration.

Previous research assessed the acceptability of the use of wrist-worn wearables, mainly focusing on activity tracking and time spent using the device as a measurement of acceptance [20]. However, to our knowledge, our research is the first to focus on the perceptions of potential users and their willingness to accept automated cardiac arrest detection. Understanding users' perspectives is imperative for research groups developing such technology, enabling them to address concerns early in the development process. Moreover, health care professionals involved in counseling patients at risk, as well as any stakeholders involved in the implementation, distribution, or marketing of the technology, should have a clear understanding of users' perspectives. This is paramount in order to increase acceptability [21-23] and to ensure effective implementation [24].

In this context, the insights gained from this study have several important implications. One key factor contributing to reluctance in adopting the technology is that some individuals do not want to be resuscitated in the event of a cardiac arrest. Remarkably, this reluctance was not limited to older people or those with significant comorbidities in the patient group but also extended to the relatively young population in the consumer group. While there are legitimate reasons for refusing resuscitation attempts, it is likely that this reluctance partially stems from a lack of understanding about the prognosis of cardiac arrest, particularly when detected and treated early. Fear of being severely handicapped or incapacitated may have played a role. However, in the Netherlands, approximately 90% - 95% of cardiac arrest survivors are known to survive with a favorable neurologic outcome [25,26]. Education and awareness campaigns may play a pivotal role in addressing misconceptions, ensuring that potential users are well-informed about the life-saving potential of the technology [27].

In the consumer group, cultural or religious objections to adopting the smartwatch-based cardiac arrest technology were frequently reported. Although our survey did not delve into the specific nature of these objections, the evident heterogeneity among potential users highlights the need for customized product development and implementation strategies. Acknowledging and understanding the cultural and religious

dynamics that influence technology adoption decisions is critical and should be investigated in more depth in future studies.

In the patient group, a significant barrier to adopting smartwatch-based cardiac arrest detection technology was the reluctance to use a smartwatch. This may partly be attributed to a lack of digital literacy. In particular, older individuals may be less accustomed to digital technology and may perceive a high complexity of operating such devices. Emphasizing simplicity and intuitive operation in the development process is therefore crucial.

Potential users also expressed concerns regarding the potentially high cost of the technology and that financial inaccessibility may exacerbate disparities in health equity [28]. It is worth noting that low socioeconomic status is associated with a higher incidence of cardiac arrest [29], suggesting that this demographic may potentially benefit the most from this technology. Therefore, future research on automatic cardiac arrest detection should include a sufficient number of participants from lower socioeconomic backgrounds. Given that low socioeconomic status is associated with a higher incidence of cardiac arrest, it is crucial to consider cost-effectiveness and affordability early in the development phase. Proactive collaboration with health insurance providers, public social welfare systems, nonprofit health care foundations, and government organizations is essential to ensure financial accessibility.

The analysis also highlighted concerns about privacy, data protection, and data use, which are common concerns when introducing novel medical technologies [30]. Governmental and regulatory bodies have been developing guidelines for software used as a medical device to ensure privacy and data protection [31-34]. For developers and researchers involved in creating such technologies, strict adherence to these regulations plays a vital role in building user trust by ensuring the robust protection of their privacy.

Another concern identified was the reliability of automated cardiac arrest detection systems. Developers are thus challenged to achieve exceptionally high levels of sensitivity and specificity [35]. The goal is to create a system capable of accurately identifying cardiac arrest events while simultaneously minimizing false alarms, which are detrimental to both user trust and system efficacy.

Strengths and Limitations

This study features a considerable sample size encompassing a diverse range of participants who might use this technology.

The questionnaire was carefully designed using the joint expertise of a leading professional market research organization, a patient federation experienced in researching patient perceptions, and a medical research group with documented experience in survey methodology [36-38].

Our research not only focuses on patients at increased risk of cardiac arrest, but also includes consumers who already own a smartwatch, which positions them to be early adopters as soon as the technology is implemented. It is noteworthy that approximately 50% of individuals experiencing a cardiac arrest have no prior history of cardiac symptoms or events, and OHCA also frequently affects middle-aged adults [39]. This underscores the applicability of this technology across a broad demographic, including those perceived as “healthy.” By encompassing both high-risk patients and regular smartwatch users, our study captures a wide spectrum of perspectives, enhancing the relevance and applicability of our findings.

We acknowledge some limitations. First, a few participants (n=30) seemed to conflate the terms cardiac arrest and heart attack, suggesting potential misunderstandings about what the technology monitors and detects. This confusion may have influenced their responses. However, both heart attack and cardiac arrest are serious medical conditions that benefit from early detection, and the rationale for continuous monitoring should logically extend from one condition to the other. This confusion also underscores the necessity for enhanced public education to improve understanding of these distinct medical events [27].

Second, the research was conducted with patients and consumers in the Dutch population, where local culture and health care systems may shape attitudes toward technology adoption [40]. This aspect has to be considered when extrapolating our results to other regions, with different health care systems or cultures.

Conclusion

The vast majority of potential users expressed a positive attitude toward automated cardiac arrest detection using smartwatch technology. The primary concerns raised by participants included privacy, data protection, reliability, and accessibility of the technology. Despite such concerns, the vast majority indicated that they would be willing to use the technology. This indicates a strong potential user base but also underscores the importance of addressing the identified concerns to optimize acceptance and effectiveness of the technology.

Conflicts of Interest

The project is supported by a grant from the Top Consortia for Knowledge and Innovation (TKI) office of the Dutch Life Sciences & Health Top Sector (Health Holland). HvS reports grants to his institution from the Zoll Foundation and Stryker Emergency Care, both outside the submitted work.

Abstract

Background: Pulse oximeters noninvasively measure blood oxygen levels, but these devices have rarely been designed for low-resource settings and are inconsistently available at outpatient clinics.

Objective: The *Phefumla* project aims to develop and validate a pediatric smartphone-based pulse oximeter designed specifically for this context. We present the process of human-centered oximeter design with health care workers in South Africa.

Methods: We purposively sampled 19 health care workers from 5 clinics in Khayelitsha, Cape Town. Using a human-centered design approach, we conducted participatory workshops with four activities with health care workers: (1) they received 3D-printed prototypes of potential oximeter designs to provide feedback; (2) we demonstrated on dolls how they would use the novel oximeter; (3) they used pile sorting to rank design features and suggest additional features they desired; and (4) they designed their preferred user interface using a whiteboard, marker, and magnetized features that could be repositioned. We audio recorded the workshops, photographed outputs, and took detailed field notes. Analysis involved iterative review of these data to describe preferences, identify key design updates, and provide modifications.

Results: Participants expressed a positive sentiment toward the idea of a smartphone pulse oximeter and suggested that a pediatric device would address an important gap in outpatient care. Specifically, participants expressed a preference for the prototype that they felt enabled more diversity in the way it could be used. There was a strong tendency to prioritize pragmatic design features, such as robustness, which was largely dictated by health care worker context. They also added features that would allow the oximeter device to serve other clinical functions in addition to oxygen saturation measurement, such as temperature and respiratory rate measurements.

Conclusions: Our end user-centered rapid participatory approach led to tangible design changes and prompted design discussions that the team had not previously considered. Overall, health care workers prioritized pragmatism for pediatric pulse oximeter device design.

Introduction

Hypoxemia, defined as an abnormally low peripheral arterial oxyhemoglobin saturation (SpO₂) of <90%, is an important risk

factor for death among children with lower respiratory infections in low- and middle-income countries (LMICs) [1-4]. An estimated 7 million children were hospitalized with hypoxemic pneumonia in 2019, and in sub-Saharan Africa, 28% (95% CI

25%-35%) of children with acute respiratory diseases were hypoxemic [5]. During outpatient care, the burden of hypoxemia may be considerable, with 2019 estimates suggesting a 23.1% prevalence among children with respiratory illnesses [5]. Pulse oximeters are medical devices that noninvasively measure SpO₂ and can therefore detect hypoxemia.

Frequent pulse oximeter use is associated with positive health outcomes such as reducing mortality rates and has been found to be cost-effective in low-resource settings [1,6]. Although oximeters are commonly used in pediatric clinical care in high-income countries, they are not consistently available in LMICs [4], especially during outpatient care where most children first access care and their illness may be more treatment responsive. The COVID-19 pandemic led to large investments being made into oxygen ecosystems, including pulse oximetry [7]; however, it did not focus on overcoming key implementation challenges for children. Pediatric pulse oximetry implementation in LMICs is restricted by barriers such as cost, lack of appropriately designed pediatric devices and probes, disruptive movements of small children, unavailability of devices, lack of training and supervision, lack of maintenance, lack of electricity, and health care provider misconceptions [8-14]. A pediatric-specialized, low-cost, smartphone-based pulse oximeter device could potentially address many of these implementation barriers and serve as a valuable tool in outpatient LMIC settings.

The *Phefumla* project aims to cocreate a low-cost, smartphone-based, reflectance pulse oximeter device for children that is optimized for LMIC outpatient contexts. Reflectance oximetry, unlike transmittance oximetry, measures the relative ratio of unabsorbed red and infrared light that is reflected off of tissues rather than through tissues to produce an estimate of

SpO₂ [15]. A key source of inequities in health is access to diagnostic services, with almost half of the global population having little or no access to diagnostics [16]. Part of this inequality stems from devices designed for high-income and inpatient settings that are cost-prohibitive to purchase, sustain consumables, and maintain. To address this challenge, there is a need for a holistic framework to guide the design of medical devices so that they may be contextually appropriate for the settings in which they will be used [17].

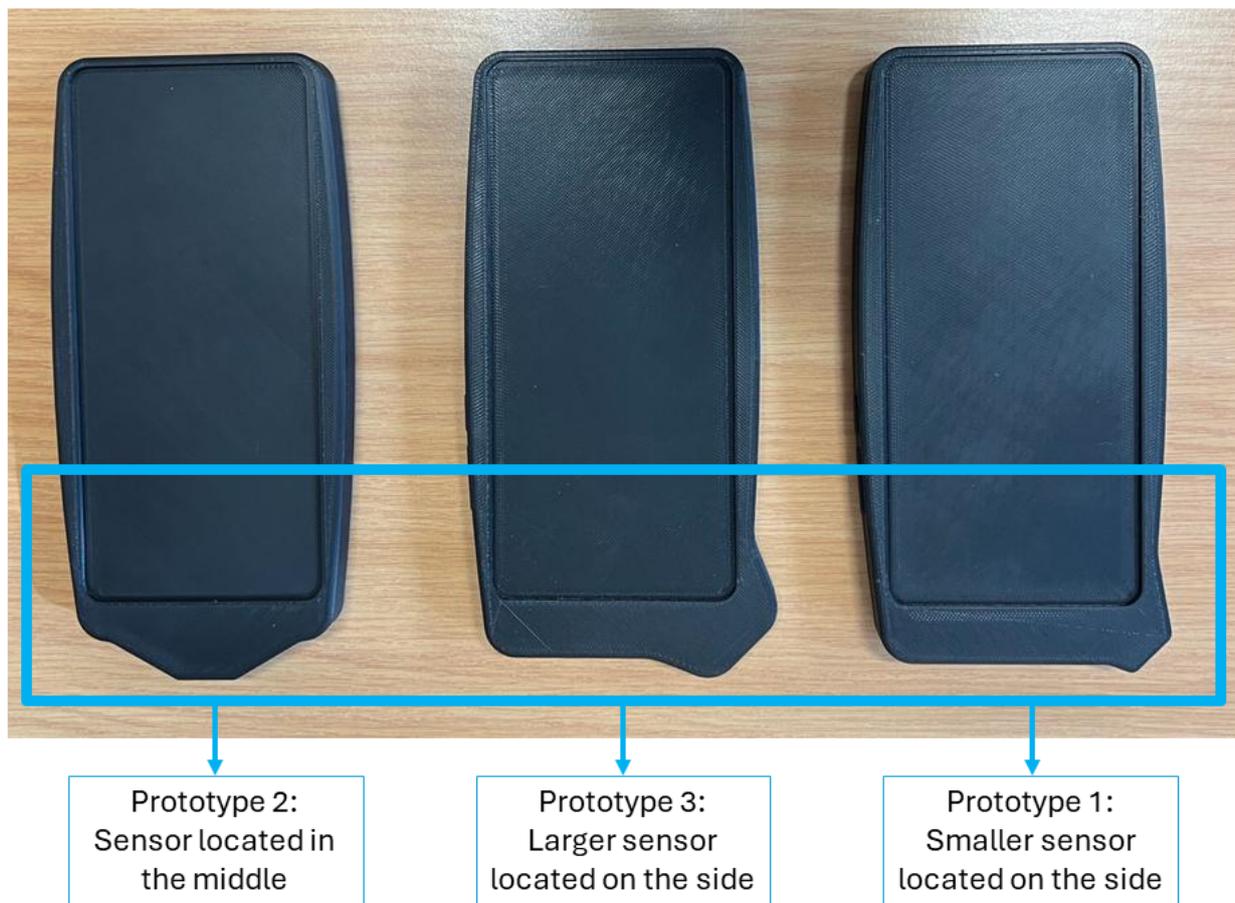

We used a human-centered design (HCD) approach, with the aim of achieving a contextually appropriate device that meets the specific health care needs of the population [18]. The HCD method is one of many approaches to co-design and was chosen for this study given its successful application in previous global health intervention and medical device development projects [19-25]. In this paper, we describe the participatory HCD processes with health care workers (HCWs) and how this led to design changes, as an example of a rapid approach to medical device development that centers inclusion.

Methods

Overview

We conducted a qualitative observation study of participatory workshops that drew on the HCD approach, with HCWs in Khayelitsha, Cape Town, South Africa, from September 1-16, 2022. For these workshops, we had 3D-printed 3 prototype reflectance devices, all based on the same smartphone model being housed inside a case that would contain the oximeter sensor and additional hardware for processing (Figure 1). These prototypes were developed by the *Phefumla* team to prompt HCW reflections on the size and positioning of the sensor while keeping all other factors consistent.

Figure 1. 3D-printed *Phefumla* reflectance oximeter prototypes.

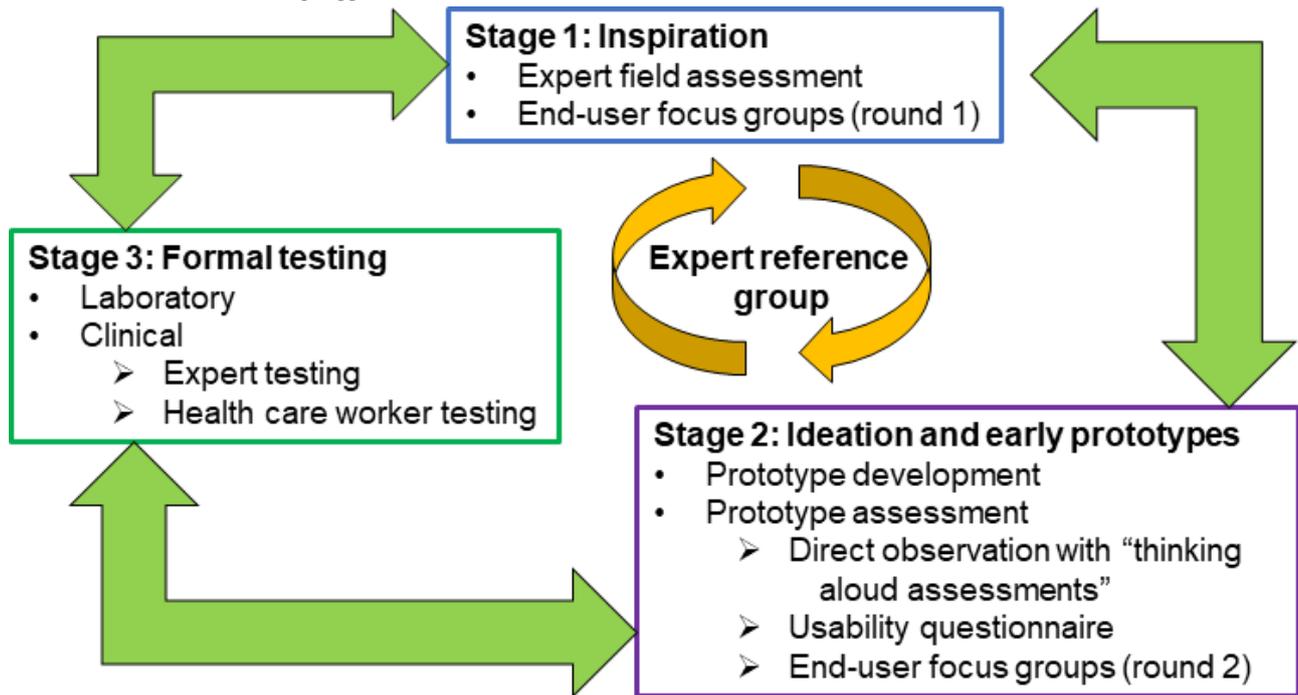

Setting

The East subdistrict of Khayelitsha is a low-income and low-resource area in Cape Town, South Africa, often referred to as a township. It has an estimated population of 450,000 people [26], who are predominantly Black African (99%) and the majority of whom live in informal housing [27]. First-tier primary health care (PHC) in South Africa is provided primarily through nurse-led clinics and community health centers, which are available within 5 km of 90% of the population and is often the first point of contact [28]. These facilities are free of cost and provide comprehensive basic services such as maternal, child, and reproductive health; HIV and tuberculosis testing and treatment; and care for noncommunicable diseases and common ailments [28]. Secondary care is delivered at district hospitals, which conduct minor procedures, and the third tier consists of tertiary hospitals that have the infrastructure, specialists, and equipment for major surgeries [29]. Many obstacles limit adequate implementation of health services at the PHC level in South Africa, including the HIV/AIDS pandemic, shortages of HCWs, unequal distribution of resources, and the legacy of the apartheid era [30]. This study was conducted at PHCs.

HCD Approach

HCD is based on using “techniques which communicate, interact, empathize and stimulate the people involved, obtaining an understanding of their needs, desires and experiences which often transcends that which the people themselves actually realized” [31]. This approach encourages stakeholders, experts, and end users—in our case, HCWs—to generate knowledge collaboratively to co-design a medical device [32]. Through involving end users in the design process, HCD allows for the development of devices that are locally and contextually appropriate and can meet the specific health care needs of the population [18]. The key principles of HCD are the active involvement of users and a clear understanding of user and task requirements; iteration of design solutions, where end users provide feedback on design solutions starting early in the process; and making use of multidisciplinary design teams [33]. The HCD approach consists of three iterative stages: (1) inspiration, (2) ideation and prototyping, and (3) formal testing. In this study, we report activities conducted in stage 2, the ideation and prototyping of the *Phefumla* smartphone oximeter development (Figure 2). This builds on our stage-1 findings that explored HCWs’ current experience with pediatric pulse oximetry, which will be published elsewhere.

Figure 2. The human-centered design approach.

Participatory Workshops

We conducted participatory workshops, consisting of 4 activities, to facilitate the process of having HCWs co-design

a smartphone-based reflectance oximeter (Table 1). The discussion guide is available in Multimedia Appendix 1.

Table . Summary of participatory design workshop activities.

Activities	Resources and tools	Description
1. Design preference	Three 3D-printed plastic prototypes of potential device designs	Participants were given 3 different rapid prototypes and asked questions about the devices' design. These included how they felt about the placement of the sensor on the device; how confident they felt placing the device on a child for a reading; how easy they believe the device would be to clean; and how durable the device was. Participants were encouraged to give suggestions and state preferences.
2. Device use	Two dolls (1 infant sized and 1 slightly larger sized)	Participants were asked to demonstrate how they would use the 3 prototypes on a child, specifically where they would place the sensor for taking a measurement on 2 different sized dolls to represent younger and older infants.
3. Feature ranking	A pile of cards with design features written on them	Participants were asked to rank 11 design features, which were deemed important from stage 1 of the HCD ^a process (eg, battery life), from most to least important. They were also given an opportunity to add their own features on blank cards with markers.
4. User interface	A magnetic board and magnets of different design features of the interface (SpO ₂ ^b reading, waveform, pulse, bouncing bar, buttons, charging symbols, date, and time)	Participants were asked to arrange interface components as they would like the screen of the device to look. They were provided with a whiteboard marker to include any other features.

^aHCD: human-centered design.

^bSpO₂: oxyhemoglobin saturation.

We conducted a pilot design workshop with 3 research nurses from the Desmond Tutu TB Centre to check the quality and coherency of the planned activities. Following the relevant

consenting procedures, 1-hour-long design workshops were held with 7 small groups of our sample's HCWs (2-4 HCWs per group). These workshops were conducted by 2 female

postgraduate research assistants with comprehensive knowledge and experience of qualitative data collection (EII and LNJ) under the supervision and with the assistance of a pediatric pulmonologist (EDM). Small groups were chosen for pragmatic reasons to minimize disruption to clinical service at the facilities and were conducted in the clinics.

Sampling and Participants

Participants were sampled from a larger pool of participants who had taken part in the previous stage of the study. Stage 1 of the HCD process (inspiration) involved small group discussions with HCWs focusing on barriers and challenges to routine pediatric oximetry use. These HCWs were therefore primed before the co-design workshops to think about the pros and cons of pulse oximeter features. Five clinics in the East subdistrict of Khayelitsha were eligible, and HCWs were purposefully sampled (rich case) using the following inclusion criteria: (1) having experience taking pulse oximeter measurements in children and (2) having taken part in the previous stage of the *Phefumla* study. Participants who had consented in stage 1 to be contacted were followed up to setup face-to-face meetings. Participants were given a small monetary voucher (worth approximately US \$15) and provided with refreshments as reimbursement for their time.

Data Collection

Data were collected via audio recordings and photographs taken of activity end results, as well as through comprehensive observation notes. A semistructured workshop guide was developed and used in English, the predominant working language in health care settings in South Africa. However, most participants were native Xhosa speakers, and some discussions were held in Xhosa; LNJ is a native Xhosa speaker and acted as a translator for these sections. The 2 researchers who facilitated the workshops alternated between (1) asking questions and leading facilitation and (2) keeping detailed field notes.

Analysis

Data were analyzed using the framework of exploratory qualitative analysis. Exploratory research is concerned with exploring a phenomenon more deeply to gain a granular understanding of it and has 2 key aspects: open-mindedness and flexibility [34]. Recordings were repeatedly listened to by the 2 researchers who conducted the workshops (EII and LNJ), alongside looking through the captured pictures and written field notes. The wider research team had preidentified key design features of interest based on a rapid scoping review, stage-1 small group discussions, and team expertise. Quotes and notes taken during the workshops were mapped together by EII and LNJ under these categories of design features, using Microsoft Excel. This initial mapping framework was shared and discussed with the entire research team, where findings were discussed and probed. This was done iteratively until the team decided on actionable feedback for the pulse oximeter prototype and shared them with the engineer (MB).

Ethical Considerations

Approval was obtained from the City of Cape Town to recruit HCWs and conduct the project at 7 clinics in the East subdistrict of Khayelitsha. Institutional approval was obtained from Johns

Hopkins University (IRB00294436), Stellenbosch University (N22/01/009), and the Swedish Ethics Board (Dnr 2022-01897-01). Facility managers and other relevant gatekeepers were approached after receiving approval to ask for permission to access HCWs. All participants provided written, informed consent. Field notes were anonymized and did not record any identifiable data from HCWs, and recordings were stored in secure local servers to safeguard participant information.

Results

Overview

A total of 7 workshops were conducted with 19 HCWs. The most common reasons for participants from stage 1 not taking part in these stage-2 workshop were being ill, on leave, or absent at the clinic on the scheduled days; having been rotated to a different PHC; or having resigned. All 19 participants retained were nursing staff (including a range of nursing cadres), with 18 (95%) female participants and 1 (5%) male participant.

Activity 1: Selecting a Preferred Prototype

Three 3D-printed prototypes were presented to the groups (Figure 1). The strongest preference was shown for prototype 2 with the sensor in the middle, with 4 (57%) of the 7 groups reaching a consensus on preferring this design. However, this was not unanimous, with 1 (14%) group preferring prototype 1, one (14%) group preferring prototype 3, and 1 (14%) group wanting a combination of prototype 3's larger sensor size with prototype 2's sensor location.

Participants primarily liked prototype 2 because of its sensor location being in the middle, noting that the device would be easier to use on a child as you would not have to angle it to get a reading, it did not matter if you were right- or left-handed, and some participants liked the larger size of the overall device and smaller size of the sensor (compared to the larger sensor of prototype 3). There were some concerns that the device itself was too large and that a smaller device would be easier to use, as well as concerns about having to hold the device without dropping it.

It's easier for me to get grasp of the monitor and put it on the child, rather than using the corner. [HCW, clinic 3]

When discussing the sensor, prototype 3's larger sensor elicited a range of responses, with some HCWs stating that it would be too difficult to use on an infant or young child (eg "it's too big"), whereas others thought the larger sensor size was a benefit, for example:

Very much easy [to use] because the sensor is bigger. [HCW, clinic 1]

The sensor is nice and big. [HCW, clinic 5]

Overall, participants displayed a positive sentiment to this style of device being easy to use on a child, and most participants felt comfortable placing the sensor correctly on a child. Robustness was a concern in several groups, as it was noted that a smartphone screen can break when dropped, and participants offered several modifications in relation to this:

It would be better if it were rubber or had a pouch, so it does not break. [HCW, clinic 1]

The back must be rubbery, and the outer part is rubbery too. [HCW, clinic 3]

If it is a glass screen it will [break easily]. [HCW, clinic 4]

All groups stated the device would be very easy to clean, with the most common suggestion for cleaning the device being wiping it with a disinfectant and cloth after each use. All groups felt it would be easy to store as well, with suggestions such as to keep it in a locked drawer, cabinet, or room or to include a storage pouch with the device:

Important that it's got a pouch—a bag, so it doesn't get too dusty. [HCW, clinic 1]

Activity 2: Using the Device on a Child

For activity 2, we asked participants to indicate for each prototype where they would take the pulse oximeter measurements on an infant-sized doll and a larger toddler-sized doll. The purpose was to understand how this novel device would be instinctively applied. The most common location of measurements for infants included the sole of foot, followed by

the palm of hand, the hand, the thumb, and toes. These were similar for the older toddler-sized doll, with the sole of foot also being preferred, although HCWs noted that toddlers can kick. Infrequent answers included the wrist, the chest, the forehead, and the neck, which a participant noted would be beneficial as it would not require a child to be undressed. We deliberately did not prompt HCWs to consider specific locations, and it is likely that HCWs defaulted to appendages (ie, hands and feet) that are the most commonly used with a standard pulse oximeter, even if the positioning on those appendages (eg, the palm of the hand) differed.

Activity 3: Design Feature Selection

Table 2 present the results from the feature pile sorting activity, showing the features considered as the 5 most important among the groups. When asked to elaborate on their ranking, participants stated that they first considered what would be essential for the device to function (eg, battery lasting) and that the rest were add-ons (eg, apps installed) that would be nice but were not necessary for core functioning. There was a strong preference displayed for pragmatism in this context:

The ones on top are the most important because they're going to sustain the device. [HCW, clinic 3]

Table . Features ranked among the top 5 for each group.

Feature	Groups (n=7), n (%)	Example quotations for prioritizing features
Portable device	7 (100)	<ul style="list-style-type: none"> • “You can take it anywhere, for example if it is needed in emergency...then you can take it there.” (HCW^a, clinic 4) • “So you can take the sick baby to another room and take the device to the next room” (HCW, clinic 2) • “Because we have three triages in this clinic” (HCW, clinic 3)
Does not break when dropped	6 (86)	<ul style="list-style-type: none"> • “We are working with kids. It’s inevitable that it will fall. It is important that it doesn’t break easily when it falls. The kids might not want it and push it away from them and then it falls.” (HCW, clinic 4) • “Because we are designing for a small baby not an adult so there’s high chances of it falling” (HCW, clinic 1) • “Maybe you’re gonna be busy with an emergency so you’re going to be scared so you’re gonna be shivering or shaking maybe, and the baby will also be fighting you, so at least if it drops it mustn’t break easily” (HCW, clinic 2)
Long battery life	6 (86)	<ul style="list-style-type: none"> • “We’re seeing more than 30 children a day and sometimes we don’t have time to charge—there’s no break when they come. They start to come as early as half past 7 to 4 o’clock so there’s no time to say we’re still waiting for the battery to get full.” (HCW, clinic 4) • “If there’s no battery, there’s no device.” (HCW, clinic 1) • “Loadshedding [of electricity] is happening so it must be charged, and the battery must last” (HCW, clinic 2)
Can measure different parts of the body	5 (71)	<ul style="list-style-type: none"> • “It doesn’t limit you so you can use it on whatever part of the body that you want” (HCW, clinic 2) • “We’ve got limited sites where you can do accurate readings” (HCW, clinic 1)
Easy to clean	4 (57)	<ul style="list-style-type: none"> • “Hygiene is very important because we’re dealing with kids, so if it’s easy to clean then it’s more safe.” (HCW, clinic 4) • “Because it’s used between many patients” (HCW, clinic 5)

^aHCW: health care worker.

We asked if there were any disagreements in the group, but all groups indicated that they were happy with the consensus reached after discussion.

Participants added the following tangible features: small size, protective cover and storage bag, device holder or stand, and time stamp. However, more generic statements such as “easy to use” and “user friendly” were also added. Some added distractions to the child, such as a colorful screen or pictures. In 1 group, the HCWs also added the inclusion of a probe—the key design feature we were proposing to move away from.

Participants who included “other apps installed” in their overall ranking of design features were asked which apps they desired. The predominant suggestion was to have an app that could also measure temperature and respiratory rate, with a high preference for a multimodal device being displayed. Other app suggestions included an app for referral to hospital emergency wards (known as the *Vula* mobile app in this setting) [35] and an app that referred participants to the emergency medicine practice guidelines [36]. However, there were mixed feelings toward additional apps, and these often were not ranked among the most important features, with the exception of 1 (14%) of the 7 groups. Some of reasons given were that other apps would

not be used; that they would negatively affect the battery life of the device; or that people would use the apps for personal reasons. As some HCWs noted:

We're not gonna use other apps. [HCW, clinic 4]

I wonder if it's not gonna affect the battery life.
[HCW, clinic 3]

People overuse it for personal things. [HCW, clinic 2]

Activity 4: Interface Design

For the user-interface design activity, participants tended to place pulse and SpO₂ readings together (6/7, 86% groups), although there was variability in where on the screen these were placed as well as variability in the size of the icons. Further, 6 (86%) out of the 7 groups included both the waveform as well as the bouncing bar, with the following reasons: if one is not working, the other will; each feature gives you different information; and it makes the device more accessible in the case someone is only familiar with either the bouncing bar or the waveform. The majority (5/7, 71%) of the groups included icons indicating temperature and respiratory rate, further indicating their preference for a multimodal device. Two (29%) groups added a distraction for the child, such as a moving video with sound. The battery was mostly placed at the top of the screen so that HCWs could immediately see whether the device needed to be charged when switched on. When asked what alarms and sounds were wanted, the main preference was for a sound when there was an abnormal reading. Furthermore, the preference was for a loud volume given the noisy environment of the clinics.

Discussion

In this study, we conducted design workshops with South African HCWs to develop a novel, pediatric-specialized pulse oximeter device, to ensure the device is context appropriate. Through the design workshops, we found that HCWs displayed an overall positive and enthusiastic sentiment toward such a device, seeing its value in clinical use with children with hypoxemia. The findings from these workshops were used to select oximeter prototype 2 (Figure 1), with the sensor in the middle, to take forward into the prototype testing stage, with key updates to the robustness and planned user-interface incorporated.

Participants displayed the strongest preference for a device design with a sensor in the middle, feeling that it was overall the easiest to work with. Although participants felt that a smartphone device would be easy to use on a child, clean, and store and felt confident in placing the sensor correctly, some had concerns over the robustness of the device. They provided multiple suggestions to overcome this, such as a pouch, case, or rubber casing, and as a result, we increased the robustness of the device to be able to resist a drop test. However, this may point toward a potential limitation in using a smartphone interface, which HCWs are largely familiar with and have likely had experiences of breakages. This prompted a discussion within the study team on whether the smartphone inside the casing could be replaced with a locally available phone, allowing for

a more sustainable repair solution than most traditional medical devices. Although this was not dealt with at this stage of design, the HCW feedback triggered us to reflect on this aspect of the device in more depth and to plan for future prototypes.

We received the least in-depth feedback on the mock placement and use of the prototypes with dolls of infants. One issue may have been the design of the activity, using infant dolls to prompt discussion. As a key challenge in pediatric oximetry, as noted by the HCWs as well, is the children's movement and them becoming agitated with measurements being done, using a real child may have resulted in more reflective responses. The locations that the HCWs largely defaulted to were the thumb, toes, hands, and feet—where oximeter probes are generally used currently, although not with the same versatility. We had hypothesized that a benefit of reflectance oximetry is the range of locations that could be used, which reduces both the HCWs' need to disturb the child and restrict their movement (eg, their forehead or upper back).

Pragmatic concerns arose most strongly during the activity where design features were ranked. These findings speak to the context in which HCWs in LMICs work, where having usable, durable, and long-lasting devices is of the essence—with participants noting that once devices break, they are unlikely to be replaced. This is due to factors such as limited technical and biomedical support and ties into other literature regarding “medical equipment graveyards”—composed of obsolete or otherwise broken biomedical, donated equipment—which are a common occurrence across LMICs [37]. These findings also speak to similar findings in other literature, where opportunities for redesign in pulse oximeters in LMICs included similar themes such as battery charging and durability, probe fit, and sensitivity in pediatric populations [11].

Participants liked the idea of a multimodal device. Although there were various suggestions given for additional design features, a device that could take temperature and respiratory rate readings in addition to SpO₂ was by far the most desirable design feature proposed. This was desirable to participants as one device with multiple modalities is pragmatically beneficial. This speaks to possible opportunities for integration in future device designs and further developments in the field of eHealth; however, this needs to be weighed against risks. There is the risk that more complex devices will be more expensive, have reduced usability, and not be optimized for the oximetry function. Therefore, the benefits need to be weighed against the added value of additional functions, as a device performing a core functionality well could be beneficial over a device that performs poorly across various functionalities [11,38].

Some of the themes raised by our participants were raised in other studies in LMICs, indicating a degree of generalizability. Khayelitsha is considered to be fairly representative of other low-resource, sub-Saharan African settings when considering HIV exposure, tuberculosis mortality rates, and quality of care. However, some contextual factors may be unique to a particular context. For example, Khayelitsha has access to electricity but frequently experiences power supply blackouts (loadshedding), which happens nationwide, meaning that mains-charged devices are acceptable but need a long battery life. In contrast, in other

settings, solar-powered charging was prioritized as access to electricity in health facilities was not universal [11].

Our study has several strengths in being able to rapidly engage with a range of HCWs. However, we also had 3 key limitations. First, we came up with the initial idea for a reflectance pulse oximeter, hypothesizing that this could solve several usability issues for LMIC outpatient settings. Our participants were therefore restricted in their first prototypes to 1 type of oximeter that the research team had chosen. It is possible participants may have preferred an alternative design or traditional transmittance pulse oximeter. It may also have biased our team's presentation of the device and interpretation of the data. However, the workshop researchers had no prior experience in oximetry and led the data collection and analysis process in an attempt to mitigate potential researcher bias. Second, given that our data collection and analysis process were designed to be rapid and pragmatic, we did not extensively pilot the

instruments. Lastly, the workshops were conducted primarily in English. Clinical training is done in English and is the language spoken in most professional South African environments. However, it was not the majority of participants' home or first language, which could be a potential limitation. We allowed participants to answer in whatever language they wanted to, and we always had a Xhosa-speaking researcher available to mitigate this limitation.

A contextually appropriate, low-cost, pediatric-specialized, smartphone-based reflectance pulse oximeter was seen to have potential clinical value in the South African context. The process of HCD allowed us to explore HCW's design preferences qualitatively to design a prototype device that would address their specific needs. The overall preference was for a multimodal and pragmatic device, with our rapid participatory approach successfully leading to changes in the oximeter design executed by our engineer.

Acknowledgments

We would like to thank all the health care workers who took part for giving both their time and their wisdom, and the research nurses for their initial feedback when piloting the workshops. The research reported in this publication was supported by the Fogarty International Centre of the National Institutes of Health under award 1R21TW012212-01. In addition, GH receives the financial assistance of the European Union (grant DCI-PANAF/2020/420-028), through the African Research Initiative for Scientific Excellence (ARISE) Pilot Programme. ARISE is implemented by the African Academy of Sciences with support from the European Commission and the African Union Commission. Abstract

Background: Cultural adaptations of digital health innovations are a growing field. However, digital health innovations can increase health inequities. While completing exploratory work for the cultural adaptation of the *Ned Clinic* virtual survivorship app, we identified structural considerations that provided a space to design digitally connected and collective care.

Objective: This study used a community-based participatory research and user-centered design process to develop a cultural adaptation of the *Ned Clinic* app while designing to intervene in structural inequities.

Methods: The design process included primary data collection and qualitative analysis to explore and distill design principles, an iterative design phase with a multidisciplinary team, and a final evaluation phase with participants throughout the design process as a form of member checking and validation.

Results: Participants indicated that they found the final adapted prototype to be acceptable, appropriate, and feasible for their use. The changes made to adapt the prototype were not specifically culturally Chinese. Instead, we identified ways to strengthen connections between the survivor and their providers; improve accessibility to resources; and honor participants' desires for relationality, accountability, and care.

Conclusions: We grounded the use of user-centered design to develop a prototype design that supports the acts of caring through digital technology by identifying and designing to resist structures that create health inequities in the lives of this community of survivors. By designing for collective justice, we can provide accessible, feasible, and relational care with digital health through the application of Indigenous and Black feminist ways of being and knowing.

Introduction

Digital health has been posited as a pathway to more equitable and holistic care [1,2]. However, the digital divide, or the capacity for digital technology to exacerbate inequities, has been widely described [3]. Its differential impacts on the social determinants of health are known as the digital determinants of health [4]. Recent years have seen an acceleration of digital health innovations (DHIs) such as digital therapeutics into health care systems, which was supercharged by the COVID-19 pandemic and the resulting widespread implementation of telemedicine [4]. One such digital therapeutic is the *Ned Clinic* (“No Evidence of Disease”), which aims to optimize clinical care and patient self-management through virtual asynchronous care delivery for prostate cancer (PCa) survivors [5]. The *Ned Clinic* platforms, including clinician-led (*Specialist Ned*) and nurse-led (*Ned Nurse*) interventions, were developed at the University Health Network in Toronto, Canada, by a consortium of stakeholders [5].

PCa is the most commonly diagnosed nonskin cancer for Canadian male individuals, and most (99%) are estimated to be diagnosed in male individuals aged 50 years and older [6]. Older adults are negatively impacted by the digital divide [7]. Race, a social determinant of health, is also linked to worse survivorship and care outcomes for PCa survivors, most notably for Black male individuals [8]. Asian (generally defined as East Asian and South Asian ethnicity) male individuals have been found to have better survival rates than the median but are more likely to present with advanced PCa, suggesting systemic issues with identifying health issues and obtaining timely appropriate care [9]. These differences carry over into the delivery of follow-up care, as PCa survivors’ care needs and access to care are affected by the complex intersection of ethnicity, culture, and other social and structural factors [10,11].

Cultural adaptation is the process of applying changes to existing health interventions based on “surface” (social and behavioral characteristics) and “deep” (worldview, norms, beliefs, and values) cultural structures [12]. As these structures are known to impact beliefs about illness and well-being, the intent is to provide intervention benefits for communities that have experienced health inequities [13]. Culturally adapted DHIs appear to have been most widely reported in the field of mental health; in contrast, cultural adaptations of cancer survivorship apps have not been published, likely owing to the few interventions in this area [2,14]. The frameworks that appear to be most widely used to adapt health interventions were developed by Bernal et al [15], Resnicow et al [16] (an adaptation of the model by Bernal et al [15]), and Barrera and Castro [17].

However, these guidelines and models often use framings of cultural sensitivity and competency (eg, Resnicow et al [16] and Castro et al [18]), continuing to place the burden of change on individuals rather than addressing the upstream structural

determinants of health. These framings can serve to “museumize” and problematize identity categories and culture as causes of ill-health, echoing the long-standing use of culture as a scapegoat to fault specific communities for health inequities. Moreover, defining “culture” for such adaptations can be a complex process in Canada, where culture, race, ethnicity, settler colonialism, and white supremacy (ie, the social and structural determinants of health) all create intersectional and differential lived experiences under a putatively shared identity—Canadian [19-21].

This research reports on the second and final phase of a project to design a cultural adaptation of the patient-facing *Ned Clinic* virtual follow-up care app for Chinese Canadian PCa survivors. In phase 1, we completed formative work distilling a set of themes relevant to survivors’ user needs for follow-up and virtual care. Following the user-centered design (UCD) framework, we describe the results of the design and formative evaluation of a culturally adapted prototype of the app.

Methods

Study Design

The overall qualitative descriptive study design was structured using the community-based participatory research (CBPR) and UCD frameworks [22-24]. This study was conducted at the University of Toronto between December 2022 and March 2023 during the COVID-19 pandemic. For communities that face barriers to care, it was found that CBPR practices such as our engagement of a key informant and invitations to community members to share their lived experiences through open-ended interviews are appropriate [1,25]. CBPR concepts were applied to meaningfully involve the community (including several authors of this study) and return the results for their benefit. Here, *community* represents a “symbolic totality as well as a practical multiplicity,” as the Chinese Canadian community is highly heterogeneous [26]. We view our participants as a coalition of self-identified Chinese Canadian individuals impacted by PCa survivorship to attend to their differences.

The Chinese Canadian community is an immigrant community that exists as a result of settler colonialism. In recognizing this, we redefine “immigrants” as “people with ancestral roots outside of Indigenous lands, who are beholden to Indigenous laws and epistemologies” [27]. This definition led us to apply a relational paradigm to this project and an axiology of relational accountability. It also provided a pathway to apply several multilevel Indigenous and Black feminist theorizations, guiding principles, and tools [27-29]. These included decolonial theory, *Etuaptmumk* (two-eyed seeing), intersectionality, and cultural safety to inform our conceptualization of digital space as intimately related to land [27,30,31]. This approach allowed us to contextualize the place-related experiences of our participants and uncover their desires for relational and culturally safe care [32]. We noted that these desires are not specifically Chinese,

and this presented an opportunity to design for relationally connected digital health.

UCD is a flexible, iterative, and evidence-based 3-step design process framework that consults, involves, and considers the needs of the end user throughout the entire project [23]. Phase 1 of this study encompasses steps 1 and 2; phase 2 encompasses steps 2 and 3. We present this study according to the Consolidated Criteria for Reporting Qualitative Research (COREQ) guidelines [33].

Step 1: Ideation and Concept Generation

To contextualize the potential use of this app, we sought to understand the structures that impact Chinese Canadian PCa survivors' experiences with follow-up care and virtual care. The results of this phenomenologically informed exploratory-descriptive qualitative study are described elsewhere [34]. Based on the findings of this formative research, we synthesized a list of design principles (Table 1), which we then categorized into the cultural adaptation taxonomy created by Spanhel et al [14] to systematically adapt the patient-facing prototype.

Table 1. Summary of design principles for the adaptation of the *Ned Nurse* patient-facing app.

Research finding	Design principle	Taxonomic classification [14] ^a
PHI ^b freedom: patients felt that they were expected to track and remember overwhelming amounts of information.	The system should automatically update, store, and provide access to PHI on demand.	Content components: <ul style="list-style-type: none"> (9) Goals of treatment (10) Methods of treatment
Access to personalized education and information: patients felt that they were unable to access information about their care options and disease status.	The system should provide access to personalized and evidence-based information regarding staging, self-management, and treatment options.	Content components: <ul style="list-style-type: none"> (9) Goals of treatment (10) Methods of treatment
Continuity of care: patients desired a connection with their provider and the ability to communicate during times of need.	The system should improve accessibility and continuity of care, as strong care relationships create a sense of safety.	Content components: <ul style="list-style-type: none"> (9) Goals of treatment (10) Methods of treatment
Security: patients expressed suspicion about digital health because they had concerns about surveillance and security.	The system should be architected and built with a high level of security and privacy.	Methodological components: <ul style="list-style-type: none"> (12) Functionality
Accessibility: patients wanted to access care in readable and accessible language formats.	The system should provide readable language and accessible language formats.	Content components: <ul style="list-style-type: none"> (5) Language translation (6) Language tailoring
Digital literacy: patients felt comfortable with their device of choice but desired simplicity, form over function, and accessible help and documentation.	The system should prioritize usability, provide straightforward instruction and support, and maintain simple user interface and user experience design.	Methodological components: <ul style="list-style-type: none"> (11) Structure (12) Functionality (13) Design and aesthetics
Care coordination: patients felt like they were expected to coordinate their care, as communication between specialists, primary care, and other services were fragmented.	The system should coordinate and provide a clear follow-up appointment schedule.	Content components: <ul style="list-style-type: none"> (9) Goals of treatment (10) Methods of treatment
Resources: patients felt unable to access, refused, or unaware of needed resources such as mental health support.	The system should provide accessible pathways to resources, such as psychological support, supportive care, and financial support.	Content components: <ul style="list-style-type: none"> (8) Difference in concepts of mental health and its treatment (9) Goals of treatment (10) Methods of treatment

^aThe design principles used to adapt the *Ned Clinic* patient app identified here are classified to the corresponding taxonomic components found in Spanhel et al [14].

^bPHI: personal health information.

Step 2: Design and Development

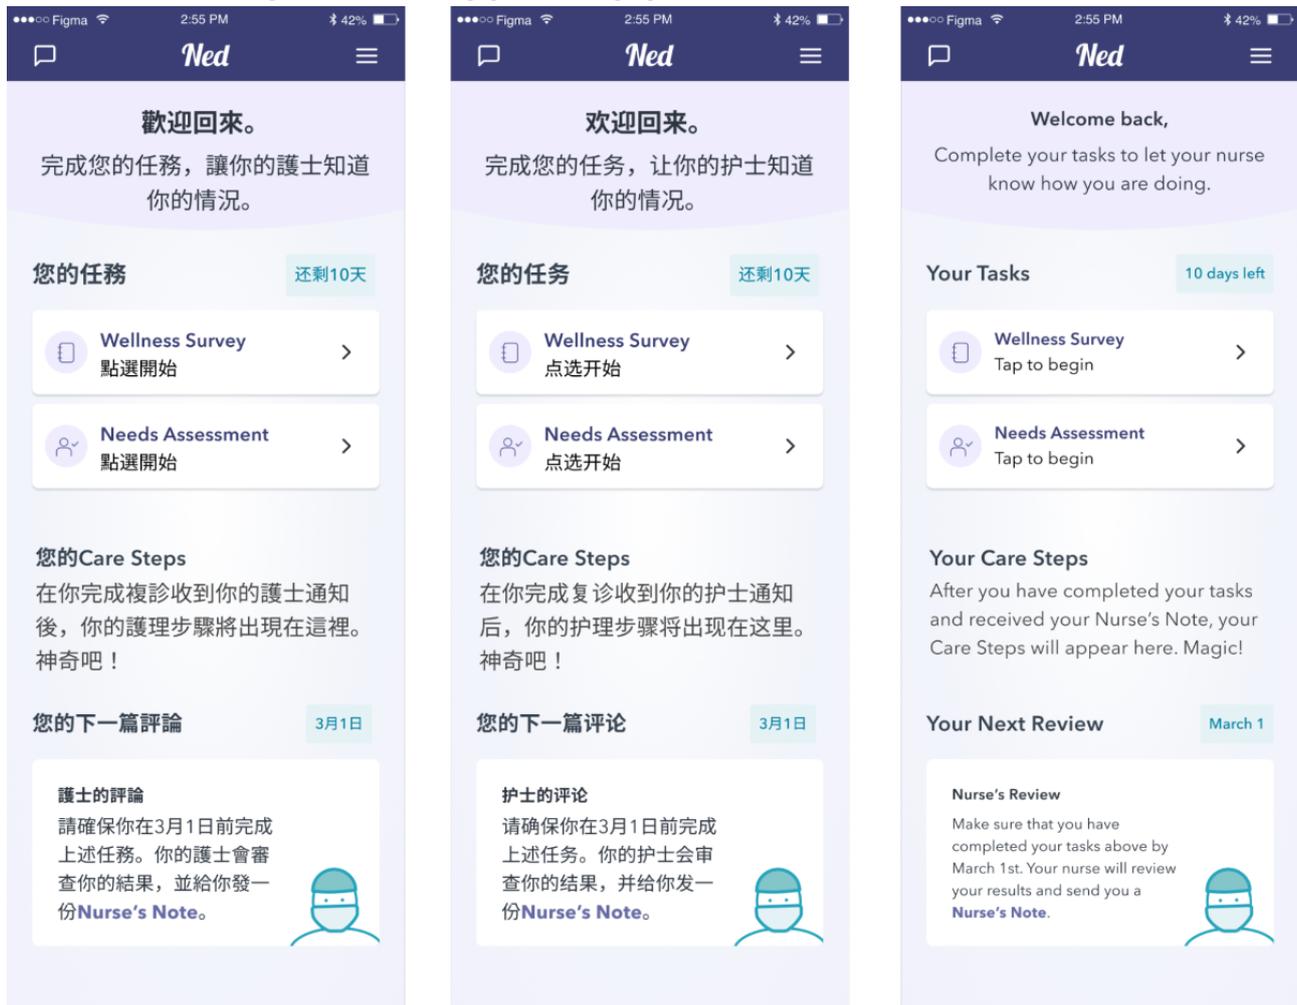

We applied these design principles to adapt the *Ned Nurse* patient app for Chinese Canadian survivors. A composite profile of a sample representative user was created to situate the design team during the development of the wireframes. A list of 5 use scenarios was created to guide the adaptation. These scenarios encompassed the design principles created in step 1 and included actions such as completing follow-up tasks, accessing a follow-up care schedule, and using the app to chat with a

clinician. All use scenarios are described in the interview guide (Multimedia Appendix 1). Then, the original *Ned Nurse* app wireframes were redesigned to reflect the features required to operationalize these scenarios through the app, resulting in a new prototype. The prototype was created in Figma (Figma Inc.) on an iPhone 13 (Apple Inc) interface. This initial adaptation was iteratively critiqued by a team of researchers and human factors designers to refine the content, user interface, and user experience. Once the adapted prototype was finalized, it was translated from English into written Chinese via the

translation process outlined in Haldane et al [35]. This resulted in 3 versions of the adapted prototype in English, Simplified

Chinese, and Traditional Chinese. The app home page in each language version is shown in Figure 1.

Figure 1. Wireframes of the adapted *Ned Nurse* homepage in all 3 language versions.

Step 3: Evaluation

Overview

We empirically evaluated the acceptability, appropriateness, and feasibility of the adaptation through a cultural safety lens [22]. These dimensions are early-stage implementation outcomes and have also been found to be core to the success of DHIs [36,37]. A moderated cognitive walkthrough approach and the think-aloud protocol were used to construct a semistructured interview guide encompassing the 5 scenarios describing usual tasks that an end user might complete through the app [38].

Usability Testing

Facilitators began each test by outlining the usability testing procedure and think-aloud protocol. Context regarding the intended use and deployment of the *Ned Nurse* system was provided. Participants were asked to complete a series of actions for each scenario on the prototype to evaluate its design and functionality. We asked participants to think and speak about improvements they desired during their evaluations. In situations where the participant was unable to access the prototype on their device, they were asked to state their intended actions

using the think-aloud protocol to the facilitator, who completed the action in the prototype on their behalf.

Interviews were completed through Microsoft Teams or Zoom (Zoom Technologies Inc). Informed consent for this work was previously obtained as part of overall study consent from participants. Participants were provided with the choice of completing their interview in Cantonese, Mandarin, or English and were also able to choose which language they wished to test the prototype in. The results of each usability test were iteratively analyzed via content analysis. Audio recordings of the participant interviews were translated into English as needed, according to the translation process described previously. A deductive and inductive content analysis approach was used, in which analysis of the data was completed by coders (TX and KY) through a process including open coding, creating categories, and abstraction [39]. Recommendations were applied in real time to create a final prototype that incorporated feedback from each user over the course of usability testing.

Positionality

An important marker of excellent qualitative research is “sincerity” or positionality, which indicates that the researcher has thought about and is reflective and aware about their values,

experiences, biases, and inclinations within their research [40]. Here, the lead researcher reports on their social position, personal experiences, and political and professional beliefs to center the active role that the researcher plays in the framing of the research problem, interpretation of data, methods used, and the reporting of the results [41].

KY is a health informatics trainee and second-generation Chinese Canadian settler who was born and raised in the Greater Vancouver Regional District (GVRD) by a working-class, first-generation immigrant family with roots in southeastern China. She does not have any direct experience with PCa and has not previously provided care for PCa survivors. KY works primarily from a relational paradigm, focusing on the structures, contexts, and relationships that shape the design, development, and implementation of digital therapeutics and health technologies. She led and participated in all study activities.

Setting and Place

This study was conducted in the GVRD, located on the current, unceded, and future territories of the  (Tsleil-Waututh, Squamish, and Musqueam) First Nations. The GVRD is home to one of Canada's oldest and largest living Chinese communities, including persons and families whose stories and identities span multiple geographies and generations [42]. The lead (KY) and senior author (QP) established relations with a supportive care program that provides care for Chinese Canadian PCa survivors and a Chinese PCa support group in this area. A key community informant agreed to guide this study and review and approve study materials.

Ethical Considerations

Research ethics approval for this study was obtained from the University of Toronto research ethics board (Human Protocol #43145). Written and verbal informed consent to participate in both phases of the project was obtained from all participants prior to interviews via the REDCap tool (Research Electronic Data Capture; Vanderbilt University), hosted at the University of Toronto. All data collected and disseminated here have been de-identified. Participants were provided with an honorarium of \$50.00 CAD (\$37.65 USD) per hour in appreciation of their time.

Results

Demographics

Usability testing was performed by 6 user testers, convenience sampled from the pool of 14 survivors and partner-caregivers who participated in the first phase of work as a form of member checking. This sample was also informed by Nielsen-Norman usability testing guidelines [43]. The reasons for nonparticipation were not collected. To protect the privacy of the participants involved in this phase, a demographic overview of the overall research project is provided here. Of the 14 participants in the first phase of this project, all survivors identified as men (n=12, 86%), and all partner-caregivers identified as women (n=2, 14%). A total of 13 (93%) participants indicated that they spoke English as an additional language. Most made an income between CAD \$15,000 (US

\$11,048) and CAD \$100,000 (US \$73,653; n=12, 86%), lived in an urban area (n=13, 93%), were married (n=12, 86%), were educated beyond high school (n=13, 93%), and were retired (n=9, 64%). A 50/50 split emerged between preferences for smartphone or desktop or laptop use. Most (n=10, 71%) self-rated as being comfortable with their device. Participants indicated that they had 2 or fewer smartphone health apps (n=13, 93%).

Phase 1: Ideation

Table 1 summarizes the user requirement findings that emerged from previous formative research in phase 1 of this project and their subsequent translation to design principles.

Phase 2: Design and Development

Overview of *Ned Nurse*

An overview of the *Ned Nurse* clinical trial protocol is described by Pham et al [5]. The findings from formative work on the perspectives of health care providers, patients from the wider PCa survivor community, and the service design of the platform are forthcoming. Briefly, *Ned Nurse* digitally operationalizes a nurse-led model of survivorship care. Patients complete a series of tasks or access resources designed to support them in their survivorship. The platform aims to facilitate holistic care for patient quality of life.

Overview of the Adapted Patient-Facing System

The patient-facing adaptation set 2 user-input “care tasks,” a validated questionnaire (Expanded Prostate Cancer Index Composite-Clinical Practice [EPIC-CP]) and a needs assessment survey, to constitute a single *Ned Nurse* “review” [5,44]. Language within the app avoided wording such as appointment, visit, and so forth to clarify the differences between synchronous and asynchronous care encounters. The user interface and user experience were designed to draw the user's attention to these tasks on the homepage immediately after login. All features were accessible via an in-app hamburger menu.

User inputs to the questionnaire were triaged via a decision-tree algorithm [45]. The algorithm was designed to return in-app self-management resources within a progress note (“Nurse's Note”) automatically available to the user after input submission. If the algorithm detected that the patient required further support, they were prompted to specify domains for follow-up and asked to select their preferred contact method. This action would flag this patient to the nurse for follow-up. Resource links would appear on the homepage after the note was read and cleared.

To ensure that patients were aware of their review schedule, a feature was designed to display the last date, frequency, and next date of their expected reviews. The name of the nurse in charge and an explanation of their *Ned Nurse* role were provided to strengthen the perceived connection between the user and the nurse. This feature also set expectations for manual response times and included a link to users' previous submissions for on-demand access.

Resources were made available in 3 separate categories: symptom self-management advice, PCa information and education, and support and programmatic resources. Within

each category, resources were further categorized. For example, symptom management included resources for symptoms such as anxiety, urinary incontinence, and hot flashes. Each resource provided an overview; relevant self-management steps; off-app links; and the ability to email, print, or save the resource. The feature home page also sectioned resources saved by the user ("Saved Resources") and resources picked for the user ("Picked for Me") by their nurse.

All available and historical prostate-specific antigen and testosterone blood work results were made available in chronological order to the user on-demand in a separate feature. Finally, a chat feature was designed to explore whether users might find it useful. It incorporated both responses in English from an automated support assistant (chatbot) and manually submitted by the nurse. This feature was simulated for evaluation.

Phase 3: Evaluation

Of the 6 participants, 2 (33%) tested in Cantonese, 3 (50%) tested in English, and 1 (17%) tested in Mandarin. These ratios correspond to testing of the Traditional Chinese, English, and Simplified Chinese versions. We note that patients who completed their testing in 1 language were functional to fluent in 1 or all of the other languages and provided critique for multiple versions.

Overall, there was strong agreement that the adaptation presented here would be acceptable, appropriate, and feasible for use, with the exception of the chat feature. Participants agreed that this app would make them feel comfortable and safe by allowing them to have more control over their care, access to resources, and stronger connections to their providers. They were encouraged by its perceived ability to meet their needs by protecting their connection with their providers, leveraging the functional flexibility of digital health, and providing resources beyond what they currently accessed. It was particularly valuable that features could be accessed at their convenience, as some felt that their follow-ups were far too short to meet their needs. Overall, 5 (83%) of 6 participants indicated that the level of support provided by this app was beneficial enough that it should be offered to patients prior to beginning treatment, or even at the point of diagnosis.

Participants' critiques centered on expanding flexibility, access to information, and streamlining responses. They felt that responses for some assessment questions (from 4 to 8 options) were overwhelming and should be reduced (3/6, 50%). English-Chinese translations would increase self-confidence in navigating the health care system. Medication names were spotlighted as particularly difficult. This was noted as an opportunity to expand the app's personal health information (PHI) storage, as a feature containing self-reported PHI (including medications) would be helpful to reference. Pictures and videos were desired instead of textual explanations. Laboratory results were asked to be displayed graphed or with severity indicators by 1 participant, and a text size adjustment function was requested by another.

Support for sexual dysfunction was not requested explicitly but appeared to be implied (3/6, 50%). A sexual therapy resource

section was requested by 1 participant. Another noted that they would be more comfortable with nurses gendered as men as they felt uneasy when discussing sexual dysfunction with women. A final participant was keen to indicate that sexual dysfunction was a major area of concern when completing the EPIC-CP questionnaire.

As resources could be accessed on demand, some indicated that more would be beneficial. However, other participants expressed that the number displayed in the prototype were more than sufficient, reflecting our previous study findings on the bifurcated information-seeking behaviors of Chinese Canadian PCa survivors. Participants were also asked if they might find having their imaging results helpful. Although the majority (4/6, 67%) said no, those who said yes (2/6, 33%) were keen on having this information, especially if they needed to travel outside of Canada.

The questionnaire and assessment were generally deemed to be acceptable by most participants (4/6, 33%), with several notable dissents (2/6, 33%). The EPIC-CP question regarding hormonal function was highlighted as confusing by some because the connection between hormonal function and fatigue was not readily apparent. The spiritual domain in the needs assessment was flagged, as some thought that it would not be appropriately addressed by the nurse. Those who felt uncomfortable with this domain noted that they would prefer speaking about these needs to a spiritual leader. Agreement on appropriate response times also varied.

The chat function was deemed possibly helpful but likely unnecessary (4/6, 67%). As all chat interactions were in English, participants who were not confident in their English communication skills felt that their use of this feature would be limited (3/6, 50%). Others felt reminded of troubleshooting cable services rather than feeling connected to their provider. It was emphasized that any opportunity to improve connections to their providers through the app would be appreciated.

Discussion

Principal Findings and Implications

This study provides an applied example of a DHI for Chinese Canadian PCa survivors, which is based on broader principles of collectivism and relationality from Indigenous and Black feminist theory. Our initial aim was to co-design a cultural adaptation of the *Ned Clinic* to provide compassionate care and meet the unmet needs of Chinese Canadian PCa survivors via digital health.

However, attending to cultural adaptation theory and the lived realities of settler colonialism identified gaps to interweave Indigenous and Black feminist teachings. We began by synthesizing design principles that surfaced as critical to our participants and their feelings of comfort and safety when receiving follow-up care. This allowed us to leverage digital health to strengthen relations between the survivor and their providers; improve accessibility to resources; and honor desires for relationality, accountability, and care [46,47]. Rather than adapting by defining Chinese Canadian culture, we co-designed

to intervene in structural causes of health inequities created by settler colonial culture instead [21,48].

We applied *Etuaptomuk* by interweaving strengths from different ways of being and knowing, including those from Indigenous, Western, Chinese, and Black feminist traditions in relation to PCa follow-up and virtual care [27,30,31]. These included prioritizing relational care, accounting for the use of prostate-specific antigen screening as a recurrence monitoring tool, and the benefits of supportive care programs to create adaptation features [30,49]. The EPIC-CP validated questionnaire is a key part of clinical follow-up care, as it allows clinicians to identify possible areas of concern during follow-up [50]. The needs assessment addresses domains beyond clinical care, reflecting the holistic nature of the medicine wheel [51]. Access to resources includes education and guidance for the self-management of concerns across multiple domains. The app presents a “care contract” in the form of a schedule that clearly states the “terms” and dates of the user’s follow-ups [52]. It also respects the user’s privacy by providing access and allowing them to share their PHI on their terms [53]. Only key inputs are communicated for triage and response. Finally, language access is built into the app as a question of communication accessibility, rather than only culture.

This design approach and these features do not deny the fact that culture is a real influence and can be a source of strength in many peoples’ lives. However, we must go beyond implicating culture when designing DHIs for communities made vulnerable and instead address the overarching and underlying structures that create health inequities. Our design approach looked “up” at these structural causes rather than looking “down” and museumizing culture for participants through cultural sensitivity and competency. We demonstrate that a structural approach that applies teachings such as cultural safety and intersectionality can result in DHIs that are found to be acceptable, appropriate, and feasible for use while still leaving room for users to self-define and practice culture on their own terms. We are supporting, not replacing, the *labor* and *acts* of caring with digital health. Beginning with a paradigm shift opened a window to design for collective care, a scalable opportunity to benefit communities beyond Chinese Canadians with this *Ned Nurse* patient-facing app adaptation.

Strengths and Limitations

We have created the first “cultural” adaptation of a PCa follow-up care application for Chinese Canadian survivors. We extended the accessibility of this prototype by offering it in 3 language versions and tested its validity through member checking by returning it to participants who had provided their experiences and expertise as part of the first phase of this project. The findings should be considered with some limitations. Our sample does not fully represent the Chinese Canadian PCa community, as the heterogeneity of the community makes it difficult to recruit a fully representative sample [42]. User testing did not differentiate between results derived from users who interacted with the app themselves and users who directed a facilitator to perform actions on their behalf. However, all participants received the same set of instructions to apply the think-aloud method. A broad description of our theoretical stance, setting and place, methods, and results are provided to enhance understanding. We think of and encourage the transferability of this research as to how it might be made meaningful (ie, valid) for other communities in places where they may be subject to similar constructs and patterns of oppression [32]. Finally, this study does not include the provider perspective, although *Ned* was developed with clinicians who provide follow-up care for patients from this community. Future studies should examine the clinician’s perspective on the design and development of similar DHIs, including provision of care through these apps, acceptability and feasibility, and implementation readiness.

Conclusions

This study demonstrates the relationality of Indigenous and Black feminist ontologies, epistemologies, and methodologies to digital health design by providing a worked example of its empirical use for an adaptation of a PCa follow-up care app, the *Ned Nurse* Clinic, for Chinese Canadian PCa survivors. We applied UCD principles to develop a prototype design that supports the relational act of caring through digital technology by identifying structures that create inequities in the experiences of this community of survivors and designing to intervene and provide accessible, connected care instead. We hope that this prototype serves as a tool to help regenerate places of caring, as we have learned from Indigenous and Black feminist scholars’ teachings on power, place, and digital technologies.

Acknowledgments

We are deeply grateful for the time and effort gifted to us by the community members who shared their stories. We acknowledge and appreciate the staff and members of the Prostate Cancer Supportive Care Program, including Dr C Higano and Ms M Sundar, and the Richmond Chinese Prostate Cancer Support Group (列治文華人前列腺癌支援網絡), led by Mr D Leung and advised by Dr W Yu Ko. We thank the *Ned* team at the Centre for Digital Therapeutics (University Health Network) for their efforts and commitment to delivering a DHI for Canadian prostate cancer survivors. We give special thanks to Laura Parente for her incisive and human-centered design guidance. The study was funded by the Canadian Institutes of Health Research (CIHR) through the CIHR Canadian Cancer Society Survivorship Grant (CCS: 706713; CIHR: 168606) and the Canada Graduate Scholarship program, as well as by AGE-WELL Networks of Centres of Excellence through the Early Professionals & Inspired Careers in AgeTech (EPIC-AT) Fellowship and Graduate Award. These agencies were not involved in the design or analysis of this study.

Data Availability

The data sets generated and analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

KY, QP, ATB, ML, and WYK contributed to project conceptualization and study design. KY, RL, and TX contributed to data collection and analysis. KY prepared the first manuscript draft, with contributions from TX, WYK, ATB, ML, and QP. All authors contributed, reviewed, and approved the manuscript.

Conflicts of Interest

QP and the University Health Network (Toronto, Ontario) jointly own intellectual property rights to the *Ned* app. Under the respective agreements with their organizations, QP is entitled to personally benefit from any commercial use of the intellectual property.

Abstract

Background: Hypoglycemia is a frequent and acute complication in type 1 diabetes mellitus (T1DM) and is associated with a higher risk of car mishaps. Currently, hypoglycemia can be detected and signaled through flash glucose monitoring or continuous glucose monitoring devices, which require manual and visual interaction, thereby removing the focus of attention from the driving task. Hypoglycemia causes a decrease in attention, thereby challenging the safety of using such devices behind the wheel. Here, we present an investigation of a hands-free technology—a voice warning that can potentially be delivered via an in-vehicle voice assistant.

Objective: This study aims to investigate the feasibility of an in-vehicle voice warning for hypoglycemia, evaluating both its effectiveness and user perception.

Methods: We designed a voice warning and evaluated it in 3 studies. In all studies, participants received a voice warning while driving. Study 0 (n=10) assessed the feasibility of using a voice warning with healthy participants driving in a simulator. Study 1 (n=18) assessed the voice warning in participants with T1DM. Study 2 (n=20) assessed the voice warning in participants with T1DM undergoing hypoglycemia while driving in a real car. We measured participants' self-reported perception of the voice warning (with a user experience scale in study 0 and with acceptance, alliance, and trust scales in studies 1 and 2) and compliance behavior (whether they stopped the car and reaction time). In addition, we assessed technology affinity and collected the participants' verbal feedback.

Results: Technology affinity was similar across studies and approximately 70% of the maximal value. Perception measure of the voice warning was approximately 62% to 78% in the simulated driving and 34% to 56% in real-world driving. Perception correlated with technology affinity on specific constructs (eg, Affinity for Technology Interaction score and intention to use, optimism and performance expectancy, behavioral intention, Session Alliance Inventory score, innovativeness and hedonic motivation, and negative correlations between discomfort and behavioral intention and discomfort and competence trust; all

$P < .05$). Compliance was 100% in all studies, whereas reaction time was higher in study 1 (mean 23, SD 5.2 seconds) than in study 0 (mean 12.6, SD 5.7 seconds) and study 2 (mean 14.6, SD 4.3 seconds). Finally, verbal feedback showed that the participants preferred the voice warning to be less verbose and interactive.

Conclusions: This is the first study to investigate the feasibility of an in-vehicle voice warning for hypoglycemia. Drivers find such an implementation useful and effective in a simulated environment, but improvements are needed in the real-world driving context. This study is a kickoff for the use of in-vehicle voice assistants for digital health interventions.

Introduction

Background

Type 1 diabetes mellitus (T1DM) is a chronic condition caused by an inability of the pancreas to produce insulin and requires lifelong insulin therapy [1]. Hypoglycemia, also known as low blood glucose, is a frequent and acute complication in patients with T1DM [2,3]. Symptoms range from autonomic reactions such as trembling, anxiety, and hunger (ie, mild hypoglycemia) to neuroglycopenic reactions such as vision impairment, weakness, or cognitive impairments (ie, severe hypoglycemia) [2,4-6]. Hypoglycemia is a major issue in the context of driving: research has shown that hypoglycemia is associated with a higher risk of car mishaps [7-9]. In fact, drivers experiencing hypoglycemia are recommended by the local authorities [10] to stop the car and treat their condition. However, drivers do not always comply with these recommendations [11,12]. Thus, to help reduce hypoglycemia-related car accidents, there should be an effective warning that informs the driver about an upcoming hypoglycemic episode and supports the driver in coping with the situation. Currently, hypoglycemia can be detected and signaled through flash glucose monitoring (FGM) or continuous glucose monitoring (CGM) devices (ie, wearable receivers connected to a sensor inserted in the subcutaneous tissue of the arm or abdomen) [13]. These allow for glucose monitoring by displaying the values either continuously (ie, CGM) or upon active retrieval (ie, FGM) and deliver alerts in the form of a tone or vibration in case of out-of-range values. However, these devices present limitations in the context of driving. For instance, FGM needs to be held close to the sensor to transfer the data from the subcutaneous sensors to the monitoring device, that is, the driver needs to actively engage in a manual gesture to access the glucose value and to look at a visual display moving the focus of attention from the driving task. In contrast, allowing the drivers to receive an alert in a hands-free mode will facilitate warning reception [14] and lower worry associated with driving with T1DM [15]. However, hypoglycemia is known to cause a decrease in attention [2,4-6], thereby challenging the effectiveness of such devices. As 90% of road accidents are caused by human error, the European Commission has set new safety technologies as mandatory equipment for vehicles as of 2022 (eg, driver drowsiness and distraction warnings and speed assistance) [16]. In-vehicle warning systems for impaired driver states, such as fatigue [17], distraction [18], and breath alcohol concentration [19], are

increasingly being developed. However, to the best of our knowledge, there is no existing implementation for hypoglycemia. Such technology would be aligned with the “healing car” concept [20], where vehicles become environments promoting well-being for passengers, including ergonomic seats, ambient lighting, relaxation exercises [21], and detection of health-critical states [22]. This concept is still in its early stages, but it may become a standard in car manufacturing in the future. So far, the only attempts of in-vehicle glucose monitoring are either only proof of concept without user validation [23] or conceptual work [24]. However, the online community clearly expressed a need for in-vehicle glucose monitoring and warning [25].

A growing number of automotive companies are introducing voice assistance technology into their products [26,27]. Voice assistants add value not only for the associated consumer experience but also for their greater safety. Indeed, vocal interactions have been observed to be the least cognitively demanding while driving compared with visual and haptic interactions [28,29]. Moreover, voice assistants are increasingly being implemented to deliver digital health interventions [30-33]. Although research is still in its infancy, efforts have been made to develop voice-based conversational agents to monitor and support individuals with chronic diseases such as cancer, cardiovascular diseases, cognitive disorders, or diabetes [30]. Other recent examples include prevention of excessive alcohol consumption [34], health education and monitoring, physical and mental exercise, and nutrition [35]. Furthermore, a voice assistant delivering a warning is a form of proactive behavior initiated by the computer rather than the user [36,37]. In-vehicle voice assistants can provide personalized and adaptive suggestions, but users may ignore proactive behavior if it is inopportune, violates privacy, or distracts from driving [38-40]. However, emergencies are the most suitable context for proactive behavior that violates privacy [39].

Objectives

Therefore, we investigate the feasibility of an in-vehicle voice warning delivered by a built-in voice assistant to alert and support drivers with T1DM during hypoglycemia. To the best of our knowledge, there have been no investigations on safe and effective in-vehicle hypoglycemia warnings to support drivers with T1DM or on the perception of such technology. Thus, we sought to answer the following research questions (RQs):

- RQ1: How do drivers perceive an in-vehicle voice warning for hypoglycemia while driving?
- RQ2: How effective is an in-vehicle voice warning in prompting drivers to cope with hypoglycemia?

RQ1 refers to the attitude of drivers toward the warning, whereas RQ2 refers to the driver's compliance behavior once the warning is delivered. Answering these RQs will allow us to conclude on the feasibility of an in-vehicle voice warning for hypoglycemia. To control for individual factors influencing the perception of the warning [41], we also assessed technology affinity.

Methods

Study 0: Preliminary Assessment With Healthy Individuals in Simulated Driving

Driving Setting

Participants performed the task in a driving simulator (Carnetsoft Inc) with 3 monitors displaying the front, left, and right views. The central monitor also showed the cockpit and navigation arrows. The participants used a steering wheel and pedals (Logitech Driving Force G29) to control the simulator, which was set to automatic (ie, no clutch or gear shifter). The simulator's computer was connected to a stereo speaker with a subwoofer, which was kept at a constant volume. To control for driving difficulty, 3 environments were used: highway, countryside, and town, with the first and last being the least and most difficult, respectively.

In-Vehicle Voice Warning Simulation

Before testing a hypoglycemia voice warning with people with T1DM, we tested the concept of a car voice assistant as an interface between a dedicated monitoring system and the user with healthy participants. As the participants were not affected by hypoglycemia, the first version of the warning was a simulated low fuel warning ("The car needs a refill. Please pull over and turn off the engine"). Although not health related, it signaled an event of reasonable urgency that required safely stopping the car. Note that the participants were informed that this message aimed to ask them to stop the car as soon as possible and that they did not need to look for a gas station.

The warning was simulated using the Wizard-of-Oz method, where the conversational turns produced by the voice assistant were played by the experimenter [42] from a laptop using predefined keyboard keys. The turns were based on the Google Cloud text-to-speech engine, with a de-DE-Wavenet-C voice, a speed of 1.11 times the normal native speed of the specific voice, and a pitch of -1.20 semitones from the original pitch. The experimenter's computer was connected to the same sound system as the driving simulators so that the voice warning could be heard as part of the driving simulation. No visuals were included.

Voice Warning Evaluation Measures

To assess the RQs, we assessed participants' perception of the warning (self-reported through the modular evaluation of key Components of User Experience [meCUE]; 10 constructs

evaluated on a 7-point Likert scale and a general evaluation evaluated on a 10-point scale [43,44]) and participant compliance with the warning (measured by the experimenter manually assessing if the participant would pull over and stop the car following the warning, and reaction time in seconds from the timestamp of the warning to the timestamp of the car fully stopped). As the perception of technology can be influenced by technology-related personality [45], we also measured technology affinity (measured by the Affinity for Technology Interaction [ATI], a 6-point Likert scale [46]). Finally, qualitative feedback was collected informally.

Evaluation Procedure

The participants were welcomed, informed about the procedure, and invited to sit in the simulator. The voice assistant introduced itself and invited the participants to familiarize themselves with the setting, including the 3 environments. The training also screened for motion sickness.

In the experimental session, participants drove 12 times, with 4 blocks of 3 drives each, for approximately 5 minutes per drive. The driving environment's order and starting point varied to minimize habituation. The drive began when the voice assistant prompted participants to start the engine. A timer started to deliver the low fuel warning at either 100 or 200 seconds to add variation and minimize habituation effects. At the end of the session, participants completed the meCUE.

Data Analysis

Participants were characterized by sex, age, and driver's license duration. The ATI was aggregated as a whole, and meCUE items were aggregated per construct. All reports were aggregated across the sample, with mean and SD. Compliance was coded as binary (0=not compliant, 1=compliant) and reported in terms of frequency. Reaction time was aggregated in seconds across participants and phases, with mean and SD.

Study 1: Assessment With Individuals With T1DM in Simulated Driving

Following the iterative approach described earlier, we conducted 3 exploratory iterations. This study was part of a clinical trial registered at ClinicalTrials.gov (NCT04035993).

Driving Setting

The driving setting was the same as in study 0.

In-Vehicle Voice Warning Simulation

On the basis of the results of study 0, we adapted the warning to hypoglycemia instead of low fuel, using the fewest conversational turns possible [47]. To ensure that the drivers were available, the voice assistant started with a receptivity check: "May I disturb you?"

We designed the warning based on the guidelines of the Swiss Diabetes Association [10], which recommends taking carbohydrates and stopping the car as soon as signs of hypoglycemia are noticed. To give the driver a sense of autonomy [48], we designed the warning to suggest eating carbohydrates rather than directly engaging in stopping the car. However, if the driver did not have carbohydrates, they were asked to pull over. On the basis of the feedback, we enhanced

the voice warning used in the following study to recommend pulling over directly (detailed conversation flow is available in [Multimedia Appendix 1](#)).

As in study 0, the warning was simulated with a Wizard-of-Oz method [42], and the turns were generated by recording the same voice. However, to reduce fatigue and cognitive load, we decreased the speed and pitch to 0.93 times the normal speed and -4.8 semitones from the original pitch, respectively. As in study 0, the experimenter would play the turns from a Microsoft Windows laptop using predefined keyboard keys to play prerecorded voice sounds. However, in study 1, the laptop program included a visualization mirrored on a smartphone. The visuals consisted of a blue circle that gradually faded in and out when the voice assistant was speaking. As in study 0, the experimenter's computer was connected to the same sound system as the driving simulators, so that the voice assistant could be heard as part of the driving simulation.

Voice Warning Evaluation Measures

Perception assessment focused on evaluating the voice assistant as a trustworthy driving companion. Specifically, participants completed the Acceptance and Use of Technology (AUT) questionnaire [49,50], the Session Alliance Inventory (SAI) [51], and the Emotional Trust and Competence Trust subscales (henceforth Trust) of the Trust and Adoption questionnaire [52].

To assess technology affinity, participants completed the streamlined scale of the Technology Readiness Index (TRI 2.0) [53]. Items were rated on a 5-point Likert scale (ie, 1=totally disagree, 5=totally agree). We also added a question on whether the participants had previous experience with in-vehicle voice assistants (ie, "Have you already had experience with in-vehicle voice assistants?" with a yes or no answer).

Finally, to obtain qualitative and more in-depth feedback for improvement, we conducted a semistructured interview about their experience with the warning (the interview questions are provided in [Multimedia Appendix 2](#)).

Evaluation Procedure

The procedure was the same as in study 0, except that participants drove only once for 5 minutes (the evaluation procedure is detailed in [Multimedia Appendix 3](#)). Before driving, we ensured that the participants had normal blood glucose levels (5-8 mmol/L).

Data Analysis

The sample of participants was characterized by sex, mean age, and mean duration of their driver's license before the study.

TRI and SAI were aggregated as a whole, and the AUT and Trust items were aggregated per construct. Scores from the negatively formulated questionnaire items were inverted. Previous experience with an in-vehicle voice assistant was reported in terms of frequency. All these reports were aggregated across participants of each iteration, with mean and SD.

To further explain results in perception, they were associated with technology affinity measures. The difference in perception between participants with and without experience with an

in-vehicle voice assistant was tested using a 2-sided t test, and it was correlated with the TRI constructs using a Pearson test.

Compliance was defined as whether the participant would comply with the warning and was coded as binary (0=did not comply, 1=complied). Reaction time was aggregated in seconds with mean and SD. Compliance behavior was aggregated across participants of each iteration.

Feedback was summarized in positive and negative topics, with a focus on the most prominent suggestions for improvement. Feedback was aggregated across participants of each iteration.

Study 2: Assessment With Individuals With T1DM in Real-World Driving Undergoing Hypoglycemia

Following the iterative approach described earlier, we conducted 2 exploratory iterations. This study was part of a clinical trial registered at ClinicalTrials.gov (NCT04569630).

Driving Setting

Participants drove in Volkswagen Touran on a closed circuit accompanied by a driving instructor. Dual pedals allowed the driving instructor to intervene and stop the car if necessary. The driving environments on the test track corresponded to the environments of the driving simulator used in the previous studies. Straight paths, turns, crossroads, stop signs, and a pedestrian crossing with a doll were used to implement the highway, countryside, and town scenarios. Artificial obstacles (eg, boxes and lines of traffic pylons) were used to simulate the traffic.

In-Vehicle Voice Warning Simulation

On the basis of the participant feedback from study 1, we revised the voice warning and addressed low trust ratings by explaining the cause of the warning. We simulated driving behavior as a trigger to detect hypoglycemia while driving, as in the study by Lehmann et al [54]. We created 2 variations of the simplified hypoglycemia notification—one with a statement of the cause (driving behavior) and one without. The final recommendation was reformulated as stricter but less directive than that in study 1.

In the second iteration, we simplified the conversational flow by removing the receptivity check ("May I disturb you?") and the final recommendation ([Multimedia Appendix 1](#) provides the conversation flow).

We used the Wizard-of-Oz method to simulate the warning, as in studies 0 and 1. We implemented the voice assistant in a smartphone with the same voice as in study 1. However, the experimenter had to control it remotely (outside the car), so we implemented the interaction in a smartphone app controlled by a remote desktop application. The experimenter used the smartphone screen to control the voice warning delivery; therefore, no visualization was included. Because of network-related slowdowns in the remote control, we used a combination of remote control and speech-to-text programing.

Voice Warning Evaluation Measures

All measures were the same as in study 1. Reaction time was calculated from the warning onset until the car reached a velocity of 0. In addition, at the end of the experiment, we

included a questionnaire item asking which of the 2 types of warning they preferred, that is, the warning including a statement of the cause that triggered the warning or the one without it, or if they would not use either of them.

Evaluation Procedure

After welcoming participants and explaining the procedure and simulated voice assistant, the voice assistant introduced itself as an in-vehicle assistant to support drivers with hypoglycemia. The participants then completed a training drive.

The warning was delivered at different stages of hypoglycemia (see the study by Lehmann et al [54]). Drive blocks were defined based on blood glucose levels. In the first phase, the participants drove at normal glucose (5-8 mmol/L). In the second phase, blood glucose level was progressively lowered below the moderate hypoglycemia threshold (3.0 mmol/L) to a target range of 2.0 to 2.5 mmol/L. In the third phase, moderate hypoglycemia was maintained. In the fourth phase, participants drove again with normal blood glucose levels (Multimedia Appendix 3).

To explore the effect of blood glucose level on warning perception and compliance, we delivered a warning at the end

of the last drive of each phase. Participants received 2 warnings with an explanation and 2 without, in randomized order.

Data Analysis

Data analysis was carried out as in study 1.

Ethical Considerations

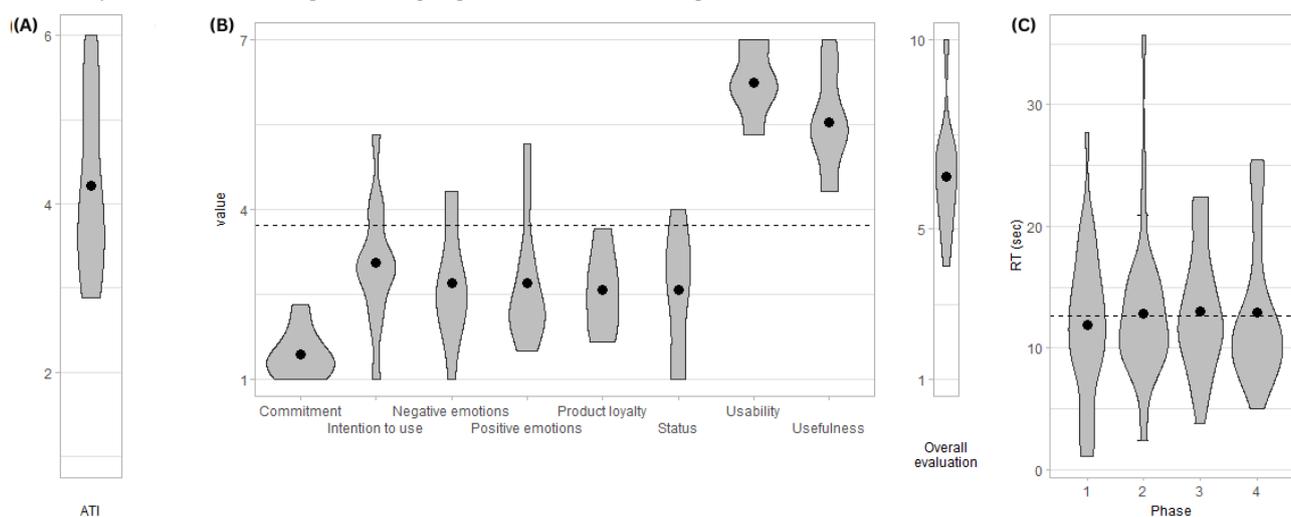

Study 0 was approved by the Ethics Board of ETH Zürich, Switzerland (2019-N-32), and study 1 and study 2 were approved within the context of the HEADWIND study by the cantonal ethics commission of Bern, Switzerland (2020-00685 and 2021-02381, respectively). Study 1 and study 2 are available at ClinicalTrials.gov (NCT04035993 and NCT04569630, respectively). All participants provided written informed consent.

Results

Study 0: Preliminary Assessment With Healthy Individuals in Simulated Driving

Results are summarized in Figure 1.

Figure 1. Violin plots of (A) Affinity for Technology Interaction (ATI; min=1, max=6), (B) score values across the constructs of modular evaluation of key Components of User Experience (meCUE; min=1, max=7, except for overall evaluation, which is min=1, max=10), and (C) reaction time across phases in study 0 (n=11). The dots represent the group mean; the dashed line represents the overall mean. RT: reaction time; sec: seconds.

Recruitment and Participants

We recruited 11 healthy individuals with a valid driver's license via a web advertisement (ie, University of Zurich marketplace). One participant was excluded owing to simulator sickness. Thus, we included 10 participants (n=4, 40% female; n=6, 60% male) with an average age of 30.4 (SD 7.8; range 23-47) years and holding a license for 11 (SD 7.5; range 2-26) years, on average.

Technology Affinity Measure

Participants showed a mean ATI of 4.2 (SD 1; Cronbach $\alpha=.91$), which is 70% of the maximal value.

Perception Measure

The meCUE (Cronbach $\alpha=.7$) revealed a mean overall evaluation of 6.4 (SD 1.6), which is 64% of the maximal value. Moreover, the highest mean values were achieved for usability

(mean 6.2, SD 0.6, 89%) and usefulness (mean 5.6, SD 0.9, 80%), whereas lower values were observed for commitment (mean 1.5, SD 0.4, 21%), positive emotions (mean 2.7, SD 1.1, 39%), negative emotions (mean 2.7, SD 1, 39%), intention to use (mean 3.1, SD 1.1, 44%), and product loyalty (mean 2.6, SD 0.7, 37%). A low value for negative emotions reflects a more positive evaluation.

To explain the perception results with the technology affinity measure, we correlated each meCUE construct with ATI. We observed a correlation between ATI and intention to use ($\rho=0.70$; $P=.02$). All the other correlations were not significant at the .05 level.

Compliance Measure

All the participants complied with the warning and stopped the car. Participants took 12.6 (SD 5.7) seconds on average.

Qualitative Feedback

Finally, some participants reported that the voice assistant spoke too fast to deliver information during a driving task without being distracting.

Study 1: Assessment With Individuals With T1DM in Simulated Driving

Results are summarized in Figures 2 and 3.

Figure 2. Violin plots of (A) count of previous experience, (B) score values across the constructs of Technology Readiness Index (TRI; min=1, max=5), (C) score values across the constructs of Acceptance and Use of Technology (AUT; min=1, max=5), (D) Session Alliance Inventory (SAI) scores (min=1, max=5), (E) Trust scores (min=1, max=5), and (F) reaction time across iterations in study 1 (n=18). The dots represent the group means; the dashed line represents the overall mean within an iteration. RT: reaction time; sec: seconds.

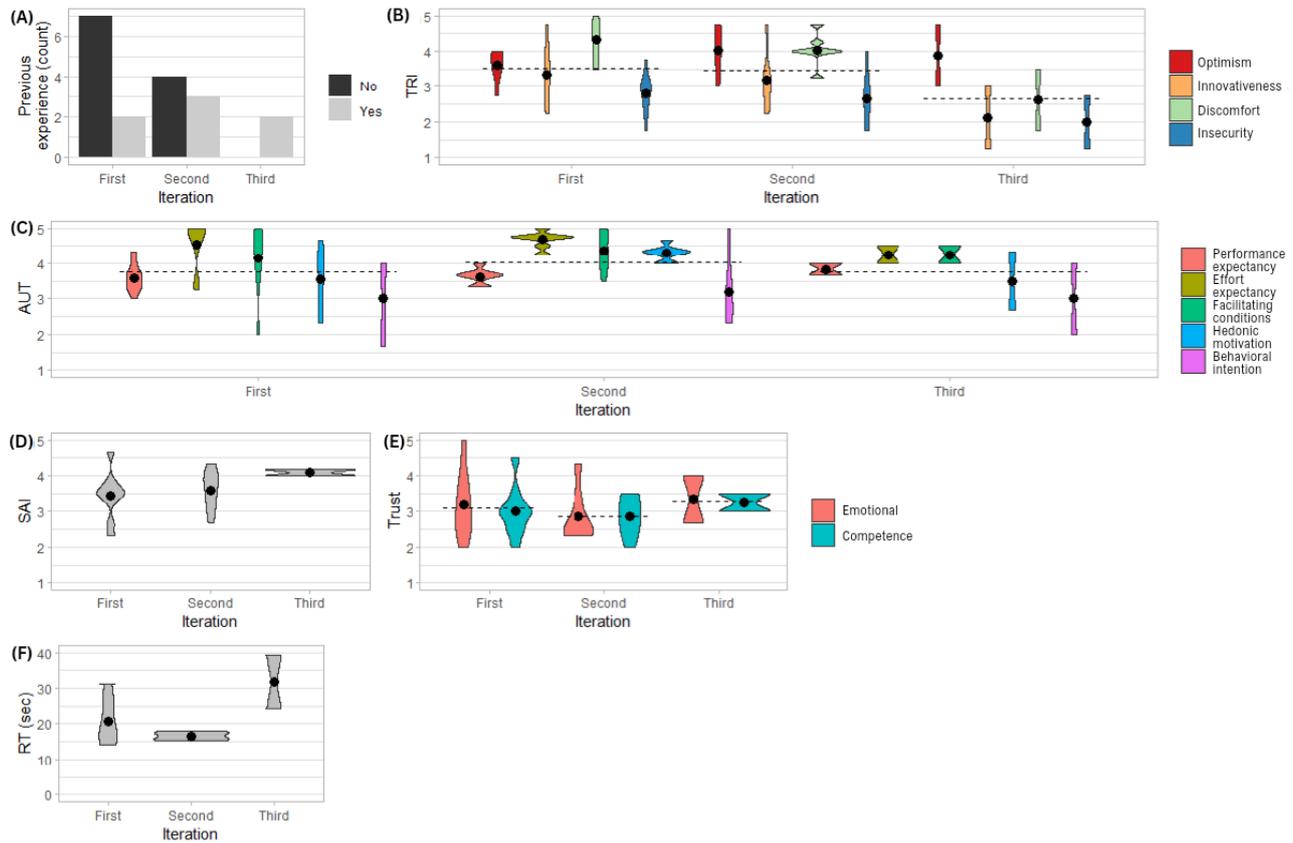

Figure 3. Thematic summary of participants' feedback in study 1 (n=18).

	Iteration		
	First (n=9)	Second (n=7)	Third (n=2)
Content to add	Always suggest to stop the car (n=4)	Always suggest to check blood glucose (n=4)	
Content to remove		Asking to wait 30 minutes may be irrelevant (n=2)	Shorter warning (n=1)
Formulation		Not dropping but too low (n=3)	

Recruitment and Participants

We recruited 20 patients with T1DM from the Department of Diabetes, Endocrinology, Nutritional Medicine, and Metabolism at the Bern University Hospital. Participants needed functional insulin treatment, good insulin self-management knowledge, a driver's license, and active driving in the past 6 months. We excluded one participant owing to simulator sickness and one participant owing to technical errors in the warning delivery. This resulted in a total of 18 participants ($n=6$, 33% female and $n=12$, 67% male; mean age 31.4, SD 7, range 24-44 years; mean driver's license age 13, SD 7.5, range 4.5-28.6 years). The first iteration had 9 participants, the second iteration had 7, and the third iteration had 2 participants. Although the last iteration's sample size was small, it provided useful feedback to improve the warning for study 2.

Technology Affinity Measure

Seven participants had previous experience with an in-vehicle voice assistant ($n=2$, 28% in the first iteration; $n=3$, 43% in the second iteration, and $n=2$, 28% in the third iteration). TRI was 3.4 (SD 0.6, Cronbach $\alpha=.85$), or 68% of the maximum. Specifically, TRI was 3.5 in the first and second iterations (SD 0.6 and 0.7, respectively) and 2.7 in the third iteration (SD 0.9).

Perception Measure

Perception averaged 3.9 out of 5 (SD 0.8, 78%) and remained stable across iterations. Average AUT (Cronbach $\alpha=.81$) values were 3.8 (SD 1) in the first iteration, 4 (SD 0.7) in the second iteration, and 3.8 (SD 0.8) in the third iteration. Effort expectancy and facilitating conditions had the highest values across all iterations, whereas behavioral intention always had the lowest values.

SAI (Cronbach $\alpha=.79$) averaged 3.7 out of 5 (SD 0.5, 74%) and increased slightly over the iterations, from 3.4 (SD 0.7) in the first iteration to 3.6 (SD 0.6) in the second iteration to 4.1 (SD 0.1) in the third iteration.

Trust (Cronbach $\alpha=.8$) averaged 3.1 out of 5 (SD 0.7, 62%), was stable across constructs, and had the lowest values of the 3 perception measures. Trust averaged 3.1 (SD 0.8) in the first iteration, 2.9 (SD 0.6) in the second iteration, and 3.3 (SD 0.6) in the third iteration.

To explain the perception results with technology affinity, we tested the difference in perception (AUT, SAI, and Trust) between participants with and without previous experience with in-vehicle voice assistants. The means of all constructs, excluding facilitating conditions, were slightly higher for participants with previous experience. However, a 2-sided *t* test revealed no significant result (ie, $P>.05$).

We also correlated perception with TRI and observed a correlation between the optimism construct and performance expectancy ($\rho=0.49$; $P=.04$), behavioral intention ($\rho=0.52$; $P=.03$), and SAI ($\rho=0.57$; $P=.01$). All the other correlations were not significant ($P>.05$).

Compliance Measure

All the participants complied with the warning. In the first iteration, all participants answered *yes* or *no* to the receptivity check ("May I disturb you?") and when asked if they had carbohydrates on hand. Five of the 9 participants answered *yes* to the latter question, although they did not. Two of those 9 participants stopped the car although they were not explicitly advised to do so. In the second iteration, all participants answered the prompts with *yes* and stopped the car as advised. One participant gave an affirmative *mhm* when asked, "May I disturb you?" during the hypoglycemic phase but were otherwise compliant. Because we used the Wizard-of-Oz method, the experimenter interpreted the affirmation. However, a current voice assistant might have interpreted it as an error. In the third iteration, both participants answered the prompts with *yes* and stopped the car. Across iterations, compliance took approximately 22 seconds. In particular, compliance took approximately 20 (mean 20.7, SD 6.2) seconds in the first iteration, approximately 17 (mean 16.7, SD 1.2) seconds in the second iteration, and approximately 31 (mean 31.7, SD 10.6) seconds in the third iteration.

Qualitative Feedback

Participants judged the voice warning as pleasant, simple, and as clear and efficient ($n=15$, $n=11$, and $n=13$, respectively). The topics for improvement are summarized in [Figure 3](#). Note that these results are best understood when compared with [Multimedia Appendix 1](#).

Given that Trust showed the lowest values in the first iteration, in comparison with the other perception measures, we decided to specifically ask participants, in our second and third iterations, what would help them trust the warning more. Of the 9 participants included in both the second and third iterations, 5 (55%) said they would just need to have a prolonged experience with the warning, whereas 3 (33%) said they would need to know what kind of data is used to infer that the driver is about to experience hypoglycemia. One participant did not know what would improve their trust.

Study 2: Assessment With Individuals With T1DM in Real-World Driving Undergoing Hypoglycemia

Results are summarized in [Figures 4](#) and [5](#).

Figure 4. Violin plots of (A) count of previous experience, (B) score values across the constructs of Technology Readiness Index (TRI; min=1, max=5), (C) score values across the constructs of Acceptance and Use of Technology (AUT; min=1, max=5), (D) Session Alliance Inventory (SAI) scores (min=1, max=5), (E) Trust scores (min=1, max=5), and (F) reaction time across iterations in study 2 (n=20). The dots represent the group means; the dashed line represents the overall mean within an iteration.

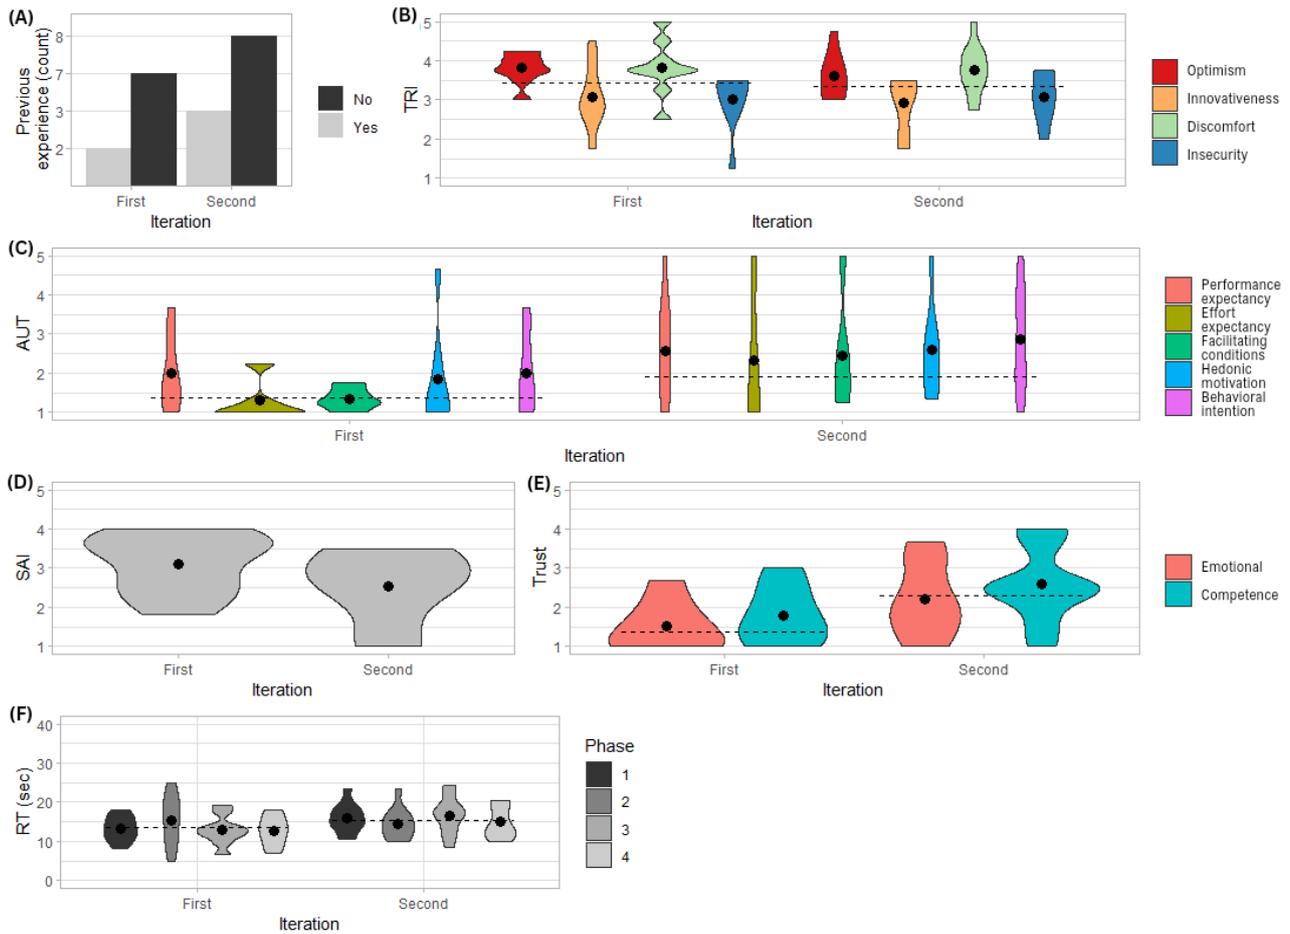

Figure 5. Thematic summary of participants' feedback in study 2 (n=20).

		Iteration	
		First (n=9)	Second (n=7)
Content to remove		Too wordy in general (n=3)	
		Recommendation is superfluous (n=4)	
		Receptivity check is superfluous (n=4)	
Formulation		Not driving style but driving behavior (n=1)	Not asking verbal confirmation but giving automatic feedback (n=2)
			Too polite (n=2)

Recruitment and Participants

The recruitment procedure was the same as in study 2. We recruited 21 individuals, and 1 participant was excluded owing to data loss. Thus, we included 20 participants ($n=3$, 15% female and $n=17$, 85% male; mean age 40.9, SD 10.6, range 23-57 years; and holding a license on average since 23.7, SD 11.1, range 3.1-42.4 years). The first iteration included a sample of 9 participants and the second iteration included a sample of 11 participants.

Technology Affinity Measure

The pretest measurements revealed that 25% (5/20) of the participants had previous experience with an in-vehicle voice assistant (2 in the first iteration, and 3 in the second iteration), whereas TRI was on average 3.4 (SD 0.7; Cronbach $\alpha=.44$), which is 68% of the maximal value. In particular, TRI was 3.4 in the first iteration (SD 0.8), and 3.3 in the second iteration (SD 0.7).

Perception Measure

The overall perception score was 1.7 out of 5 (SD 1.3, 34%). The results showed a slight increase in mean AUT (Cronbach $\alpha=.95$) and Trust (Cronbach $\alpha=.85$) values between the first and the second iteration, whereas SAI (Cronbach $\alpha=.80$) showed a slight decrease. AUT also showed a considerable increase in SD. In particular, AUT values were on average 1.4 (SD 1) in the first iteration, and 1.9 (SD 1.6) in the second iteration; SAI was overall 2.8 out of 5 (SD 0.8, 56%). Values were on average 3.1 (SD 0.7) in the first iteration and 2.5 (SD 0.9) in the second iteration; Trust values were on average 1.4 (SD 0.8) in the first iteration, and 2.3 (SD 1.1) in the second iteration.

Similar to study 1, to explain the perception results with the technology affinity measure, we tested the difference in perception (ie, AUT, SAI, and Trust) among participants who had previous experience with in-vehicle voice assistants and those who did not. The means of all perception measures, excluding SAI, were consistently slightly higher in the second iteration. The means of all constructs, excluding SAI, were consistently slightly higher for participants who had previous experience with in-vehicle voice assistants. However, a 2-sided t test revealed no significant result (ie, $P>.05$). When correlating each perception measure with TRI, we observed a correlation between innovativeness and hedonic motivation ($\rho=.052$; $P=.02$), a negative correlation between discomfort and behavioral intention ($\rho=-0.46$; $P=.04$), and a negative correlation between discomfort and competence trust ($\rho=-0.45$; $P=.05$). All the other correlations were not significant ($P>.05$).

Compliance Measure

All the participants complied with the warning. Two drives were excluded: one participant stopped once before the warning was delivered and data from one drive of one participant was lost. The results showed that the reaction time does not seem to vary across glycemic phases and, although minimal, there is a tendency for the reaction time to increase in the second iteration. Participants took 13.6 (SD 4.5) seconds in the first iteration and 15.5 (SD 4.1) seconds in the second iteration.

Preference for the Disclosure of the Triggering Cause

One participant was excluded because of data loss. The results showed that although 10 participants preferred when the warning was delivered with an explanation for the warning being triggered (in this case, driving behavior), 8 participants preferred it without the explanation. One participant stated that they would not use this in-vehicle voice warning either way.

Qualitative Feedback

In general, and similar to study 1, the participants found the communication style pleasant and efficient ($n=4$ and $n=5$, respectively). The topics for improvement are summarized in Figure 5. Note that these results are best understood when compared with Multimedia Appendix 1.

Discussion

Principal Findings

Most participants had not previously used an in-vehicle voice assistant, and technology affinity was similar across studies. In general, the voice warning elicited a positive perception, although the perception values were lower in the real-car study. In addition, participants complied with the warning in all studies, and reaction times were shorter in the real-car study than in the simulator study. Finally, the participants preferred the voice warning to be less verbose and prompt fewer interactions with the driver.

Technology Affinity

Although we did not observe a significant effect on the perception of the warning, we suspect that the participants may have experienced a double novelty: using a voice assistant while driving and experiencing a warning from an in-vehicle voice assistant. Thus, future research should include a more balanced sample and compare the perception of a voice assistant-based warning with a standard warning (eg, an acoustic tone). Moreover, although we cannot directly compare ATI (used in study 0) with TRI (used in study 1 and study 2), we can observe that technology affinity was similar across studies. Although ATI showed a mean of 4.2 over 7 (60%), TRI showed a mean of 3.4 over 5 both in study 1 and study 2 (68%). The change in technology affinity measure was the result of an internal discussion between the coauthors, and we recommend the scientific community to use TRI in future research, as it is more widely used and focuses not only on the interaction but also on the general attitudes toward new technologies.

Perception

We observed that AUT, SAI, and Trust values were higher in study 1 (simulated driving) than in study 2 (real-world driving). This evaluation might have been influenced by the driving setting. There can be 2 possible reasons. First, participants may have found the warning to be more distracting in the real car than in the simulator. However, research shows that drivers are more in control in real-world driving than in simulated driving [55]. Second, the technical difficulties in controlling the driver-assistant interaction owing to network slowdowns might have affected the user experience, and thus the perception measures. Future Wizard-of-Oz studies may account for this

methodological weakness with a more accurate text-to-speech technology, avoiding remote control, and reducing interactions.

In addition, TRI seemed to have influenced behavioral intention (AUT) but did not consistently influence the other perception measures (ie, other constructs of AUT, SAI, and Trust). Thus, participants may have been excited about the potential of the voice warning, but they may not have been happy with the actual experience of using it.

Compliance

The reaction times were short enough to ensure a timely reaction to the critical event. Blood glucose can change with a maximum rate of 0.22 mmol/L/min [56]. This means that someone driving with a normal glucose of 5.5 mmol/L might reach hypoglycemia (ie, 3.9 mmol/L) within a minimum of 7.5 minutes. Thus, although experiencing hypoglycemia while driving does not require an abrupt stop but rather a careful pullover maneuver and treating the condition, measuring reaction time provided an insight into the time required to take the first measure (ie, pullover). Interestingly, the reaction time was shorter in the real car (study 2) than in the simulator (study 0 and study 1). This difference may be attributed to the lack of traffic in study 2, which allowed the driver to pull over faster.

Feedback

Although we aimed to keep the warning conversational, participants preferred a more direct notification of the problem without specific recommendations (eg, recommending waiting until the blood glucose is at its normal level) or polite formulations (eg, asking for permission to talk). To the best of the author's knowledge, there was no in-vehicle voice warning at the time of the study, and we mostly relied on the guidelines of the Swiss Diabetes Association [10], while keeping the conversation as simple as possible. The participants' feedback allowed us to improve the warning in this direction.

Implications and Future Directions

Hypoglycemia Warnings

Reportedly, no research has been conducted for in-vehicle applications providing a hypoglycemia warning. However, smartphone apps for hypoglycemic events tracking have been investigated [57]. Although most of the research on glucose monitoring solutions conducted so far focused on diary apps rather than warning delivery, a pilot study on a smartphone-based hypoglycemia warning showed an improved hypoglycemia awareness and a reduction in daytime hypoglycemia [58] (other research is still in the phase of validation [59]). Future research should investigate such outcomes with an in-vehicle extension of this type of application.

In-Vehicle Warnings

Although there seems to be no related work testing the voice assistant of a private vehicle to deliver hypoglycemia warnings, there is a need for "driver-friendly" in-vehicle glucose monitoring solutions, expressed by the online community [25]. In particular, drivers with T1DM have contributed to the Nightscout Foundation [60], a nonprofit organization founded in 2014 and supporting open source technology for T1DM

management, with the development of a data-sharing app, able to connect a car to a CGM, and display the glucose trends while driving on the dashboard of the private vehicle [25]. Moreover, there has been conceptual work manifesting the need for collaboration between automotive and medical industries to improve the safety of drivers with T1DM [24]. However, this work has not been followed by any implementation. Furthermore, no testing with the actual users has been conducted. Our work provides preliminary evidence, both in a simulated and a real-world environment.

Needless to say, recognizing hypoglycemia is only one part of glucose monitoring while driving; general imbalance of blood glucose (including hyperglycemia) can be problematic for the driver, if not dangerous [61]. Our work can be extended to hyperglycemia and, therefore, support further the safety of drivers with T1DM.

Finally, using the in-vehicle voice assistant to deliver a warning is compatible with current technology: not only are cars increasingly equipped with voice assistants [26,27] but also the automotive industry is aware of the relevance of using the upcoming "in-car proactivity" [62].

Warning Escalation

Our results showed 100% compliance in all 3 studies. This can only mean that the warning was clear enough for the participant to understand that it was time to pull over. That is, as all studies were run in a controlled setting, where an experimental team was present, and the participant knew they would be recommended to pull over eventually, we can safely assume that the experiments experienced a participant bias [63]. Thus, we cannot conclude that the warning was compelling enough to motivate the participants to comply (see the Limitations section). Nevertheless, the warning should be designed to allow for escalation, whereas in case the driver does not pull over in due time (eg, 2-3 min [56]) or explicitly rejects the warning, delayed reprompts with an increasingly severe tone would be delivered by the voice assistant (eg, "You are at risk of hypoglycemia. Please stop the car safely and check your blood sugar, then risk of hypoglycemia. Pull over now").

Hypoglycemia Detection

Finally, in this paper, we focus on the interface between the hypoglycemia detection system and the driver, with the aim of visually distracting them as little as possible. Although the detection side is beyond the scope of this study, the designed warning is intended to be produced by a voice assistant built into the vehicle. Therefore, how a vehicle monitors blood sugar depends on the technology of the car. For instance, the aforementioned open source app displaying the glucose levels on the dashboard of a private vehicle [25] could be enhanced to connect with the in-vehicle voice assistant and use a voice warning instead of a visual one. Furthermore, research has been conducted on how to detect hypoglycemia from the car's data [54] and from consumer-available wearable devices [64], with the argument that CGM devices can impose a social and financial burden on the individual.

Limitations and Strengths

Despite our best efforts, this research has 3 main limitations.

First, the studies included a relatively small sample size. However, this study includes 3 feasibility studies (ie, a preliminary study with healthy individuals and 2 feasibility studies with individuals with T1DM), and the research presented in this paper is intended to be understood as an iterative development of a hypoglycemic warning. As such, this research aimed to pioneer the use of in-vehicle voice assistants for a driver health-related warning, rather than draw conclusions to be generalized to the population with T1DM. Thus, although we included a total sample size of 48 individuals, each feasibility study provides insight into the changes required by the users, and we provide the scientific community with an opening to the design of in-vehicle voice assistant-based health-related warning. Furthermore, previous studies on digital health systems used a similar sample size [65-67]. Thus, we believe that although the sample size does not allow drawing conclusions on the interaction of drivers with T1DM with in-vehicle hypoglycemia warnings, it still reports pioneer research.

Second, the studies were conducted over a short period. The participants had only a short-term experience with the warning. Perception and compliance may therefore be influenced by the novelty of such an experience, whereas perception may stabilize with repeated experience [68]. Future research should investigate the user experience of the warning in a longitudinal study. Third, these studies did not control for all potentially confounding variables related to real-world traffic and driver's priorities. For instance, both simulator and real-car experiments involved disadvantages: while assessing the warning in a simulator allowed a controlled and safe experiment, such a setting remains artificial and lacks external validity. In contrast, while testing it in a real car increased the ecological validity of the human-machine interaction, it did not allow for as much traffic and speed variation as was possible in the simulator. Future research should investigate the effects of real-world traffic on the perception of the warning and compliance behavior. Moreover, receiving a warning in the presence of a team of experimenters may have influenced the participant's verbal and behavioral responses; participants knew they would receive the

warning sooner or later and had no reason not to follow it (eg, ignoring the warning because of being late for an appointment). In a real situation, drivers may not respond as expected or may even ignore the warning. Future research should test such a warning in a more ecological context, for instance, in a field study where the driver may not fall for a participant bias [69].

Finally, as we aimed to test a voice warning, our studies used a Wizard-of-Oz methodology to avoid problems related to natural language processing. Note that our studies were conducted in German-speaking Switzerland, where the German accents easily vary from region to region. As this aspect was beyond the scope of our research, we did not implement a working voice assistant or account for potential fallback intents triggered by the voice assistant's failure to understand the user. Future research should push this research further and examine the potential danger of delayed treatment of hypoglycemia owing to the voice assistant's natural language processing errors.

Conclusions

Although hypoglycemia increases the risk of car mishaps [7,8], current solutions (eg, CGM and FGM) require visual human-machine interaction, which is inappropriate for an in-vehicle context. As voice assistants are increasingly present in private vehicles [26,27] and the European Commission fosters safety technologies inside the car [16], we propose to warn the driver of their critical health state through a voice assistant-based health warning. This paper reports on an iterative development and assessment of a hypoglycemia warning. In particular, we conducted in 3 studies: a preliminary study using a simulator with healthy participants, a test with individuals with T1DM in a simulator, and a test with individuals with T1DM in a real car. This gradual increase in authenticity in the experimental design allowed us to increase the ecological validity of our results while keeping experimental control. To the best of our knowledge, this is the first attempt of such a comprehensive feasibility assessment of an in-vehicle voice warning for hypoglycemia. Our results suggest that a voice warning can be useful, but that proactive behavior in voice assistants is still emerging and unfamiliar. We hope that these preliminary findings will foster future research to further develop in-vehicle hypoglycemia warnings.

Acknowledgments

The authors would like to thank the Swiss Federal Department of Defense, Civil Protection and Sports for providing the closed circuit used in study 2.

This work was partly funded by the Swiss National Science Foundation, Sinergia Project (CRSII5 183569).

Abstract

Background: Falls are common in people with multiple sclerosis (MS), causing injuries, fear of falling, and loss of independence. Although targeted interventions (physical therapy) can help, patients underreport and clinicians undertreat this issue. Patient-generated data, combined with clinical data, can support the prediction of falls and lead to timely intervention (including referral to specialized physical therapy). To be actionable, such data must be efficiently delivered to clinicians, with care customized to the patient's specific context.

Objective: This study aims to describe the iterative process of the design and development of Multiple Sclerosis Falls InsightTrack (MS-FIT), identifying the clinical and technological features of this closed-loop app designed to support streamlined falls reporting, timely falls evaluation, and comprehensive and sustained falls prevention efforts.

Methods: Stakeholders were engaged in a *double diamond* process of human-centered design to ensure that technological features aligned with users' needs. Patient and clinician interviews were designed to elicit insight around ability blockers and boosters using the capability, opportunity, motivation, and behavior (COM-B) framework to facilitate subsequent mapping to the Behavior Change Wheel. To support generalizability, patients and experts from other clinical conditions associated with falls (geriatrics, orthopedics, and Parkinson disease) were also engaged. Designs were iterated based on each round of feedback, and final mock-ups were tested during routine clinical visits.

Results: A sample of 30 patients and 14 clinicians provided at least 1 round of feedback. To support falls reporting, patients favored a simple biweekly survey built using REDCap (Research Electronic Data Capture; Vanderbilt University) to support *bring-your-own-device* accessibility—with optional additional context (the severity and location of falls). To support the evaluation and prevention of falls, clinicians favored a clinical dashboard featuring several key visualization widgets: a longitudinal falls

display coded by the time of data capture, severity, and context; a comprehensive, multidisciplinary, and evidence-based checklist of actions intended to evaluate and prevent falls; and MS resources local to a patient's community. In-basket messaging alerts clinicians of severe falls. The tool scored highly for usability, likability, usefulness, and perceived effectiveness (based on the Health IT Usability Evaluation Model scoring).

Conclusions: To our knowledge, this is the first falls app designed using human-centered design to prioritize behavior change and, while being accessible at home for patients, to deliver actionable data to clinicians at the point of care. MS-FIT streamlines data delivery to clinicians via an electronic health record-embedded window, aligning with the *5 rights* approach. Leveraging MS-FIT for data processing and algorithms minimizes clinician load while boosting care quality. Our innovation seamlessly integrates real-world patient-generated data as well as clinical and community-level factors, empowering self-care and addressing the impact of falls in people with MS. Preliminary findings indicate wider relevance, extending to other neurological conditions associated with falls and their consequences.

Introduction

Background

Falls are common in patients with multiple sclerosis (MS), occurring in 50% to 70% of published cohorts, a rate similar to that of older adults [1]. Falls often lead to injury, result in significant health care costs [2-5], and increase *thefear of falling* [6,7]; furthermore, they lead to a decline in physical activity and participation in daily life as well as cause loss of independence [8,9]. Targeted interventions such as physical therapy (PT) can reduce falls and the fear of falling [10-12], but patients often underreport and clinicians undertreat this issue. Indeed, fewer than half of the people with MS who report falls receive falls prevention information from their clinician [13], and there is a lack of self-management apps to engage and empower people with MS about falls prevention [14-16].

To address this gap, multimodal closed-loop tools hold promise. Closed-loop tools can use real-time feedback and patient-generated data (PGD; such as those already validated in MS [17-22]) to continuously monitor and adjust interventions to improve outcomes. Such an approach has been used in biological functions and symptoms, such as insulin delivery or depression [23-25]. Unfortunately, in MS, apps on the commercial market exist outside of the health system, that is, away from the point of care. To close these gaps in care, a tool should close the loop of information flow from the patient to the appropriate clinician (depending on the diagnosis and symptoms being treated, ie, neurologist) at the point of care and back to the patient to support patient-centered care. Furthermore, the tool must address the behavioral barriers to change to promote the behaviors (eg, reporting, screening, treatment recommendations, and follow-up with timely refills or referral scheduling) likely to lead to falls prevention. From previous work, real-time PGD such as prospective near-falls reports, patient-reported outcomes, and changes in step count captured by wearable sensors all provide useful input for the closed-loop models [26,27]. The integration of these in a multimodal tool would enhance falls prediction accuracy and could act as an early warning system for timely PT referrals, reducing falls risk and related injuries [28,29]. However, challenges lie in

delivering PGD to the point of care, granting access for prompt intervention, and active self-management. To be actionable, these PGD, generated from remote devices or patient-reported outcomes, must be delivered according to the *5 rights* [30]: the right information, to the right person, in the right format, through the right channel, at the right time in the workflow. This is a hurdle that health systems have for the most part not yet overcome, and PGD are not typically integrated into care systems.

To address these challenges, we developed Multiple Sclerosis Falls InsightTrack (MS-FIT), a closed-loop falls monitoring and prevention app. MS-FIT enables seamless information exchange between patients and clinicians, driven by stakeholder input and human-centered design (HCD) principles [31,32]. It empowers individuals with MS to *track* falls, enhances clinician decision-making by providing real-world *insights*, and fills a crucial gap in self-management for falls monitoring and prevention.

Objectives

This paper describes the iterative process of the design and development of MS-FIT. MS-FIT is designed to integrate various data types to personalize falls risk assessments and interventions for individuals with MS. To achieve this, a planned process of engagement of patients and clinicians (ie, neurologists) was performed to ensure that MS-FIT aligns with user needs, whereas usability evaluations validated its potential impact on falls prevention. Subsequently, we will test the feasibility of implementation and effectiveness of MS-FIT in a larger clinical trial.

Methods

Study Setting

The primary clinical setting is the University of California San Francisco (UCSF) Multiple Sclerosis and Neuroinflammation Center, which provides specialized care to >6000 adults with MS annually. Clinician stakeholders were approached via email or in person and invited to participate in the study. Patients who had given permission to be contacted for research participation

or who had sustained falls in the past year were invited via secure email to participate as stakeholders.

Ethical Considerations

The University of California San Francisco Institutional Review Board approved all study activities (22-36680). Informed consent forms and Health Insurance Portability and Accountability Act documents were signed by each study participant (patients, clinicians, and other interviewees). Patients received US \$50 (1-time compensation) for their participation in the study.

Study Design

The overarching approach was grounded in the principles and phases of HCD [31]. This process focuses on the usability and needs of those whom the tool is meant to serve, in this case, patients and clinicians. The development protocols included (1) thorough engagement from a comprehensive range of stakeholders, (2) models based on HCD approaches to ensure alignment with the needs of the intended users (patients and clinicians), (3) an evaluation of the tool’s usability using an established framework: the Health IT Usability Evaluation Model (Health-ITUEM) [33], and (4) plans to support the generalizability and scalability of the tool to other clinical settings associated with falls.

HCD involves a series of steps, articulated initially in the context of design [34] and expanded to health care [35]: inspire (empathize with all stakeholders), ideate (define the problem

and conceptualize in an open-minded manner), implement (prototype solutions and test), and iterate. Figure 1 illustrates these phases in a *modified double diamond* approach as they were undertaken in the current project, depicting the iterative broadening and narrowing of content and layout throughout the phases [36]. Figure 2 shows the trajectory of MS-FIT and the assimilation of insights obtained from user interviews (involving patients and clinicians) throughout the phases of discover, define, develop (iterative), and deliver.

The initial prototype (prediscover) was developed based on feedback from extensive HCD of the BRIDGE point-of-care clinical dashboard (refer to the Technological Building Blocks subsection) summarized elsewhere [37,38], where both patients and clinicians expressed a desire for the integrations of features and episodes of falls to be incorporated into the design. The study team initially identified key elements for MS-FIT through a combination of clinical expertise and literature review [39,40] (Figure 3). These elements were then amalgamated into mock app screens using PowerPoint (Microsoft Corp) for the first round of patient interviews. Figure 3 illustrates the inaugural prototype, which was informed by valuable insights from observational [41] and interventional [39] studies that used PGD to monitor walking and falls in individuals with MS. In addition, the prototype draws inspiration from clinician-facing [42] and patient-facing [43] apps designed using HCD principles to promote shared decision-making and evidence-based practice in MS.

Figure 1. Modified double diamond approach: phases of development and stakeholder engagement. The double diamond depicts the human-centered design principles and framework, with iterations through the discover, define, develop, and delivery phases. The timeline and workflow of the human-centered design phases depict corresponding interviews and products. The curved arrows between “Define” and “Develop” indicate an iterative process between these 2 phases. MS: multiple sclerosis; MS-FIT: Multiple Sclerosis Falls InsightTrack; MVP: minimum viable product; PD: Parkinson disease; REDCap: Research Electronic Data Capture.

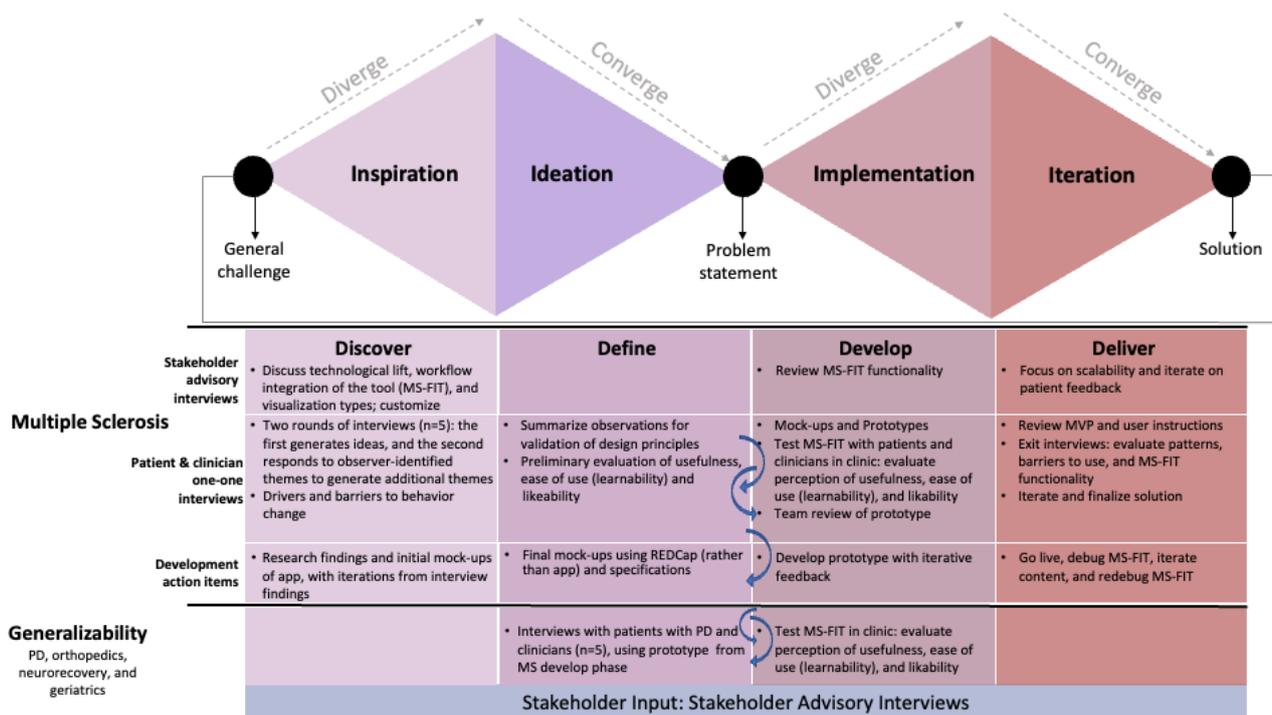

Figure 2. The trajectory of Multiple Sclerosis Falls InsightTrack (MS-FIT) through the phases of development and stakeholder engagement. The final tool components include a patient survey (MS-FIT patient survey) and a clinical dashboard (MS-FIT BRIDGE). The trajectory integrates feedback from user (patient and clinician) interviews through the phases of discover, define, develop (iterative), and deliver. The version numbers indicate a revised version of the patient- or clinician-facing prototype. “Other patients” refers to patients with Parkinson disease as well as orthopedics, neurorecovery, and geriatrics populations. “Full test” refers to the prototype testing in the contextual environment. MS: multiple sclerosis.

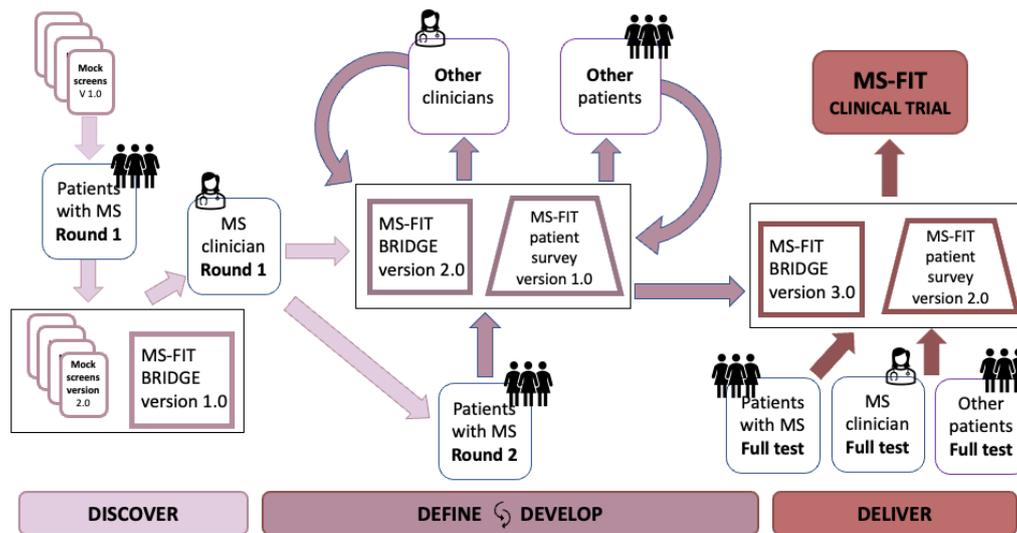

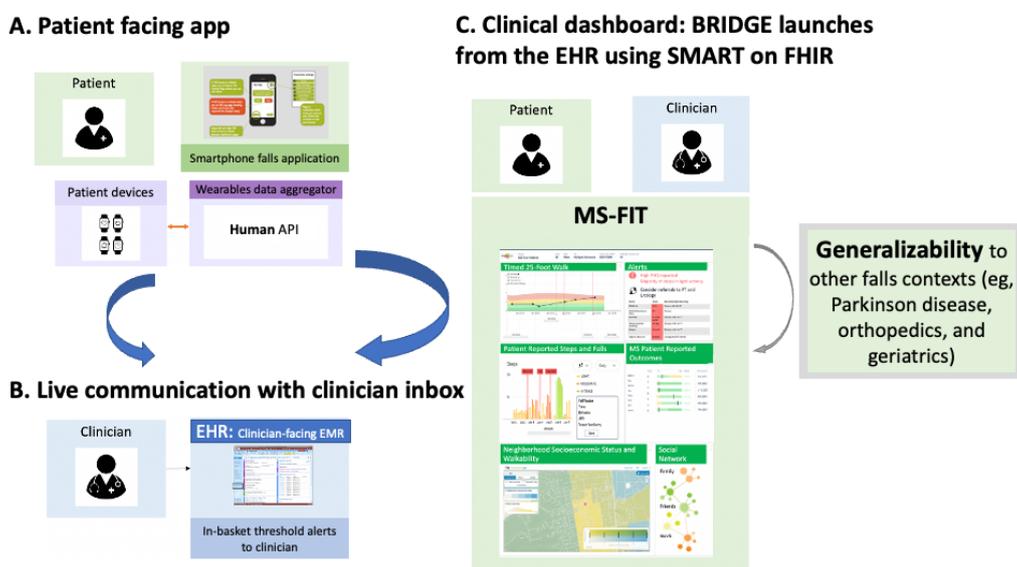

Figure 3. Initial proposal for Multiple Sclerosis Falls InsightTrack (MS-FIT), which involved designing a closed-loop integrated MS-FIT personal health library. MS-FIT is designed to enable patients to track their falls in the context of their lived experience, report them to their care team, and gain insight into multimodal contributors to falls, falls’ impact on daily life participation, and interventions likely to prevent falls. Clinicians, by using BRIDGE, can gain insight into which patients are falling between clinical encounters and how best to personalize risk reduction interventions for the individual patient. This prototype was generated from a number of insights from observational and interventional studies that used patient-generated data to monitor walking and falls in people with multiple sclerosis (MS) and from clinician-facing [42] and patient-facing [43] apps designed using human-centered design to facilitate shared decision-making and evidence-based practice in MS. (A) Patient facing app; (B) Live communication with clinician inbox; (C) Clinical dashboard: BRIDGE launches from the EHR using SMART or FHIR. API: application programming interface; EHR: electronic health record; EMR: electronic medical record; FHIR: Fast Healthcare Interoperability Resources; MS-FIT: Multiple Sclerosis Falls InsightTrack; SMART: Substitutable Medical Apps and Reusable Technologies.

Framework for Tool Evaluation

The Health-ITUEM framework appraises both subjective and objective outcomes that inform a tool’s usability [44]. In the design phases described herein, the subjective outcomes (satisfaction measured by the perceived ease of use and perceived usefulness) were primarily evaluated. Furthermore, the 4 key variables proposed by Mathews et al [45] to determine both (1) whether the tool (MS-FIT) reflects HCD principles and

(2) whether it is likely to engage patients were applied. These four domains encompass (1) usefulness, (2) ease of use or learnability, (3) likability, and (4) effectiveness. These frameworks were used to categorize critical data and visualization elements, as well as the technological and clinical workflow aspects of MS-FIT [46].

Technological Building Blocks

The architecture of the tool was built leveraging existing tools, primarily BRIDGE and REDCap (Research Electronic Data Capture; Vanderbilt University).

BRIDGE

The BRIDGE precision medicine platform at UCSF is an application programming interface (API) that assembles clinical and research data from a variety of sources into a dashboard customized for a given clinical context, displaying a series of digestible, actionable visualizations [38]. BRIDGE is integrated with the Epic electronic health record (EHR; Epic Systems Corporation), launches from Epic using Substitutable Medical Apps and Reusable Technologies (SMART) on Fast Healthcare Interoperability Resources (FHIR; a standard approach for building reusable and extendable EHR-integrated apps), and is integrated with Epic FHIR APIs and other data integrations. The back-end of BRIDGE is built using Python, the flask framework, and PostgreSQL to store configuration data. Although individual-level data will populate the tool, cohort-level data can become the reference cohort against which an individual's data can be contextualized. BRIDGE pulls data not only from the EHR but also from a range of custom research databases as well as other APIs, such as REDCap [38]. BRIDGE was developed based on extensive HCD processes both within the field of MS [42,43] and beyond [37]. The data visualizations can be developed using HTML, cascading style sheets (CSS), JavaScript, Data-Driven Documents–JavaScript, and other front-end libraries. Each front-end visualization is modular, allowing for asynchronous loading, and is a parameterized JavaScript component, allowing us to extend the code to additional platforms and data sources. Data formatting standards are also applied to make all visualizations and data inputs modular. All API calls are made in real time; BRIDGE does not store patient data, but there is an option to write back to the EHR by pasting the visuals into a clinical note. Furthermore, the development team follows universal design principles, influenced by the Agency for Healthcare Research and Quality Toolkit for Designing Consumer Health IT [47].

REDCap Tool

REDCap [38] includes editable or annotatable functions to enable patients to keep track of, and annotate, their PGD. Design choices reflect digital health literacy principles and feedback provided from diverse patients. Together, these enhancements make the data understandable and actionable.

Investigator Team

The core team included an MS neurologist with HCD expertise (RB), software engineers (NM and NS), a health literacy and patient engagement expert (JR), and an MS physical therapist with remote ambulatory and falls monitoring expertise (VJB). Additional key scientific input was provided by a digital health cloud infrastructure expert (IS), an implementation science expert (CL), a health disparities and population health expert (CL), and an expert in large-scale mobile health (IS). Patient stakeholders included National Multiple Sclerosis Society advocates (LG) and patients (3 core stakeholders). Research team members included a program manager (KK) and clinical

coordinators (JW and KH). Before starting the project, this team met to determine the phases of research and design an initial mock-up of the tool that could be used during the discover phase. Volunteer consultants included a software engineer (JR) and user interface or user experience experts.

Phases of Design

Phase 1: Discover

Stakeholder Advisory Team

An initial stakeholder meeting took place, during which the goals and phases of the project were outlined. Next, the core team met biweekly as a group or as subgroups to discuss an agenda that included the development of patient and clinician interview guides, interview coding schemes and thematic analysis, the practical aspects of the technological lift, the workflow integration of MS-FIT, and the visualization types and customizations. The iterations of mock-ups were revised based on patient and clinician interview feedback.

Interviews

One-on-one interviews were conducted by the health literacy and patient engagement expert (hereinafter referred to as the interviewer) with patients (round 1) and clinicians. Because of ongoing COVID-19 restrictions on in-person engagements, interviews were conducted via the UCSF Zoom video platform (Zoom Video Communications, Inc) using interview guides developed for each audience to elucidate how a tool might be designed to promote behavior change around falls ascertainment, reporting, and prevention. All questions were administered verbally, and interviews lasted between 45 and 60 minutes. With participant consent, interviews were simultaneously recorded and transcribed using Zoom's video transcription feature.

Interview guides included qualitative and quantitative components. Open-ended questions probed around the domains of the capability, opportunity, motivation, and behavior (COM-B) framework to facilitate subsequent mapping to the Behavioral Change Wheel (BCW) proposed by Michie et al [48]. Quantitative questions with Likert-style responses (ranging from 1=lowest to 5=highest) were administered verbally throughout each interview to assess specific aspects of patient and clinician experience related to capability, opportunity, and motivation, as well as the perceived usefulness of mock screen views and workflows. Participants were asked to comment on their Likert-style responses.

Patient interviews were semistructured around 2 key thematic topics: patient experience with (1) falls and activity, including ability to be active, knowledge, communication with care team, experience, feelings, and expectations; and (2) use of technology, including smartphone, tracking devices, apps, and communication with care team. To complement qualitative insights, patients were asked to use a Likert scale to rate the perceived usefulness of each of 3 app screen views featuring different design elements.

Semistructured interviews with clinicians started with a review of the activity blockers and boosters identified during the discover phase interviews with patients. With this insight,

clinicians were asked a series of open-ended qualitative questions to elicit their perspectives on whether a falls reporting tool might promote sustainable falls prevention, as well as gather feedback on the initial closed-loop design (Figure 3) intended to support falls treatment and clinical decision support. To assess each design feature, clinicians were asked to rate perceived usefulness on a Likert scale.

Analysis

After all interviews were concluded for each audience, the interviewer reviewed each transcript and used inductive coding to develop a coding scheme on the basis of responses to the open-ended questions [46]. Frequently occurring topics were assigned a unique thematic category, and less frequent topics were coded *other*. Categories were defined by the interviewer, and quotations from the transcript were used to illustrate the type of text coded into the category. Although the interviewer was the sole coder, the stakeholder advisory team provided ongoing consultation on the coding scheme and how to code less frequently occurring responses.

The interviewer transferred Likert-style response data to a spreadsheet to calculate means and SDs for each question. To analyze questions designed to map to the COM-B framework, the interviewer created a data grid where the rows were COM-B categories with subthemes of ability blocker and booster types, and the columns were evidence (quotes) of specific blockers or boosters [49]. Evidence of blockers or boosters that spanned >1 category were placed in all relevant categories to ensure that they would be represented when considering BCW-guided interventions.

After developing the initial COM-B data grid, the interviewer, in consultation with the stakeholder advisory group, expanded the grid to include (1) BCW intervention functions to help users overcome barriers to performing target behaviors and (2) potential intervention solution features designed to be effective for each corresponding blocker category. Intervention solution features were subsequently added to the design road map for immediate or future implementation.

Phases 2 and 3: Define and Develop (Iterative)

Stakeholder Advisory Team

In these phases, the team reviewed qualitative and quantitative findings from additional patient (2 rounds) and clinician (1 round) interviews and used this feedback to further refine MS-FIT tool functionality, including design and technological features. Changes were prioritized according to the strength of feedback (occurrence of themes and usability scores) and technical feasibility.

Interviews

The define and develop phases encompassed a second round of patient interviews, followed by 2 rounds of interviews with clinicians and patients designed to assess MS-FIT generalizability to other high-risk clinical contexts. The same process was followed as that described in phase 1 (discover). One-on-one interviews were conducted by the interviewer via the UCSF Zoom video platform using interview guides. All questions were administered verbally, and interviews lasted

between 45 and 60 minutes. With participant consent, interviews were simultaneously recorded and transcribed using Zoom's video transcription feature.

Patient Interviews (Round 2)

Interview guides included qualitative and quantitative components. In an effort to validate the patient experience findings from round 1 interviews, patients interviewed during round 2 were similarly asked to share qualitative feedback around personal experiences with falls, falls and near-falls reporting, perceived benefits and concerns around using a falls tracking app, and thoughts on what supports would be helpful between appointments. Quantitative questions with Likert-style responses (ranging from 1=lowest to 5=highest) were used to rate 9 mock screens for usefulness, understandability, and importance for each view. Mock screens had been iterated after the discover phase; therefore, patient feedback during this second round further validated and helped refine the designs.

Generalizability to Other High-Risk Clinical Contexts

To ensure that the technological build was not *overdesigned* for MS and to support the scalability of the tool to other clinical settings, interviews were expanded to intended users in other clinical specialties associated with falls, including geriatrics, orthopedics, neurorecovery (after stroke or traumatic brain injury), and Parkinson disease (PD). Clinicians from each discipline and patients with PD were interviewed. Interview protocols used during the discover phase were adapted to reference specific disciplines and diseases, whereas the questions (qualitative and quantitative) remained the same to yield a parallel assessment of each audience's experiences, preferences, capabilities, opportunities, and motivations.

Analysis

Qualitative and quantitative interview analysis used the same inductive coding and calculation techniques, respectively, used during the discover phase. The results were analyzed by the interviewer, with ongoing thematic consultation with the stakeholder advisory team, and used to inform and prioritize design and content iterations.

Phase 4: Deliver

Stakeholder Advisory Team

The core team met with stakeholders on an ad hoc small-group basis during this phase to plan observation and tool-scoring protocols, specifically to identify a subset of questions from the Health IT Usability Evaluation Scale (Health-ITUES) derived from the Health-ITUEM to assess the 2 *subjective* components of usability—usefulness and ease of use [33]—as well as the Patient Education Materials Assessment Tool for Audiovisual Materials to assess understandability and actionability [50]. As recommended for digital tool validation [45], a single survey question—Net Promoter Score (NPS)—was asked regarding the likelihood that users (patients and clinicians) would recommend the MS-FIT to colleagues or friends. Additional conversations focused on the scalability of the tool, as well as the qualitative and quantitative feedback received.

Observations and Scoring

Observations and scoring for the patient-facing falls assessment survey took place with 2 audiences: people with MS and people with PD. Patients scheduled for a routine upcoming in-person clinical visit with their neurologist were contacted and invited to participate in testing and evaluating the tool. After providing informed written consent, and while being observed by the interviewer, participants were asked to engage with the MS-FIT minimum viable product consisting of the falls assessment survey and accompanying patient instructions while being observed by the interviewer. Patients were specifically asked to complete the falls assessment survey by entering up to 5 falls (real or hypothetical) that had occurred in the prior 2 weeks and responding to on-screen prompts to provide context about each reported fall. Patients could ask questions of the interviewer, if needed. After survey submission, each patient was asked to complete an 18-item survey about their experience to assess usability, usefulness and ease of use, likability, understandability, actionability, and NPS. Patients were subsequently asked if they had any feedback about their experience. Feedback was documented in field notes captured contemporaneously.

Clinicians seeing people with MS and those with PD who had just been observed entering data in the falls assessment survey were asked to launch the MS-FIT BRIDGE app in real-time clinical encounters with these patients to review the falls and contextual data the patient had entered and to engage with the various widgets designed to help evaluate and address reported falls. The interviewer met with the clinicians immediately after the encounters to conduct in-person exit interviews and administer a 9-item survey to assess usability, usefulness and ease of use, likability, understandability, actionability, and NPS. Clinicians were subsequently asked whether they had any feedback about their experience, including any barriers to use and functionality challenges. Feedback was documented in contemporaneous field notes.

Analysis

Qualitative feedback, although limited, was analyzed by the interviewer using the same inductive coding technique used during the previous 2 interview phases. Quantitative questions with Likert-style responses (ranging from 1=lowest to 5=highest) were used to score likability, usability, usefulness, and ease of use. Understandability and actionability were assessed using a binary *agree* or *disagree* scale. Another member of the research

team entered quantitative responses into REDCap, which was used to calculate means and SDs for all Likert-style responses and total binary responses. NPS responses (0-10 scale) were calculated by the interviewer by subtracting the percentage who were detractors (those who scored 0 to 6) from the percentage who were promoters (those who scored 9 or 10). An NPS >0 was considered good, >20 was considered favorable, and >50 was considered excellent.

Development Action Items

Once the tool was live, the developer was able to debug MS-FIT; iterate based on patient, clinician, and stakeholder feedback; and redebug as needed.

Results

Overview

Demographic information about each interview panel is shown in [Multimedia Appendix 1](#) [42]. Altogether, 30 patients of diverse ages, disability levels, and technological literacy as well as 14 clinicians provided at least 1 round of feedback. The level of involvement from the users ranged from testers to informants [32]. Feedback from both rounds of interviews with people with MS, MS clinician comments, and feedback from other high-risk clinical context patient and clinician interviews were integrated into the final MS-FIT design. Iterative interview feedback was categorized into activity blockers (what keeps people from performing a behavior) and boosters (what is already working well that we can build on) in the COM-B model. Examples of how interview feedback findings fit into the COM-B and BCW, along with intervention function solution features integrated into MS-FIT, are shown in [Figure 4](#). Details are provided in [Table 1](#). Further discussions with clinicians and patients in other high-risk clinical contexts confirmed the findings from the MS context. Across these specialties, the main barriers to falls prevention efforts included access to specialized PT (availability and physical ability to access it), insurance coverage, ability to adapt the home to improve safety, the adequate use of assistive devices, and COVID-19-related restrictions to community exercise areas.

The overview of findings from interviews with clinicians and participants with MS, highlighting areas that block or boost patient and clinician behavior change with regard to falls and falls prevention, are shown in [Multimedia Appendix 2](#).

Figure 4. Example of mapping blockers and boosters relating to falls prevention (findings from interviews with patients with multiple sclerosis [MS]) to the Behavioral Change Wheel [49] and associated behaviorally informed intervention solution features. Examples for each of the sections of the capability, opportunity, motivation, and behavior (COM-B) model are highlighted, showing how these integrate into the Behavioral Change Wheel. The examples provided relate to patients’ reported goals, blockers (features that block falls prevention behavior), and boosters (features that boost behaviors related to falls prevention).

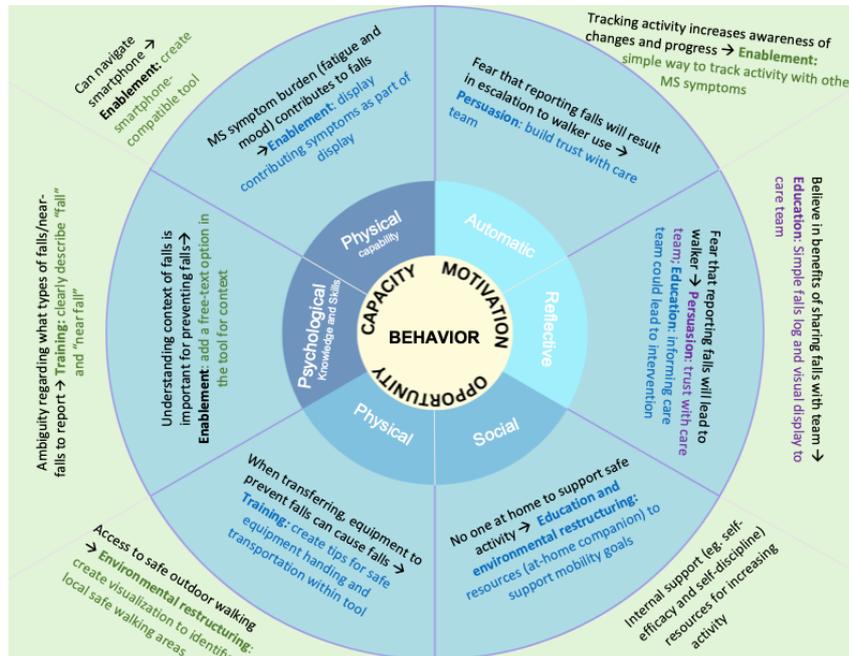

Table 1. Scoring of the final University of California San Francisco Multiple Sclerosis Falls InsightTrack app (REDCap [Research Electronic Data Capture]) by patients with multiple sclerosis: usability, ease of use, and likability (n=10).

Health-ITUES ^a -based questions for usability, ease of use, and likability	Score, mean (SD)	Score <4 out of 5, n (%)
“It is useful to report if I’ve had any falls or near falls every 2 weeks”	4.80 (0.42)	0 (0)
“It is useful to have my survey answers sent to my care team”	4.90 (0.32)	0 (0)
“The survey asks about important topics”	4.70 (0.48)	0 (0)
“I am comfortable with my ability to complete the survey”	4.80 (0.42)	0 (0)
“I find the survey easy to use”	4.80 (0.42)	0 (0)
“I can easily remember how to access the survey through my email”	4.60 (0.70)	1 (10)
“I like the survey”	4.80 (0.42)	0 (0)

^aHealth-ITUES: Health IT Usability Evaluation Scale (scores range from 1=strongly disagree to 5=strongly agree).

Tool Components

Thematic saturation was reached after 5 patient interviews (round 1), and we incorporated these insights into prototypes for an additional 5 patient interviews (round 2), which were then iteratively reviewed.

UCSF Support Self-Monitoring: A Patient-Facing Tool to Track Falls and Self-Monitor

Tool Architecture

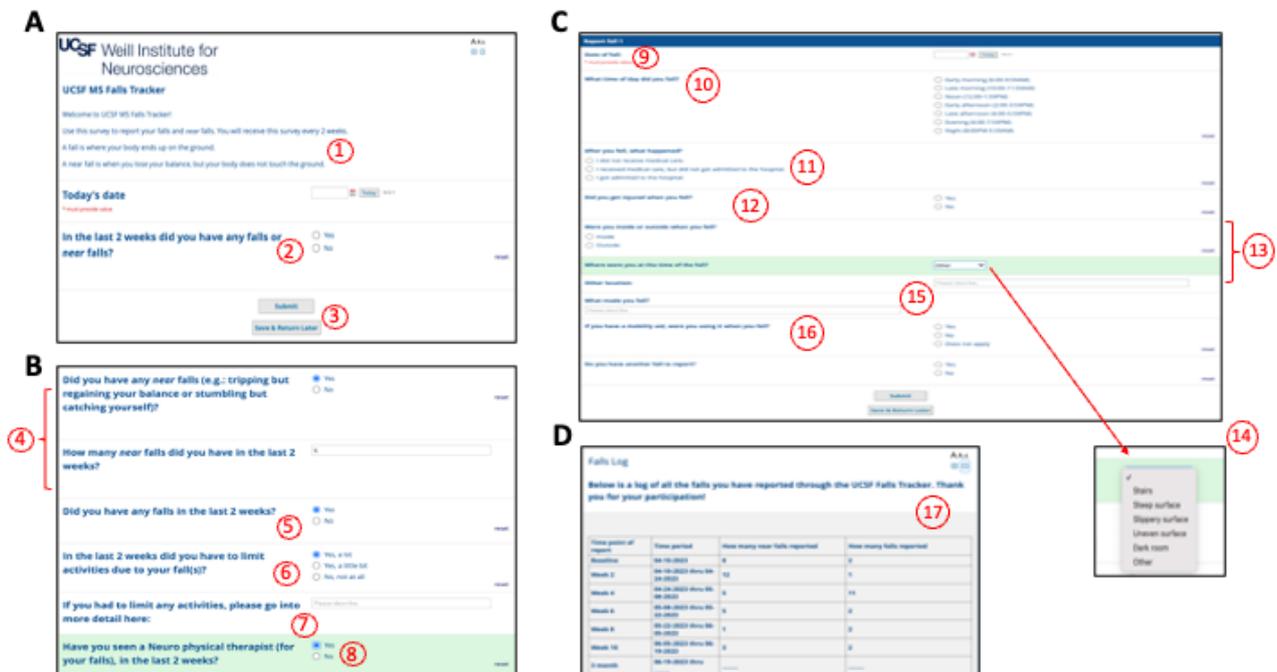

One key and consistent theme emerging from patient interviews was a preference for a simpler design for the patient-facing tool

than had been initially conceived. Combined with a goal of maintaining confidentiality and keeping personal information within our university firewall, the study team opted for a tailored REDCap app rather than a custom new app.

Tool Components

Key features informed by patient and clinician feedback are detailed in Figure 5. Key features mapping to the COM-B framework (Multimedia Appendix 2 and Figure 4) are denoted by a red number and described in Textbox 1.

Figure 5. University of California San Francisco (UCSF) Multiple Sclerosis (MS) Falls Tracker: a patient-facing tool to track falls and support self-monitoring. This is the “MS-FIT [Multiple Sclerosis Falls InsightTrack] patient survey V2.0,” sent via email to patients with a REDCap (Research Electronic Data Capture) survey link. Key features mapping to user-generated perspectives and feedback and to the capability, opportunity, motivation, and behavior (COM-B) framework are denoted by a red number and described in Textbox 1.

Textbox 1. University of California San Francisco Multiple Sclerosis Falls InsightTrack: key features. The numbers correspond to the red numbers in Figure 5, which denote key features mapping to the capability, opportunity, motivation, and behavior (COM-B) framework.

Concise and precise falls screening

1. Clear definitions were preferred to distinguish between a fall and a near fall to support the reporting of meaningful data.
2. An easy-to-use and simple 1-question tool that could be completed frequently (every 2 wk) was preferred to relying on “flawed memory” to report falls during sporadic clinic visits: if “No,” then the survey ends at this point; if “Yes,” then branching logic continues.
3. The ability to easily report each fall or near fall separately was preferred. The ability to edit (return later) was important for reducing burden.
4. Simple reporting for near falls (yes or no and overall number) was preferred, given the large volume of near falls experienced by some patients and the potential burden and time commitment of providing details.
5. The 2-wk epoch between reporting was determined feasible (balance between memory and overburdening).
6. The ability to report activity limitations was preferred because these pertain to primary goals with regard to the “ability to continue independence for activities of daily living” and to “stay active.”
7. Because of the heterogeneity in answers, a free-text option would allow patients to add further details regarding activity limitations.
8. Indicating whether the patient has seen a neurorehabilitation specialist could help clinicians triage the continued plan of care.

Detailed context of falls (optional)

1. Recording the date of the fall using a simple button allows the tool to display each fall into the longitudinal representation (refer to [Textbox 2; Figure 6](#)).
2. The time of falls can also inform falls context (eg, in the dark or when fatigued). The 24-h day was divided into time blocks for clarity and to reduce recall error of exact time.
3. Information regarding the medical consequences of a fall can inform both its severity and the clinical follow-up needed.
4. Injury after a fall is considered distinct from seeking and receiving medical attention.
5. Fall location can inform prevention efforts, including home safety; “some falls inside the home can be avoided through modifications such as removing a rug, better lighting etc.”
6. Other details of the fall location can also inform home safety and prevention (eg, curb, stairs, and poor lighting).
7. Specifying whether falls occur because of factors related to multiple sclerosis or other factors (obstacle, etc) is important owing to the heterogeneity of fall triggers and of clinical responses.
8. The question “If you have a mobility aid, were you using it when you fell?” can remind patients to use the assistive device and can cue clinicians of the need to modify or change the current assistive device.
9. A falls log is provided to patients and shows the reported falls over time.

Closing the loop: real-time in-basket messaging

1. Enabling the reporting (patient) and ascertainment (clinician) of falls at regular intervals optimizes timeliness (vs periodic visits) while maintaining low burden (vs daily or “at time of fall”). If a severe fall is reported on the biweekly survey, an in-basket message to the electronic medical record alerts the care team in a manner integrated into the clinical workflow ([Figure 6, #15](#)).

Textbox 2. Multiple Sclerosis Falls InsightTrack clinical management dashboard integrated into the Epic electronic health record: key features. The numbers correspond to the red numbers in Figure 6, which denote key features mapping to the capability, opportunity, motivation, and behavior (COM-B) framework.

Longitudinal multiple sclerosis trajectory widget (visualizes patients' disease and medication trajectory over time with integrated normative ranges)

1. Ability to toggle through disability measures (eg, Expanded Disability Status Scale [EDSS] and Timed 25-Foot Walk)
2. Succinct overview of patient's longitudinal MS trajectory, including relapses, disability, medications, and normative data

Longitudinal falls widget (visualizes falls reported every 2 wk by the patient using their patient-facing app [Figure 5] data regarding date, time, and severity of each fall on 1 display)

1. Fall severity visualized by color shade (grading falls by severity considered important to trigger an alert to the care team and to inform type of clinical response)
2. Ability to include a way to visualize the falls log with falls over time
3. Estimated time of day of the fall can inform further interventions needed, including vision check, home safety evaluation, and medication review (especially for Parkinson disease)
4. Time of day visualized with colors for daytime (lighter: yellow) and nighttime (darker: blue) preferred by all stakeholders

Community resources widget (map automatically displays the patient's home community and allows for web-based identification of MS health care professionals in their community)

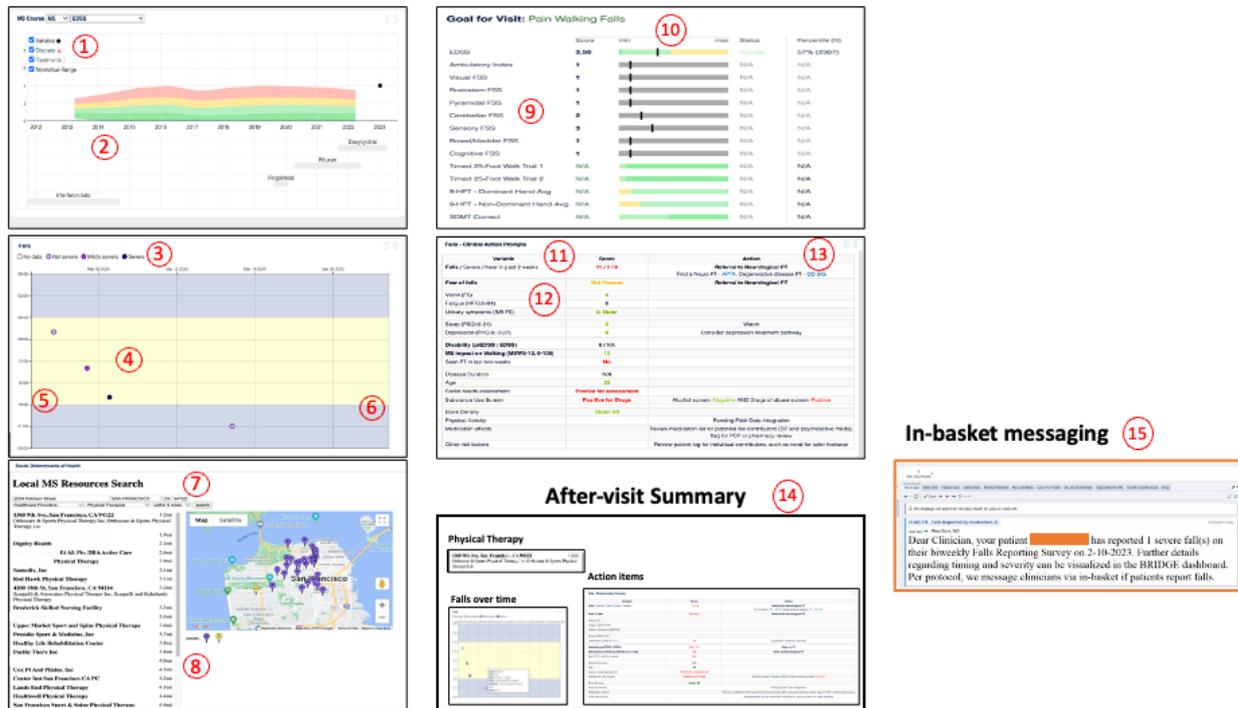

1. Automated display of MS professionals (physical therapist, occupational therapist, and talk therapist) in the patient's community, which reduces barriers for patient to identify local recourses once physical therapy or other referrals have been placed
2. Contact information and driving navigations between the patient's home and the resources automated, can be pasted into the patient's after-visit summary or the clinician's note

Cross-sectional widget (summary display with 2 tabs displaying clinical disability outcomes and patient-reported outcomes [PROs]; clinician can toggle between time points)

1. Clinic-based performance measures (walking speed, hand function, and cognition) and disability outcomes (EDSS with separate functional system scores) as well as PROs can inform a more global assessment of the patient at given time point
2. Color-coded normative ranges can provide rapid assessment of whether patient's given function is within "normal" range

Falls treatment- and action-prompt widget (tabulates core data needed for a comprehensive assessment of falls risk and prevention; for each category, patient's score is colored according to severity, and possible action prompts are displayed)

Figure 6. Multiple Sclerosis Falls InsightTrack (MS-FIT) clinical management dashboard, integrated into the Epic electronic health record (Epic Systems Corporation). This is the “MS-FIT BRIDGE version 3.0,” which is viewable from Epic in the electronic health record at the time of the clinic visit. Key features mapping to user-generated perspectives and feedback and to the capability, opportunity, motivation, and behavior (COM-B) framework are denoted by a red number and described in Textbox 2.

Phase 4: Deliver

Altogether, 15 patients (10 with MS and 5 with PD) with an age range of 34 to 79 years and 6 MS clinicians with a clinical experience range of 2 to 22 years (Multimedia Appendix 1) launched the tool components *live* and provided feedback.

Patient-Facing UCSF MS-FIT

People With MS

Of the 15 patients, 10 (67%) had been diagnosed with MS; they had a mean age of 48.8 (SD 8.8; range 34-60) years, with disability level (EDSS score) ranging from 1.5 to 6.0 and a median disease duration of 14.5 (IQR 6.3-24; range 2-27) years. The feedback from people with MS was overwhelmingly positive (Table 1). Likability scores were all NPS≥100 (all promoters). The survey was found to be brief and clear. Patients appreciated the benefit of the closed-loop system and the overall impact on clinical encounters.

Patients With PD

Of the 15 patients, 5 (33%) had been diagnosed with PD; they had a mean age of 60.6 (SD 13.2; range 46-79) years, with a median disability level (Unified Parkinson’s Disease Rating

Scale score) of 31 (IQR 30.3-8.5; range 17-42) and a median disease duration of 4 (IQR 1.5-8.5, range 1-10) years. Overall, the NPS was found to be 0 (20%-20%, with 1/5, 20% detractor, 1/5, 20% promoter, and 3/5, 60% passive scores that trended toward promoters), indicating that patients with PD could be easily swayed to use MS-FIT. The mean scores on the Health-ITUES questions were all >4 (ie, agree or strongly agree), and only 1 score was <3 out of 5 (Table 2).

Qualitative insights from the interviews revealed that *falling*, *fear of falling*, and *thinking about falling* were “not at the top of their list,” in contrast to people with MS. Nevertheless, patients with PD found the tracker “easy to fill out,” and they “liked the idea of reporting falls and reporting if [they] experienced fear of falling.” Patients with PD felt that it was important to have the ability to increase the font size (incorporated into MS-FIT patient survey v 2.0; Figure 5).

For future use in PD, patients reported that it would be important for ease of use and usability to have the ability to report motor vehicle accidents and specific PD symptoms as they relate to falls risk. Patients with PD also reported greater issues with using an iPad (motor or tremor issues).

Table 2. Scoring of the final University of California San Francisco Multiple Sclerosis Falls Tracker (REDCap [Research Electronic Data Capture]) by patients with Parkinson disease: usability, ease of use, and likability (n=5).

Health-ITUES ^a -based questions for usability, ease of use, and likability	Score, mean (SD)	Score <4 out of 5, n (%)
“It is useful to report if I’ve had any falls or near falls every 2 weeks”	4.40 (0.89)	1 (20)
“It is useful to have my survey answers sent to my care team”	4.20 (1.22)	1 (20)
“The survey asks about important topics”	4.00 (1.00)	2 (40)
“I am comfortable with my ability to complete the survey”	4.60 (0.89)	1 (20)
“I find the survey easy to use”	4.60 (0.89)	1 (20)
“I can easily remember how to access the survey through my email”	4.20 (1.10)	2 (40)
“I like the survey”	4.20 (1.10)	2 (40)

^aHealth-ITUES: Health IT Usability Evaluation Scale (scores range from 1=strongly disagree to 5=strongly agree).

MS-FIT Clinical Management Dashboard

Overall, the MS clinicians (n=6) rated the dashboard highly (NPS=16.67; Table 3):

I like that [the app] summarizes important clinical information in an easily digestible format, and the new widget that includes an MS [multiple sclerosis]-specific review of systems and actionable items seems like it will help ensure well-rounded MS care! [Clinician 1]

With regard to reporting falls and near falls, the MS clinicians noted multiple benefits to aiding with patient care:

You can infer a lot from [fall data] in terms of disease activity, disease course, changes in a patient’s life,

their living setting, their support. If you see a jump in falls or the onset of falls in a patient who wasn’t falling—it is worthy of clinical attention and needs to be addressed. It would give us an objective way to know if interventions are helping to reduce falls. [Clinician 2]

Near falls are particularly underscreened, so any granularity on near falls would be helpful. [Clinician 3]

For some patients, near falls may not be worth reporting—may just be part of life. But other patients it could make sense for. Any change from baseline has potential to be significant. Near falls can be [a] canary in a coal mine. [Clinician 5]

Table 3. Scoring of the final University of California San Francisco Multiple Sclerosis Falls BRIDGE dashboard by multiple sclerosis clinicians: usability, ease of use, and likability.

Health-ITUES ^a -based questions for usability, ease of use, and likability	Score, mean (SD)	Score <4 out of 5, n (%)
“The information that appears in BRIDGE is useful to me.”	4.80 (0.41)	0 (0)
“It is useful to be updated on my patient’s significant fall activity between appointments.”	4.50 (0.84)	1 (17)
“I find BRIDGE easy to use.”	4.20 (0.75)	1 (20)
“I can always remember how to access BRIDGE.”	4.00 (1.10)	1 (20)
“I like BRIDGE.”	4.50 (0.55)	0 (0)

^aHealth-ITUES: Health IT Usability Evaluation Scale (scores range from 1=strongly disagree to 5=strongly agree).

Discussion

Principal Findings

To our knowledge, this is the first tool designed using the HCD framework, anchored in the COM-B approach to behavior change, and capable of delivering relevant information at the point of care in line with the 5 rights with the aim of preventing falls in people with MS. Other apps have been developed, although the focus has mainly been on 1 component of falls (eg, evaluating falls risk [51]) at a time. In addition, many large-scale clinical research projects, such as those conducted at the Stanford Center for Digital Health and the Remote Assessment of Disease and Relapse–Central Nervous System program, are exploring applications of wearable data. However, most of the collected wearable data remain inaccessible for visualization

or integration within a clinic’s EHR. This limitation can impede the effective use of PGD by clinicians and compromise patient-physician collaboration related to PGD [52]. MS-FIT fills a critical gap in multimodal closed-loop self-management apps for falls monitoring and prevention.

Through extensive stakeholder engagement, MS-FIT offers novel aspects of customization, generalizability, and scalability, integrating multiple data streams relevant to reducing falls. It provides rapid personalized in-basket notifications, limited to severe falls, and digitally displays PGD through the EHR, increasing the likelihood of adoption by patients and clinicians.

Designed in collaboration with patients and clinicians, MS-FIT has emerged as a well-received closed-loop tool for tracking falls and reducing falls risk in individuals with MS. Patients liked its brevity, simplicity, and overall utility, recognizing its

potential to enhance clinical discussions. The utility of between-visit reporting and contextualized information for identifying modifiable falls risks was acknowledged by both patients and clinicians. The trial phase aims to validate its low-burden design in practice. Clinicians welcomed the closed-loop system, foreseeing proactive interventions and streamlined implementation. Longitudinal falls visualization, incorporating time and severity, along with clinician prompts targeting MS symptoms and medication effects, was favored for its ability to capture often overlooked components during regular visits.

Another noteworthy finding was the minimal number of interviews required to attain thematic saturation in our initial discover phase, indicating that some clear guidance for potentially high-value initial design features was achieved with a minimal sample size. This could be due to the fact that MS-FIT was based on an initial prototype developed during a prediscover phase using patient and clinician feedback. It could also be attributed to homogeneous samples of study participants consulted throughout the discover and design phases. Overall design efficiency was likely aided by the experience and regular input of interprofessional teams.

The ongoing process involves testing MS-FIT in a prospective longitudinal study in a cohort of 100 adults with MS over 12 months. The primary objectives of this larger study include assessing the adoption rate of the tool, evaluating the level of sustained use of the tool, monitoring adherence to falls reporting, and assessing study retention over the 12-month period. Secondary and exploratory analyses will center around the prediction of adoption, sustained use, adherence to action prompts, and study retention. To determine effectiveness, the study will compare in-study falls with a prior falls data set (Fitbit remote monitoring in MS) [41], and patient satisfaction will be assessed during an exit interview.

Scalability

Our approach, characterized by the selection of key technological and clinical features, allows for the scalability and generalizability of the tool's modular infrastructure to various symptoms, conditions, and clinical settings for other high fall-risk diseases as well as other symptoms within MS

(eg, bladder dysfunction). Technological factors for scalability include (1) high-quality, widely shareable static visualizations; and (2) optimized industry standards for code sharing with clinicians in other health care settings, such as other MS centers using Epic EHR. However, successful integration into other health systems depends on the internal governance and motivation within each system.

Limitations

All interviews were conducted remotely, using the UCSF Zoom video platform, which may have biased the patient stakeholders to people who are technologically literate and have access to the internet. However, 92% of people in the United States have access to the internet [53], and given that MS-FIT is an app, users (patients or caregivers) are expected to possess a certain level of technical proficiency. Only clinicians at UCSF and patients seen by this (broad) group of clinicians were interviewed; therefore, we may have missed important feedback from a wider cohort of users. Although HCD is favored for user-driven eHealth innovations, certain limitations exist [32], including a narrow focus; thus, exploring alternatives such as value-sensitive design, citizen science, and more-than-human design could enhance inclusivity and impact within eHealth innovation [54]. Finally, having the interviewer serve as the primary coder could have introduced bias into the qualitative analysis process. Stakeholder advisory group engagement in the coding process was an effort to reduce any potential bias.

Conclusions

MS-FIT delivers relevant data to clinicians through an embedded window within the EHR, following the *5 rights* approach. By using MS-FIT for data processing and algorithms, we reduce clinician burden while enhancing care. Our innovation extends to enabling and integrating real-world PGD as well as clinical and community-level factors, providing actionable information to empower self-care and addressing the impact of falls in people with MS. Our preliminary data indicate that this tool and design extend beyond MS and can be applied to other conditions associated with falls as well as the fear of falls and their associated consequences. To test the feasibility and effectiveness of the app, a clinical trial is ongoing (University of California San Francisco Clinical Trials identifier: NCT05837949).

Abstract

Background: Digital triage tools for sexually transmitted infection (STI) testing can potentially be used as a substitute for the triage that general practitioners (GPs) perform to lower their work pressure. The studied tool is based on medical guidelines. The same guidelines support GPs' decision-making process. However, research has shown that GPs make decisions from a holistic perspective and, therefore, do not always adhere to those guidelines. To have a high-quality digital triage tool that results in an efficient care process, it is important to learn more about GPs' decision-making process.

Objective: The first objective was to identify whether the advice of the studied digital triage tool aligned with GPs' daily medical practice. The second objective was to learn which factors influence GPs' decisions regarding referral for diagnostic testing. In addition, this study provides insights into GPs' decision-making process.

Methods: A qualitative vignette-based study using semistructured interviews was conducted. In total, 6 vignettes representing patient cases were discussed with the participants (GPs). The participants needed to think aloud whether they would advise an STI test for the patient and why. A thematic analysis was conducted on the transcripts of the interviews. The vignette patient cases were also passed through the digital triage tool, resulting in advice to test or not for an STI. A comparison was made between the advice of the tool and that of the participants.

Results: In total, 10 interviews were conducted. Participants (GPs) had a mean age of 48.30 (SD 11.88) years. For 3 vignettes, the advice of the digital triage tool and of all participants was the same. In those vignettes, the patients' risk factors were sufficiently clear for the participants to advise the same as the digital tool. For 3 vignettes, the advice of the digital tool differed from that of the participants. Patient-related factors that influenced the participants' decision-making process were the patient's anxiety, young age, and willingness to be tested. Participants would test at a lower threshold than the triage tool because of those factors. Sometimes, participants wanted more information than was provided in the vignette or would like to conduct a physical examination. These elements were not part of the digital triage tool.

Conclusions: The advice to conduct a diagnostic STI test differed between a digital triage tool and GPs. The digital triage tool considered only medical guidelines, whereas GPs were open to discussion reasoning from a holistic perspective. The GPs' decision-making process was influenced by patients' anxiety, willingness to be tested, and age. On the basis of these results, we believe that the digital triage tool for STI testing could support GPs and even replace consultations in the future. Further research must substantiate how this can be done safely.

Introduction

Background

The use of eHealth, health services delivered through the internet or related technologies, is increasing, especially since the COVID-19 pandemic [1,2]. The COVID-19 pandemic has shed light on the crucial role of digitization in health care [2]. An important and promising element of digitization in health care are digital triage tools consisting of a questionnaire for patients to identify the risk of a medical problem. These tools use a digital questionnaire typically administered by a health care professional, and an algorithm based on a medical decision tree generates automatic advice for follow-up, for example, a web-based symptom checker. In this paper, we discuss a digital triage tool that advises whether a specific diagnostic test for a specific combination of symptoms is necessary. This specific digital triage tool is based on Dutch medical guidelines.

Such a digital triage tool for different problems and symptoms could be an efficient and accessible method for citizens with medical questions. In addition, this digital triage tool could possibly lower the workload of general practitioners (GPs) as it can replace the triage that health care professionals would do themselves [3]. However, it is important that triage leads to responsible and appropriate care given the situation. Digital triage tools should not result in “over-triage” or “under-triage” [4]. Overtriage is when a patient is advised to undergo a medical treatment or diagnostic test when they do not have an (urgent) medical problem [4]. Undertriage is when a patient is told that they do not have an (urgent) medical problem when they do, with the advice that a diagnostic test or medical treatment is not necessary [4]. It is important to know whether the digital triage tool for diagnostic tests is in line with daily medical practice to maximize its validity.

In daily practice at GPs' offices, medical guidelines are used to support their decision-making. GPs following guidelines has been an important research subject into the decision-making process of GPs in dermatology has shown that GPs do not always adhere to medical guidelines [5]. For example, concerns about the patient or the relationship between the GP and the patient were sometimes part of the decision-making process [5]. Furthermore, a meta-synthesis of qualitative studies identified GPs' attitudes toward and experiences with clinical guidelines [6]. First, this study showed that GPs experience tension between their own experiences and the guidelines they must adhere to as guidelines do not consider personal circumstances. Second, GPs are afraid of missing a patient diagnosis. Third, GPs experience that the guidelines do not always fit with patients' needs, and therefore, GPs act differently from what the guidelines instruct them to do. Earlier reviews have revealed other factors that play a role in the decision-making process of GPs in referrals for diagnostic tests

[7-9]. These are, among others, demographic and nonclinical factors such as patient characteristics (eg, age, sex, and social class [8]). In addition, the patient's quality of life and wishes are nonclinical factors that influence the decision-making process of the GP [7]. Not all those factors are included in medical guidelines and, consequently, in digital triage. All these factors clearly show that the GP makes decisions from a holistic perspective, which makes it even more interesting and important to critically consider decision-making using digital tools from the perspective of the GP. Regarding diagnostic testing, to our knowledge, our study is the first one that compares the advice of GPs with that of a web-based tool. At the same time, this study identifies what factors influence a GP's decision-making process for a diagnostic test.

Objectives

If a digital triage tool is of high quality and the patient is adequately advised, a consultation with the GP could be avoided, resulting in an efficient care process for the patient. The GP can also be supported in the hectic daily workload as the patient uses the tool independently [9]. The first objective of this study was to identify whether the advice of the studied digital triage tool aligned with the daily medical practice of the GP. The second objective was to learn which factors influenced the GP's decision regarding a referral for diagnostic testing. In addition, this research provides insights into the GP's decision-making process and whether factors are possibly missing from a digital triage tool. As a starting point, we investigated these research questions for sexually transmitted infection (STI) triage as the medical guidelines are straightforward (eg, clear risk factors and answer categories). Much research has been conducted on digital applications for STI testing, such as websites in which tests can be ordered, with positive feedback from patients about their usability [10]. Moreover, research has shown that a digital triage tool can potentially lower the threshold for STI testing [10] as this problem can be associated with feelings of shame [11]. To answer the research questions, a vignette-based qualitative study was conducted based on different STI-related patient cases [12].

Methods

Study Design and Participants

A qualitative vignette study was conducted using semistructured interviews with GPs as participants. Data saturation was expected after 10 interviews [13]. There were no specific exclusion criteria. GPs in training, practicing, or retired (for ≤ 5 y) could participate. In the interviews, the participants were presented with different patient vignettes (see the *Materials* section for details). After each vignette, the participants were asked about their clinical decision regarding STI diagnostic testing and to describe their thinking and decision-making process. This approach is called the “Think Aloud” method,

which allows for a description of how information is structured during a problem-solving task [14]. In addition, it provides rich data for analysis [15].

Ethical Considerations

This study was declared not to fall within the scope of the Dutch Medical Research Involving Human Subjects Act by the departmental ethics committee of the Leiden University Medical Center (reference 22-3002).

Materials

A vignette is a short hypothetical description of a patient representing a standardized combination of specific characteristics [16]. Vignettes made it possible to present patients with the same characteristics to every participant (eg, complaints, relationship status, and age) and, in this way, minimize variations between patients, which is not possible in real life. In this study, the vignettes were based on different aspects of the Dutch medical guidelines for STI testing [17]. In

the medical guidelines, different aspects are taken into account to calculate the risk of an STI, such as endemic areas, unsafe sex, and different complaints. The following factors were incorporated into the vignettes: age, gender, sexuality, relationship status, employment (eg, full-time job or student), history of unsafe sex and how long ago it took place, number of sexual partners, frequency of unsafe sex, frequent GP visits, symptoms, and ethnicity. Some of these factors are not in the guidelines but were included to research whether they influenced the decision-making process of the GP (eg, situation and if the GP was visited often by that patient). In addition, the vignettes were designed in such a way that they would lead to advice from participants to undergo a diagnostic test for STIs or not. In total, 6 different vignettes were created and used ([Multimedia Appendix 1](#)). In [Textbox 1](#), a short description of the vignettes is provided. The Dutch vignettes were designed with a GP and checked by another GP. An example of a translated vignette can be found in [Textbox 2](#).

Textbox 1. Short description of the vignettes.

Vignette 1

- Woman, aged 20 years, from Spain, student, had unsafe sex multiple times >3 weeks ago, itching of the vagina, does not visit her general practitioner (GP) often

Vignette 2

- Man, aged 26 years, plumber, steady relationship, has irritation at the urethra and sensitivity when urinating, visits GP often

Vignette 3

- Woman, aged 17 years, high school student, had unsafe sex <3 weeks ago with no complaints, the first time she comes to the practice

Vignette 4

- Man, aged 24 years, has a relationship with a man, his partner has sexual contact with other men, has difficulty urinating

Vignette 5

- Woman, aged 45 years, has a steady relationship but thinks her partner cheated 6 months ago, has contact bleeding, visits the GP often

Vignette 6

- Woman, aged 35 years, has a steady relationship, comes from Surinam, has a burning sensation when urinating, visits her GP often

Textbox 2. Vignette 1 translated from Dutch to English.

- Mrs A is aged 20 years and studies in the Netherlands but comes from Spain originally. She has not visited you at the practice often. She is not in a committed relationship and has had unprotected sex several times in the past 6 months for more than 3 weeks. She experiences vaginal discharge and itching and irritation in her vagina. She wonders whether she might have a sexually transmitted infection.

Procedure

Participants were recruited via a LinkedIn post that included the email address of the researcher. Interested participants were instructed to send an email if they wanted to take part. In addition, participants were emailed from the network of the researchers, and the GPs could reply to the email if they wanted to participate. Interested participants were sent information and the informed consent form. In addition, different data and time points were included in the interviews, which could be

face-to-face or digital (based on the preference of the participant). Participants had the right to withdraw at any time.

An interview protocol guided the semistructured interviews ([Multimedia Appendix 2](#)). All interviews were audio recorded. Each interview started with a short explanation of the study. The first vignette was then read out loud to the participant. They were asked whether they would advise undergoing diagnostic tests for STIs. Next, they were asked to share their reasoning process. These 2 steps were repeated for each vignette (ie, 6 in total). The first interviews were conducted with both interviewers present (KS and Fleur Rekveld), and KS was the

lead. The other interviews were conducted by KS, Fleur Rekveld, or both.

Service: Digital Triage Tool

The digital triage tool was developed by a Dutch diagnostic center [18] based on a decision tree with Dutch medical guidelines [17]. The digital triage tool was developed in cocreation with GPs and clinical chemists. A Dutch academic knowledge center assessed the digital triage [19]. During triage, users first go through a series of questions. Their answers determine what question they have to answer next and, in the end, what advice is given. For example, the first question is “Did you have unsafe sex?” If the answer is “no,” the advice is not to be tested. If the answer is “yes,” a follow-up question appears: *what is your gender?* Gender is asked about as differences in gender result in different advice (eg, for women users who are advised to undergo a chlamydia test, it means that the service could advise doing a vaginal swab). Ultimately, the digital triage tool advises whether a diagnostic test for STIs is necessary and, if yes, which one (eg, chlamydia, gonorrhea, or HIV). The digital triage tool is now used in 2 digital services of the diagnostic company where patients can order diagnostic tests themselves with or without a health care professional. These diagnostic services are Directlab, where users can order web-based diagnostic test packages independent of a health care professional, and Homelab, where patients in the digital environment of their GP can order diagnostic test packages. In regular daily practice in the Netherlands, the patient needs to ask for a consultation with the GP (on the phone or in person) and ask for a diagnostic test for STIs. In this situation, the GP performs triage to identify whether it is necessary to conduct an STI test.

Table 1. Characteristics of the participants.

Participant	Age (y)	Gender	Employment status
1	32	Woman	Part time
2	55	Man	Full time
3	38	Man	Part time
4	59	Man	Full time

Testing Advice of Digital Triage Tool Versus GPs

Table 2 shows, for each vignette, whether the digital tool would advise conducting an STI test and what each participant would advise to do. For 50% (3/6) of the vignettes (ie, numbers 1, 4, and 5), the digital triage tool’s advice aligned with all participants’ advice. For all 3 vignettes, the advice was to conduct a diagnostic test for STIs. For those 3 vignettes, the patients’ risk factors were sufficiently clear for the participants to advise to conduct a test.

Data Analysis

To determine the diagnostic test advice of the digital triage tool, the characteristics of each vignette were entered into it. The ensuing advice was compared with the test advice of the GPs per vignette. To learn which factors influenced the GPs’ decision-making process, the combination of the think-aloud process, vignettes, and semistructured interviews was used as a triangulation method to obtain a complete range of data to result in a strong conclusion [12,20]. All interviews were transcribed (intelligent) verbatim. When the transcripts were completed and uploaded to ATLAS.ti (version 22; ATLAS.ti Scientific Software Development GmbH), the audio recordings were deleted. In total, 2 authors (Fleur Rekveld and KS) conducted the qualitative data analysis according to the principles of thematic analysis. Fleur Rekveld and KS developed a preliminary coding scheme based on the coded data from the first 8 participants. The final coding scheme emerged after all the coding was performed by the 2 authors independently. The codes were grouped into themes and subthemes.

Results

Characteristics of the Study Population

Data saturation was reached after 10 interviews. The characteristics of the participants are presented in Table 1. Their ages ranged from 32 to 70 years, with a mean of 48.30 (SD 11.88) years. The number of men and women was almost equal (6/10, 60% and 4/10, 40%, respectively). Of the 10 GPs, 1 (10%) was retired, 3 (30%) were working part time as GPs, and 6 (60%) were working full time.

In vignette 1, the most important decision-making factor was the patient’s age; young age combined with women was an important factor influencing the participants’ test advice as having an STI could make this woman infertile. Participant 7 answered the following:

I would test her, always with women of her age who are sexually active.

In addition, unsafe sex was an important factor in the decision to test.

For vignette 4, the main factor in advising to test was the “men having sex with men” risk factor. Participant 5 answered the following:

It is male-male contact, and in addition, there are changes in sexual contacts so that he can do an STI test.

For vignette 5, all participants would advise conducting an STI test as well. Furthermore, 80% (8/10) mentioned that they would also conduct cervical cancer diagnostic tests because of the symptom of contact bleeding. Participant 9 mentioned the following:

In the case of contact bleeding, more research than only an STI is needed. It could be Chlamydia, but a smear test is needed to exclude cervical cancer.

For the other 50% (3/6) of the vignettes, not all participants gave the same advice as each other or as the digital triage tool. For vignette 2, a total of 60% (6/10) of the participants agreed with the advice of the digital tool, and for vignettes 3 and 6, the proportions were 70% (7/10) and 80% (8/10), respectively. It is important to mention that the initial answer of the participants is presented in Table 2. It could be the case that participants answered “no” to advising an STI test for the patient initially. However, the participants mentioned that they would advise conducting an STI test after excluding other diseases. In addition, sometimes, the participants wanted more information about the patient’s situation before advising to conduct an STI test.

For vignette 2, most participants wanted to know more about the patient’s case before giving the advice to test for an STI. In

addition, they wanted to conduct a physical examination or other tests, such as a test to exclude urinary infection, as the patient’s symptoms seemed not totally compliant with those of an STI. Participant 2 said the following:

I would like to know a little more; why does he think he has an STI? Does he have other contacts next to his current relationship or an open relationship? Has he heard anything from his wife?

Participant 4 answered the following:

I would check his urine.

Participants answered that the symptoms and risk factors were too unclear to advise an STI test. A minority of the participants would test for an STI to exclude it or to satisfy the patient’s request. Participant 2 answered the following:

He asked for an STI test so I would do one.

The participants mentioned that, sometimes, a patient does not have an apparent reason for wanting to take an STI test or the patient has no symptoms that fit with those of an STI. However, sometimes patients do not want to discuss this in detail, and participants found it important to allow for testing at a low threshold if patients asked for it themselves. Participant 9 mentioned the following:

Maybe he (or his wife) is cheating, and they do not want to tell you that directly...It is always the question if the patient is honest with you, so I would test at a low threshold after I did a urine infection test, and then I think he would accept that.

Table 2. Advice of the digital tool and the participants to test for a sexually transmitted infection.

^aP: participant.

^bPercentage of participants who agreed with the advice of the digital triage tool.

For vignette 3, most participants (7/10, 70%) answered that the patient could take an STI diagnostic test but at a later time. At this time, it was too early to detect an STI. A total of 20% (2/10) of the participants also mentioned that they would talk to the patient about her contraception and provide education about safe sex. Participant 2 said the following:

She had unsafe sex, so I would do two things. Maybe check if she uses birth control, and I would tell her that she can do an STI test after two weeks.

Vignette 6 involved a patient from an endemic area. In total, 25% (2/8) of the participants who agreed with the advice of the

digital tool mentioned the endemic area as a reason for testing. Participant 10 mentioned the following:

I would ask her some more questions; however, she is from Surinam, a risk area. So I would test her at a low threshold, especially for a serological test.

The other 62% (6/8) of the participants mentioned low-threshold testing because of the patient’s symptoms. Most participants (6/10, 60%) mentioned that they would check for a urinary infection, some before conducting an STI test and others in addition to it. Participant 1 mentioned the following:

I would check her urine first to ensure she has no urinary infection.

It is important to note that almost all participants mentioned that, if a patient requested an STI test, they would meet the request. They also mentioned that, in some cases, they would also give patients more information about safe sex or conduct a physical examination. The decision to do so often depended on age or other risk factors such as contact bleeding. Especially in the case of younger patients, GPs educated them about safe sex and birth control. However, this information provision was not part of their decision-making process but rather of their consultation.

Extra Factors That Influenced the Decision of the GPs

There were several factors that the participants considered in their decision that were not included in the digital triage tool. The most important additional patient-related factors were anxiety about infection, the wishes of the patient, and age. Among all participants (10/10, 100%), the patient's anxiety was an additional reason for referring them to an STI test. The participants reasoned that a request for an STI test is not made easily and that there may be an unknown reason behind it. In their opinion, when patients experience fear-related stress, it might harm their health. Participant 10 mentioned the following:

Sometimes you feel that there is more than they want to say, and then you decide to test at a low threshold.

Age played a role in the decision-making process of the GPs. This was especially the case in vignettes 1 and 3. The GPs mentioned that checking for STIs was important at a fertile age, especially for women. In the Dutch medical guidelines, it is noted that, below the age of 25 years, there needs to be a low threshold for STI testing even if patients report no complaints. Participant 6 answered the following in the interview about vignette 3:

Especially in younger patients, you want to know what they know about sex and the transmission of STIs.

In 2 vignettes, the GPs felt the need to ask additional questions or conduct a physical examination. The digital triage tool only provides advice on an STI test. However, the symptoms may also indicate a urinary tract infection or a stage of cervical cancer. These tests are not advised via the digital tool but were advised by the participants in this study for those 2 vignettes.

One GP also considered who had to pay for the test and whether it was affordable. Participant 3 mentioned the role of the payer or possible reimbursement in the decision. He answered the following about vignette 6:

If she wants to pay for a test and she wants to do a test...Then, she can do a test.

In summary, it can be generally said that GPs in this study paid extra attention to patient-related factors such as fear of infection, desire to undergo the test, and young age when deciding whether to request an STI test.

Discussion

Principal Findings

In this study, we tried to identify whether the advice of a digital triage tool based on medical guidelines aligned with GPs'

medical practice. The results showed that other factors, which are not part of the guidelines, played a role in the GPs' decision-making process when determining whether to advise an STI test for a patient. The most important additional patient-related factors were the patient's anxiety, wishes, and age. The GPs also considered who had to pay for the test and whether it was affordable. Finally, the GPs were willing in some vignettes to ask additional questions or conduct a physical examination. The most notable factors are discussed in this section and compared with the literature.

In line with other research, the GPs' decision to test depends sometimes on the anxiety and wishes of the patient [7]; these factors were not included in the studied digital triage tool. This additional aspect aligns with the research by Hajjaj et al [5,7]. In addition, our results align with those of a study that researched the barriers to following guidelines among GPs [6] that showed that the patient's preferences were considered more important than following guidelines.

The interviews showed that the age of the patients was an important factor that influenced the GPs' advice. Specifically, younger age was an important reason to advise an STI test because of the risk of infertility and the sexual activity in this group. Age was not included as a factor in the digital triage tool. As STIs mainly occur under the age of 30 years, it is not surprising that GPs tend to advise testing more for patients in this age group [21].

From the literature, it was found that the factor "knowing the patient" influences the decision-making process of GPs [22]. Accumulated knowledge about the patient influences the context and interpretation of the conversation between the patient and the health care professional, especially in the case of psychosocial or unspecific problems such as fatigue. However, in this study, knowing the patient was not a factor that was considered in the vignettes. For this reason, the decisions that the GPs made in this study could be different in real life as they might know the patients.

In addition to patient-related factors (eg, the wishes of the patient), GP-related factors also influenced the decision-making process. The extent to which GPs were open to discussion with patients about why they wanted an STI test or to which GPs were willing to address patients' concerns influenced the decision. In addition, based on the findings of this study, it seems that the GPs expressed a preference for obtaining a complete set of information before deciding. For example, some GPs wanted to have more information about the situation of the patients and their partners. In some cases, GPs wanted to conduct a physical examination or other diagnostic tests (eg, urinary infection) to exclude other diseases. The digital triage tool is strictly bound to the guidelines set up without paying attention to, for example, the anxiety of the patient or the need for additional information. Other guidelines have been developed for possible symptoms of urinary tract infection or cervical problems, which have not yet been combined on the internet.

The advice of the digital triage tool is straightforward and always in line with a strict algorithm. In this study, GPs were found to recommend a diagnostic test for STIs more often than

the digital tool. In the Netherlands, a study showed that unnecessary diagnostics (overdiagnostics) are a common problem among Dutch GPs; slightly more than half of the participating GPs indicated that patients could submit a complaint for not requesting an examination that was indicated and that this played a role to some or a significant extent in the request for diagnostic testing [23].

Our study did not investigate whether the digital tool can prevent overdiagnostics, but we assume that it can be a powerful decision support tool for daily general practice, just as tools for pharmacotherapy are already in use. More research is needed to confirm this.

Another possible reason why GPs are more inclined to test seems to be that it could save them time [24]. For example, if a patient has vague symptoms, it would be easy to request some tests first without having a thorough conversation. Another possible reason specifically for low-threshold STI testing could be feelings of embarrassment to ask about sexual behavior [25]. Recently, a Dutch center for sexual health found that talking about sexual behavior is not done as often as it should by health care professionals [26]. This could be seen as an additional justification for supporting GPs with digital tools for STI testing.

This study does not suggest that digital triage is the holy grail to prevent overdiagnostics or that it is *the* solution to lower the work pressure of GPs. However, this vignette study confirms that GPs have a more holistic approach to their patients compared with a digital triage tool. A digital triage tool primarily relies on specific responses to predefined questions, whereas a GP can consider more factors such as social factors, lifestyle, and personal context. On the one hand, the comprehensive perspective of GPs might result in a higher frequency of diagnostics when compared with a digital triage tool. This is due to the GPs considering additional factors. Given the high workload and time constraints of GPs, the investigated digital tool can play a helpful role in daily decision-making. In contrast, this holistic approach by GPs could potentially lead to fewer diagnostics. Given their deep understanding of the patients' condition, GPs are better positioned to assess the necessity of tests.

This study has several limitations. It could be that social desirability influenced the GPs' answers on the vignettes and interviews. Potentially, the advice of the GPs was more in line with the guidelines compared with that in their daily practice as they were aware of the fact that they were part of research on this topic [12]. It is also worth mentioning that there could be a disparity between what people think they would do in a particular situation and their actual behavior [27]. In addition, this study is not generalizable to the entire field of diagnostics at general practices because of its focus on STI testing. As a starting point, this study identified factors that influenced the decision-making process of GPs for STI testing. In future research, we recommend investigating digital tools and the decision-making process of GPs for other common diagnostic tests.

A strength of this study is the combination of the vignette method, the think-aloud process, and the semistructured interviews, which aimed to obtain a complete range of data on

the topic (triangulation). Although no actual patients were included in this study, we aimed to make the vignettes as valid as possible by developing and testing them with GPs. In addition, providing the same vignettes to different GPs made it easier to compare patients within different general practices instead of comparing real-life patients with different complaints and characteristics. Currently, we are working on a real-life study in which patients in the waiting room of a GP's office complete digital triage for STI testing (the result of the digital triage tool is not shown to the patient), after which they go on to have their planned consultation with the GP. At this consultation, the GP will also advise whether to test for an STI; the advice of the digital tool and of the GP will be compared. We expect more detailed and practical information to further refine this working method using a digital tool.

A qualitative study in which GPs were interviewed about their general attitude toward the use of digital tools by patients in their practice showed that GPs' attitudes toward digital STI diagnostic services were positive, and they acknowledged that the use of eHealth in their practice could result in a more efficient workflow [28].

It will be interesting to further investigate whether GPs are also willing to use digital triage tools as a standard gateway for their practice for some diagnostic tests. When a digital triage tool is implemented and integrated into the care pathway, it is important to investigate what users think of this integration and whether they are satisfied with this change in their way of working. For future research, it could be beneficial to make a comparison of the experiences of patients with a digital triage tool, triage at the GP's office, and a mix. Notably, recent studies on digital chatbots for medical questions have shown that patients perceived the chatbot's responses to be superior to those provided by GPs [29]. For future applications, it is essential to consider patients' eHealth literacy before using a digital triage tool as the primary tool in daily general practice [30,31]; hybrid care might be a solution to address all types of patients. Finally, it is important to realize that the tool in the care pathway needs to stay up-to-date and needs to be changed when the medical guidelines are updated [32]. This study showed that (holistic) factors that are not part of the digital triage tool affect GPs' decision-making. This is an interesting topic for future research as digital tools and artificial intelligence are increasingly being used in health care. Nowadays, GPs use digital medication prescription tools to support their decision-making, which could help with handwriting errors but also with poor treatment decisions [33]. Another example is an artificial intelligence system that could help GPs decide on the early detection of skin cancer [34,35]. Digital technologies such as these should be researched carefully to see what the impact and consequences are for both GPs and patients.

Conclusions

This study shows that, in some cases, patients receive different advice to undergo an STI test from a digital tool and from a GP. Other factors that are not part of medical guidelines play a role in the GPs' decision-making process when deciding whether to request an STI test. The most important additional patient-related factors were the patient's anxiety, wishes, and age. One GP also

considered who had to pay for the test and whether it was affordable. Finally, some GPs expressed a desire to ask additional questions or conduct a physical examination in certain vignettes. In comparison, the digital triage tool adhered more closely to the medical guidelines, with GPs being more inclined than the digital tool to recommend an STI test for the same patient case. Alignment between the digital tool and GP advice only occurred when the risk factors for STI testing were unequivocally evident. This confirms that GPs decide from a holistic perspective. On the basis of these initial findings, we

cautiously posit that a digital triage tool for STI testing can potentially support GPs and may even serve as a substitute for in-person consultations in the future. However, it is imperative to conduct further research to establish safe and effective methods for implementing such a transition.

These conclusions should be approached carefully, recognizing that this study represents an initial exploration and that additional research is required to substantiate and refine these findings.

Acknowledgments

The authors would like to thank all general practitioners who participated in this study. They appreciate the time they invested in this research. In addition, the authors want to thank Fleur Rekveld for her contribution to this paper. Funding was provided by Unilabs. Unilabs played no role in the research design or data collection, analysis, or interpretation.

Abstract

Background: Wearable devices permit the continuous, unobtrusive collection of data from children in their natural environments and can transform our understanding of child development. Although the use of wearable devices has begun to emerge in research involving children, few studies have considered families' experiences and perspectives of participating in research of this kind.

Objective: Through a mixed methods approach, we assessed parents' and children's experiences of using a new wearable device in the home environment. The wearable device was designed specifically for use with infants and young children, and it integrates audio, electrocardiogram, and motion sensors.

Methods: In study 1, semistructured phone interviews were conducted with 42 parents of children aged 1 month to 9.5 years who completed 2 day-long recordings using the device, which the children wore on a specially designed shirt. In study 2, a total of 110 parents of children aged 2 months to 5.5 years responded to a questionnaire assessing their experience of completing 3 day-long device recordings in the home. Guided by the Digital Health Checklist, we assessed parental responses from both studies in relation to the following three key domains: (1) access and usability, (2) privacy, and (3) risks and benefits.

Results: In study 1, most parents viewed the device as easy to use and safe and remote visits as convenient. Parents' views on privacy related to the audio recordings were more varied. The use of machine learning algorithms (vs human annotators) in the analysis of the audio data, the ability to stop recordings at any time, and the view that the recordings reflected ordinary family life were some reasons cited by parents who expressed minimal, if any, privacy concerns. Varied risks and benefits were also reported, including perceived child comfort or discomfort, the need to adjust routines to accommodate the study, the understanding gained from the study procedures, and the parent's and child's enjoyment of study participation. In study 2, parents' ratings on 5 close-ended items yielded a similar pattern of findings. Compared with a "neutral" rating, parents were significantly more likely to agree that (1) device instructions were helpful and clear ($t_{109}=-45.98$; $P<.001$), (2) they felt comfortable putting the device on their child ($t_{109}=-22.22$; $P<.001$), and (3) they felt their child was safe while wearing the device ($t_{109}=-34.48$; $P<.001$). They were also less likely to worry about the audio recordings gathered by the device ($t_{108}=6.14$; $P<.001$), whereas parents' rating of the burden of the study procedures did not differ significantly from a "neutral" rating ($t_{109}=-0.16$; $P=.87$).

Conclusions: On the basis of parents' feedback, several concrete changes can be implemented to improve this new wearable platform and, ultimately, parents' and children's experiences of using child wearable devices in the home setting.

Introduction

Background

Advances in pervasive sensing, internet of medical things, and digital health strategies more broadly [1-6] have rapidly accelerated over the past decade. Although digital health research among adults and adolescents has predominantly used smartphones [7-9], parallel work with infants and children tends to use wearable devices [10], including motion sensors to detect body posture and physical activity [11], audio recorders to assess language environment and development [12,13], heart rate sensors to assess psychophysiology [14], and head-mounted cameras to capture infants' visual perspective of the physical and social environment [15]. Such wearable technology, especially when paired with machine learning algorithms, permits the automated detection of children's behavioral and physiological states, as well as caregivers' responses, and has the potential to transform the field of child development through the collection of big data in real-world environments [16].

At the same time, the use of wearable devices among infants and young children in home environments raises unique ethical, legal, and social implications and logistical challenges. As such, careful attention to the perspectives and experiences of end users of such technology, in this case, parents and their children, is required. In this study, we assessed parents' perceptions of and experiences with a novel wearable device, LittleBeats, developed specifically for use with infants and young children. Little Beats, which is not Food and Drug Administration approved and used only for research purposes, integrates a microphone, a 3-lead electrocardiogram (ECG) sensor, and an inertial motion sensor to synchronously collect information about infant vocalizations, cardiac physiology (heart rate and respiratory sinus arrhythmia), and motion (eg, physical activity level, position, and discrete movements). The electronics are housed in a 3D-printed case (55×57×13 mm), which is placed on a specially designed shirt that the child wears. Data can be collected throughout the day at home, without the researchers present. In prior papers, we reported on machine learning algorithms used to detect and classify child and parent vocalizations using audio data from the LittleBeats device [17] and child sleep states using all 3 sensor modalities [18]. We also conducted technical validation studies to assess the signal quality of each sensor modality in relation to established laboratory protocols and gold-standard equipment [19]. Complementing these prior reports, we focus here on the critical issue of "user experience" among families and their children aged 1 month to 9.5 years. Using semistructured interviews and parent questionnaires to assess parents' experiences and perceptions, our mixed methods investigation examined usability, privacy, and perceived risks and benefits.

The "Digital Health Checklist" for Use in Child Development Research

The proliferation of digital health technologies has spurred a parallel examination of ethical practices and related

decision-making processes around the use of such technologies with human participants. To evaluate the LittleBeats platform, we used the Digital Health Checklist developed by Nebeker et al [20,21]; it is grounded in the ethical principles of the *Belmont Report* [22], which speaks to beneficence, respect for persons (or autonomy), and justice, and the *Menlo Report* [23], which added the principle of respect for law and public trust. These principles form the foundation of a 4-domain framework that includes privacy, access and usability, data management (eg, collection, storage, interoperability, and sharing), and assessment of risks and benefits (Figure 1).

To date, the research and development of the Digital Health Checklist has been applied to digital health protocols in adult samples, including for use in cardiovascular disease prevention [24]; studies of human emotion [25]; and improvement of informed consent communications [26]. The current investigation extended the use of the Digital Health Checklist to research involving parents of infants and children. In doing so, we integrated ethical considerations specific to research with children [27]. Specifically, children are a heterogeneous group, and the potential benefits and risks to child participants need to be understood within the context of the child's age and related physical, cognitive, and socioemotional abilities.

For instance, infants and toddlers may be more susceptible to risks related to emotionally stressful procedures because their coping abilities are less well developed and depend, in part, on support from caregivers. By contrast, older children may be better able to regulate emotions and exert their autonomy, although they might be at an increased risk in other domains. For instance, owing to their growing self-awareness and other awareness, preschool- and school-aged children may be increasingly susceptible to experiencing shame and embarrassment, heightened concerns about privacy, and other related risks to the child's self-concept.

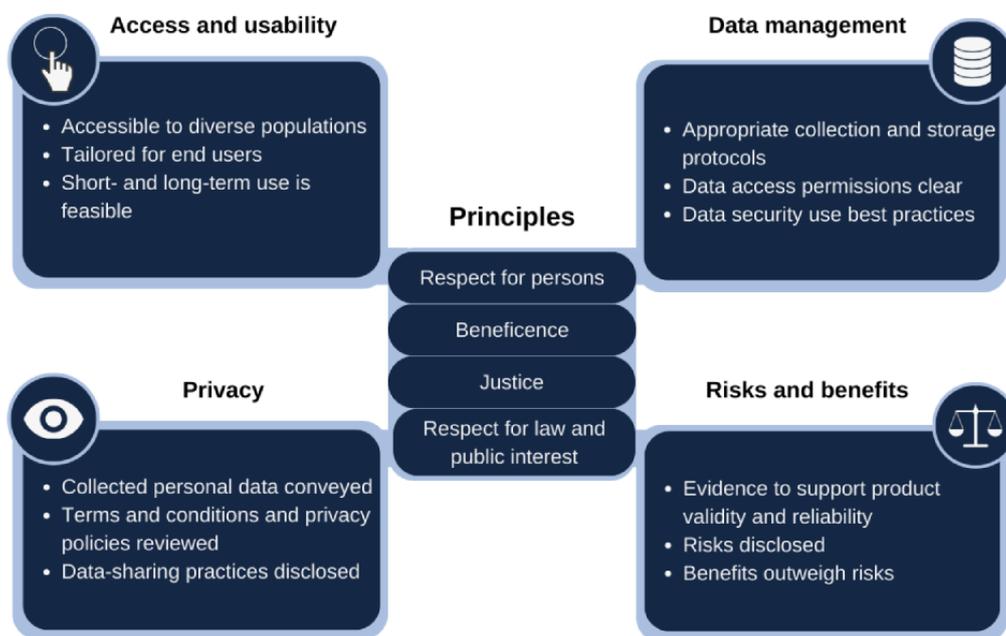

With developmental differences in risk assessment in mind, we assessed LittleBeats user experience among children representing a large age range (infancy through middle childhood). Although we did not interview children about their study experiences, we considered the children's age in our analysis of parents' open-ended responses and parents' perspectives regarding how their children felt about and responded to the research procedures. Research with children requires parental consent and, depending on the child's age, the child's assent to affirm their willingness to participate in the research. The consent process related to the LittleBeats technology has been addressed in a prior report [26]; therefore, we did not consider issues related to the provision of parental consent before participating in this research. Instead, our focus here was on parents' perceptions of and reflections on their own and their children's experiences following the use of LittleBeats at home.

Although child development research incorporating the use of wearable devices is rapidly expanding [28-32], systematic assessment of parents' perspectives and experiences (or ethical

considerations more broadly) of such research has been sparse. A notable exception is a report by Levin et al [33], which outlines several key concerns parents may have about participating in research using wearable or remote sensing devices. These concerns focus on privacy expectations, particularly regarding audio or video data (considered “high fidelity data streams”), data management, and data use (eg, for scientific vs commercial purposes). Although we know of no study that assessed parents’ perceptions and experiences of using wearable devices at home *after* data collection, Levin et al [33] provided valuable insights into parents’ general willingness to participate in such research. Among a nationally representative sample of 210 parents (n=105, 50% mothers)

with at least 1 child aged ≤ 5 years, 71.4% (n=150) of parents responding to hypothetical scenarios indicated at least some willingness to participate in studies involving motion or physiological sensors (low fidelity), whereas a significantly lower percentage of parents (n=99, 47.1%) endorsed willingness to participate in studies gathering audio recordings at home. It remains unknown whether the concerns expressed in the study by Levin et al [33], in which parents hypothetically considered participating in different types of remote sensing research, would also be voiced among parents who participated in research in which their children wore a wearable device with multiple sensor types (eg, motion, physiology, and audio).

Figure 1. Four-domain framework of the Digital Health Checklist for researchers. The Digital Health Checklist for researchers depicts the 4 ethical principles undergirding the 4 key domains of access and usability, privacy, risks and benefits, and data management. Source: this figure is published with permission and reflects an adaptation of the Digital Health Checklist Developed for Researchers (DHC-R) [34,35].

This Study

Guided by the domains of the Digital Health Checklist [20], we assessed parents’ experiences with and perceptions of using LittleBeats at home using a mixed methods approach. In study 1, we conducted a qualitative (thematic) analysis of parental responses to a semistructured interview following the completion of 2 day-long LittleBeats recordings at home; children in this study were aged between 1 month and 9.5 years. In study 2, we collected data on parents’ perspectives of using LittleBeats (again, following the completion of several day-long recordings at home) from a separate, larger sample. In this second study, we administered close-ended questionnaire items developed considering the qualitative themes identified in study 1. The parents in study 2 also had the opportunity to provide open-ended comments. In study 2, we narrowed our developmental focus to children aged 1 month to 5 years because our substantive interests focused on early childhood, and analytic tools are currently being developed for LittleBeats data collected among children aged ≤ 5 years.

Study 1

Methods

Participants

A total of 47 families with children aged 1 month to 9.5 years were recruited through web-based forums (eg, Facebook [Meta Platforms, Inc] parenting groups) and flyers distributed to local organizations (eg, libraries and day care centers) in a small Midwestern city. Because the larger study from which data were drawn included assessments of child stress physiology, families were excluded if their children had any known cardiac abnormalities. Of the 47 families that participated in the larger study, 42 (89%) completed the follow-up interview about their experience of using LittleBeats at home. Interviews were not completed with 5 (11%) families because of losing contact with them or because interview procedures were not finalized at the time of their study participation.

From these 42 families, 43 children (n=20, 47% female) participated. In 1 instance, 2 (5%) children (aged 13 and 71 mo) were from the same family. Children were aged 1.1 month to

9.5 years (mean 44.9, SD 38.36 mo) and represented 6 age groups: young infants (aged 1-5 mo; 7/43, 16%), older infants (aged 6-17 mo; 10/43, 23%), toddlers (aged 18-35 mo; 7/43, 16%), preschool-aged children (aged 36-59 mo; 6/43, 14%), early school-aged children (aged 5-7 y; 7/43, 16%), and school-aged children (aged 8-10 y; 6/43, 14%). Overall, 22 (51%) children were first born, 11 (26%) were second born, and 9 (21%) were third or later born. Mothers were aged, on average, 35.04 (SD 4.09) years, and fathers were aged, on average, 37.42 (SD 4.48) years. Across mothers and fathers, the highest level of education reported included a high-school degree (1/79, 1%), some college or 2-year degree (18/79, 23%), a bachelor's degree (22/79, 28%), or an advanced degree (38/79, 48%). Parents identified as Black (2/79, 3%), Asian (3/79, 4%), White non-Hispanic (70/79, 89%), Hispanic (2/79, 3%), or >1 race (2/79, 3%). These demographic data were missing for 2 (5%) of the 42 mothers and 3 (7%) of the 42 fathers. The mean family income was US \$79,500 (SD US \$25,000).

Ethical Considerations

This study was approved by the institutional review board at the University of Illinois Urbana-Champaign (protocol #21032).

Overview of LittleBeats Procedures

LittleBeats collects 3 streams of data (ECG, motion, and audio data) simultaneously while participants go about their everyday routines (Figure 2). Owing to COVID-19 protocols, all participant engagement was remote. LittleBeats kits (ie, LittleBeats device and shirt, ECG leads, disposable ECG electrodes, alcohol swabs to remove residue from electrodes, medical tape to secure wires on the child's chest, charging cable and block, and setup instruction cards) were either mailed or delivered by a research coordinator to the family's home. After receiving the kit, the mother and child met with the study coordinator through Zoom, a secure video web-conferencing platform. During this 40-minute Zoom visit, the study coordinator guided the mother through the LittleBeats setup (described in more detail subsequently), and the mother-child dyad participated in a series of tasks (video recorded for subsequent coding), including a baseline assessment of child stress physiology at rest and a mother-child play session.

For child participants aged <7 years, the mother-child dyads were also asked to complete a brief series of age-appropriate motion interaction tasks, such as the mother picking up her child

(aged 1-4 mo), the mother and child (aged 11 mo) clapping together, or the mother and child (aged 6 y) playing "Simon Says." Toward the end of the Zoom visit, the study coordinator provided instructions for completing the LittleBeats home recordings. Families were asked to complete 2 day-long recordings (approximately 8 hours per day). All adults present at home during the recordings (eg, parents, grandparents, and babysitters) were required to provide consent to the LittleBeats recordings using a secure web-based form provided by the research team. If any nonconsenting adults were at home, parents were asked to turn off the device while these individuals were present. At the end of each day of recording, parents (usually mothers) completed a brief questionnaire about the day's recording (eg, recording start and stop times). To compensate the families for their time, parents were sent a US \$100 e-gift card.

With regard to setting up LittleBeats, the research coordinator walked the mother through the following setup steps at the beginning of the Zoom visit: (1) threading a set of ECG lead wires (20 cm) through the back of the shirt pocket, (2) connecting ECG leads jack (2.5 mm) to the LittleBeats device, (3) turning the device on by sliding the switch to the "on" position (confirmation that the beginning of the recording is indicated by a red flashing light displayed on the device), (4) placing the device in a snug, specially designed shirt pocket, which is secured using 2 snaps, (5) snapping leads to 3 repositionable latex-free gel electrodes, (6) putting the LittleBeats shirt on the child, (7) cleaning the skin (where the electrodes will be placed) with an alcohol prep pad and then placing the electrodes on the child's skin, and (8) applying a small strip of 3M Micropore medical tape to each ECG wire approximately 5.1 cm below each ECG sticker to help secure the wires in place.

At the end of the Zoom visit, the research coordinator also walked the mother through how the LittleBeats device should be removed. The removal steps include (1) removing electrodes from the child's skin and using provided alcohol wipes, as needed, to remove residual gel from the electrodes; (2) unsnapping the electrodes from the ECG wires; (3) taking off the LittleBeats shirt; (4) removing the device from the shirt pocket; (5) sliding the slide switch to the "off" position; and (6) plugging the device into the provided charging cable (microUSB cable).

Figure 2. (A) LittleBeats device case; (B) LittleBeats supplies, including electrocardiogram leads, electrodes, charger, and shirt; and (C) an infant wearing LittleBeats at home.

LittleBeats Device Design and Study Implementation for End Users

LittleBeats was developed with parents and children (ie, end users) in mind. To provide a context for parents' interview responses about their study experiences, we noted several aspects of the device design and study implementation intended to proactively increase usability and decrease concerns about privacy. With respect to usability, we provided participants with clear, illustrated instructions in several formats (eg, hard copy and on the web). The device was also designed to be simple to use, with an on-off switch and a charging port, and we provided parents with the all the materials in the LittleBeats kit (refer to the *Overview of LittleBeats Procedures* section) that they would need to set up and use LittleBeats at home. For the child's comfort, the device is compact (55×57×14 mm) and lightweight (1.48 oz), with foam padding lining the inside of the shirt pocket in which the device is to be placed. The shirts are adorned with a variety of pocket designs (eg, hearts, animals, trucks, and dinosaurs) to appeal to toddlers and preschool-aged children, and, as part of the LittleBeats kit, families received 2 shirts with different designs. For older children, we provided more age-appropriate solid shirt pockets.

With respect to privacy, audio recordings provide high-fidelity information regarding participants' lives and require special considerations related to participant privacy, data confidentiality, and recording bystanders (for review, refer to the study by Cychosz et al [13]). Our approach to protecting participant privacy aligns with user-centered privacy protections recommended for mobile health research [36] and a "rights-based" approach adopted increasingly in the United States and used by the European Union (ie, General Data Protection Regulation), according to which individuals have the right to control their personal data, including but not limited to consent, erasure, secure data management practices, and transparency. For example, an important strategy to minimize privacy risks includes giving participants control over recordings [37,38]. In this vein, parents were told at several points during their participation (eg, consent process and consent form, verbally during the Zoom visit, and written instruction card) that they were free to turn off or pause the device at any time and that they could request that their recordings be partially or fully destroyed and not be used in the research. With respect to third-party individuals, parents were also instructed to use the device at home when only immediate family members or other consenting adults are present. Parents were informed that all data files were marked only by identification numbers, machine learning algorithms would be used to process the audio data, research personnel would listen to only snippets of the audio files as part of checks on algorithm development and accuracy, and research personnel were trained to protect participant privacy and would immediately cease listening to audio snippets in instances where personal information (discussion of medical, financial, or other personal issues) is being relayed. To minimize the risk of data being intercepted during transfer (ie, uploading data via wireless or Bluetooth networks), data were stored directly on a microSD card on the physical device, and files were configured in such a way that only study personnel could access the data in a human-readable format (eg, wav files for

audio) using a data processing pipeline developed specifically for LittleBeats. Because LittleBeats is not a commercial device, simple modifications can be made to the device firmware (eg, "turning off" ≥ 1 of the sensors) to suit research goals (refer to the study by Islam et al [19] for details about technical specifications).

Parent Interview and Coding Procedures

Upon the completion of the LittleBeats recordings, parents (41 mothers and 1 father) completed a brief phone interview about their experiences of using LittleBeats in the home. To help minimize social desirability biases in parental responses, such as parents' reports of positive experiences with LittleBeats instructions received during the Zoom visit, these interviews were conducted by a second study coordinator who was not present during the Zoom visit. Guided by the dimensions outlined in the Digital Health Checklist [20], as well as special considerations related to research with children [27], our semistructured interview was designed for the purpose of this research to capture information about parents' experiences and perspectives regarding access, usability, privacy concerns, and risks and benefits with respect to the use of the LittleBeats device and the process of carrying out home recordings. Participants rarely provided information specific to the fourth domain of the Digital Health Checklist, data management, which encompasses how data are collected, stored, and shared and the extent to which the data are accessible to other systems or interoperability. Given the nature of the LittleBeats data (ie, they are not shared outside the research team, not accessible or integrated with other systems, and not transferred via a wireless or Bluetooth network that might be susceptible to security breaches), the data management theme is somewhat less relevant to LittleBeats than to health applications that might be accessed by multiple users (eg, patients, health care providers, and insurance providers). When parents expressed their views on the processes of data collection, storage, and security in the interviews, they almost exclusively focused on the audio recordings and privacy considerations. Therefore, we coded these responses under the privacy domain.

The interview included 11 open-ended questions, and the study coordinator conducting the interviews used standard probes to gain more insight into parents' experiences, perceptions, concerns, and questions (Multimedia Appendix 1). The interview questions allowed for feedback from all family members' perspectives (ie, the participating child, participating parents, and any other children or adults in the home). All parent interviews, conducted by the same study coordinator to ensure consistency, were audio recorded with the participant's permission. Interview recordings were manually transcribed, and identifiable information (eg, names and birth dates) and conversational placeholders (eg, "uh-huh") were omitted from the transcripts.

We used Taguette [39], an open-source web-based tool for coding textual qualitative data, to capture prevalent themes in our interview data and followed the 6-step approach to thematic analysis defined by Braun and Clarke [40]. At step 1, a review of the transcripts provided preliminary ideas for codes. At step 2, initial codes were generated based on the data from 5

interview transcripts of parents with children from different age groups. Through a series of team discussions, we developed an initial codebook focusing on areas that fell into the larger categories outlined in the Digital Health Checklist [20]. Three transcripts were then used for training purposes, and 3 researchers individually coded the transcripts. Discrepancies were discussed, and additional changes were made to the codebook. Upon the completion of the training, 1 researcher (who was not informed of the specific study objectives) coded all the transcripts using the refined codebook. Reliability was assessed by having the fourth author code 8 randomly chosen transcripts, and among the parent responses that both coders deemed codable, agreement was excellent (Cohen $\kappa=0.967$). At step 3, the research team met on a regular basis throughout the coding process to identify and discuss potential themes. At step 4 and after the completion of coding, final themes were reviewed by checking themes in relation to the entire data set to ensure an accurate representation of the data. At step 5, themes were refined and finalized by providing descriptive labels and definitions. At the final step, we organized the results based on the key domains of the Digital Health Checklist and created a summary table of themes with selected interview excerpts to illustrate the findings.

Results

Overview

Themes identified under the major categories of access and usability, privacy, and risks and benefits are summarized in the subsequent sections. Overall, similar themes were identified across developmental periods, although specific examples illustrating a given theme often differed depending on whether the parent reported on their infant, toddler, preschool-aged child, or school-aged child.

Access and Usability

According to the Digital Health Checklist, the domain of access and usability prompts researchers to consider whether the participant will be able to use the device as intended. This may involve evaluating whether the product has infrastructure requirements, such as internet access, as well as whether the device has been successfully used in the target population. In this study, usability refers to parents knowing how and being able to successfully use the LittleBeats device and materials (eg, ECG leads). Furthermore, usability encompasses families' experience of and ability to adhere to the study procedures more generally (ie, participant burden, eg, completing multiple day-long recordings), beyond the use of the device itself (Table 1).

A majority of parents expressed sentiments regarding their ability to easily operate the device (ie, turning the device on-off and charging the device). Some parents indicated feeling comfortable given their previous experience with comparable equipment, yet other parents with no such prior experience expressed similar views about the ease of use. Parents also commented that the instructions were helpful and appreciated

having a variety of resources to refer to, if needed (eg, written instruction card, website, and study personnel contact). Aside from operating the device itself, parents had varying views on the materials needed to place the device on their child. Some parents noted that the design was well thought out and that setting up the electrodes was not complicated. However, other parents indicated some challenges with the materials, such as with threading the electrodes through the back of the shirt pocket.

Parents also expressed differing perspectives about the ease of setting up (and removing) the device. Although many parents felt comfortable placing LittleBeats on their children, some parents noted that gaining their children's cooperation was sometimes a challenge. For instance, some parents reported difficulty putting the device on their "wiggly, squiggly" infants. Other parents reported reluctance on the part of their toddlers or preschool-aged children, who could express their opinions and desires verbally. Typically, if challenges related to child cooperation were experienced, it was during the setup phase, and parents suggested that once their child was wearing LittleBeats, it was quickly forgotten. Parents expressed that the placement of the device on the upper anterior torso (ie, chest) may be disruptive to some activities, such as napping for a child who is a tummy sleeper. Relatedly, the device being concealed in the shirt pocket, with the ECG leads underneath the shirt, was viewed as a disadvantage by some parents who wanted to know whether the device was recording properly or whether there was a malfunction (eg, device turned off or ECG electrodes fell off).

With respect to participant burden, parents expressed a mix of perspectives. Many parents described day-long recordings (ie, >8 h/d) as feasible but challenging. However, parents noted factors that mitigated this challenge, such as the need to record for only a limited number of days spaced across multiple weeks, the ability to schedule their recordings when it worked for them, and the reduction in other competing activities due to the COVID-19 pandemic. In the same vein, parents expressed wanting more features to help them fulfill project expectations. Currently, the device provides no information to the user beyond an indicator light showing that the device is powered on. Parents found it difficult to know how long they had recorded for or how much battery charge was left when using the device.

In addition, many parents described the project as convenient, indicating that the remote data collection procedures were appealing. Being able to collect data at home, on their family's own schedule, made it relatively easy to participate. Parents were not burdened by the need to travel to a research laboratory, and they could set up the device and start recording when it fit their schedule. Concerns about being able to keep the device on securely or ensure that the device was collecting data were voiced by some parents of older and more active children (eg, increased unsupervised time and gel adhesive weakening owing to perspiration). Other parents expressed their worry that their children would damage the device during data collection.

Table 1. Themes, subthemes, and example excerpts related to the access and usability of the LittleBeats device and study procedures (study 1).

Themes and subthemes	Example excerpts
Operating the device	<ul style="list-style-type: none"> “Everything was pretty easy. It was easy to charge, it was easy to you know put the stickers on and attach, and like I said I don’t think she really felt like it was on. The first day after she asked after an hour ‘how long have I had it on’ I was like ‘why is it uncomfortable’ she was like ‘no I was just wondering’ and I was like ‘oh okay.’ I don’t think she even realized she had it on half the time.” (Parent of a school-aged child)
Instructions	<ul style="list-style-type: none"> “They [the instructions] were very clear. I mean they made it so that I felt confident putting it on her and doing what I was supposed to do.” (Parent of an older infant)
Support materials (specially designed t-shirt, wires, and electrodes)	
Ease of use	<ul style="list-style-type: none"> “I think the t-shirt definitely made it easier to use. That was a nice little set up, and it made it, you know, stay in place and like see where it [the device] needed to be for it to be hooked up and stay in place...And then even with the hole on the inside [of the shirt] to make it easy to get all the cords. That was really a unique design tool but effective.” (Parent of a school-aged child)
Challenges	<ul style="list-style-type: none"> “It was a little hard getting the black metal piece through the back of the shirt. Like I needed that hole to be a little bigger. So, I’m sure I ripped mine just a little bit...But I just made it a little bit looser.” (Parent of an older infant)
Setting up and removal of LittleBeats	
Comfort with set up	<ul style="list-style-type: none"> “I’m pretty comfortable getting it set up and turning it on. It seems pretty straightforward.” (Parent of a school-aged child)
Child cooperation	<ul style="list-style-type: none"> “It was mostly the initial putting it on. She didn’t want to cooperate with letting us get it on...but after a little bit she forgot it was there because she didn’t have any issues messing with it and then when it was time to take it off she was fine.” (Parent of a preschool-aged child)
Location of device	<ul style="list-style-type: none"> “I wish the device itself was a little more discreet. Well, he’s a stomach sleeper so for naps I had to take it off but if it was a little more discreet or was not in front of the t-shirt but maybe on the arm it would be more convenient.” (Parent of an older infant)
Participant burden	
Time commitment	<ul style="list-style-type: none"> “You know once we broke it up a little bit we could [complete recordings]. I was more worried about you know were rarely all home just the four of us especially now that quarantine is over...We’re just more on the go than we were a year ago.” (Parent of an early school-aged child)
Convenience	<ul style="list-style-type: none"> “It was really easy for me as a parent. I drive my other son like I said to [research lab in different city] a bunch...and so that is just a drag, a lot of back and forth. But for I would say from a parent’s standpoint, this was very easy for me to do.” (Parent of an early school-aged child)
Worry about recordings	<ul style="list-style-type: none"> “My son’s pretty active, so he sweats a lot over the course of the day. The little stickers would kind of migrate a little bit...So, I worry a little bit that the first recording like the second half of the day might not be as accurate as it was supposed to be.” (Parent of a preschool-aged child) “It would be nice if there were some kind of indicator of battery more visible. And it was also, you know, since I had to take it on and off then count the time, that was also kind of challenging...so some kind of indication of time would also be awesome but I don’t know how complicated it would be to make it.” (Parent of an older infant)
Worry about device	<ul style="list-style-type: none"> “A lot of the activities that she wants to do involve painting or drinking water...those kinds of worrying me every time she picks them up. I was more concerned about the hardware.” (Parent of a preschool-aged child)

Privacy

The privacy domain focuses on the types of personal information that are or will be collected about participants. In this study, privacy relates to participants’ expectations about and understanding of the process of data collection, in general, and the audio recordings, specifically. Furthermore, this category

encompasses the control that participants had over the data collected (Table 2).

Many parents commented that they were initially apprehensive about the home audio recordings but that their worries subsided when provided with more details during the initial informational call with the study coordinator. Other parents noted feeling more comfortable with the audio recordings over time as they participated in the study. Some parents discussed that although

they had no concerns, their spouse or partner did. Typically, only 1 parent (usually the mother) was present for the initial informational call with the study coordinator, and this parent then conveyed information to the other parent, which often sufficed to relieve privacy concerns.

By contrast, for some parents, positive views of research, such as having trust or placing value in research, negated concerns about privacy. Other participants described not being concerned with the audio recordings because they “had nothing to hide.” From this view, the audio would capture a typical day in their life, and participants elaborated by describing that the recordings would include everyday family discussions as well as arguments, which participants conveyed as just part of ordinary family life. Others’ lack of concern regarding the audio recordings stemmed from their ability to control when they were recording and, consequently, what was being recorded. They described the process of turning the device on and off as relatively easy and, therefore, reported turning the device off when they were

discussing private matters. Some participants mentioned developing ground rules ahead of time to ensure that private information was not discussed when recordings were taking place and, if needed, would alert or remind other family members of the recordings.

The possibility of recording other individuals beyond immediate family members was considered. In working to respect others’ privacy, the participants mentioned several challenges. Some participants expressed that they altered their typical day to avoid interacting with others so that they would not have to worry about unintentionally recording a nonconsenting individual. Other participants stated that although they had planned to record at convenient times when no nonconsenting individuals were around, unexpected situations arose. In addition, although parents had the ability to control when the device recorded, some parents acknowledged that remembering to turn off the device when others were around could be challenging.

Table 2. Themes, subthemes, and example excerpts related to privacy concerns about the LittleBeats audio recordings (study 1).

Themes and subthemes	Example excerpts
Initial apprehension about audio recordings	<ul style="list-style-type: none"> “Cause that was my husband’s big question like ‘are they just going to sit and listen to our day?’ So, he was a little worried about that but once it was explained [that machine learning algorithms would be used to analyze the audio data] he was more comfortable and on board.” (Parent of an early school-aged child)
Unconcerned about audio recordings	
Former views or experiences of research	<ul style="list-style-type: none"> “She [study coordinator] also told me that it is only used for research purpose and nothing else...I actually love to participate [in research studies]. It is only used for research purposes, so that’s okay.” (Parent of a preschool-aged child) “I was in a study when I was pregnant and we did something similar...my understanding was that the recordings just gets run through the software so we really don’t have anything any interesting happening here so I wasn’t terribly concerned about that [the audio recordings].” (Parent of an older infant)
Just an ordinary family context	<ul style="list-style-type: none"> “I explained everything to everybody [family members, including older children in home]. I do remember there was one particular situation where my 10-year-old was getting into trouble and afterwards he said, ‘Well, they’re gonna hear that!’ And I said this is just a regular family, there’s nothing to be embarrassed about or whatever.” (Parent of a toddler)
Ability to control the recordings	<ul style="list-style-type: none"> “My husband’s a veteran, and he works at the V.A...., so we had to make sure we turned it off before he came home from work because a lot of times he talks about his day.” (Parent of a toddler)
Respecting others’ privacy	
Adjusting routines or activities to accommodate the study	<ul style="list-style-type: none"> “I think the only thing is that we didn’t go play with some friends across the street those days where we would’ve otherwise. Like it impeded a little bit of our typical routine, but it felt pretty unobtrusive.” (Parent of a preschool-aged child)
Unexpected situations	<ul style="list-style-type: none"> “When something was happening that I wasn’t expecting, like when I would get a phone call or something like that, and I was just a little concerned about remembering to turn off the device.” (Parent of an older infant)

Risks and Benefits

Evaluating the risks of possible harms in relation to the possible benefits resulting from the knowledge to be gained from the research is linked to the principle of beneficence. Study benefits should outweigh the possible harm to participants and the groups they represent. Risk assessment includes evaluating the type of harm, psychological, physical, reputational, or economic. In addition, researchers must consider the duration, severity, and intensity of the possible harm. Specific to the risks associated

with the use of LittleBeats at home, parents expressed varying views along several dimensions, including safety, child comfort, and understanding of the research and its direct outcomes for participants (Table 3).

Many parents expressed that they thought the device was safe for their children to wear. These parents described not being concerned about safety because of the design of the device and the protective features built into it (eg, device was enclosed, tape-covered wires, fitted shirt, and pocket with secure snaps).

Some parents indicated that they initially had safety concerns (eg, the device being close to the skin and use of Bluetooth to transfer data) before learning more about the device and its setup (eg, the device itself is not in contact with the skin but is placed in a padded pocket, data are stored directly on the device, and Bluetooth is not used for data transfer). In some instances, parents detailed concerns about their children wearing the device in unsupervised contexts, such as during naptime, and they preemptively removed the device before naps.

Parents also commented on their children's level of comfort or discomfort. Several parents mentioned that they observed their child functioning normally, such as engaging in typical routines and activities. Parents also stated that their children did not express any discomfort and did not seem to notice that they were wearing the device after a while. Other parents noted their children's discomfort in putting on or removing the electrodes and medical tape used to secure the wires on the chest. Some parents worried about how comfortable it would be if the child were to hit the device on another object, such as the edge of a table.

Finally, parents' understanding of the research and its direct outcomes for their families may confer risks and benefits. Some parents revealed a limited understanding of how the data would be used (ie, the ultimate outcome of the research process) or wanted direct feedback on their children's development, which could pose unintended risks (eg, unfulfilled expectations of direct benefits). Other parents voiced the benefits attributed to participating in the research project itself. For instance, participation provided dedicated time spent together as a family, or completing the surveys was an opportunity to reflect on their children's activities and development. Several parents expressed their desire to contribute to the project because they recognized the importance of the research. Some parents indicated that they had enjoyed participating in previous studies, and others stated that this project's description seemed interesting and fun. Other parents of older children revealed that when they initially talked to their children about the study, their children seemed interested in participating, so they signed up. Some participants communicated that their children enjoyed participating in the project, with one parent acknowledging that their children felt special for a day while wearing the LittleBeats shirt.

Table 3. Themes, subthemes, and example excerpts related to the risks and benefits of participating in the LittleBeats study (study 1).

Themes and subthemes	Example excerpts
Safety	<ul style="list-style-type: none"> • “No [safety concerns] because all of the wires were covered by her shirt and taped down.” (Parent of an older infant) • “Not really [any safety concerns]. I mean the wires were short enough that I wasn't worried about them.” (Parent of an early school-aged child) • “I thought it will get like hot because I recorded for the 8 hours straight, I didn't stop it at all, I was worried maybe it's gonna be hot or something, but it wasn't hot at all. That was my main concern only.” (Parent of a younger infant) • “And then I did have an initial concern...about the safety of having that device running on Bluetooth. I'm not sure how it communicates data and that being so close to skin.” (Parent of an older infant)
Child's comfort or discomfort	<ul style="list-style-type: none"> • “I guess putting them [electrocardiogram electrodes] on wasn't the hard part. The hard part was taking them off, especially the was a little bit hard, and my son is also not very fond of changing clothes.” (Parent of an older infant) • “I'd probably take it off especially because my little one is about 10 1/2 months and she's a tummy sleeper so that would be uncomfortable.” (Parent of a preschool-aged child) • “I mean it seemed it was fine. My sons were playing outside you know riding their bikes and everything and they didn't...say anything was uncomfortable.” (Parent of an early school-aged child)
Outcomes of participating in the research	
Limited understanding	<ul style="list-style-type: none"> • “I would love to know what kind of information. I know what kind of information they collected with the device and I'm just curious what they are going to use it for in the future.” (Parent of an older infant)
Understanding gained	<ul style="list-style-type: none"> • “[Filling out] this survey, I found that I am pretty lucky that my son is more adaptable. The question, was for example, ‘when you want him to go to bed, he just cried or tantrum’ but he never does that.” (Parent of a preschool-age child)
Parent's enjoyment or satisfaction	<ul style="list-style-type: none"> • “I just like participating in research and helping out the scholars. In my undergrad, I was doing some research and I know how important it is and how hard it can be so...I think it's good to help.” (Parent of an older infant) • “I actually like to spend time with my son. He goes to school every day, so I like to do something with him like the zoom interview. And also I want to show him new technologies.” (Parent of a preschool-aged child)
Child's enjoyment	<ul style="list-style-type: none"> • “I didn't mind the surveys or anything, and my son loved wearing the LittleBeats. He kept asking if he could put them on. So, I think it captured the kid's interest too.” (Parent of an early school-aged child) • “We had fun doing it [the study], and I think [my son] enjoyed being special, wearing his special shirt for a day.” (Parent of a toddler)

Study 2

Overview

Building on the key themes of access and usability, privacy, and risks and benefits identified in study 1, we administered a brief survey among a larger sample of parents participating in a different LittleBeats study with children aged 0 to 5 years. Although our main interest was to complement the qualitative findings of study 1 with a quantitative assessment of parents' perceptions using close-ended rating scales, parents were also able to provide open-ended comments. Therefore, we have also summarized the main themes reflected in these open-ended comments.

Methods

Participants

In study 2, a total of 110 parents ($n=108$, 98% mothers and $n=2$, 2% fathers) completed a user experience survey after completing 3 days of LittleBeats recordings at home. Recruitment procedures were similar to those described in study 1. Children ($60/110$, 54.5% female) were aged, on average, 23.4 months (SD 16.87 mo; range: 2–65 mo) and were identified by parents as Black ($n=5$, 4.7%), Asian ($n=8$, 7.5%), White non-Hispanic ($n=67$, 63.2%), Hispanic ($n=15$, 14.2%), or >1 race ($n=11$, 10.4%). Children were first born ($n=50$, 47%), second born ($n=39$, 38%), and third or later born ($n=17$, 15%). Parents were aged, on average, 34.85 (SD 5.01) years, and their highest level of education reported included some high school or high-school degree ($4/106$, 3.8%), some college or 2-year degree ($9/106$, 8.5%), a bachelor's degree ($33/106$, 31.1%), or an advanced degree ($60/106$, 56.6%). Parents identified as Black ($7/106$, 6.6%), Asian ($13/106$, 12.3%), White non-Hispanic ($75/106$, 70.8%), Hispanic ($8/106$, 7.5%), or >1 race ($3/106$, 2.8%). The mean family income was US \$83,250 (SD US \$26,470). Of the 110 parents, 4 (4%) were missing responses on the demographic survey but did complete the LittleBeats user experience survey described subsequently.

Ethical Considerations

This study was approved by the institutional review board at the UIUC (protocol #22631).

Procedure

Families were mailed a LittleBeats kit and participated in a Zoom visit, during which a study coordinator walked the parent through the LittleBeats setup and a visit procedure consisting of a baseline assessment of child stress physiology and parent-child interaction tasks (eg, play). At the end of the visit, parents received instructions about completing the day-long recordings and were asked to complete 3 day-long recordings over the course of 2 weeks. Parents also completed a series of web-based questionnaires about family demographics, child

behavior, and family functioning. Parent questionnaires were administered either via Qualtrics or REDCap (Research Electronic Data Capture; Vanderbilt University [41,42]) hosted at the UIUC, with the support of the Interdisciplinary Health Sciences Institute and Research IT—Technology Services at the UIUC. Both web-based software platforms are designed to support secure data capture for research studies. Once parents returned the LittleBeats kit by mail, 1 parent in the household (who had been involved in setting up and carrying out the LittleBeats recordings) was asked to rate 5 items about their experience of using LittleBeats, including setting up LittleBeats, along with their perceptions of safety, privacy, and participant burden. Each item was rated on a 5-point scale ranging from 1 (*strongly agree*) to 5 (*strongly disagree*). Following each item, parents had the opportunity to add comments or elaborate on their rating. A final open-ended item also asked parents whether there was anything else they would like to share about their experience or anything they would tell someone who was considering joining a LittleBeats study.

Data Analytic Plan

Descriptive statistics, including the frequency distribution, for parental ratings on each of the LittleBeats user experience items were examined. For each close-ended item, we conducted a single-sample t test (2-tailed) to determine whether the mean rating significantly differed from the midpoint of the scale (ie, value of 3="neutral"). Finally, using the coding scheme developed in study 1, we assessed themes from parents' responses to the open-ended items.

Results

Parents' Ratings on User Experience Items

Percentage frequency distributions of parents' ratings on the user experience items are shown in Table 4. Single-sample t tests indicated a significant difference between the item average (lower ratings indicated greater agreement; higher rating indicated greater disagreement) and the midpoint of the rating scale (3="neutral") for 4 (80%) of the 5 items. Compared with a "neutral" response, parents were significantly more likely to *agree* that (1) the LittleBeats instructions were helpful and clear (mean 1.21, SD 0.41; $t_{109}=-45.98$; $P<.001$), (2) they felt comfortable setting up LittleBeats on their child (mean 1.42, SD 0.75; $t_{109}=-22.22$; $P<.001$), and (3) they felt their child was safe while wearing LittleBeats (mean 1.33, SD 0.51; $t_{109}=-34.48$; $P<.001$). Compared with a "neutral" response, parents were significantly more likely to *disagree* that they worried about being recorded by the LittleBeats device (mean 3.62, SD 1.06; $t_{108}=6.14$; $P<.001$). The final item tapped parents' perceptions of burden ("I felt that completing LittleBeats recordings for full 3 days was challenging"), and the item average (mean 2.98, SD 1.17) did not significantly differ from "neutral" ($t_{109}=-.16$; $P=.87$).

Table 4. Frequency distributions of parental rating of the LittleBeats user experience survey (study 2; n=110).

Survey item	Strongly agree, n (%)	Agree, n (%)	Neutral, n (%)	Disagree, n (%)	Strongly disagree, n (%)
The instructions to setup LittleBeats were helpful and clear.	87 (79.1)	23 (20.9)	0 (0)	0 (0)	0 (0)
I felt comfortable setting up LittleBeats on my child.	75 (68.2)	29 (26.4)	2 (1.8)	3 (2.7)	1 (0.9)
I felt my child was safe while wearing LittleBeats.	76 (69.1)	32 (29.1)	2 (1.8)	0 (0)	0 (0)
I was worried about being recorded when the LittleBeats device was on.	3 (2.7)	13 (11.8)	32 (29.1)	35 (31.8)	26 (23.6)
I felt that completing LittleBeats recordings for 3 full days was challenging.	11 (10)	32 (29.1)	26 (23.6)	30 (27.3)	11 (10)

Parents' Responses to Open-Ended Items

A review of parents' responses to the optional item to add further comments following each of the rating scales revealed themes that closely mirrored study 1 findings. Regarding the ease-of-use item, 29 (26.4%) of the 110 parents added comments. Most parents noted that having an instruction card included in the kit, as well as a QR code to easily link to the website for more detailed instructions, increased usability.

Regarding comfort in setting up the device, 23 (20.9%) of the 110 parents added comments. Parents noted that they felt comfortable and that the setting up of the device was easy. However, parents also noted that the process of setting up the device was difficult when their child moved around. Other parents mentioned the comfort level of their child (eg, noting that their child felt discomfort when removing the ECG electrodes).

Regarding safety, 25 (22.7%) of the 110 parents added comments. Parents noted few concerns because the device was concealed in a pocket and not easily accessible to the child. Parents who expressed a concern commented on the placement of the device on their child's chest.

Regarding concerns about being recorded, 32 (29.1%) of the 110 parents added comments. Some parents noted feeling self-conscious about their parenting or other family members' language choices. Typically, these comments were followed by comments about feeling relieved that the audio would be processed by a machine (vs a human coder). By contrast, many parents explained that they went about their day as usual, which typically contained some sort of sibling argument or other family disagreements.

Regarding participant burden, 68 (61.8%) of the 110 parents added comments. Unlike in study 1, where participants were asked to use the device for 2 days, study 2 participants were asked to use the device for 3 full days (or a total of about 24 hours) over the course of 2 weeks. Several parents commented on their families' busy schedules and difficulty finding 3 full days when only immediate family members were present.

Finally, a number of parents (46/110, 41.8%) responded to the final open-ended question asking whether they had any other comments they would like to share. Responses mirrored study 1 themes in several respects, including parents' and children's

enjoyment in participating in the study (eg, "fun and easy" and "I would recommend to my friends"), children's ability to forget about the device and go about their usual day (eg, "did not interfere with our day"; "[Child] did not notice the device...he was able to nap with it on and so it was really pretty simple to participate!"; and "once the shirt was on, she forgot it was there and so did I!"), and suggestions for ways to minimize burden and improve the experience (eg, adding a display on the device that provides more information about battery charge, power status, and recording length).

Discussion

Summary

Digital health technologies have largely been developed with adults in mind. Interest in and attention to the use of wearable devices among infants and young children, however, has been growing, and data collection using wearable devices provides several advantages over traditional data collection methods, including continuous assessment, greater ecological validity, and the automated detection of behaviors using machine learning algorithms. Given these advantages, combined with rapid technological advances, it is likely that the use of wearables in child development research will burgeon in the coming years. Therefore, assessing how such devices and related data collection protocols are perceived and experienced by parents and their children is critical. User experience studies not only address ethical considerations but can also lead to important changes in research protocols that address parents' concerns and increase the benefits for future families who participate. Indeed, our mixed methods investigation across 2 studies yielded consistent findings that shed light on parents' experiences and perceptions of LittleBeats' usability and safety, the privacy of the audio recordings, and potential risks and benefits of participating in research of this kind. A large majority of parents indicated that device instructions were helpful and clear, the device was easy to use and safe, and remote visits were convenient. Parents' views about privacy, risks, and benefits were more varied, although, on average, parents reported feeling comfortable with the audio recordings. In summarizing the major themes identified within the major categories, we consider ways in which the findings can inform the future design and implementation of wearable platforms in child development research.

Key Findings

Results across all themes underscored the variability in parents' (mostly mothers') perspectives and experiences. With respect to access and usability, some parents expressed interest in having access to information that indicated the cumulative time recorded as well as the battery charge remaining. Such additions to the platform would eliminate parents' need to track the recording length and minimize parents' concerns about whether the device was sufficiently charged and recording. Some parents also noted difficulty with threading the ECG lead wires through the back of the shirt or were worried that their child would tug on the wires. These challenges can be remedied by changing the shirt design such that the ECG wires would be more fully integrated into the shirt fabric or design. Although parents indicated that day-long recordings (ie, >8 h/d) were feasible, some parents noted challenges. To alleviate the burden of day-long recordings, the time requirements can be adjusted to be more flexible. For instance, parents can be asked to complete recordings for fewer hours per day across multiple days (ie, 3 to 4 h/d across 4 to 5 d), although the optimal length and frequency of recordings needed to reliably capture the constructs of interest will vary as a function of the research questions being addressed. Importantly, such burdens were balanced by parents' comments regarding the convenience of remote visit procedures and the ease of using LittleBeats.

Privacy was a theme that also garnered a variety of responses. Some parents indicated few concerns about the privacy of the home audio recordings, whereas other parents worried that the recordings captured private conversations. In the latter case, some families used rules or reminders to control or limit when audio recordings were collected. It is also notable that parents within the same family sometimes expressed differing levels of comfort or concern with the audio recordings. When this pattern emerged, it was largely fathers who voiced concern about invasion of privacy, perhaps because they were not present for initial conversations with the study coordinator, who detailed how the data would be collected and used.

We consider 2 main ways to address parents' privacy concerns about the home audio recordings (also refer to the study by Cychosz et al [13]). First, providing specific and concrete examples of how the audio recordings are processed and analyzed, perhaps by illustrating a hypothetical example of the data collection, processing, and analysis steps, may help ease privacy concerns. Indeed, some parents noted that the use of machine learning algorithms to analyze the data alleviated their concerns about the audio recordings and privacy-related issues. Thus, describing the machine learning algorithms in a detailed yet accessible manner for nontechnical users and stating ways in which the data will not be used or analyzed (eg, no transcriptions of speech) may help reassure parents. Such information should be provided to all family members participating in the home recordings, including older siblings, and should be presented in various formats (eg, brief informational videos, hard copy pamphlets, interactive web page), along with multiple ways to contact study personnel for questions or comments. As part of this solution and building on some parents' perspectives that the recordings were just capturing "typical family life," researchers conducting day-long

recordings may also explicitly highlight the family as an important context for development, coupled with appreciation for the fact that all families are different, and that, as researchers, we want to capture what life is like for each family and infant.

A second solution to alleviate parents' concerns about privacy could involve technological innovations, such as collecting audio recordings in which speech content is not intelligible (refer to the study by Levin et al [33]) or data processing (eg, machine learning algorithms) that occurs on the device or hub in the home so that the audio recordings are not stored or released to the researcher. However, these solutions require further technological advances in audio signal processing and raise issues regarding data-quality assurance. That is, without high-fidelity recordings, the validation and quality checks of machine learning algorithms become difficult. Furthermore, when parents were presented with several hypothetical scenarios for collecting child sensor data in the home environment, parent-reported willingness to participate did not significantly differ between study scenarios in which lower resolution audio data were collected (eg, recording 1-min snippets every 20 min and processing audio data automatically so that raw audio data are not stored) and study scenarios in which higher resolution data (eg, continuous audio recordings) were collected [33]. Taken together, although technological solutions aimed at increasing privacy protection seem to be a reasonable avenue to pursue, future studies on users' experiences of child wearables, particularly home audio or video recordings, should systematically assess parents' concerns, needs, and desires when it comes to balancing the privacy of day-long home recordings with the benefits of participation.

Third-party or bystander privacy is also a complex issue [37,38]. In this study, there were two categories of potential third parties: (1) nonparental caregivers or relatives at home who were part of the child's regular routine and (2) individuals who were not part of the home environment (eg, delivery persons and neighbors). In the first case, nonparental caregivers can be included in the recording if they provided consent. In the second case, the parent would need to turn off the device while the individual is present or change their routine to avoid third parties, which may have consequences for ecological validity. Concerns about third-party recordings can also be resolved by the same types of technical solutions outlined earlier.

The principle of beneficence yielded a variety of responses regarding the risks and benefits of the study procedures. First and foremost, safety was a key theme, and across both samples, parents predominantly expressed views that LittleBeats was safe. When concerns about safety were mentioned, parents often presented hypothetical concerns (eg, the device being close to the skin, the device radiating heat, and the child accidentally falling on the device; the last scenario is mentioned as a potential risk in the parental consent form), which were usually alleviated once the parent learned more about the study. Some parents also mentioned concerns about the child wearing the device during unsupervised times, such as naps, and removed the device during these times. Because infants and young children are much more likely to take ≥ 1 naps over the course of the day, this subtheme differed across age groups, with parents of children in younger age groups being more likely to mention

device use with respect to nap times. Another set of risks is related to the child's discomfort, particularly around the application and removal of the ECG electrodes. This potential risk is also mentioned in the parental consent form, and we aimed to ameliorate this risk using latex-free electrodes designed specifically for pediatric populations.

Potential or perceived risks were balanced by parents' perceived benefits, including increased understanding of their child's development through the completion of the parent surveys, parents' satisfaction in contributing to the scientific process, children's enjoyment of the study procedures (eg, play session with parents), and wearing the novel LittleBeats shirt and device. We note that we did not ask directly about perceived benefits in study 2 close-ended items, although parents in this study did indicate the benefits of participation in the final open-ended question asking whether they had any other comments they would like to share. These responses often paralleled the positive sentiments that study 1 parents expressed. Nevertheless, items that assess the perceived benefits of study participation will be important to include in future studies.

With respect to increasing direct benefits to participants, we gave families personalized books summarizing information that we have collected about their children (eg, height and weight at different ages) in prior studies. Such summaries have been well received and appreciated. Similar types of summaries can be made from data extracted from day-long recordings (eg, frequency and duration of infant babbling or crying). Providing this type of study feedback to parents may also promote effective participant recruitment and retention, particularly among studies that involve high-fidelity data, such as audio recordings. As noted by Levin et al [33], individuals are likely to evaluate intrusiveness and data privacy, on the one hand, and direct benefits to themselves and their children (such as receiving useful, personalized information or feedback from the data collected), on the other hand, when making decisions about whether to participate in such research.

Study Limitations and Future Directions

We note several limitations of our user experience studies. First, we did not ask our older child participants about their experiences directly, although parents reported on a variety of child experiences, including compliance with putting on the device, excitement in wearing the shirt, feeling special while wearing the shirt, and comfort or discomfort. The device hardware was relatively compact and lightweight, and parents reported that children tended to forget about it once it was on. Nonetheless, these reflections clearly highlight the need to directly assess not only parents' perspectives but also children's perspectives. Thus, parental reports of their child's experiences

should be augmented by direct observations of infants and younger children while wearing the device as well as interviews with older children. Second, we tracked parents' reported experiences based on the child's developmental stage. Similar themes were found across developmental periods, although specific examples of how themes manifested often differed by the child's age. However, because the subsamples of children in different age groups were relatively small, future research with larger subsamples is needed to more thoroughly investigate developmental considerations related to user experiences in the context of research using child wearables. However, an age-specific consideration that did clearly emerge relates to daytime sleep. Third, in both samples, parents reported high levels of educational attainment. Future research on parents' perspectives of using child wearable devices in the home setting should include families with diverse demographic characteristics. Including samples characterized by sociodemographic factors in user experience studies is especially critical for child wearables developed for the purposes of mobile health interventions.

Conclusions

Wearable sensors designed for and validated with infants and young children present researchers and clinicians with tremendous opportunities to assess developmental processes and outcomes in more ecologically valid and potentially less burdensome ways than laboratory assessments. Furthermore, LittleBeats' multiple modalities provide especially rich data to assess an array of constructs central to child development researchers and clinicians, including parent-child vocal turn-taking, regulation of stress, sleep-wake cycles, physical activity, and developmental disorders. At the same time, although we have validated LittleBeats sensors and machine learning algorithms to accurately capture some of these key constructs [17-19,43], the degree to which LittleBeats and similar child wearables deliver benefits (eg, high ecological validity and low burden) will largely depend on acceptance by the end users (eg, parents and children), making user experience studies critical to this research space. In short, if the technology is not acceptable to the end user, it is less likely to be adopted and used as intended. The user experience assessment presented in this paper goes hand in hand with technical validations of the device, and both are critical for successful implementation. The current results suggest that parents predominantly view LittleBeats as easy to set up and use at home, although views regarding privacy and burden were more varied. On the basis of parents' thoughtful and specific feedback, several concrete changes can be implemented to improve the LittleBeats platform and, ultimately, parents' and children's experiences.

Acknowledgments

The authors are grateful to the families who participated in this research and to Jenny Baldwin for her assistance with participant recruitment and data collection. This work was supported by funding from the National Institute on Drug Abuse (R34DA050256), National Institute of Mental Health (R21MH112578), and USDA National Institute of Food and Agriculture (ILLU-793-368).

Abstract

Background: Early identification of quality of life (QoL) loss and side effects is a key challenge in breast cancer therapy. Digital tools can be helpful components of therapeutic support. *Enable*, a smartphone app, was used in a multicenter, prospective randomized controlled trial in 3 breast cancer centers. The app simultaneously serves as a therapy companion (eg, by displaying appointments), a tool for documenting QoL (eg, by enabling data collection for QoL questionnaires), and documentation of patient-reported side effects. The need for digital tools is continually rising. However, evidence of the effects of long-term use of mobile health (mHealth) apps in aftercare for patients with breast cancer is limited. Therefore, evaluating the usability and understanding the user experience of this mHealth app could potentially contribute valuable insights in this field.

Objective: A usability study was conducted to explore how patients with breast cancer receiving neoadjuvant, adjuvant, or palliative outpatient treatment rated their engagement with the app, the user experience, and the benefits of using the app.

Methods: A mixed methods approach was chosen to combine subjective and objective measures, including an eye-tracking procedure, a standardized usability questionnaire (mHealth App Usability Questionnaire), and semistructured interviews. Participants were surveyed twice during the study period. Interviews were transcribed verbatim and analyzed using thematic analysis. Analysis of the eye-tracking data was carried out using the tracker-integrated software. Descriptive analysis was conducted for the quantitative data.

Results: The mHealth App Usability Questionnaire results (n=105) indicated good overall usability for 2 different time points (4 wk: mean 89.15, SD 9.65; 20 wk: mean 85.57, SD 12.88). The qualitative analysis of the eye-tracking recordings (n=10) and interviews (n=16) showed that users found the *Enable* app easy to use. The design of the app, information about therapies and side effects, and usefulness of the app as a therapy companion were rated positively. Additionally, participants contributed requests for additional app features and suggestions for improving the content and usability of the app. Relevant themes included optimization of the appointment feature, updating the app's content regularly, and self-administration. In contrast to the app's current passive method of operation, participants expressed a desire for more active engagement through messaging, alarms, or emails.

Conclusions: The results of this study demonstrate the good usability of the *Enable* app as well as the potential for further development. We concluded from patients' feedback and requests that mHealth apps could benefit from giving patients a more

active role (eg, being able to actively document side effects as they occur). Additionally, regular updates of app content could further contribute to encouraging continued use of mHealth apps. Our findings may also assist other researchers in tailoring their mHealth apps to the actual needs of patients undergoing breast cancer therapy.

mobile health; mHealth; usability; breast cancer; eye tracking; user interface; mixed methods; mobile phone

Introduction

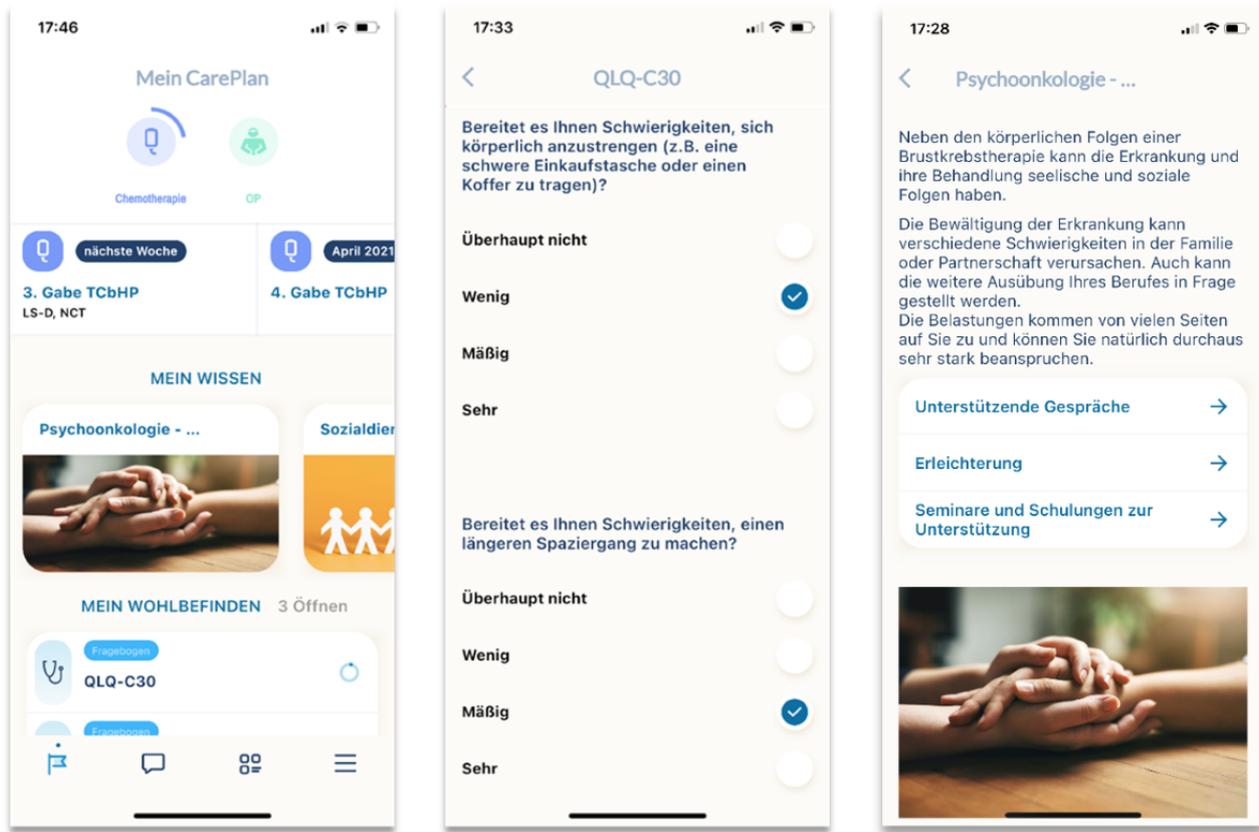

Background

Breast cancer is the most common type of cancer detected in women in the Western world. One in 8 women will develop breast cancer during her lifetime. In Germany, there are 69,000 new cases per year [1]. The diagnosis is a drastic event in the lives of those affected. Although the mortality rate has decreased in recent years, processing and dealing with the new life situation is a great challenge for patients and their social environment [2]. At the onset of therapy, patients can have a strong desire for education and information. Therefore, providing patients with reliable sources of information and support services is a major and important task for the treatment team. Digitalization in medicine offers great potential for supporting the exchange of information and communication between patients and health care providers [3-5]. These benefits can be realized through the use of mobile health (mHealth) apps, which can encompass several helpful functions for patients, such as the provision of educational materials, appointment or medication reminders, and diaries. For the cohort of patients with breast cancer, many of these mHealth apps are already available or are in development [6]. This cohort also shows a high readiness for using health technology, indicating that mHealth apps are an appropriate means of support in the early phase of breast cancer treatment.

A recent study by Chen et al [7] also found that remote monitoring of symptoms between clinical visits could not only improve patient-provider communication but also prepare patients for subsequent chemotherapy cycles and support

symptom management. Within the joint *Center for Innovative Care* project, a network of 5 university hospitals in southwest Germany, a new mHealth app for patients with breast cancer was developed. This therapy support tool, called the *Enable* app, aims to combine known benefits of mHealth tools with an innovative reactive assessment of patient-reported outcomes (PROs). It was conceptualized as an iOS or Android mobile app for smartphones and developed by members of the research team with the support of software developers. It includes educational content, information about the side effects of therapies and medications, and information about other support services such as psycho-oncology or nutritional counseling in the form of static text and images. A progress bar illustrates the patient's individual therapy status in terms of clinical treatment over time (ie, cycles of treatment). In addition to its role as a therapy companion, the app serves as a measurement tool to systematically record patient satisfaction, health-related quality of life (QoL), and patient-reported adverse events. It monitors the neoadjuvant, adjuvant, and follow-up situations in patients with indications for surgery, chemotherapy, radiation, or systemic therapy with primary or metastatic breast cancer. [Figure 1](#) shows exemplary screenshots of the *Enable* app's start page, the questionnaire display, and information about treatments. As studies have shown that physicians generally underestimate a large proportion of relevant side effects, patients are empowered to report PRO data and side effects directly through the app. In cases of significant treatment-related deterioration, the care team is alerted, and recommendations are sent to the patient. This more relevant treatment information, in turn, helps improve therapy monitoring, treatment quality, and patient satisfaction [8,9].

Figure 1. Exemplary content of the Enable app. Left: On the start page of the app, patients can see their current therapy status, a selection of articles from the "My Knowledge" collection, and upcoming questionnaires; Middle: View of the QLQ-C30 questionnaire to assess the quality of life of cancer patients; Right: Sample article on psycho-oncology with the aim of patient education.

The clinical outcomes of the use of the *Enable* app were studied in the *ENABLE* randomized controlled trial (RCT). Other research questions addressed in the *ENABLE* RCT related to improving patients' adherence to therapy, recognizing and treating critical side effects in a timely manner, and measuring the health-related QoL of different therapy strategies. All study participants underwent QoL assessments at 6 time points during and after adjuvant or neoadjuvant chemotherapy. In the intervention group, an additional short weekly EuroQol Visual Analogue Scale questionnaire was administered. In case of deteriorating results, further screening for side effects was triggered, alerting study staff and enabling immediate contact with the patient to provide support in all phases of breast cancer therapy (reactive PRO assessment). The control group received only the app without the reactive PRO assessment.

The body of scientific literature shows that good usability is an important factor for the success of an mHealth app. More specifically, usability can influence patients' acceptance and adoption of mHealth [10,11]. Usability is defined by Nielsen [12] as a "quality attribute that assesses how easy interfaces are to use." According to the International Organization for Standardization (ISO) 9241-1, usability is the "extent to which a system, product, or service can be used by specified users to achieve specified goals with effectiveness, efficiency, and satisfaction in a specified context of use" [13]. Although usability focuses exclusively on the process of using an app or device, user experience involves the users' subjective feelings that result from the use or anticipated use of a system or a

product. For the evaluation of mHealth, both concepts are relevant to obtain a comprehensive view of influencing factors [14].

Good usability can help ensure that the app can be used intuitively by patients and health care providers, which in turn improves compliance and increases the effectiveness of the app. A review by Zapata et al [10] demonstrated the importance of adapting mHealth apps to patients' needs. Relevant usability themes of similar apps were, for example, streamlining of the navigation paths, a clearer information architecture, or the desire for personalization [15,16]. Recent research has also shown that usability assessment is an essential step in the mHealth app development process [17,18]. It is important to ensure that the app is easy to use for the target group and provides the desired benefits [12]. However, a systematic review by Jongerius et al [6] showed that only 1 of 29 mHealth apps for breast cancer care that were studied in their work underwent and published a usability assessment. To address the aforementioned requirements and achieve sustainable and effective use of the *Enable* app, the investigation of usability and user experience is indispensable. Therefore, the study presented in this paper intended to gain an understanding of how patients use the app. The aim was to investigate how patients evaluate their engagement with the app, the user experience, and the benefits of using the app. These findings will serve as a basis for further optimization and adaptation of the app to the patients' needs.

A mixed methods approach provides the opportunity to collect, triangulate, and analyze qualitative and quantitative data,

allowing for the possibility of interpreting the findings from one research approach (ie, qualitative and quantitative) to explain the data generated from the other research approaches. Furthermore, it allows for the use of a qualitative approach to illustrate quantitative findings or the integration of various research approaches to provide a thorough and comprehensive picture of the study [19,20]. Previous studies [15,21,22] have indicated that interviews and usability questionnaires are prevailing methods used for assessing the usability of mHealth apps. However, there are limited studies regarding the real-time capture of users' visual interactions and the subsequent retrospective analysis of user engagement with mHealth apps through techniques such as eye tracking. Eye tracking, a sensor technology, is used to ascertain an individual's presence and record their real-time eye movements. This approach is also used to assess the usability of technologies by showcasing decision-making processes through the analysis of eye movement patterns [23,24].

Objectives

Developing new mHealth apps can be time-consuming and requires several iterations of testing and evaluation. The *ENABLE* project aims to evaluate both the usability and clinical outcomes of the *Enable* app within the same RCT, which could be a promising approach to speed up development, testing, and planning for further implementation. This paper presents a usability study nested within the *ENABLE* RCT and following a mixed methods approach incorporating the eye-tracking method. The objective of this usability study was to explore how patients with breast cancer receiving neoadjuvant, adjuvant, or palliative outpatient treatment rated their engagement with the app, the user experience, and the benefits of using the app.

Methods

Study Design

This study was designed following a mixed methods approach combining real-world user experience and standardized observations in a laboratory setting. The study took place at the Department of Obstetrics and Gynecology, Heidelberg University Hospital, Germany.

Procedure

Study Population and Recruitment

The study participants were recruited from the intervention and control groups of the *ENABLE* RCT patient cohort (German Clinical Trials Register—DRKS ID: DRKS00025611). The *ENABLE* RCT had the following inclusion criteria: diagnosis of invasive or metastatic breast cancer and planning of neoadjuvant, adjuvant, or palliative therapy in an outpatient treatment setting (indications for surgery or chemo-, radio-, or systemic therapy); minimum age of 18 years; German language skills; and possession of a smartphone with internet access. Owing to technical requirements for eye tracking, patients wearing bifocals were excluded from participation. At study enrollment, patients were asked about their interest in participating in the usability study. All interested patients at the Department of Obstetrics and Gynecology, Heidelberg University Hospital, Germany, received written and verbal

information regarding the content and aim of the study and the respective data protection regulations. On the informed consent form, patients could indicate whether they were interested in participating in the usability aspect of the *ENABLE* RCT. Patients who consented to participate in the nested usability study were contacted individually to schedule appointments for participation following a convenience sampling strategy. No reimbursement was provided. The target sample size was 100 questionnaires, 15 qualitative interviews, and 10 eye-tracking studies. Patient recruitment took place from March 2021 to September 2023.

Instruments

The German translation of the mHealth App Usability Questionnaire (MAUQ) [25] was chosen to quantitatively assess the usability of the *Enable* app [26]. The MAUQ enables the usability assessment of mHealth apps from the user's perspective. The MAUQ stand-alone version was formulated to evaluate 3 constructs of usability—ease of use, interface and satisfaction, and usefulness—as well as the overall usability score for the app through descriptive statistics. Each of the items of the MAUQ is rated on a Likert scale ranging from 1 (*strongly agree*) to 7 (*strongly disagree*), with the overall score ranging from 0 to 100. In addition, the questionnaires were complemented with a set of questions developed by the authors. Newly added questions concerned the use of other mHealth apps, smartphone ownership, sociodemographic information, and a free-text field to be able to describe the study sample more precisely. The target sample size was 100.

In addition to the questionnaire, open-ended, semistructured, and guide-based interviews with patients were conducted to explore their perspectives on the usability of the *Enable* app. The interviews were conducted by 2 female researchers (CA and LW) with a professional background in health services research and implementation science. Both researchers have profound experience with qualitative interviewing. The interview guide ([Multimedia Appendix 1](#)) was developed by a team of health services researchers (LW and JM) based on an extensive literature review and recommendations from the app developers. Afterward, the interview guide was pretested. This study is reported according to the COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines ([Multimedia Appendix 2](#) [27]).

Furthermore, to objectively assess how patients interact with the app and identify potential usability issues, an eye-tracking study was conducted. The eye-tracking study was conducted by a usability expert (PM) and a team of health services researchers (CA and LW). A total of 5 tasks were formulated for the eye-tracking study ([Multimedia Appendix 3](#)): app log-in, filling in a questionnaire, searching and reading an article, and logging out from the app. To determine the comprehensibility of the tasks, the duration of the study, and the workings of the *Enable* app, 2 pilot tests were conducted. Following the pilot test outcome, the eye-tracking studies were carried out for 60 minutes with each participant, including the eye tracker setup and the retrospective interview.

The chosen mixed methods approach is designed to systematically collect, cross-validate, and analyze both

qualitative data (derived from semistructured interviews and eye tracking) and quantitative data (obtained through the MAUQ). The inclusion of the eye-tracking method in the usability study enriches the capacity to integrate subjective and objective metrics. The qualitative aspect of the eye-tracking analysis enhances the understanding of the user's app perception within the context of individual interactions and app usability. Simultaneously, semistructured interviews enable an assessment of the practicality of integrating the *Enable* app into daily routines. In contrast, the quantitative data derived from the questionnaire provide precise metrics related to usability measurements.

Hence, the mixed methods approach investigates the *why* and *how* aspects through qualitative inquiry, supplementing conventional quantitative and visual data analyses. The fusion of direct observations of user interactions with the app, poststudy retrospective interviews, semistructured interviews, and the usability questionnaire collectively supports the contextualization and comprehensive interpretation of the gathered data.

Data Collection and Analysis

Quantitative Measures

The MAUQ and sociodemographic questionnaire were mailed twice to all patients after inclusion in the RCT. Data collection lasted from May 2021 to October 2022. Study data were collected and managed using REDCap (Research Electronic Data Capture; Vanderbilt University) tools [28] hosted at Heidelberg University Hospital. REDCap is a secure, web-based software platform designed to support data capture for research studies. After completion, all data were exported from REDCap to the R statistical software (version 4.0.4; R Foundation for Statistical Computing). All data were checked for completeness and analyzed by study team members. A descriptive analysis of the questionnaires was performed using R. Means and absolute and relative frequencies were calculated.

Qualitative Measures

Interviews were conducted after participants had used the app for 8 weeks. The interviews took place partly face-to-face at the clinic and by telephone in consideration of current guidelines for preventing infections with SARS-CoV-2 (ie, participants and researchers wore appropriate masks and distance was kept at all times). Nonparticipants were not present during the interviews. No relationship with participants was established before taking part in the study. No repeated interviews were conducted. No field notes were taken. All interviews were audiotaped, pseudonymized, and transcribed verbatim. Transcripts were not returned to participants for verification. Data were transcribed, managed, and analyzed using MAXQDA Standard 2020 (version 20.4.1; VERBI GmbH). After 16 interviews, data saturation was discussed among the researchers. As no new themes emerged in later interviews, the researchers agreed that data saturation had been reached and no additional interviews were necessary. After completion of data collection, thematic analysis of the data was conducted independently by 2 researchers (CA and LW) [29]. First, the researchers reviewed the transcripts independently and identified themes from the

literature and the interview guide and inductively from the data. Second, discrepancies were discussed in iterative cycles until a consensus on themes and the final coding scheme was reached. All themes were organized into main themes and subthemes. Each theme was clearly defined by a quote from the interview transcripts (Multimedia Appendix 4). Quantitative and qualitative data were analyzed separately.

For the eye-tracking data collection process, an assigned room where the Tobii Pro Nano (Tobii AB) was installed at the hospital was used; the Tobii Pro Nano is an eye-tracking device specifically designed for small screens, including smartphones. This hardware features a sampling rate of 60 Hz, measures 17 × 1.8 × 1.3 cm, and includes a USB type-A connector. The Tobii Pro Nano was securely affixed to the mobile phone stand, and the *Enable* app was installed on a smartphone. To facilitate data capture, both the smartphone and the eye tracker were connected to a laptop running the Tobii Pro Lab software (version 1.194) via USB cables. For the purposes of this study, both an Android device (Samsung Galaxy 10, Android version 11) and an iOS device (iPhone 11, iOS version 14.6) were available to users. The choice of smartphone was contingent upon the user's preferred operating system. The eye tracker recorded the participants' interactions with the *Enable* app, such as task completion time, participants' navigation, gaze plots, and heat maps [30-32]. A heat map was used when fixation duration data were collected [30,31], and a gaze plot was used when location of eye movement data were collected [33,34]. For this study, after the completion of tasks, the study moderators composed post hoc questions pertaining to the interactions, participants' experiences, and usability issues observed during the procedure. The post hoc questions were discussed with the participants in a short debrief. The debriefing sessions were held to gather direct feedback from participants after interacting with the *Enable* app, allowing for a deeper understanding of the participants' behavior and interaction with the app. Through these debriefing sessions, participants could provide context and commentary on their behavior and interaction [35]. Engaging users using post hoc questions, such as using images or live content from recorded sessions, allowed for a better understanding of the real-life context with minimal disruption as it facilitated the recall of situational information prompted by data, sound, or visual imagery.

The data analysis was based on the recordings of the study sessions concurrent with the eye movements of participants. The retrospective analysis involved transcribing participants' feedback from the audio recordings obtained during the debriefing sessions. Data analysis also included the completion of predefined tasks by the participants, task completion time, and completion status of the tasks. The analysis focused on task performance analysis and the problem analysis of eye-tracking metrics and participants' feedback.

Ethical Considerations

The study was conducted in accordance with the Declaration of Helsinki and approved by the Ethics Committee of Heidelberg University Hospital (S-685/2020). All participants provided written informed consent for taking part, audio recording of the interviews, and video recordings during the eye-tracking

procedures. Confidentiality and anonymity were ensured throughout the study. The data was protected against unauthorized access. No incentives or compensation was provided to participants for study participation.

Results

Overview

The MAUQ was sent to 165 patients recruited from the *ENABLE* RCT. The response rate was 63.6% (105/165) for the MAUQ at week 4 and 56.4% (93/165) for the MAUQ at week 20. A total of 105 questionnaires for the MAUQ at week 4 (including

sociodemographic data) and 93 questionnaires for the MAUQ at week 20 were analyzed. In total, 16 patients were recruited for the interviews, and 10 were recruited for the eye-tracking procedure. The mean duration of the interviews was 25 (SD 7.34) minutes.

Sociodemographic Characteristics

The sociodemographic data of the participants in the *ENABLE* usability study are shown in [Table 1](#), and additional characteristics of the participants regarding smartphone and app use are shown in [Table 2](#). The mean age of all participants (n=105) was 51.3 (SD 10.9) years.

Table 1. Sociodemographic characteristics of the participants.

Characteristic	Interview participants (n=16), n (%)	Eye-tracking study participants (n=10), n (%)	Questionnaire participants (n=105), n (%)
Gender			
Woman	16 (100)	10 (100)	105 (100)
Age group (y)			
<30	2 (12.5)	2 (20)	2 (1.9)
30-40	2 (12.5)	1 (10)	16 (15.2)
41-50	6 (37.5)	3 (30)	32 (30.5)
51-60	4 (25)	2 (20)	33 (31.4)
61-70	1 (6.3)	0 (0)	16 (15.2)

Quantitative Measures

The MAUQ [25] was used to collect quantitative data on the usability of the *Enable* app. The data were collected at weeks 4 and 20 starting from the baseline of the study. Quantitative data gathered from the MAUQ were analyzed using descriptive statistics. Only complete questionnaires for which the MAUQ score could be calculated were evaluated. Hence, 32.4% (34/105) of incomplete questionnaires collected at week 4 and 29% (27/93) of incomplete questionnaires collected at week 20 were excluded from the analysis. According to Zhou et al [25],

the usability of an app is calculated based on the average of the responses to all statements. The higher the overall average, the higher the usability of the app. In this study, the overall usability scores for weeks 4 and 20 were 89.15 (SD 9.65) and 85.57 (SD 12.88), respectively. The mean for each of the subscales from week 4 to week 20 was also calculated and is presented in Table 3. The results show that the usefulness score declined over time from week 4 (80.89) to week 20 (77.33). In addition, the *interface and satisfaction* score also decreased but not as much as that of the *usefulness* subscale. The *ease of use* score, in contrast, remained constant at both weeks 4 and 20.

Table 3. Quantitative analysis of the mHealth App Usability Questionnaire and subscales.

Time point	Overall, mean (SD)	Ease of use, mean (SD)	Interface and satisfaction, mean (SD)	Usefulness, mean (SD)
Wk 4 (n=71)	89.15 (9.65)	92.41 (11)	91.6 (10.15)	80.89 (15.67)
Wk 20 (n=66)	85.57 (12.88)	92.27 (11.91)	88.23 (13.6)	77.33 (16.63)

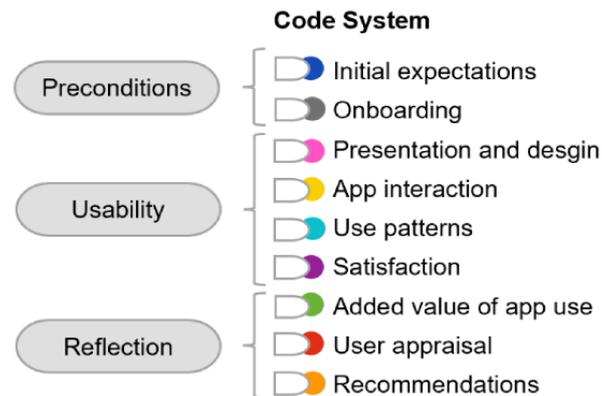

Qualitative Measures

Interviews

In total, 527 text passages were coded during the interviews. A total of 9 themes and 60 subthemes were identified, each of

which could still be categorized under the superordinate themes of preconditions for app use, usability, and reflection. These themes are summarized in Figure 2.

Figure 2. Overview of identified themes.

Preconditions

Initial Expectations

As an opening question in the interview, patients were asked about their initial thoughts when they first heard about the *Enable* app. The most frequently mentioned expectations were related to the quality of information. Patients expected the information in the app to be updated regularly, understandable, and in line with the latest research. Another expectation was that the app would provide contemporary therapy support and be perceived as modern, including replacing printed brochures. Patients expected the app to provide guidance over the course of therapy, contact options, and easy access to relevant information. Approximately half of the participants had neutral expectations for the app:

Yes, I already thought that it [the app] would support me through everyday life and therapy, that I can also use it to organize myself a bit. [Interview 9; transcript position 2]

Onboarding

The aspect of the onboarding process was not part of the interview guide. However, individual participants reported that they felt well supported by the study staff at the beginning of their app use. Even if they were initially overwhelmed by the app or experienced technical difficulties, participants expressed that they received the necessary support and were able to handle the app:

Oh dear, now I have to dig into yet another app. I don't know if I can handle it. But the more I got a grip on it, the better it worked. [Interview 3; transcript position 2]

Usability

Presentation and Design

Patients were asked to describe their impressions of specified design aspects. Overall, patients were content with the color scheme and perceived it as pleasant without being boring or flashy. For some patients, this cheerful esthetic contributed to a sense of joy when using the app and encouraged them to use it more often:

[The design is] very friendly. Very beautifully visualized. I always enjoy opening the app. It is also well designed, you always have the feeling that it is not draining in any way, it is more playful with all these images and visualizations. I find it very very clear. [Interview 11; transcript position 34]

Regarding the layout of the written information, patients appreciated how the most relevant parts were highlighted through the positioning of boxes. The font size, design, and structuring of the information were seen as adequate. The selection of accompanying images was described as empathetic and not too explicit. The app included a personalized visual representation of the therapy progress. This display was also rated as clear and useful. Patients explained that the presence of this display motivated them:

I found this progress bar, which shows me how long I will be in therapy for, especially beautiful. It...motivated me, showing me that there is always a path forward and that the therapy will soon be over. [Interview 13; transcript position 43]

App Interaction

Regarding usability, 4 important aspects emerged while interacting with the app. Neither the positioning nor the design of the app icons were perceived as entirely intuitive. However, patients grew acclimated to the icons, and thus, this did not further impede usability:

Yes, the icons that were down in this bar. In the beginning, I didn't know the meaning of each icon. But when I took a closer look once, I knew it for the next time. [Interview 7; transcript position 39]

Log-in and log-out procedures were described as easy and quick and did not pose any problems for the patients in this study. Most patients had no issues working with the app's structure. They could easily navigate within the app and were able to find what they were looking for:

I found my way around the app really quickly. I haven't tried all the features yet, I haven't clicked on everything because I don't need it all. But I have always been able to find the things that I wanted very quickly, and everything is right there when you click on it. [Interview 11; transcript position 44]

Overall, patients liked using the app as it enabled them to access information *on the go*. Patients described that having their smartphones with them at all times allowed them to read information given the absence of other electronic devices such as laptops or tablets. However, a few patients mentioned the additional benefits of having a web-based version of the *Enable* app.

Use Patterns

This code encompasses descriptions of how and when patients used the app. Most patients experienced changes in the frequency of app use. In the beginning, they used the app often, and some patients used it multiple times per day:

In the beginning, shortly after my diagnosis, I had a lot of questions—for my physicians, how things work and so on. During this time, it (the app) really helped me a lot. [Interview 10; transcript position 24]

Over time, use declined. This development was mostly due to lower demand for support and information as patients became used to therapy proceedings. Patients also used the app less as they felt that they had already read everything.

After this initial phase, patients reported using the app whenever they needed to look up appointments, had free time (eg, during waiting times before physician's appointments), had or experienced new side effects from their treatment, were prescribed new medications, or were prompted by push notifications:

I always used it shortly before my [chemotherapy] appointments. Or when I had questions regarding diet and exercise. And sometimes there were questionnaires I had to fill in. And yes, as soon as the app said "there is news," I opened it...And to look up times for my appointments. [Interview 10; transcript position 12]

Satisfaction

Patients praised the general aspects of the app and liked the idea of having a digital tool accompanying them throughout their therapy; for example, the app provides a good overview of relevant topics, especially at the beginning of the disease. Except for 1 interviewee, all participants (15/16, 94%) would recommend the app to others:

...because it really provides a great overview...because so many aspects are addressed. Not only the type of therapy, but also just different things about cancer. Especially at the beginning these keywords—Yes, these terms in the boxes from tiredness to fatigue and polyneuropathy and different things. [Interview 7; transcript position 47]

Reflection

Added Value of App Use

When asked about the concrete benefits of the app in everyday life, several aspects were mentioned. The most important aspect for the participants was the information on therapies and side effects, which was perceived as helpful, especially in the initial phase of therapy. The quality of the information was praised as

the app's information was considered understandable and its origin was considered reliable:

You feel informed, you feel—that gives you a form of security, because you say to yourself: Well, if I have the information from here [the app], then it was completely clear to me: I don't have to look it up again. That's true for me because these are reliable information providers who wrote this. [Interview 12; transcript position 81]

The comprehensibility and language level were also perceived as adequate. Statements on the amount of information were heterogeneous according to individual information needs. However, the amount of information was predominantly perceived as sufficient in the context of the app. Furthermore, the appointment display, contact information, and progress bar were found to be helpful and clear. With regard to the contact information provided in the app, the fact that it was easy to find was rated positively.

Some patients reported that the questionnaires in the app gave them a positive feeling as they reflected on their condition and (in the intervention group) it was experienced positively that the questionnaires were read by the study staff and that staff could react proactively to them if necessary. Overall, patients perceived the app as a good therapy companion that guided and supported them through the various phases of the disease and therapies.

User Appraisal

Users' opinions on the existing functions and features of the app were added to this category. Most patients complained about the appointment display as the date and time on the app did not always correspond to the actual clinic appointments (eg, in the case of last-minute postponements):

It's a shame that the—I don't know how the appointments displayed in the app, how often those are matched. I've had frequent differences there. Especially when appointments had to be postponed, the chronology was no longer correct for me. [Interview 9; transcript position 2]

Regarding the quantity of information, some patients wished for more in-depth information or links to other information platforms. It was remarked that the amount of information available varied depending on the topic. Regarding the quality of the content, patients noted that the listed side effects or drugs were grouped differently. For instance, the patients were unable to locate paclitaxel as it belonged to the taxane drug class. In total, 12% (2/16) of the patients in particular perceived errors in spelling, punctuation, and grammar as distracting. The presentation of the contact information on the app was described as difficult to find, especially in emergencies. The additional pop-up notifications of the app updates were rated negatively as it was not apparent to the user what exactly was new in the app. Furthermore, respondents ascertained that the menu navigation was not intuitive enough and, therefore, needed to be improved.

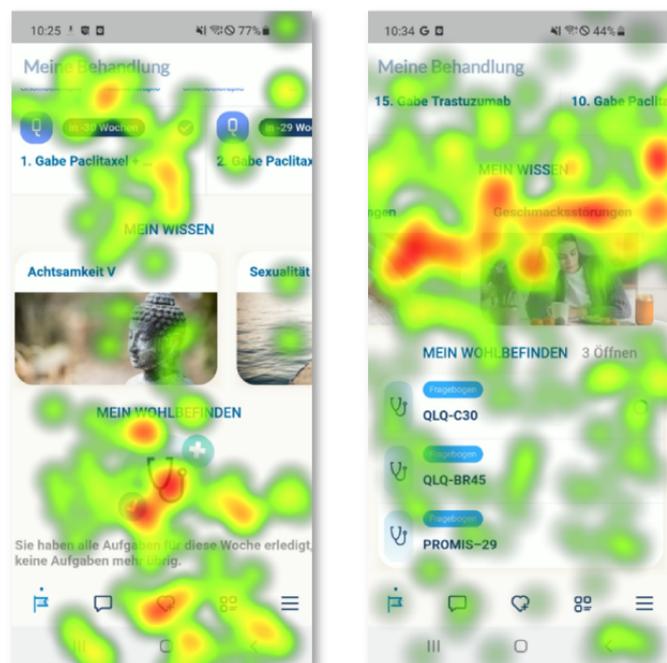

Recommendations

Statements about features of the app that are not yet offered were classified as recommendations or wishes. Most wishes were mentioned in relation to the appointment display. Patients would like to have additional information about appointments, such as directions, a reminder function, the ability to export appointments from the app to private calendars (eg, Google or Outlook calendars), or the ability to make appointments directly from the app. The desire for self-administration (ie, areas such as appointments, questionnaires, or therapy progress that can be actively managed by the patient) was also frequently voiced. In addition, some patients wished to view the questionnaires that had already been completed to be able to monitor their condition over the course of therapy:

With the exception of filling in the questionnaires, you can't work with the app yourself. Therefore, if you could manage things in the app by yourself, then of course I would think that would be great. [Interview 9; transcript position 2]

Patients also wanted the content of the app to be updated, expanded, and adapted to new scientific findings. In this context, there was a desire for more explanatory videos to be included in the app. Patients also suggested that the app should offer more information about current and upcoming clinical trials for patients with breast cancer. To see what content in the app has already been read, patients suggested a read status, where content that has already been read is highlighted. Emergency contacts should also be highlighted in the app to make them easier to find, for example, by displaying them on the home page:

Figure 3. Heat maps from the eye-tracking analysis.

Design and Layout of the App

Many of the participants had problems understanding and interpreting the icon at the bottom of the screen. The

Especially the emergency numbers, I don't know how to get something like that into the app, but that might be an idea, because I've been looking a lot for the right contact person. Maybe that would also be something that you could highlight a little bit or display as a button. [Interview 4; transcript position 32]

To be able to find certain topics more quickly, the need for a search function was mentioned several times. Furthermore, to improve the readability of the content, patients would like to be able to adjust the font size. It was also suggested that the app could be used on other devices, such as tablets.

Eye Tracking

Overview

The analysis of the data collected from the eye-tracking recordings as well as the retrospective interviews showed that the participants found the app easy to use. We observed that most participants completed the given tasks, although the time taken to complete a few tasks proved to be challenging. On the observations and retrospective interviews during the eye-tracking study, we discovered 3 noticeable patterns related to the design and layout of the app, content and navigation through the app, and additional features the participants would like to have in the app. [Figure 3](#) shows exemplary heat maps from the eye-tracking analysis. The data collected during the task performance, such as the task completion rate and task completion times, are provided in [Multimedia Appendix 5](#).

eye-tracking data showed fixations at the bottom of the screen while the patients clicked each of the icons displayed to view the content of the page. Patients expressed a preference for finding the most important information, such as appointment

dates and the progress of a questionnaire, at the top of the screen. This finding indicates that patients expect important information to be located at the top of the app's layout. Furthermore, the patients actively mentioned that the retrievability and visibility of the questionnaire were low. Although the questionnaires were available on the home screen of the app, patients believed that the questionnaires were available on the menu. In contrast, patients found the overall layout of the app to be acceptable.

Content and Navigation of the App

Regarding the content of the app, patients showed more interest in the titles of the articles (eg, topics such as symptoms or side effects) than in the images displayed. When asked during the retrospective interviews, patients mentioned that they did not pay attention to the images as they provided no information on what the article was about. Patients preferred to read the title of the article as it gave them information about its content, as shown by the red areas of the heat maps in [Figure 3](#). Moreover, many participants explored the app to find the right information or icon to perform the tasks. However, this correlates with how frequently patients used the app. During the interviews, some patients said that they used the app frequently, for example, every day, to read articles on side effects or symptoms and fill out questionnaires regularly, whereas some patients used the app frequently at the start phase of the *ENABLE* RCT and later minimized the use of the app except to fill out questionnaires. The data showed that patients also had issues navigating through the app, especially related to the task of finding a specific article. Analysis of the recorded data of the participants' navigation and gaze plots from the Tobii Eye Tracker showed that patients looked for a search function. Most patients clicked the menu icon; however, they did not proceed further to find the article nested under the *Symptoms* category on the menu. In addition, some patients searched for the article on the start page along with the other articles already displayed.

“Would Like to Have” (Wishes)

Participants identified a need for additional features in the *Enable* app as a consequence of the challenges they encountered during the eye-tracking study tasks. These suggested features were considered as *nice-to-have* options and were based on the specific problems faced by the participants during the study. The first was the availability of an option to mark an article as a favorite and be able to view the favorite article on the start page. Second, patients desired to have more articles or information about the symptoms and side effects of breast cancer and its treatments. Third, the icon currently representing contact information for health care providers (*My Care Team*) was misleading. Patients preferred to have another icon that indicates contact or communication as this would enable them to contact the study nurses more quickly. Finally, a search option was suggested by all participants.

Discussion

Principal Findings

The aim of this study was to investigate how patients with breast cancer rated their engagement with the *Enable* app, the user experience, and the benefits of using the app. In particular, the

design, layout, navigation, content, and requests for new features were identified as important outcomes of interest for evaluating the app and further improving it to meet user needs. The interviews provided valuable suggestions for optimizing the app and the implementation process. The design and color scheme were rated very positively overall. In terms of use patterns, it was noticeable that the frequency of app use decreased over the therapy period.

Patients found the app easy to navigate. However, there was some criticism that the menu icons were not intuitive enough, especially at the onset of use. Perceived benefits were discussed extensively in the interviews. Patients found the information on therapies and side effects very useful. The appointment display and progress bar were also found to be helpful and motivating. At the same time, the appointment display was most often criticized, and it was the feature for which there were the most recommendations for change (eg, to be able to manage appointments autonomously in the app or set reminders). In terms of content, it was mentioned that there was a lot of information on some topics and not enough on others. Patients also wanted more content updates within the app (eg, on current topics such as the COVID-19 pandemic) and a search function to access specific content.

A study by Ansaar et al [36] showed that nearly 78% of all usability evaluation studies in their systematic review used a questionnaire-based method. However, using mixed methods approaches in usability evaluation studies provides benefits such as the possibility to balance the advantages and disadvantages of the different methods. Moreover, by applying the mixed methods approach, both subjective and objective aspects can be combined to assess usability [36]. In many aspects, such as the *navigation*, *recommendations*, and *perceived benefits* codes, the results of the different survey methods support each other. However, the interviews and eye-tracking study sometimes provided different findings. For example, the importance of images within the app was positively highlighted in the interviews. In contrast, the eye-tracking study and retrospective interviews revealed that images played a subordinate role for patients, with titles being more important for finding relevant content in the app. Although participants reported in the interviews that they were able to navigate easily within the app and find the content they were looking for, we observed in the eye-tracking study that there were difficulties with finding specific content. Furthermore, the interview inquiries primarily centered on the practicality of incorporating the *Enable* app as a follow-up intervention in daily life. Meanwhile, the use of eye-tracking technology allowed for direct, real-time observation of user behavior while engaging with the app through task performance. Despite patients reporting the ability to regularly use the app without difficulty, the eye-tracking study's direct observation unveiled valuable insights into their actual use patterns within their everyday routines. In this context, disparities between the results obtained from the 2 methods emerged, possibly stemming from users' lack of awareness regarding any issues until they were prompted with specific inquiries.

Comparison With Prior Work

Our results on the MAUQ indicate good usability. The results for the total scale showed that usability decreased from weeks 4 to 20. A decrease in usability over time has also been observed in previous studies [37-39]. Possible explanations for this decline in our study can be found in the interviews, indicating that the extent of app use also decreased over the course of therapy. Patients found the app to be particularly advantageous at the start of their therapy because of their great need for information. However, as they gained more knowledge about the disease and its treatment, their demand for information decreased. In addition, patients reported that the app lost its appeal once all the available articles had been read, often leading to a desire for new content to be added. Patients also expressed a need for additional features or improvements as they continued to use the app. As a result, the decrease in the app's usability score could be attributed to patients perceiving it to be less useful after an extended period of use owing to the lack of content updates and unmet desires.

Looking more closely at the subscales of the MAUQ, *usefulness* had the lowest score compared with *ease of use* and *user interface and satisfaction*. These items assess whether the app is helpful and useful for patients' health and well-being. This relationship is also apparent when looking at the *usage patterns* category from the interview analysis. It appears that patients are less likely to use the app because of the lack of new content. This is consistent with the findings of other studies on mHealth apps for patients with breast cancer [16,40,41]. As an implication for similar apps for other chronic conditions, it seems important to update the app content on a regular basis to provide patients with an incentive to continue using the app as well as strengthening patients' satisfaction and information needs. Consistent with the findings from the interviews and eye-tracking study, only the *ease of use* subscale remained almost stable over the duration of app use.

In the context of other usability studies on mHealth apps, the importance of paying more attention to the user group of older adults is emphasized. The different age ranges of patients and the different levels of technical affinity for older patients are mentioned as possible factors causing usability problems. Some studies emphasize that these factors are often overlooked and need to be considered when developing mHealth apps [42,43]. In our study, these aspects were less evident. With an average age of 51 years, our study participants do not represent a predominantly older population but are close to the German population average for women, which is 46 years [44]. In contrast, the study participants were also far below the average age of 64 years for patients with breast cancer. Therefore, further research on app development and usability with a focus on older participants should be conducted to more adequately represent the typical population of patients with breast cancer.

Considering the preferred device for using the *Enable* app, most participants were content with using the app on their smartphones. However, there were isolated requests to be able to increase the font size of the content and use the app on a larger-scale device, such as a tablet or PC. This issue was also mentioned by participants in a usability study by Jessen et al

[45], in which an mHealth app for self-management of chronic diseases was evaluated.

Although the onboarding process was not part of the interview guide, some patients actively recalled how they were introduced to the app as well as how they perceived the technical onboarding process. The patients did not experience issues with these steps and reported being content with the process, mostly because of the strong support of the study team. Previous research has pointed out that complex registration and log-in procedures can be perceived as especially cumbersome by patients and can lead to stopping app use [46-48]. Our study identified the strong interpersonal connection with and continued support from the study team as a positive influence on the perceived ease of onboarding. This support took place in the context of a research study and is not viable in a real-world implementation. However, the issue of technical support arose exclusively during the qualitative interviews. We did not collect any quantitative data on this topic. Thus, further streamlining of the onboarding process while being mindful of health care workers' limited time resources should be an area for future research.

Strengths and Limitations

The chosen mixed methods approach can positively support the further development of the app. The expansion of the classic social science method spectrum to include technical methods such as eye tracking made it possible to combine the subjective patient perceptions reported in interviews and questionnaires during everyday use with objective measurements under laboratory conditions.

However, the integration of qualitative results and the objective measurement from the eye-tracking procedure introduced discrepancies. As noted previously, interviewees appreciated the use of images in the app, whereas eye-tracking results showed that more time was spent on the article titles than on the images. Another example is that the interviews and the questionnaire produced good ratings of usability, but the eye-tracking study showed that patients found it difficult to find defined content. Although difficult to analyze, these discrepancies are common in mixed methods studies [19]. In our study, these discrepancies could be explained by methodological differences. For example, reading a title naturally takes longer than glancing at an image, leading to a long fixation time. Therefore, this result does not allow for the conclusion that titles are more important than images. Here, the qualitative interviews were helpful in interpreting this finding. Regarding the second example—overall good usability scores in comparison with eye-tracking times—several interpretations appear plausible. First, it is possible that social desirability led patients to rate the usability more favorably in both the interviews and the questionnaire. Consequently, the objective measure via eye tracking revealed that usability was worse than in subjective measures. Second, the setting of the eye-tracking procedure (eg, unusual or uncomfortable sitting position, being observed by ≥ 2 researchers, or using a different device) could have led to changed patterns in (app use) behavior. Although we acknowledge these discrepancies, we conclude that the mixed methods approach and its results deepened the understanding

of the studied topic and produced valuable insights, with discrepancies leading to vigorous and fruitful discussions among the researchers.

However, the generalizability of the study results is limited by several factors. To ensure that patients with lower digital health literacy could participate in the quantitative data collection without constraints, we decided to use printed surveys sent by mail. Patients returned them at their discretion. Hence, it cannot be verified whether the surveys were filled out at the correct time. In addition, some values were missing from the returned surveys, and manual data entry could have led to documentation errors. Incomplete or inconclusive questionnaires had to be completely excluded from the analysis as it was not possible to calculate the score. Although all necessary steps were taken to ensure high-quality and reliable data (eg, data entry was always checked by another researcher), using a web-based survey instead of a printed survey could have made data collection easier, faster, and more reliable. These trade-offs have to be balanced in future research projects.

This study population contained an above-average proportion of academics, especially among the subgroups of interviewees and eye-tracking study participants. This should be taken into account when interpreting these results. A systematic review by Niazkhani et al [49] showed that patients with lower educational attainment and limited health literacy were less likely to intend to use an electronic patient health record and were more likely to use it ineffectively. Moreover, previous experience with computers or health technology has been associated with increased acceptance, and acceptance increases with higher education [7]. Although these results refer to electronic health records, they indicate that this aspect should be further investigated in future studies. Given the median age at breast cancer diagnosis of 64 years and the relatively younger median age of this study cohort, conclusions from this study must be interpreted with caution as they may not represent the views and digital literacy of older women with breast cancer [50].

The *Enable* app was developed specifically for patients with breast cancer. Consequently, our study sample included only female patients with breast cancer. Some of our results and recommendations may have limited generalizability to other patient populations. Nevertheless, we think that aspects such as the relevance of content updates, the accuracy of displayed appointments, or the intuitiveness of the app navigation might also be relevant beyond the target group. This should be verified in further research.

As part of the *ENABLE* RCT, reasons for dropping out were documented where available. These reasons were examined to see whether there were any indications of usability problems. A small proportion of the included study participants in the RCT dropped out because of physical exertion or feelings of being overwhelmed by the app. In this respect, further research is needed to understand how patients in later stages of the disease or with greater disease burden perceive the usability and benefits of the intervention. Furthermore, mHealth apps

should be designed to be usable and helpful for these patient groups as well, especially in the context of patients living with cancer. As the mean age of participants in this study was relatively low, it can be assumed that there is a risk of selection bias. It is possible that younger patients decided to participate in the study and use the app because of a higher affinity for smartphones [11].

In addition, using the eye-tracking device led to further limitations. Potential participants in the eye-tracking study had to undergo an additional screening process to exclude patients wearing bifocal glasses. Although patients were recruited for the study, this criterion did not allow us to cast a wider net for the participant recruitment process. Furthermore, we also had the challenge of asking patients to sit still so that the eye-tracking data could be captured without breaks. However, this request is generally against the natural way in which users sit and interact with mobile devices. Another point to note is that the execution of the tasks on the app by the patients was deviated as the tasks were presented on paper and this retracted some of the gaze points of the patients. This is, in general, a common problem when tasks are not integrated into mobile apps during development for testing purposes.

Conclusions

The results of this usability study demonstrate good usability of the studied app and potential for purposeful development. The design and color scheme were rated very positively overall. However, there was some criticism that the menu icons were not intuitive enough, especially at the onset of use. Noticeably, the frequency of app use decreased over the therapy period. Perceived benefits of the app were information on therapies and side effects. The appointment display and progress bar were also found to be helpful and motivating. Still, participants offered recommendations for changing the appointment display (eg, to be able to manage appointments autonomously in the app or set reminders). In terms of content, it was mentioned that there was a lot of information on some topics and not enough on others. Patients also wanted more content updates within the app (eg, on current topics such as the COVID-19 pandemic) and a search function to access specific content. The interviews and eye-tracking study revealed valuable suggestions for improvement as well as requests for additional app features. An important point is that the app currently provides information to the patient mainly passively. The patients' wishes indicate that the app needs to be further developed so that they can actively enter information into the app and work with it. The overlap between decreasing usability and decreasing usefulness also suggests that the app needs to be regularly updated with new content to maintain its usefulness over time. These findings will be incorporated into the further development of the *Enable* app. We concluded from patients' feedback and requests that similar mHealth apps could benefit from giving patients a more active role (eg, being able to actively document side effects as they show up instead of being prompted to do so). In addition, regular updates to app content (eg, adding new informational pieces) could further contribute to and, thus, encourage the continued use of mHealth apps.

Acknowledgments

This study was funded by the Baden-Württemberg (Germany) Ministry of Science, Research, and Arts under reference 42-04HV.MED (19)/15/1 as part of the Center for Innovative Care project. The authors would like to thank all patients in this study for their participation and valuable input. They would also like to thank Corinna Hartmann for her support in recruiting patients for this study. Thank you to Bendix Harms for his support with the quantitative analysis.

Data Availability

The data sets used and analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

CA, PM, and LW collaborated on the draft of the manuscript, PK contributed. MW is the principal investigator of the *ENABLE* project. LW, JM, and PM were responsible for the study design and protocol, and OH contributed. MW and TMD prepared and submitted the study protocol, and LW, JM, and PM contributed. LW, JM, and PM collaborated on the construction and testing of the interview guides and the quantitative data collection tools, and LS supported the finalization of these instruments. CA and LW conducted the interviews, analyzed transcripts, and interpreted the interview data. PM, CA, and LW conducted the eye-tracking study and retrospective interviews, TL contributed. PM analyzed and interpreted the eye-tracking data. PM analyzed and interpreted the survey data, and CA and LW supported data interpretation. OH contributed to the acquisition of funding. All the authors provided substantial comments and approved the final version of the manuscript.

Abstract

Background: The feasibility of implementing home-based pulmonary rehabilitation (PR) can be assessed from the perspectives of patients with chronic lung disease and health care professionals involved in PR.

Objective: Through a qualitative inquiry using interviews and the adoption of the people-object-environment framework, this study aims to understand the influences of interpersonal, environmental, and situational factors on the perceptions and considerations of individuals involved in home-based PR for patients with chronic lung disease.

Methods: One-on-one interviews were conducted with 20 patients with chronic lung disease and 20 health care professionals for investigating their attitudes and opinions based on their experiences regarding home-based PR as well as for identifying the key factors affecting the benefits and drawbacks of such therapies. This study further evaluates the feasibility of using digital tools for medical diagnosis and treatment by examining the technology usage of both parties.

Results: The 4 key issues that all participants were the most concerned about were as follows: distance to outpatient medical care, medical efficiency, internet connectivity and equipment, and physical space for diagnosis and treatment. Interviews with patients and health care professionals revealed that the use of technology and internet was perceived differently depending on age and area of residence. Most participants reported that digital tools and internet connectivity had many benefits but still could not solve all the problems; moreover, these same digital tools and network transmission could lead to problems such as information security and digital divide concerns. This study also emphasizes the significant impact of human behavior and thinking on shaping the design of health care interventions and technologies. Understanding user perspectives and experiences is crucial for developing effective solutions for unmet needs.

Conclusions: The results of this study indicate that despite the different perspectives of patients and health care professionals, their considerations of the key issues are very similar. Therefore, the implementation of plans related to telemedicine diagnosis, treatment, or rehabilitation should take the suggestions and considerations of both parties into account as crucial factors for telehealth care design.

KEYWORDS

chronic lung diseases; home-based pulmonary rehabilitation; telehealth; remote health care

Introduction

As the third leading cause of morbidity and mortality worldwide, chronic obstructive pulmonary disease (COPD) is a significant public health issue [1-4]. In 2019, the number of individuals diagnosed with COPD exceeded 328 million worldwide [5-8]. A significant correlation between physical activity and lung function [9-12] emphasizes the importance of regular exercise for individuals with COPD who require pulmonary rehabilitation (PR) [13-19]. However, patients with COPD often report reluctance to engage in physical activities due to dyspnea, the effects of which include chronic cough, exacerbations, reduced exercise capacity, and impaired quality of life [20-25]. PR is a tailored and comprehensive intervention conducted via a thorough assessment of the patient. In individuals with chronic pulmonary diseases, the primary objective of the pulmonary intervention is to improve not only their overall health but also their psychosocial well-being in the long term [26-28]. Typically, PR programs are customized for personal symptomatic conditions [29-31]; hence, PR interventions entail tailored exercises and educational sessions aimed at enhancing activity tolerance, mitigating symptoms, and augmenting skills that aid in managing chronic respiratory diseases [31,32]. The majority of PR treatments usually require one-on-one sessions and the assistance of a therapist [33-35]. However, the one-on-one care approach is limited due to shortages in health care personnel, elevated work-related stress, and prolonged working hours [36]. Moreover, when the COVID-19 pandemic hit, lockdowns and personnel restrictions forced the interruption of PR for many patients with chronic lung disease, which posed a threat to their lives [37-40].

Due to the COVID-19 pandemic, telehealth has become increasingly attractive owing to its functionality, importance, and prospects [41,42]. In addition to reducing human contact and easing the burden on health care workers, telehealth leverages technology communication and transmission to alleviate the workload of respiratory therapists and improve the accuracy of respiratory rehabilitation records [43-45]. Using telehealth, patients can undergo rehabilitation at home and be monitored remotely by medical personnel [46,47]. Home-based PR can also mitigate the difficulties of outpatient care for patients living in remote areas and those with physical disabilities [48-50]. Furthermore, it can be used as an auxiliary means of physical PR to assist in self-management and precisely modify behavior, thereby reducing hospitalization and medical costs [51,52].

Traditional PR usually relies on one-on-one human monitoring through observation or physiological monitors to examine a patient's health condition. Remote health care has the advantage of prescribing home-based PR, enabling patients who are unable to leave their homes due to physical conditions such as disability or living in rural areas to partake in rehabilitation programs at

home [53,54]. However, there are also many limitations and considerations of remote health care, as follows:

1. Lack of security and limited interpersonal interaction: The safety of patients is the primary concern of clinical physicians [55,56]. The biggest challenge of home rehabilitation is emergency treatment, which has been the main hurdle for remote health care since many years [57]. In addition, remote therapy can only provide limited physical and mental assessments [58,59]. Due to the lack of face-to-face interpersonal interactions, patients may develop loneliness, helplessness, and frustration, which may reduce the effectiveness of treatments and the speed of recovery [60,61].
2. Privacy and security issues: Most remote health care is performed through network transmission. Many clinical physicians believe that network transmission may lead to data leakage or theft of medical records or personal information of patients [62,63].
3. Technological and equipment limitations: The implementation of remote health care requires specific technological equipment such as smartphones or computers with network functions. However, for many remote users or special groups such as older persons, lack of equipment, poor network communication quality, or unfamiliarity with network-related technology hinder utilization [64].
4. Insurance payment limitations: Different regions or countries have different standards for remote health care services. Therefore, many insurance companies do not have a remote health care reimbursement system or only cover specific services [65-68].

Despite its limitations and by taking people, object, and environment into consideration, telemedicine remains a valuable tool for the provision of health care services, especially for patients who have difficulty visiting medical facilities in person or those affected by infectious diseases and related restrictions such as lockdowns and quarantine. Telemedicine enables uninterrupted treatment and continued assistance for patients in their recovery. However, in establishing a home-based PR, it is essential to consider the various environments of participants to effectively maximize the benefits of this medical service.

Methods

Ethics Approval

This study was approved by the institutional review board of Chang Gung Memorial Hospital (approval 202200070B0). The participants were patients with chronic lung disease and respiratory health care professionals who had provided written informed consent from both urban and rural areas. Due to the COVID-19 pandemic, all one-on-one interviews were conducted by videoconferencing.

Participants and Procedures

The 20 patients recruited for the interviews included those who had participated in PR programs and those who had not. During the interviews, the patients provided insights into the implementation of PR programs from a patient-centric standpoint. All interviewees had a medical history of 5 years or more.

The 20 respiratory health care professionals included registered thoracic surgeons, respiratory therapists, physical therapists, and PR specialists. Most of these professionals had experience treating patients with chronic lung disease and had participated in designing exercise prescriptions, patient tracking and monitoring, and disease progression research in PR programs. Furthermore, the majority of the interviewees had treated a specific proportion of patients with chronic lung disease within the past 3 years (Table 1).

Table 1. Characteristics of the health care professionals (n=20).

	Values
Gender (male:female)	8:12
Age (years), min-max; mean (SD)	27-65; 46 (11)
Experience in pulmonary rehabilitation (years), mean (SD)	5.2 (8.47)
Type of health care professional in pulmonary rehabilitation, n (%)	
Thoracic surgeons	3 (15)
Respiratory therapists	12 (60)
Physical therapists	2 (10)
Pulmonary rehabilitation specialists	3 (15)

Prior to the interviews, all participants were required to complete a survey questionnaire, which included demographic information and details of their use of smart devices and the internet. Daily use was defined as regular usage. The patients provided information about their pulmonary disease status, duration of illness, and a self-assessment of their health status (on a 5-point scale ranging from excellent to poor) as well as recalled their activity frequency over the past 7 days. Health care personnel were required to answer questions related to their primary clinical responsibilities. Each participant took part in a 1.5- to 2-hour interview session conducted by the primary author, who was also a clinical researcher and an assistant professor affiliated with the Chang Gung Medical Foundation. In-depth interviews were primarily used to collect the data. After collecting the interview data, all identifiable personal information was removed from the transcripts. The data were then coded, organized, and analyzed using NVivo 12.0 software (Lumivero) for qualitative data analysis. For accurate and detailed data interpretation, the transcripts were provided to the interviewees for review and cross-checked with relevant researchers to confirm the accuracy of data interpretation.

Results

Characteristics of the Participants

This study consisted of 40 participants: 20 health care professionals specializing in PR and 20 patients with chronic lung diseases. The background characteristics of the 20 health care professionals are shown in Table 1; nearly 60% (12/20) were respiratory therapists, and the remaining health care professionals were pulmonary surgeons, physical therapists, and rehabilitation physicians. Their mean age was 46 years, and all had more than 3 years of experience in PR and treatment (mean 5.2 years). The background characteristics and activity habits of the 20 patients interviewed are shown in Table 2; the majority of the patients had COPD (12/20, 60%), and 25% (5/20) were lung transplant recipients. The majority of the participants (15/20, 74%) had never participated in a PR program, and 70% (14/20) of the patients rated their physical condition as poor. Regarding exercise over the past week, 65% (13/20) of the patients chose a 10-minute walk as their exercise indicator, followed by strength training (5/20, 25%). Notably, 55% (11/20) of the patients reported preferring to sit rather than stand and to stand rather than move.

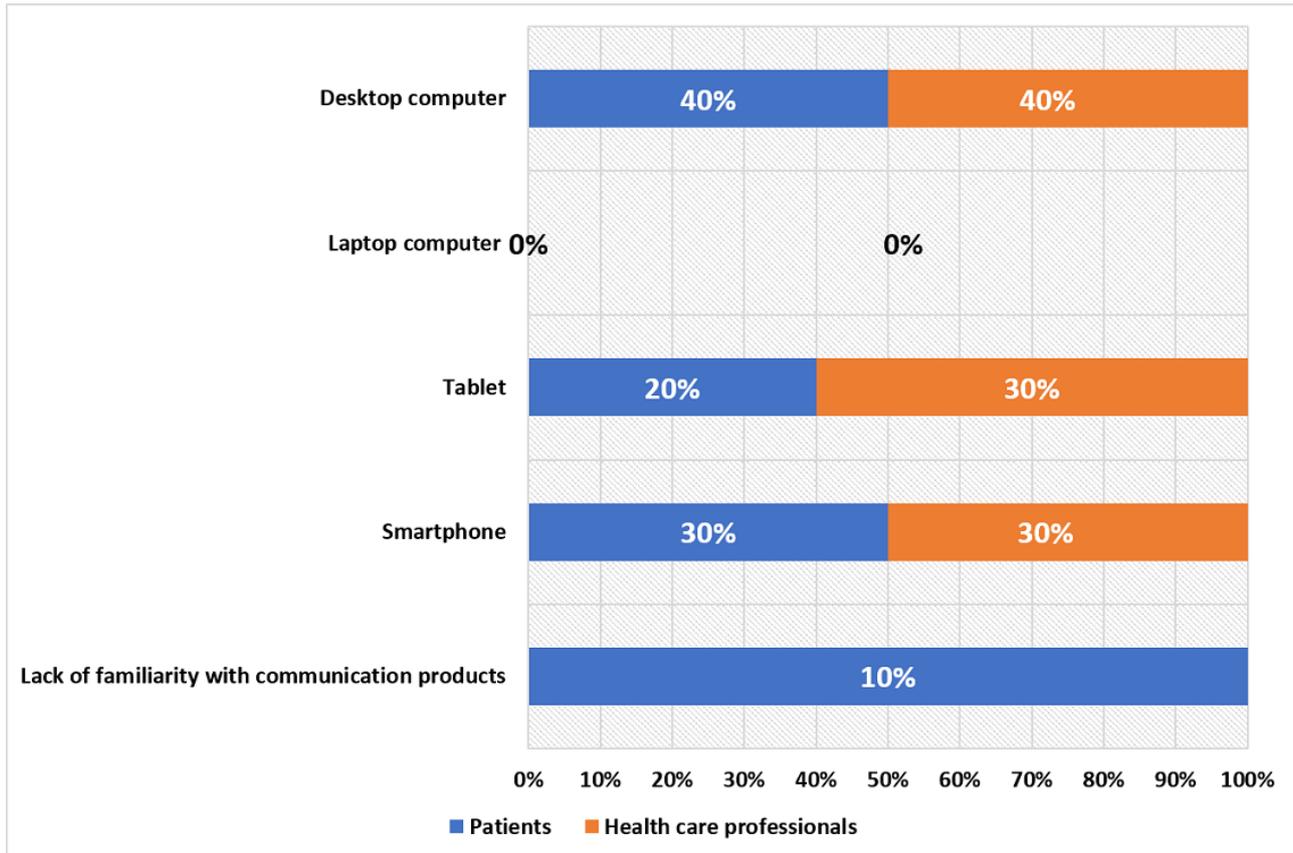

Table 2. Characteristics of the patients (n=20).

	Values
Gender (male:female)	10:10
Age (years), min-max; mean (SD)	51-85; 68 (9.8)
Participation in pulmonary rehabilitation programs, n (%)	
Yes	5 (26)
No	15 (74)
Chronic lung diseases, n (%)	
Chronic obstructive pulmonary disease	12 (60)
Asthma	3 (15)
Lung transplantation	5 (25)
Self-assessment of their health, n (%)	
Excellent	0 (0)
Very good	0 (0)
Good	1 (5)
Fair	5 (25)
Poor	14 (70)
Exercise frequency and quantity over the past week, n (%)	
I have engaged in high-intensity strength training, including aerobic exercise, fast cycling, and swimming.	2 (10)
I have participated in moderate physical activities such as stretching exercises and flexibility training.	5 (25)
I have walked for at least 10 minutes every day.	13 (65)
What statement best characterizes my exercise habits? n (%)	
Given the option, I will opt to sit rather than stand.	11 (55)
I frequently require standing but not for the purpose of lifting heavy objects.	5 (25)
Climbing slopes and stairs is a common necessity for me.	4 (20)
I often transport heavy objects and engage in manual labor.	0 (0)

Survey Results

In order to better examine the potential of telehealth, we conducted a survey targeting contemporary electronic communication tools, specifically computers, cellphones, and tablets, which were widely utilized by both patients and health care professionals, as shown in [Figure 1](#). The majority of the patients and health care professionals reported using desktop computers as their most frequently used electronic

communication device, constituting the largest proportion at 40% (8/20), followed by smartphones at 30% (6/20). Notably, health care professionals reported a higher usage rate (by 10%) of tablet computers compared to patients. Note that neither group of participants reported habitually using laptops. Overall, the patients were less proficient with technology compared to the health care professionals, which is a crucial determinant in implementing telehealth programs.

Figure 1. Survey results of the usage of electronic communication devices among patients and health care professionals in this study.

People-Object-Environment Framework

This study adopts the people-object-environment framework as the focal point for the interview investigation to improve the understanding of the feasibility of home-based PR. This study analyzes the advantages and disadvantages of remote PR in the current context, with the aim of bridging the gap between ideal use and reality (Table 3). Activities involving various elements such as individuals, entities, and environmental factors often result in the emergence of diverse concerns among different participants. Through the analysis presented in Table 3, we identified the gaps in home-based rehabilitation services from

the perspectives of health care professionals and patients. Subsequently, this facilitated a thorough discussion of potential solutions to meet the needs and expectations of all involved parties. Our research findings reveal that the use of telehealth for home-based PR programs had both advantages and disadvantages. Using a people-object-environment framework to analyze the results, we describe 4 dimensions: reduced time and transportation constraints to access medical care; improved medical efficiency; changes in equipment, network, and physical space; and information transmission security, about which health care professionals particularly raised concerns in telehealth.

Table 3. Analysis of the pros and cons of telerehabilitation with the people-object-environment framework.

	People (patient)	Object (patient)	Environment (patient)
People (health care professionals)			
Pros	<ul style="list-style-type: none"> Promoting health care access in remote areas: Telehealth facilitates convenient health care services, which enhance medical care for patients in remote areas and promote community health. Boosting patient involvement: Telehealth enables interactions with health care professionals via web-based platforms, providing medical information and guidance as well as fostering active engagement of patients in their own health management. 	<ul style="list-style-type: none"> Improving health care resource allocation: Telehealth enables physicians to diagnose and treat patients across different geographical areas, alleviating shortages in local health care resources and enhancing the efficiency of health care resource allocation. 	<ul style="list-style-type: none"> Reducing health care burden: Telehealth reduces the health care burden for long-term patients or those requiring regular follow-ups; this minimizes the time and effort associated with transportation and waiting as well as provides cost-effective health care options. Decreasing cross-infection risks: Telehealth minimizes contact between patients and health care professionals, thereby lowering the risk of cross-infection and promoting the health and safety of both health care professionals and patients.
Cons	<ul style="list-style-type: none"> Bridging communication barriers: Telehealth reduces physical interactions and social contact between patients and physicians, which may have long-term effects on patients' psychological and social well-being. 	<ul style="list-style-type: none"> Operational and communication barriers: Older or technologically inexperienced patients may encounter difficulties in understanding instructions from remote health care professionals through telehealth. 	<ul style="list-style-type: none"> Environmental limitations: Home environments often impose spatial constraints that may limit various rehabilitation, diagnostic, and treatment activities.
Object (health care professionals)			
Pros	<ul style="list-style-type: none"> Advantages of telehealth: Telehealth provides a convenient health care model, particularly beneficial for regions facing constraints related to time, geographical location, and transportation. The utilization of basic computer equipment enables the provision of medical consultations, making health care more accessible and efficient for patients in such areas. 	<ul style="list-style-type: none"> Wireless transmission: Wireless transmission significantly reduces the workload of health care professionals and makes health care services more efficient by transitioning from a one-on-one service to a one-to-many format. 	<ul style="list-style-type: none"> Digital health care infrastructure: Telehealth accelerates the transmission and exchange speed of health care information, leading to improved overall health care efficiency.
Cons	<ul style="list-style-type: none"> Digital divide: Individuals who are from lower socioeconomic backgrounds or have limited access to digital resources may face barriers to participation in telehealth due to the lack of appropriate technological equipment or internet connectivity. This highlights inequalities in the distribution of health care resources. Technological dependency: Users with limited technological skills or resources may encounter difficulties in operating telehealth, which requires adequate knowledge of technology, suitable equipment, and stable internet connectivity. Health care quality and patient experience: Although telehealth provides convenient remote health care options for certain diseases or conditions, in-person consultations or measurements from medical instruments may offer more accurate health care services. 	<ul style="list-style-type: none"> Disparity in health care resources between urban and rural areas: Despite the convenience of telehealth for remote consultations, operational difficulties may still exist for areas lacking proper equipment. 	<ul style="list-style-type: none"> Equipment and infrastructure requirements: Telehealth relies on high-speed internet and appropriate equipment, which can still pose challenges in certain rural areas.
Environment (health care professionals)			

	People (patient)	Object (patient)	Environment (patient)
Pros	<ul style="list-style-type: none"> Expansion of health care service areas: Through telehealth, physicians can diagnose and treat patients remotely without being limited by geographical location while providing real-time medical services. Expansion of professional scope: Telehealth enables physicians to engage in remote meetings and collaborations with other health care experts, enhancing medical efficiency. Enhancement of diagnosis and treatment efficiency: Telehealth reduces time and space limitations between physicians and patients, improving the efficiency of the overall health care services. Increased convenience: Telehealth offers patients greater convenience, particularly for those residing in remote areas or facing mobility challenges, thereby reducing the time and costs associated with hospital visits. 	<ul style="list-style-type: none"> Enhancement of diagnostic and treatment capabilities: Through remote imaging and information sharing, physicians can access additional support and assistance, which improve diagnostic accuracy and treatment outcomes. Improvement of health care resource utilization: Telehealth aids physicians in managing and allocating regional health care resources more effectively, enhancing utilization efficiency and reducing unnecessary health care costs. 	<ul style="list-style-type: none"> Reducing reliance on physical space: Telehealth reduces the need for physical space such as clinics and hospitals, thereby lowering costs and burdens associated with facilities and resources for health care institutions.
Cons	<ul style="list-style-type: none"> Lack of physical contact: Telehealth may not provide opportunities for face-to-face contact with patients, which can make it challenging for physicians to conduct comprehensive physical examinations or assessments. Limitations in comprehensive treatment: Some diagnoses and treatments may require physical contact and assistance from specific equipment, which cannot necessarily be substituted by telehealth. 	<ul style="list-style-type: none"> Technical requirements: The use of telehealth requires stable internet connectivity and appropriate device support, which may be challenging for users who are not familiar with technology. Medical responsibility and risk management: Telehealth may involve issues of medical responsibility and risk management, such as misdiagnosis, treatment errors, or incomplete medical records, which may result in medical disputes and litigation. Physicians and health care institutions need to ensure compliance with relevant medical responsibility and risk management principles in telehealth as well as maintain a high level of medical practice. 	<ul style="list-style-type: none"> Health care security and privacy risks: The use of telehealth may involve health care security and digital privacy risks such as patient identity verification and medical record protection. Physicians should exercise caution in handling such issues.

Dimensions

Dimension 1: Distance, Time, and Transportation Issues

Both patients and health care professionals acknowledged the significant benefits of telehealth in addressing the challenges of distance in accessing medical care. Reductions in travel and wait times due to telehealth allowed patients to actively participate in their health care decision-making through web-based platforms. The digitization of medical records for better disease management was also facilitated. For residents in remote areas, telehealth eliminated geographical barriers to health care, promoted more efficient allocation of medical resources, and prevented the closure of regional hospitals and the “medical deserts” phenomenon. Nevertheless, health care professionals identified potential risks and quality-of-care issues associated with telehealth. Due to the absence of physical interactions, physicians were limited to relying on surface-level symptoms for diagnosis. Comprehensive physiological

examinations and physical evaluations were also limited due to the lack of suitable equipment, which could in fact jeopardize the safety of critically ill patients who require urgent or emergency treatment. Moreover, prolonged social isolation resulting from telehealth may have adverse effects on patients’ psychological and social well-being.

Dimension 2: Enhancing Medical Efficiency Through the Use of Telehealth

Health care professionals described that the popularization of telehealth was due to its advantages in improving the efficiency of disseminating medical information. Through online platforms, health care professionals can access patients’ medical history instantaneously and collaborate to provide optimized treatment. This approach reduced constraints on patients’ time and space, expanded the scope of medical services, reduced the workload of health care professionals, and transformed the traditional one-on-one respiratory treatment mode into a one-to-many model. Health care professionals also noted that the advantages

of data and imaging arising from telehealth actually improved diagnostic and treatment efficiency, which could as a result achieve precision medicine. However, health care professionals also raised concerns about telehealth. The mode of transmitting medical information through data still harbored many risks and considerations such as diagnostic and treatment errors. Additionally, injuries (such as falls or respiratory distress) that could occur during treatment raised issues related to medical responsibility and risk management. Therefore, handling patient identity verification and medical records with caution when administering telehealth is crucial in order to safeguard patient privacy during medical treatments.

Dimension 3: Leveraging Internet Connectivity and Device-Based Solutions for Rehabilitation and Health Monitoring

Patients and health care professionals both identified that digital health care had the potential to significantly reduce medical wait times and enhance efficiency, which complemented the services of regional hospitals, lowered the medical burden of chronic patients, and eliminated limitations due to transportation, geography, and time. However, many challenges still remain with the use of digital tools for rehabilitation and monitoring

systems. Most patients who require PR are older, aged ≥ 65 years, and unfamiliar with digital devices and networks, and they often lack the knowledge and understanding of how to install and configure such devices and applications. In addition, remote areas lack stable networks, technology, and equipment. This digital divide inhibits a subset of patients in certain areas from fully utilizing relevant medical services, highlighting the problem of an uneven distribution of medical resources.

Dimension 4: Advantages and Disadvantages of Converting Medical Spaces

The changing medical environment has brought many advantages to patients and health care institutions through telehealth, particularly during the COVID-19 pandemic, by reducing hospital-acquired infections and patients' reliance on medical space and resources, thereby alleviating the burden of health care costs. However, as previously mentioned, some health care professionals reported that not all diagnoses and treatments could be properly conducted remotely due to the availability or operation of equipment and the limitation of patients' home space and environment, which restrict the implementation of many treatment regimens. All the 4 dimensions supported by quotes from patients and health care professionals are shown in [Table 4](#).

Table 4. Verbatim quotes supporting the main dimensions by patients and health care professionals.

Dimensions	Patient	Health care professional
Dimension 1: Distance to outpatient care		
Positive	<i>...During the pandemic, being able to have online consultations reduced a lot of my stress. I heard many of my friends around me were infected while at hospital. [Female, 48 years old]</i>	<i>...Telemedicine has reduced a lot of transport-related issues. Through online connections, we can access all of the patient's data and make more accurate assessments. [HCP^a #12]</i>
Negative	<i>...I live in a very rural area where there are no taxis, so every time I see a doctor, I have to take four different buses. The journey alone takes me over three hours, so I avoid seeing a doctor if I can help it. [Female, 64 years old]</i>	<i>...To be honest, not every patient is suitable for telemedicine. For example, older patients may have difficulty understanding what I ask them to do. Also, some patients' conditions cannot be determined solely by questioning and require examination using medical instruments and devices, so it is difficult for me to make a diagnosis without a proper examination. [HCP #8]</i>
Dimension 2: Medical efficiency		
Positive	<i>...Because I get breathless when I walk, I try not to go out if I don't have to. I'm also afraid of falling when I go out, and I don't want to bother my children. So if I can see a doctor through a computer, I prefer that. [Male, 66 years old]</i>	<i>...The biggest advantage of telehealth is saving a lot of time and manpower. Of course, this refers to medical work that is more repetitive and lower risk. But I hope that in the future, online systems will have warning functions that can quickly let me know which patient has an issue that needs special attention. [HCP #3]</i>
Negative	<i>...I would rather see a real doctor. Just talking on the phone doesn't give me a feeling that I've really seen a doctor. [Female, 72 years old]</i>	<i>...To be honest, although the internet is convenient, I feel that its effectiveness is sometimes limited. Perhaps respiratory therapy needs to be divided into stages, and not every stage is suitable for being done at home. It may need to be classified/graded. [HCP #17]</i>
Dimension 3: Internet connectivity and equipment		
Positive	<i>...Every time I go out to see a doctor, I'm always in a rush and get so nervous that I forget to ask the doctor any questions. By seeing the doctor through a computer, I have more time to chat with the doctor. [Female, 70 years old]</i>	<i>...The internet connection is very convenient. As long as the health insurance card is inserted, all the patient's information can be accessed. Telehealth has not only changed a patient's medical treatment mode but also prevented many regional hospitals from closing down. [HCP #11]</i>
Negative	<i>...To be honest, I don't really understand the internet. If no one helps me set it up, I won't know how to see a doctor online. And if the doctor doesn't see me, how will they know what's wrong with me? [Male, 76 years old]</i>	<i>...Sometimes, the reason why I cannot wait for a patient is because the foreign caregiver has not set up the computer properly. When communicating with the patient through the computer, sometimes the elderly cannot understand, and it is also difficult to communicate with the caregiver. If I were there in person, I could still teach them how to do it. [HCP #8]</i>
Dimension 4: Space for diagnosis and treatment		
Positive	<i>...I am old and unable to move around easily. It would be best for me to see the doctor at home. [Male, 86 years old]</i>	<i>...A patient receiving online medical care at home will require much less space for us, such as waiting rooms and registration areas. It will also significantly reduce the demand and burden on staff. [HCP #1]</i>
Negative	<i>...There are many things that I cannot do at home. I need to have my blood pressure measured, but there is no one to help me at home. Also, I like to chat with people, but at home, there's only me. [Female, 70 years old]</i>	<i>...Online medical care now is quite good, with many complete functions such as registration, appointment progress, and electronic medical records. However, I personally have reservations about having many medical records stored in the cloud, as there is no absolute security. Also, if a patient falls at home, how to allocate responsibility and the risks involved are also concerns. [HCP #14]</i>

^aHCP: health care professional.

Discussion

This study explores the perspectives and barriers of respiratory health care professionals and patients toward telehealth for rehabilitation for respiratory diseases. Based on the participant interviews, the use of home-based telerehabilitation for patients with lung diseases was perceived to have both advantages and disadvantages, which could be categorized under 4 domains:

location, digital technology, internet connectivity, and physical space requirements. Unlike previous research [69], we adopted the people-object-environment framework and interviewed patients as well as health care professionals, with the aim of obtaining feedback from all participants in the same context. The 4 aspects mentioned above were found to be the most important concerns for health care institutions and patients.

Previous studies have reported that distance to outpatient care has a profound impact on chronic patients; in other words, the farther away from home, the lower is a patient's willingness to seek medical care [70]. However, Bhatt et al [71,72] highlighted that patients often exhibit a reluctance to engage in PR, regardless of proximity, for several reasons. Both groups of interviewees in our study reported that the provision of alternative options would reduce the number of hospital visits, which would benefit patients and health care institutions. Although digital health care has its limitations, leveraging the internet to expand regional hospital services is not only beneficial to the public but also makes medical services more effective [73]. In special circumstances such as the outbreak of a pandemic, issues such as patients being unable to attend in-person treatments cannot be ignored. It is undeniable that digital health care, in particular, spawns numerous benefits in such situations. However, there are still limitations to digital health care for people (doctors or the public), equipment and network, and the environment (urban or rural). For example, most older patients feel that only consultations in person with doctors generate the feeling of being treated. Furthermore, without physical examinations, it could be difficult for doctors to diagnose the cause of symptoms. Nonetheless, digital technology remains a good choice for patients with respiratory disease who do not want to venture outside or exercise; however, not every patient's home is equipped with remote medical devices or equipment, especially in rural areas [74]. Most patients with respiratory disease are also older, and without caregiver assistance, operating such devices can be difficult. In addition, due to limited professional knowledge, equipment, network, and living space, home care cannot replace all hospital diagnoses and rehabilitation. Therefore, in consideration of the findings from our study and a previous study [75], the implementation of hierarchical medical care requires that patients first undergo video consultations and then be referred to nearby medical institutions for appropriate treatment based on the severity of their condition. Patients can be referred to a larger medical center when necessary for treatment through an electronic referral platform between institutions. This approach not only effectively improves the utilization efficiency of medical resources but also significantly reduces medical expenses and transportation costs for patients.

This study has some limitations. First, as our study was conducted in a specific health care institution, our findings may

not be generalizable to other regions or institutions. Second, most patients had poor health conditions and no prior experience with PR; thus, they relied only on limited experience and information. Lastly, the majority of the participants were older, which may have influenced their responses regarding computer use or internet issues. Additionally, health care service needs likely vary between urban and rural areas, and our study does not distinguish between the challenges and differences in home-based PR between these 2 types of areas. Future research should consider this aspect in their study design.

Most study participants reported that telehealth could greatly benefit patients with chronic pulmonary diseases; however, these benefits were not without limitations. Reflections on these limitations by patients or health care professionals revealed that telehealth is not suitable for all patients. For example, diagnosis and treatment via telehealth can only accomplish certain tasks and merely serve as a tool for preliminary diagnostic assessments. Nonetheless, preliminary assessments can determine whether a referral to a regional hospital or a large teaching hospital is necessary. This classification and referral system will also be applicable to rehabilitation therapy. Not all patients are suitable for home-based PR, considering patient safety, the required space and equipment, or the need for further precision testing, among other factors. In addition, although telehealth brought many conveniences to patients and health care professionals, both parties still faced significant psychological pressure. Patients noted that digital medicine lacked warmth, and they tended to prefer human care, while physicians had doubts about medical decision-making without the ability to perform physical examinations. The degree of control over digital technology was also an issue. Both parties lacked confidence that effective treatment could be achieved solely through the internet. Even though digital care has the advantage of long-term patient monitoring, some patients were unfamiliar with internet devices, and health care professionals were concerned that patients may not always respond correctly to instructions. Moreover, patients often neglect their physician's advice (such as following prescribed exercise schedules) due to lack of motivation and the need to physically meet with the physician. Both groups of study participants indicated that significant improvements in telerehabilitation technology were still needed, particularly for patients in rural areas or those who were older and living alone, who require more support and services.

Abstract

Background: Information and communication technologies (ICTs) have been positioned as useful tools to facilitate self-care. The interaction between a patient and technology, known as usability, is particularly important for achieving positive health outcomes. Specific characteristics of patients with chronic diseases, including multimorbidity, can affect their interaction with different technologies. Thus, studying the usability of ICTs in the field of multimorbidity has become a key element to ensure their relevant role in promoting self-care.

Objective: The aim of this study was to analyze the usability of a technological tool dedicated to health and self-care in patients with multimorbidity in primary care.

Methods: A descriptive observational cross-sectional usability study was performed framed in the clinical trial in the primary care health centers of Madrid Health Service of the TeNDER (Affective Based Integrated Care for Better Quality of Life) project. The TeNDER technological tool integrates sensors for monitoring physical and sleep activity along with a mobile app for consulting the data collected and working with self-management tools. This project included patients over 60 years of age who had one or more chronic diseases, at least one of which was mild-moderate cognitive impairment, Parkinson disease, or cardiovascular disease. From the 250 patients included in the project, 38 agreed to participate in the usability study. The usability variables investigated were effectiveness, which was determined by the degree of completion and the total number of errors per task; efficiency, evaluated as the average time to perform each task; and satisfaction, quantified by the System Usability Scale. Five tasks were evaluated based on real case scenarios. Usability variables were analyzed according to the sociodemographic and clinical characteristics of patients. A logistic regression model was constructed to estimate the factors associated with the type of support provided for task completion.

Results: The median age of the 38 participants was 75 (IQR 72.0-79.0) years. There was a slight majority of women (20/38, 52.6%) and the participants had a median of 8 (IQR 7.0-11.0) chronic diseases. Thirty patients completed the usability study, with a usability effectiveness result of 89.3% (134/150 tasks completed). Among the 30 patients, 66.7% (n=20) completed all tasks and 56.7% (17/30) required personalized help on at least one task. In the multivariate analysis, educational level emerged

as a facilitating factor for independent task completion (odds ratio 1.79, 95% CI 0.47-6.83). The median time to complete the total tasks was 296 seconds (IQR 210.0-397.0) and the median satisfaction score was 55 (IQR 45.0-62.5) out of 100.

Conclusions: Although usability effectiveness was high, the poor efficiency and usability satisfaction scores suggest that there are other factors that may interfere with the results. Multimorbidity was not confirmed to be a key factor affecting the usability of the technological tool.

KEYWORDS

user-centered design; multimorbidity; comorbid; self-care; medical informatics; primary health care; chronic disease; chronic condition; chronic illness; primary care; usability; telemedicine; telehealth; information and communication technologies; ICT; digital health; eHealth; human-computer interaction

Introduction

Multimorbidity, which is generally defined as the presence of two or more simultaneous chronic diseases in a patient, is a major challenge for health systems [1]. In the European Union, up to 50 million people are estimated to have multimorbidity [2]. Barnett et al [3] estimated a multimorbidity prevalence of 64.9% among patients aged 65-84 years and of 81.5% for those 85 years or older [3]. In recent years, patient-centered care models [4] and, more specifically, interventions aimed at self-care education have made it possible to optimize how patients with multimorbidity manage their chronic diseases [5]. This type of intervention makes it easier for patients to identify their health-problem needs and to identify techniques that can help them make decisions, take appropriate actions, and modify them as they present changes in their diseases [6].

Information and communication technologies (ICTs) have been positioned as useful tools to facilitate self-care [7]. The different self-care strategies using ICTs include those dedicated to the monitoring of biometric parameters through wearable technologies or portable devices and mobile apps [8,9]. To achieve positive health outcomes from these interventions, the interaction between a patient and technology is particularly important. The description of this interaction between the technology, the specific tasks to be developed, and the end user is a property known as usability [10].

Research on usability has grown in parallel with the development of ICTs in health [11]. Reports from international organizations such as the 2012-2020 eHealth Action Plan of the European Commission [12] and the World Health Organization Global Strategy on Digital Health 2020-2025 [13] summarized the importance of the development of technological tools that take into account their interaction with the special conditions of older adults. The study of usability can help determine the reasons for low patient adherence and adoption of a specific technological tool. The improvements in usability could facilitate interaction through several mechanisms: reducing anxiety related to the use of new tools, increasing accessibility and distribution among a greater number of users, and reducing the possible risks derived from misuse [10].

In evaluating usability, the International Organization for Standardization (ISO) 9126 standard [14] assesses the quality of the product [15] and the ISO 9241 standard focuses on

processes, referred to as “the extent to which users in a specific environment can use a product to achieve objectives of effectiveness, efficiency and satisfaction in a particular task” [16]. Thus, usability comprises the effectiveness in usability, defined as the degree of completion [11,17,18] and the total number of errors per task; efficiency in usability, defined as the average time to perform the task; and satisfaction in usability, defined as the degree to which the user’s physical and emotional responses resulting from the use of a product satisfy their needs and expectations. The most commonly used methods for usability evaluation are questionnaires and interviews carried out after the use of the technological tool for a certain period of time.

The systematic reviews of Saeed et al [17] and Zapata et al [18] analyzed the definitions of the ISO standards and the methods used in evaluating the usability of health-related technological tools. Their results indicate that the most frequent usability problems are those related to visual aspects of the system and the ability to learn and use specific features [17,18]. However, because the results are limited to a specific technology and may not be generalizable, their interpretation should take into account the special characteristics of the end users, including their health conditions.

The specific characteristics of patients with chronic diseases can affect their interaction with different technologies. For example, in the usability evaluation studies of an app for diabetes self-management [19,20] and that conducted on an automatic drug dispenser for patients with dementia [21], characteristics of the patients were identified that interact with different aspects of usability. Relatedly, Wildenbos et al [22] differentiated four traits related to aging and chronic diseases that act as barriers to usability: cognitive, physical, motivational, and perceptual. Although the development of technological tools aimed at self-care is increasing, their usability has thus far mainly been evaluated in patients with specific isolated pathologies such as in the previous examples. Research from the perspective of patients with multimorbidity has been increasing in recent years [23,24] but remains insufficient [25], even though multimorbidity is the most common way of reporting chronic diseases in the population over 60 years of age [3].

Thus, studying the usability of ICTs has become a key element in the field of multimorbidity [26] to ensure its relevant role in

promoting self-care [7]. Along these lines, the TeNDER (Affective Based Integrated Care for Better Quality of Life) project [27,28] was a multisectoral project funded by Horizon 2020, the EU Framework Programme for research and innovation. The TeNDER project developed an integrated care model to manage multimorbidity in patients with dementia, Parkinson disease, and cardiovascular disease in four European countries: Spain, Germany, Italy, and Slovenia. One of the clinical studies related to the TeNDER project was a multicenter, randomized, parallel-group clinical trial carried out in Spain with the main objective of evaluating the effectiveness of the TeNDER system to improve quality of life in patients with chronic diseases. Secondary aims were to describe the satisfaction of patients and their caregivers and the usability of the TeNDER system [29].

The objective of this study was to analyze the usability of a technological tool (TeNDER) dedicated to health and self-care in patients with multimorbidity in primary care.

Methods

Design

This was a descriptive observational cross-sectional study of usability. This study was framed in the clinical trial in the primary care health centers of Madrid Health Service of the TeNDER project (ClinicalTrials.gov NCT05681065) [29].

Ethical Considerations

This study respects the basic ethical principles of autonomy, beneficence, justice, and nonmaleficence, and its development followed the norms of Good Clinical Practice and the principles enunciated in the latest Declaration of Helsinki (Seoul 2013). The study obtained a favorable report from the Research Ethics Board of the Hospital Universitario 12 de Octubre (20/450) and was approved by the Central Research Commission of the Community of Madrid (PC:39/20). Informed consent was obtained from all participants involved in the study. No camera recording or any other identification was made. Patients were included with an anonymous identifier in the data collection logbook (DCL). All data were processed based on the provisions of the EU General Data Protection Regulation 2016/679 of the European Parliament and the Council (April 27, 2016) and the Organic Law on Data Protection and Guarantee of Digital Rights

in the Spanish territory (LOPDGDD 3/2018 of 5 December). Participants did not receive any financial compensation for their participation in the study. The only compensation was that received through the user experience during the use of the technological tool.

Population and Sample

The study population included patients with one or more chronic diseases recruited from four primary care health centers in the Community of Madrid that had been included in the TeNDER project by their referring professionals [27,28].

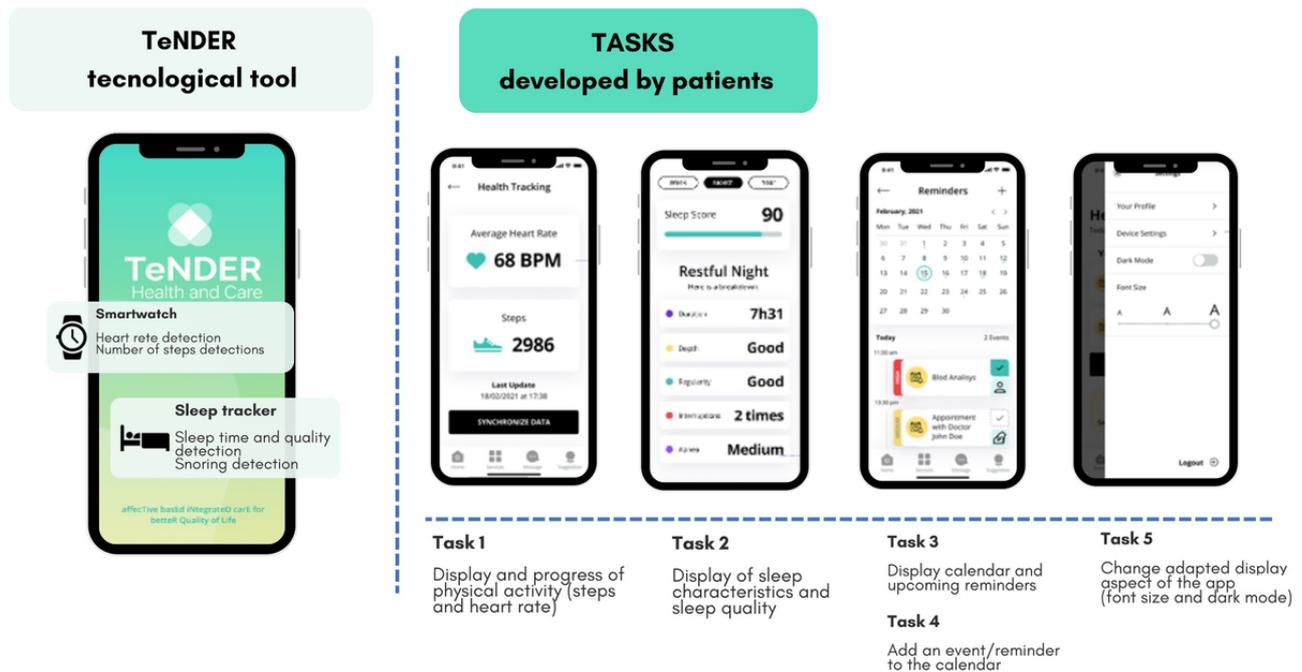

Patients over 60 years of age who had visited their health center in the last year and who had any of the following chronic diseases were included: mild-moderate cognitive impairment (Mini-Mental State Evaluation [MMSE] score 19-28 points), Parkinson disease, or cardiovascular disease, which includes patients with heart failure, chronic ischemic heart disease, or atrial fibrillation. Patients with a life expectancy of less than 6 months based on the opinion of their health care professionals, severe mental illness, incapacity for autonomous movement, or an MMSE score of less than 19 points were excluded.

The 250 patients included in the primary care health centers of Madrid Health Service for the TeNDER project were invited to participate via text messages with a mobile instant messaging app. Thirty-eight patients with multimorbidity (≥ 2 chronic diseases) agreed to participate. Considering an approximate 90% completion rate of tasks in previous usability evaluation studies of monitoring tools [19,25,30], with this sample size, we report a precision of 9.6% with the 95% CI.

TeNDER Technological Tool

The TeNDER technological tool is a web-based platform that included integrating sensors such as a smartwatch for monitoring physical activity, a sleep tracker to study sleep activity, and a mobile app in which the data collected are displayed and tools for self-management are offered (Figure 1). All of the TeNDER ecosystem technology was developed through a co-design process with all relevant stakeholders using a patient-centered approach. During the project, the functionalities and the mobile app were validated and released after user validation within an incremental development approach, ensuring a feedback framework that provided iterative refinement and improvements of the mobile app.

Figure 1. TeNDER technological tool and tasks to be performed by patients for the usability evaluation.

Variables

The main variable of the study was usability effectiveness, which was determined by the degree of completion and the total number of errors per task. Five tasks were designed using the TeNDER system (Textbox 1). The tasks to be evaluated were based on real case scenarios to simulate how patients would interact with the system in a real-life situation according to the care and self-management process based on the main functionalities of the TeNDER app [29]. The tasks were validated by a panel of three health professionals with

experience in the study of usability to verify the accuracy of the content and the context. The degree of completion of the tasks was coded using three categories: (0) not completed when the subject was unable to complete the task (inability to progress or to request advanced help or interruption in task execution), (1) completed with personalized help in the form of comments or directed indications, and (2) completed independently when the user was able to carry out the task either without any help from the person in charge of the test or with the aid of minor indications. An error was coded when the subject made errors that could not be solved or that prevented further progress.

Textbox 1. Tasks evaluated for the usability study.

- Task 1: Display and progress of physical activity (steps and heart rate).
- Task 2: Display of sleep characteristics and sleep quality.
- Task 3: Display calendar and upcoming reminders.
- Task 4: Add an event/reminder to the calendar.
- Task 5: Change-adapted display aspects of the app (font size and dark mode).

As secondary variables, usability efficiency was determined by timing each individual task and calculating the average time in each task. Usability satisfaction was quantified by administering the System Usability Scale (SUS) (Multimedia Appendix 1) in its Spanish-validated version [31]. For this scale, the global score ranges from 0 to 100, where higher values indicate greater usability satisfaction. According to Bangor et al [32], SUS scores of 70-100 indicate acceptable, whereas scores of 0-50 indicate not acceptable; scores between 50 and 70 are considered to indicate marginally acceptable results.

Sociodemographic variables collected included age, sex, and education level, and clinical variables included type and number of chronic diseases. Chronic pathologies were identified

according to the proposals in the O'Halloran classification [33] (Multimedia Appendix 2).

Technology-related variables included previous use of touch screens and the affinity for technology interaction (ATI) scale [34]. For this scale, the global score ranges between 1 and 6, where higher values indicate a greater affinity for the technology (Multimedia Appendix 3).

Data Collection

The variables were collected by interview with the patient in consultation with their referring professional and were recorded in an electronic DCL designed ad hoc with the Research Electronic Data Capture (REDCap) tool hosted on the secure storage server of the institution. REDCap is a secure, web-based

software platform designed to support data capture for research studies [35,36].

The patients received the TeNDER technological tool. The usability study was carried out 48 hours afterward based on the execution of tasks in a face-to-face session with a member of the research team who could provide assistance. To record the variables that measure usability, a real-time screen recording of the mobile device was performed during the entirety of task performance. One member of the research team analyzed the recordings. The start and end times were determined from the time the instructions were offered until the moment each task was completed; that information was subsequently transferred to the DCL.

Statistical Analysis

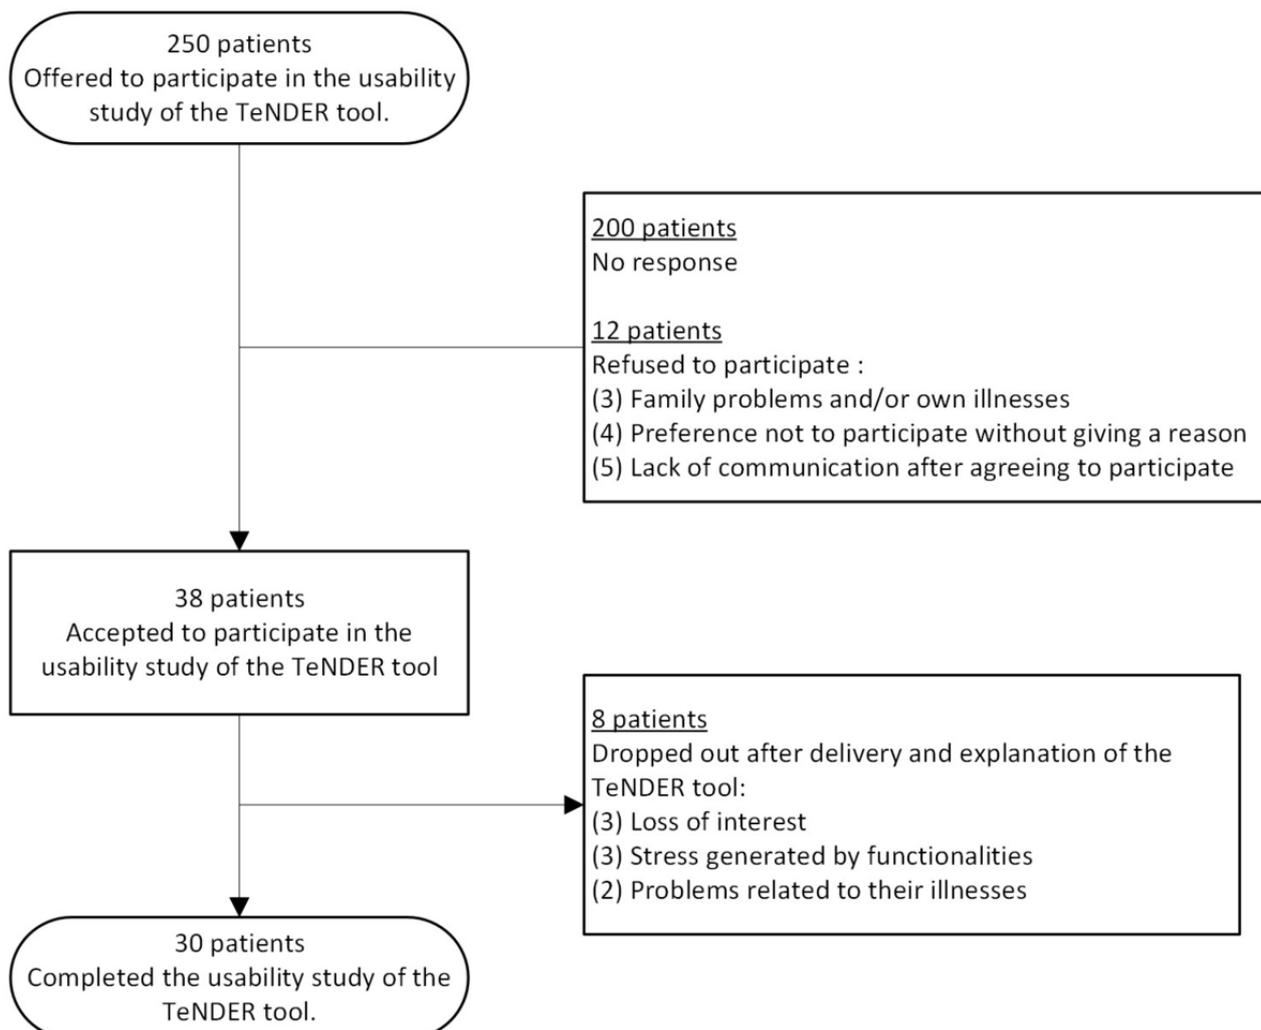

The categorical variables are described as frequencies and percentages. The quantitative variables are described as medians and IQR, as they were nonnormally distributed for the number of patients under study. The main result variable was the proportion of completed tasks (usability effectiveness) with its 95% CI. As secondary outcome variables, the mean effective time to perform each of the tasks (usability efficiency) and the

mean score in the SUS questionnaire (usability satisfaction) were estimated. The association of the different usability components (efficacy, effectiveness, and satisfaction) with the sociodemographic and clinical variables was evaluated using the χ^2 test for categorical variables and the Student *t* test for quantitative variables (the Mann-Whitney *U* test was used for comparison of variables that did not follow a normal distribution). The factors associated with completing the task in an independent manner were analyzed using a multiple logistic regression model with robust estimators. The dependent variable was completing the task autonomously. The independent variables were those found to be statistically significant in the bivariable analyses or variables that are otherwise considered to be clinically important. STATA 14 software was used for all statistical analyses.

Results

Among the 250 patients included in the TeNDER project invited, 38 (15.2%) agreed to participate in this study (Figure 2). There were no differences in sociodemographic characteristics between those who refused to participate and the final sample. Finally, 30 patients completed the usability study.

Figure 2. Flowchart of the participants.

The median age of the participants was 75 (IQR 72.0-79.0) years and 20/38 (52.6%) were women. With a median of 8 (IQR 7.0-11.0) chronic diseases, 89.5% of the patients had at least one cardiovascular risk factor. Syndromes that include anxiety and depression occurred at significantly different rates between women (11/20, 55%) and men (3/18, 16.7%). A total of 83.8% of the patients had previously interacted with touch screens, and the median result on the ATI scale was 3.4 (IQR 3.0-3.8), which differed between men and women.

The baseline characteristics of the patients are presented in [Table 1](#).

Thirty patients completed the usability study. Among them, 66.7% (20/30) completed all the tasks to be evaluated. All patients were able to complete at least three of the five proposed tasks and 10 patients did not complete at least one task. At least one mistake was made while carrying out the tasks in 28/30 patients. A total of 66.7% (10/15) of the women required personalized help in at least one of the tasks for their completion. The median usability satisfaction in the SUS questionnaire was 55 (IQR 45.0-62.5).

A total of 150 tasks were carried out among all users and 89.3% (134/150) of the tasks were completed. Tasks 1 and 2 were completed 100% (60/60) of the time. Task 4 was completed at a lower proportion than the other tasks (22/30, 73.3%) and presented the highest number of errors (mean 2.5, SD 0.47). Task 3 and task 4 required personalized help to be completed (10/30, 33.3% and 8/30, 26.7%, respectively). The results of the different usability components are shown in [Table 2](#) (also see [Multimedia Appendix 4](#)) and the details according to the different tasks are shown in [Table 3](#) (also see [Multimedia Appendix 5](#)). The results of the subgroup usability analysis considering patients with cognitive deficits are provided in [Multimedia Appendix 6](#).

In the multivariate analysis of the characteristics of the total tasks evaluated that were completed ([Table 4](#)), education level emerged as a facilitating factor to complete the task in an independent manner. Being male, having diseases related to cognition, and age hindered the completion of the task without help, with the latter factor being statistically significant.

Table 1. Patient baseline characteristics.

Discussion

Main Findings

The usability effectiveness of the TeNDER technological tool was 89.3% (134/150). Overall, 40% (12/30) of the patients completed all tasks independently. Task 4 was completed at a lower proportion than the rest of the tasks (22/30, 73.3%) and presented the highest number of errors (mean 2.5, SD 0.47). The usability efficiency, evaluated as the median time to complete the total tasks, was 296.0 seconds (IQR 210.0-397.0), with an average value per task of 65.4 seconds (SD 92.7). The satisfaction in usability perceived by the patients was acceptable (mean 52.2, SD 16.9). Being male, having diseases related to cognition, and age were factors that hindered the completion of the task without personalized help, among which only age was statistically significant.

Comparison With Other Studies

The usability effectiveness of the TeNDER technological tool was 89.3%, which is similar to the results of previous studies carried out on different categories of patients for similar technological developments. Sánchez-Morillo et al [30] evaluated the usability of a technological tool aimed at monitoring the symptoms of patients with chronic obstructive pulmonary disease, and Georgsson et al [19] evaluated a system designed for the management of self-care in patients with diabetes. The proportion of tasks completed was 88% and 91%, respectively, despite the opposite characteristics of the participants with respect to the level of education and affinity for technology in each of the studies. As in our study, the degree of task complexity could have been adapted to the characteristics of the potential users: tasks 1 and 2 were completed by all patients, whereas the rest of the tasks, of greater complexity, were completed by only those with higher education. For those who did not have higher education, the task completion rate reached up to 55.6%. These differences in the use of technology depending on the level of education have been confirmed in previous studies [37].

Despite the high proportion of completed tasks, 56.7% of the patients required personalized help to complete at least one of the tasks. Older age and cognition-related diseases were risk factors for requiring personalized help to complete the tasks. Previous experience in evaluating the usability of a computerized system for self-care management aimed at patients with chronic diseases yielded similar percentages of

effectiveness in usability and help for task completion [25], which points to the importance of having family members or professionals assist patients with chronic diseases to interact with a mobile app [38].

The median value for usability satisfaction was 55.0 (IQR 45.0-62.5), which is a low marginal score over not acceptable [32]. Ligons et al [21] obtained similar results and indicated that the degree of response in satisfaction with a technology or system may not be related to the ability for the completion of its tasks. That is, patients may be able to complete tasks without knowing why they have completed them or how they can benefit from them in their day-to-day lives. Other studies, including that of Sánchez-Morillo et al [30], suggested that high levels of satisfaction may be caused by the presence of qualified professionals who assisted during the usability evaluation.

The median age of the patients in our study was 75 years and a high degree of multimorbidity was notable, with a median of up to eight chronic diseases. Previous studies have analyzed the usability of a technology from the perspective of patients with a chronic index disease in particular [19,20,30,39]. For example, Wildenbos et al [22] analyzed how chronic diseases can affect the usability of technological tools. Thus, a single chronic disease can be the cause of physical, cognitive, and perception barriers [22]. Medical conditions that could favor the appearance of these barriers are represented in our study: diabetes, cardiovascular disease, cognitive impairment, and vision problems. However, as in previous studies, no differences were found in the different aspects of usability based on the number of chronic diseases.

Only 38 patients out of a total of 250 who signed prior informed consent agreed to participate in this usability study. It should be noted that a mobile instant messaging app was used as the method of offering participation and there was a nonresponse rate of 80% (200/250). This means of communication, although common in current society, could have caused a lack of confidence or security in patients [40]. Among the 38 patients who agreed to participate, 6 (15.2%) decided to leave the study as a result of the stress generated by the proposed tasks or due to lack of interest. Few previous usability studies have reported the number of losses [41], perhaps due to the small number of patients involved. Wildenbos et al [22] mentioned lack of motivation as a key element to achieving acceptance of technology by older people. The benefits of using a technology should be made evident quickly and easily; otherwise, feelings of frustration and of giving up its use are likely. In a time-limited

usability evaluation, these benefits are not evident, and their nonparticipation can help to avoid feelings of uncertainty, wasting the time invested in learning a technology, or the shame of making mistakes.

Differences based on sex in the use of ICTs have been described in previous studies [37,42]. Among older people, access to technology and their degree of involvement in daily activity is greater in men than in women [37]. These differences are also identified in the different aspects of usability. In our study, the average number of errors committed per task was significantly higher in women (mean 1.4, SD 2.0) than in men (mean 0.6, SD 1.2). In addition, the proportion of women who needed personalized help to complete tasks was higher (10/15, 67%) than that in men (7/15, 47%). These differences have been largely justified by the fact that the labor participation of women has been lower, particularly in computerized jobs due to less training over the years [43].

Limitations

Although the number of participants in our study is similar to that of other studies and the findings obtained provide valuable information, a larger sample size would provide a larger data

set to conduct more sophisticated and detailed statistical analyses. Moreover, given the characteristics of the research, it has not been possible to collect opinions, sensations, and emotions in relation to the technological tool that the patients experienced during task execution. For this reason, including a qualitative methodology such as focus groups [44], think-aloud tasks [45], or a user-centered cognitive walkthrough [20] could provide essential information for understanding the decision-making of patients with multimorbidity when faced with a mobile app aimed at health.

Another limitation identified is the time of tool use being limited to 48 hours. Studies such as those of Tahsin et al [46] and Baek et al [47] showed how usability results can change at different times over longer intervals of use for up to 1 year.

Conclusions

Although usability effectiveness was high, the poor efficiency and usability satisfaction results suggest that there are other factors that may interfere with these results. Sex and education level can influence the degree of completion of tasks. It has not been possible to show that multimorbidity is a key factor in the usability results of a technological tool.

Acknowledgments

This work received funding from the European Commission under the EU Horizon 2020 program (grant agreement number 875325; TeNDER project, Affective Based Integrated Care for Better Quality of Life). Abstract

Background: Hypoglycemia threatens cognitive function and driving safety. Previous research investigated in-vehicle voice assistants as hypoglycemia warnings. However, they could startle drivers. To address this, we combine voice warnings with ambient LEDs.

Objective: The study assesses the effect of in-vehicle multimodal warning on emotional reaction and technology acceptance among drivers with type 1 diabetes.

Methods: Two studies were conducted, one in simulated driving and the other in real-world driving. A quasi-experimental design included 2 independent variables (blood glucose phase and warning modality) and 1 main dependent variable (emotional reaction). Blood glucose was manipulated via intravenous catheters, and warning modality was manipulated by combining a tablet voice warning app and LEDs. Emotional reaction was measured physiologically via skin conductance response and subjectively with the Affective Slider and tested with a mixed-effect linear model. Secondary outcomes included self-reported technology acceptance. Participants were recruited from Bern University Hospital, Switzerland.

Results: The simulated and real-world driving studies involved 9 and 10 participants with type 1 diabetes, respectively. Both studies showed significant results in self-reported emotional reactions ($P < .001$). In simulated driving, neither warning modality nor blood glucose phase significantly affected self-reported arousal, but in real-world driving, both did ($F_{2,68} = 4.3$; $P < .05$ and $F_{2,76} = 4.1$; $P = .03$). Warning modality affected self-reported valence in simulated driving ($F_{2,68} = 3.9$; $P < .05$), while blood glucose phase affected it in real-world driving ($F_{2,76} = 9.3$; $P < .001$). Skin conductance response did not yield significant results neither in the simulated driving study (modality: $F_{2,68} = 2.46$; $P = .09$, blood glucose phase: $F_{2,68} = 0.3$; $P = .74$), nor in the real-world driving study (modality: $F_{2,76} = 0.8$; $P = .47$, blood glucose phase: $F_{2,76} = 0.7$; $P = .5$). In both simulated and real-world driving studies, the voice+LED warning modality was the most effective (simulated: mean 3.38, SD 1.06 and real-world: mean 3.5, SD 0.71) and urgent (simulated: mean 3.12, SD 0.64 and real-world: mean 3.6, SD 0.52). Annoyance varied across settings. The standard

warning modality was the least effective (simulated: mean 2.25, SD 1.16 and real-world: mean 3.3, SD 1.06) and urgent (simulated: mean 1.88, SD 1.55 and real-world: mean 2.6, SD 1.26) and the most annoying (simulated: mean 2.25, SD 1.16 and real-world: mean 1.7, SD 0.95). In terms of preference, the voice warning modality outperformed the standard warning modality. In simulated driving, the voice+LED warning modality (mean rank 1.5, SD rank 0.82) was preferred over the voice (mean rank 2.2, SD rank 0.6) and standard (mean rank 2.4, SD rank 0.81) warning modalities, while in real-world driving, the voice+LED and voice warning modalities were equally preferred (mean rank 1.8, SD rank 0.79) to the standard warning modality (mean rank 2.4, SD rank 0.84).

Conclusions: Despite the mixed results, this paper highlights the potential of implementing voice assistant-based health warnings in cars and advocates for multimodal alerts to enhance hypoglycemia management while driving.

Introduction

Overview

Around 9 million adults worldwide experience type 1 diabetes mellitus (T1DM) [1]. One of the most relevant acute complications associated with T1DM is hypoglycemia (ie, low blood glucose). This condition is associated with impaired cognitive, executive, and psychomotor function [2-4] and is linked to driving mishaps [5-7].

Previous work introduced the development of a voice warning for hypoglycemia while behind the wheel, whereas the voice assistant (VA) would work as a warning interface [8]. The hypoglycemia warning was intended as an app compatible with the VA that is already available in the car and that would allow delivering an alert in a hands-free manner. The study reported on the iterative development and evaluation of an in-vehicle hypoglycemia voice warning. It demonstrated that it is deemed useful and effective by drivers with T1DM, especially if the warning is kept simple and direct (ie, avoiding initiating a conversation with the driver). However, the paper did not investigate the effect of proactive behavior in the VA in such a context. Proactivity in VAs can cause a startling reaction, which is prone to annoyance [9] and driving impairments [10-12].

Ambient lighting can communicate with drivers without distracting them from their main task [13] or eliciting a strong emotional response [14]. This interface has been investigated as an indicator of several driving-relevant events, such as obstacle warnings or vehicle-state communication [15]. However, to the best of our knowledge, in-vehicle ambient lighting through LEDs has never been investigated as an indicator of a critical health state.

Our previous work [8] tested the concept of an in-vehicle voice warning delivered by the VA with healthy participants and then with individuals with T1DM, both in a driving simulator and a real car. The concept was developed following an iterative approach, and study participants provided feedback that we used to enhance the voice warning and test it on new participants. Thus, our previous work focused on technology acceptance and on improving it through user feedback. However,

the voice warning was not evaluated against a standard warning (ie, beep with text), which could be used as a benchmark. Moreover, our previous work did not focus on the emotional reaction generated by getting a warning while driving. Therefore, this work investigates the effect of LEDs (ie, a possible solution to alleviate emotional reaction) and is to be understood as a continuation of our previous work. To foster experimental control and external validity, the same procedure is replicated in a simulated driving setting (ie, a computer simulator) and a real-world driving setting (ie, a car in a closed circuit).

Background

Hypoglycemia Warnings

Hypoglycemia is a common complication of diabetes. The monitoring of blood glucose is essential to prevent hypoglycemia. Intermittent self-monitoring of blood glucose, flash glucose monitoring, and continuous glucose monitoring are commonly used methods. However, these methods are not adapted to the in-vehicle context, as they require the driver to visually attend to a handheld mobile device displaying the current blood glucose value. This behavior is known to impair driving performance [16], thus leading to dangerous situations while driving.

Tentative hands-free solutions have been proposed to address this issue in academia [17] and in the community of individuals with T1DM [18]. Specifically, prior research [17] suggested using vehicles as a platform to display blood glucose data on infotainment screens. Moreover, a digital community [18] created an open-source program to show their continuous glucose monitoring data on infotainment screens. However, these solutions are limited to visual information display, thus failing to be ergonomically suitable for the in-vehicle context while driving. Therefore, solutions must be developed, which can provide hypoglycemia warnings while driving. One approach is to use voice-first warnings (ie, delivered by the built-in in-vehicle VA), where the driver can be informed of the issue without having to attend to a display.

In-Vehicle Warnings

In-vehicle health-state warning systems are a part of advanced driver–assistance systems [19]. From a human-computer interaction perspective, in-vehicle warnings should be effective and communicate urgency without being annoying [20]. Currently, in-vehicle warnings vary from classic car warnings, visually presented on the dashboard with traffic-light colors and unspecific tones, to advanced driver–assistance system warnings that use visual, auditory, and haptic modalities [21]. Even though the visual signal should be redundant to the auditory and haptic signals, some driver-state warnings, such as the driver attention alert, are predominantly visual (eg, mug symbol with an indicative text such as “Time for a break”).

To decrease the demand for drivers’ visual attention, it is necessary to develop attention-attractive warnings without relying on visual displays as the main source of information. One approach would be to use the in-vehicle VA already built into the car to warn or alert drivers for critical situations, such as hypoglycemia (or drowsiness). This approach could ensure warnings’ effectiveness while reducing drivers’ visual distraction.

In-Vehicle VAs

VAs are increasingly being integrated into cars [22–24], allowing digital health interventions to be delivered via such an interface in a scalable way. In the in-vehicle context, VAs have ergonomic and experiential advantages: they reduce visual distraction compared to other infotainment technologies [25], foster a natural interaction [26], create a sense of social presence [27], and increase engagement [28]. Ultimately, VAs can create a sense of being in the presence of a copilot [29]. Therefore, in-vehicle VAs have great potential for delivering real-time and effective hypoglycemia warnings to drivers while driving.

Proactive VAs and the Risk of Startle

Proactivity is not part of the current common mental model of a VA. However, it does not necessarily affect driving performance [30] and is well-accepted by drivers [31,32]. Nevertheless, a sudden auditory stimulus can create a startling reaction, which could interfere with driving performance [10,33]. Hence, when it comes to critical situations such as hypoglycemia [34], it is important to develop warnings that gradually prepare the driver to be receptive to them. Ambient lighting can be used to gradually prepare the driver and add information without consequentially distracting the driver [13]. This technology has been previously investigated for in-vehicle driving behavior support such as collision and blind warnings, lane change decision support, and speed and attention direction recommendations [15]. In addition, it has been investigated to inform the driver about the vehicle’s decision-making in autonomous cars [35].

Objectives

To this end, a hypoglycemia warning delivered by a mock-up of a built-in in-vehicle VA is designed and tested with individuals with T1DM and compared to a standard format of in-car warning (ie, unspecific alert tone with visual information) regarding driver experience.

Specifically, this work aims (1) to design a hands-free multimodal health intervention for hypoglycemia (ie, warning) compatible with the in-vehicle context and (2) to investigate the effect of warning modality (visual, vocal, and vocal with ambient lighting) on the emotional reaction and the acceptance of such technology.

Methods

Overview

Two studies were carried out, a simulated driving study and a real-world driving study. Across these studies, participant recruitment, study design, material and apparatus, procedure, and data analysis were the same. The difference lied in the setting. For this reason, all the following subsections, except for *Setting*, are described only once.

Participants

Sampling, Inclusion Criteria, and Compensation

Patients diagnosed with T1DM attending the diabetes outpatient clinic of the Bern University Hospital were recruited. A physician (VFL) of the study team performed recruitment during regular outpatient visits with a face-to-face assessment. For the simulated driving study, participants were recruited between November 2021 and March 2022. For the real-world driving study, participants were recruited between April and June 2022. Inclusion criteria were age between 21 and 60 years, hemoglobin $A_{1c} \leq 9\%$ (ie, a blood test indicating how well the patient’s diabetes is being controlled), functional insulin treatment (with insulin pump therapy or multiple daily injections) for at least 3 months with good knowledge of insulin self-management, possession of a Swiss driver’s license at least 3 years before study inclusion, and have driven at least once in the last 6 months. Each participant received an expense allowance of US \$209.62 to cover general expenses caused by study participation (eg, transport).

Experience and Beliefs Questionnaires

Upon inclusion in the study, participants were asked to report the frequency of driving per week, their previous use of in-vehicle VAs, and their technology affinity. Technology affinity was assessed with the 16-item Technology Readiness Index [36]. This scale measures constructs susceptible to influencing the adoption of cutting-edge technology, such as optimism, innovativeness, discomfort, and insecurity.

Study Design

The study was designed as quasi-experimental with 2 independent variables, that is, blood glucose phase and warning modality, and 1 main dependent variable, that is, emotional reaction. The blood glucose variable had 3 levels, that is, euglycemia, decreasing, and hypoglycemia (see the *Procedure* section). The warning modality variable had 3 levels as well, that is, standard, voice, and voice+LED (see the *Warning* section). The blood glucose phase was varied in a nonrandomized fashion (see the *Procedure* section), while the warning modality was pseudorandomized, and each modality was crossed with each blood glucose phase. Secondary outcomes included self-reported user experience measures, such as

warning acceptance, perceived urgency, alerting effectiveness, annoyance, and preference.

Material and Apparatus

Overview

In this section, the operationalization of the design variables is described. An overview is listed in [Table 1](#).

Table 1. Study design variables.

Variable	Tool	Levels or values
Blood glucose ^a	Controlled hypoglycemia protocol [37]	Normal, decreasing, and hypoglycemia
Warning modality ^a	Hypoglycemia warning app [38]	Standard, voice, and voice+LED
Emotional reaction (objective) ^b	Empatica E4	Skin conductance response
Emotional reaction (subjective) ^b	Affective Slider [39]	Score (0-100)
Warning perceived urgency ^b	Baldwin and Moore scale [20]	Score (1=very urgent and 5=very insignificant)
Warning alerting effectiveness ^b	Baldwin and Moore scale [20]	Score (1=effective and 5=ineffective)
Warning annoyance ^b	Baldwin and Moore scale [20]	Score (1=I dislike it very much and 5=I like it very much)
Warning acceptance ^b	Van Der Laan Acceptance Scale [40]	Score (-2=negative extreme and +2=positive extreme)
Warning preference ^b	Arbitrary 3-point scale	Rank (1=best and 3=worst)

^aManipulation.

^bMeasure.

Blood Glucose

Blood glucose was manipulated by inserting 2 intravenous catheters: one for blood glucose measurement with an interval of 5-10 minutes and the other for the infusion of a combination of insulin and glucose, according to the patient's current blood glucose and the experimental target blood glucose range. Euglycemia (ie, normal blood glucose) was defined as a concentration of 5-8 mmol/L; decreasing blood glucose was identified when blood glucose was below the euglycemia range (5-8 mmol/L) and progressing toward a target hypoglycemic range (3-3.5 mmol/L); and hypoglycemia was defined as a concentration of 3-3.5 mmol/L. For more technical details, refer to related research [37].

Warning

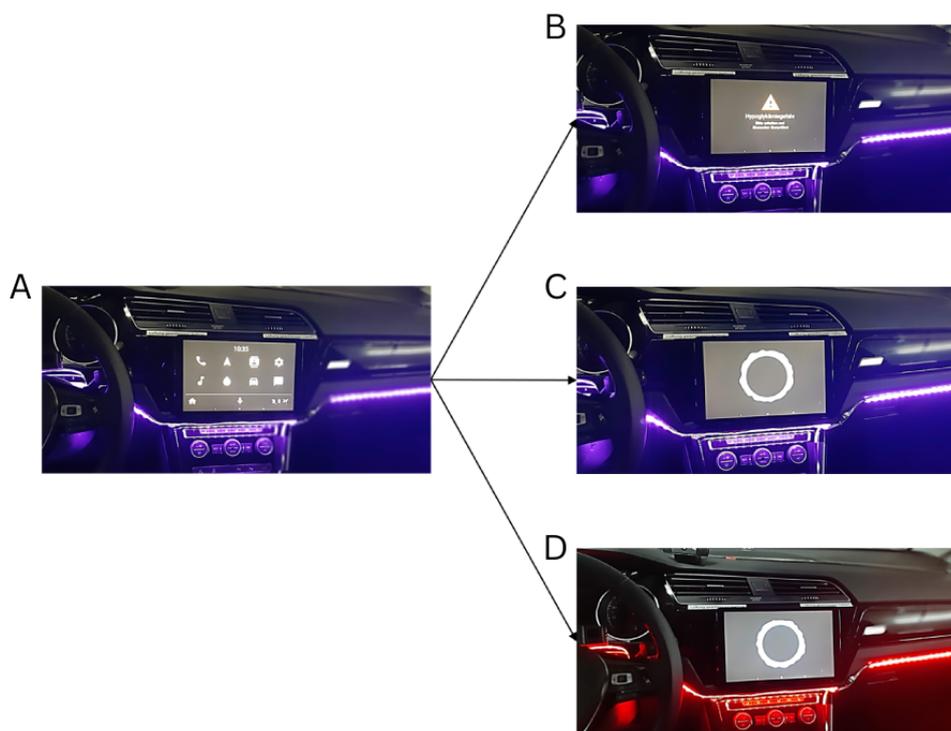

The Hypoglycemia warning app operationalized into a tablet (model SM-T590, Samsung) simulated the infotainment system's touchscreen, and LED strips (RGB Light Strip Pro, Cololight) simulated the interior ambient lighting. The warning system was controlled through the Wizard of Oz method [41], that is, the system was controlled by the experimenter behind the scene and acting as if it was fully automated.

The LED strips had 60 LEDs per meter and could be remotely controlled with the Cololight app (Klaus Stephan GmbH). The

tablet was used to run the Hypoglycemia warning app (publicly available on GitHub [38]), remotely controlled via a remote desktop app (AnyDesk, AnyDesk Software GmbH).

The warning system had 4 possible states: a default state and 3 intervention modalities (standard, voice, and voice+LED). The default state involved the LED strip being turned on in blue and the tablet showing a fake navigation menu ([Figure 1A](#)). The standard modality displayed a yellow warning sign with an informative text and was accompanied by an earcon. The text said "Risk of hypoglycemia. Please pull over and verify blood sugar." The LED strips remained blue ([Figure 1B](#)). The voice modality displayed a VA animation accompanied by a prerecorded synthesized female voice (de-DE-Wavenet-C with speed=0.85 and pitch=-3.20, Google Inc). The voice said "I have detected a risk of hypoglycemia. Please pull over safely and verify your blood sugar" (translation from the German formulation "*Ich habe eine Hypogefahr erkannt. Bitte sicher anhalten und deinen Blutzucker überprüfen*"). The voice warning was designed based on the results reported in our previous work [8]. Once again, the LED strips remained blue ([Figure 1C](#)). The voice+LED modality displayed the same VA animation and prerecorded synthesized female voice but, before the onset of the voice warning, the LED strips turned red ([Figure 1D](#)).

Figure 1. Illustration of the warning app and modalities. (A) The default state was shown during the drive and simulated the infotainment menu of the car. The (B) standard, (C) voice, and (D) voice+LED modalities were activated when a warning was delivered.

Participants knew that they would receive a warning during each drive. Still, the warning presentation was pseudorandomized, where they would receive a complete permutation of the 3 warning modalities within a blood glucose phase. Participants were not explicitly informed about which warning was “the intervention of interest” and which one was the “comparator.”

Objective Emotional Reaction

Emotional reaction was measured physiologically through skin conductance response (SCR). SCR is the result of the sympathetic nervous system promptly regulating the activity of the sweat glands in response to a stimulus. This measure is associated with emotional arousal [42] and can be used to measure event-related emotional reactions objectively [43]. In this study, the Empatica E4 (Empatica Inc), a Conformité Européenne–certified wristband collecting physiological data in real time, was used. Participants wore the E4 during the main visit (see the *Procedure* section). Note that this measure provided solely the arousal dimension of emotion.

Subjective Emotional Reaction

Emotional reaction was also measured subjectively through the Affective Slider [39]. This digital scale is a self-reporting tool measuring valence and arousal on 2 separate sliders. Participants did not see any numerical anchor, but the score ranged from 0 to 100. Thus, valence is rated between a frowning and a smiling face (0=frowning and 100=smiling), and arousal between a sleepy and a widely awake face (0=sleepy and 100=widely awake).

Warning Perceived Urgency, Alerting Effectiveness, and Annoyance

To measure the perceived urgency mapping of the 3 modalities, for each modality, participants rated the perceived urgency, alerting effectiveness, and annoyance according to a scale from prior work [20]. The 3 dimensions were rated using a 5-point Likert scale (1=very urgent or effective or I like it very much and 5=very insignificant or ineffective or I dislike it very much). This questionnaire was filled out during the posttest visit (see the *Procedure* section).

Warning Acceptance

To compare the acceptance of the 3 modalities, participants filled out the Van Der Laan Acceptance Scale [40], once per modality. This scale consists of the 2 constructs, usefulness and satisfaction, with items answered on a 5-point semantic differential from -2 to $+2$, which means participants had to select a point between 2 opposite adjectives (eg, unpleasant or pleasant). This questionnaire was filled out during the posttest visit (see the *Procedure* section).

Warning Preference

To formalize their preference, patients were asked to rank the 3 modalities from best to worst. The scale was implemented as a radio button questionnaire with 1 item per modality (ie, beep with a warning sign and text, voice, and LED with voice) and a 3-point scale (ie, 1=best and 3=worst). Participants were also encouraged to provide comments to their answers, which were topically (ie, without verbatim transcription) recorded in written form. This questionnaire was filled out during the posttest visit (see the *Procedure* section).

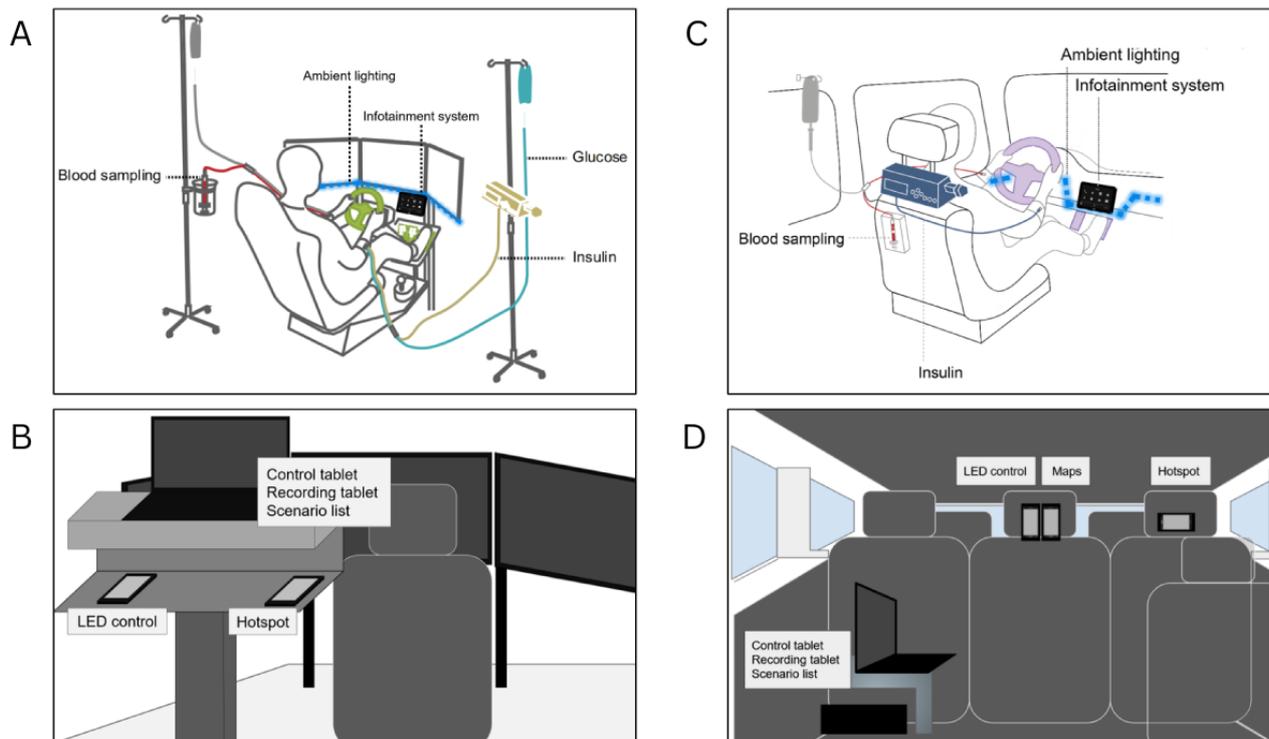

Setting

Simulated Driving

Patients used a driving simulator (Carnetsoft Inc), featuring 3 monitors displaying the front, left, and right views of the driving cabin. The central monitor also displayed the cockpit and navigation arrows, which directed the patient through the environment. To control the simulator, participants used a

steering wheel and pedals (Logitech Driving Force G29, Logitech), set to the automatic transmission. The simulator was connected to a stereo speaker and maintained at a constant volume (Figure 2A and C). The infotainment system simulator tablet (see the *Warning* section) was placed under the right side of the central monitor and connected to the simulator's sound system. The LED lights were attached at the bottom of the 3 monitors. Figure 2A and 2C illustrates the patient's setup.

Figure 2. Comparison of patient's and experimenter's setup between simulated and real-world driving. The left figures represent the simulated driving setting, the right figures represent the real-world driving setting, the top figures (A and C) show the patient's setup, and the bottom figures (B and D) show the experimenter's setup.

The experimenter was standing behind the patient and controlled the LED stripes with a smartphone (Redmi Note, Xiaomi Inc) and the tablet via a laptop computer (ThinkPad X1 Carbon, Lenovo PC HK Ltd). A stopwatch app was used to manually onset the warning. Figure 2B and 2D illustrates the experimenter's setup.

Three environments were used, namely, highway, countryside, and town, with the highway being the easiest to navigate due to variable traffic but no turns, the countryside having a moderated amount of traffic and turns, and the town being the most difficult with the most turns and traffic. Participants drove in the environments for about 5 minutes before receiving a hypoglycemia warning (run-in phase).

Real-World Driving

Patients drove in a minivan (Touran, Volkswagen) with an automatic transmission. The car was equipped with dual pedals to allow for intervention from a trained driving instructor, in case of emergency. In case the instructor needed to intervene, the event was recorded.

The infotainment system simulator tablet (see the *Warning* section) was placed on top of the infotainment screen and connected to the car's sound system, maintained at a constant

volume. The LED lights were attached along the cockpit from the left to the right extremities, passing by under the steering wheel, the infotainment system, and above the aperture of the glove compartment. The experimenter was sitting in the third row of the car and controlled the LED stripes with a smartphone and the tablet via a laptop computer (6th Gen ThinkPad X1 Carbon, Lenovo PC HK Ltd). A Google Map was used to manually onset the warning.

Patients were exposed to real-world driving on a test track provided by the Swiss Federal Department of Defense, Civil Protection and Sports. The driving scenarios on the track were designed to correspond with simulated environments used in the simulator setting (ie, highway, countryside, and town), featuring various driving elements such as turns, crossroads, stop signs, and a pedestrian crossing equipped with a dummy. As traffic simulation was not feasible, artificial obstacles, including boxes and traffic pylons, were used. Participants drove in the environments for 5-7 minutes before receiving a hypoglycemia warning (run-in phase).

Ethical Considerations

The experiments were approved within the context of this project by the cantonal ethics commission of Bern, Switzerland

(BASEC2020-00685 and BASEC2021-02381). Before any study-related procedure, informed consent specifying the analysis and the study protocol presented in this paper was obtained in written form from all participants. All collected data were deidentified by associating individual data to a numerical identification number. The data reported in this paper are part of the HEADWIND Study, a clinical trial registered under ClinicalTrials.gov (Part 3: NCT05183191 and Part 4: NCT05308095).

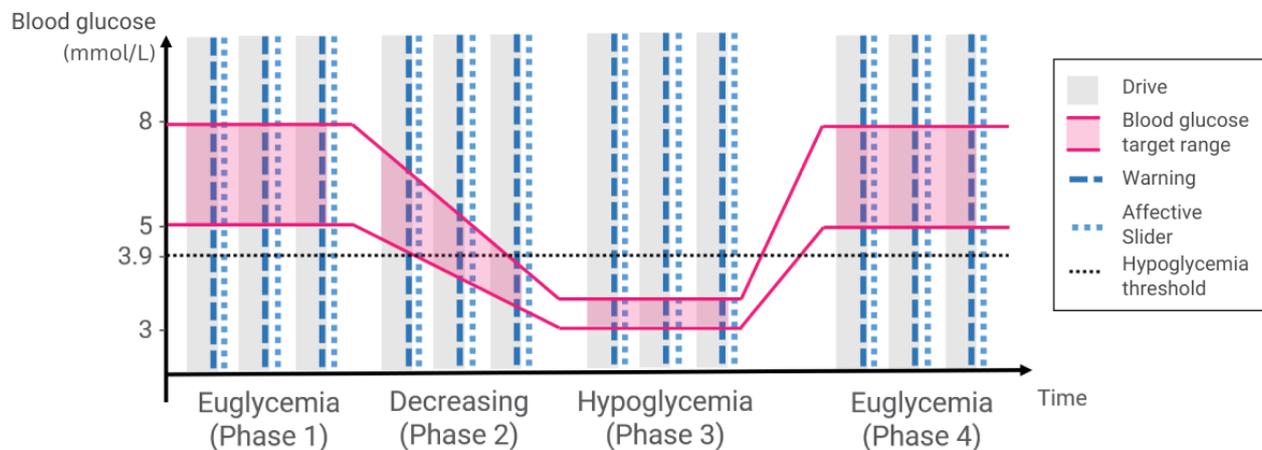

Procedure

The procedure was divided into 3 visits. In a pretest visit, patients were welcomed to the Bern University Hospital, informed about the procedure and the warnings, and asked to fill out demographic and experience and beliefs questionnaires.

In the main visit, participants were welcomed to the relevant setting for the blood glucose manipulation and the objective emotional reaction measurements. Participants were aware that their blood sugar would be manipulated to reach specific goal ranges, but they were not informed of their blood glucose during the experiment. In the real-world driving setting, the driving instructor was also aware of the blood glucose manipulation and was blinded to the current blood glucose. The experimental team was not blinded to the blood glucose level.

Each participant went through a fixed sequence of blood glucose phases: (1) a first drive with normal blood glucose (phase 1: euglycemia), where participants were first experiencing all types of environment and warning (and was thus considered as training); (2) a phase where blood glucose was progressively decreasing toward the moderate hypoglycemia threshold (ie, <3.0 mmol/L) with a target range of 3-3.5 mmol/L (phase 2: decreasing); (3) a phase with stable moderate hypoglycemia (phase 3: hypoglycemia); and (4) a final phase with normal blood glucose (phase 4: euglycemia). A warning was delivered at the end of each drive to explore the effect of the blood glucose phase. Participants drove in the 3 types of environments in each phase. The sequence of environment type was pseudorandomized [8], that is, participants were exposed to all 3 warning modalities within each phase, but the sequence of modalities within 1 phase was random. Similarly, the warning modality was pseudorandomized to balance modality with environments. Once participants received a warning, they were expected to stop, and the drive came to an end. At the end of each drive, participants filled out the Affective Slider referring to the warning they just received. Figure 3 shows an overview of the procedure.

Figure 3. Overview of the procedure. The vertical gray bars represent the drives, the ribbon delimited by solid lines represents the blood glucose manipulation, the vertical dashed lines represent the warning deliveries, the vertical dotted lines represent the Affective Slider submission, and the horizontal dotted line represents the hypoglycemia threshold.

In a posttest visit, participants were once more exposed to the 3 warning modalities and were required, after each exposure, to fill the Baldwin and Moore scale [20] and the Van Der Laan Acceptance Scale. Finally, they ranked the 3 warning modalities.

Data Analysis

The continuous variables of sample characteristics (ie, demographics and previous experience) are presented with mean and SD. Frequency variables of sample characteristics are presented in count numbers (ie, n) and percentages of the total experiment sample.

Emotional reaction (objective and subjective) measures were analyzed as a function of blood glucose (excluding phase 1) and warning modality and verified with a mixed-effects linear model, ANOVA test, and a significance threshold of $P=.05$.

Effect size was calculated with partial η^2 (0.01 indicates a small effect, 0.06 indicates a medium effect, and 0.14 indicates a large effect). Moreover, the objective emotional reaction was analyzed following established guidelines [43]: SCR (ie, rapid phasic component) was standardized for individual differences by dividing the SCR signal by the individual maximum SCR and by reducing the noise. In addition, SCR was calculated by considering the change in skin conductance between the average skin conductance in the 5-second window before the warning onset and the average skin conductance in the 5-second window after the warning onset itself (including latency of 1 second). For each measure of emotional reaction, a mixed-effects linear model was estimated with warning modality (3 levels: standard, voice, and voice+LED) and blood glucose (3 levels: normal, decreasing, and hypoglycemia) as independent variables and

with emotional reaction measure (ie, either self-reported arousal, self-reported valence, or SCR) as the dependent variable.

Warning evaluations (ie, perceived urgency, alerting effectiveness, annoyance, and acceptance) were aggregated with means and SDs, presented in a table. Moreover, perceived urgency, alerting effectiveness, and annoyance were centered on 2 to match the acceptance scores, for the sake of comparison.

Preference ranking was aggregated across modalities in the frequency of rank as best, middle, or worst (ie, how many times 1 modality was ranked as the best, middle, or worst in comparison to the other 2). If participants were commenting on their choices, highlight note-taking was performed.

Data analysis and graphical representations were performed using RStudio (Posit Software) packages such as *lmerTest* or mixed-effects linear modeling and *ggplot2* and *patchwork* for data visualization. All results are separated by experiment (ie,

simulated vs real-world driving) and juxtaposed to allow direct comparison.

Results

Overview

The data of 2 participants of the simulated driving study were excluded due to partial data loss. In the real-world driving setting, the driving instruction had to intervene in 1 instance, as the participants did not follow the driving path (ie, did not turn left) during phase 4 (ie, while in euglycemia).

Sample Characteristics

Overall, the majority were male participants, who drove multiple times per week and did not have previous experience with in-vehicle VAs. Participants were approximately 40 years of age and had a Technology Readiness Index between 3.5 and 4 (over a maximum of 5). Details are shown in [Table 2](#).

Table 2. Sample characteristics across studies.

Characteristics	Simulated (n=9)	Real-world (n=10)
Sex, n (%)		
Male	8 (89)	7 (67)
Female	1 (11)	3 (33)
Age (years), mean (SD)	45.7 (11.79)	37.3 (11.1)
Frequency of driving, n (%)		
1 time per month	1 (11)	1 (10)
2-5 times per month	— ^a	2 (20)
2-5 times per week	5 (56)	4 (40)
Every day	3 (33)	3 (30)
Previous use of in-vehicle voice assistants, n (%)		
Never	4 (44)	6 (60)
Rarely	1 (11)	2 (20)
Sometimes	2 (22)	1 (10)
Often	2 (22)	1 (10)

Emotional Reaction

Overview

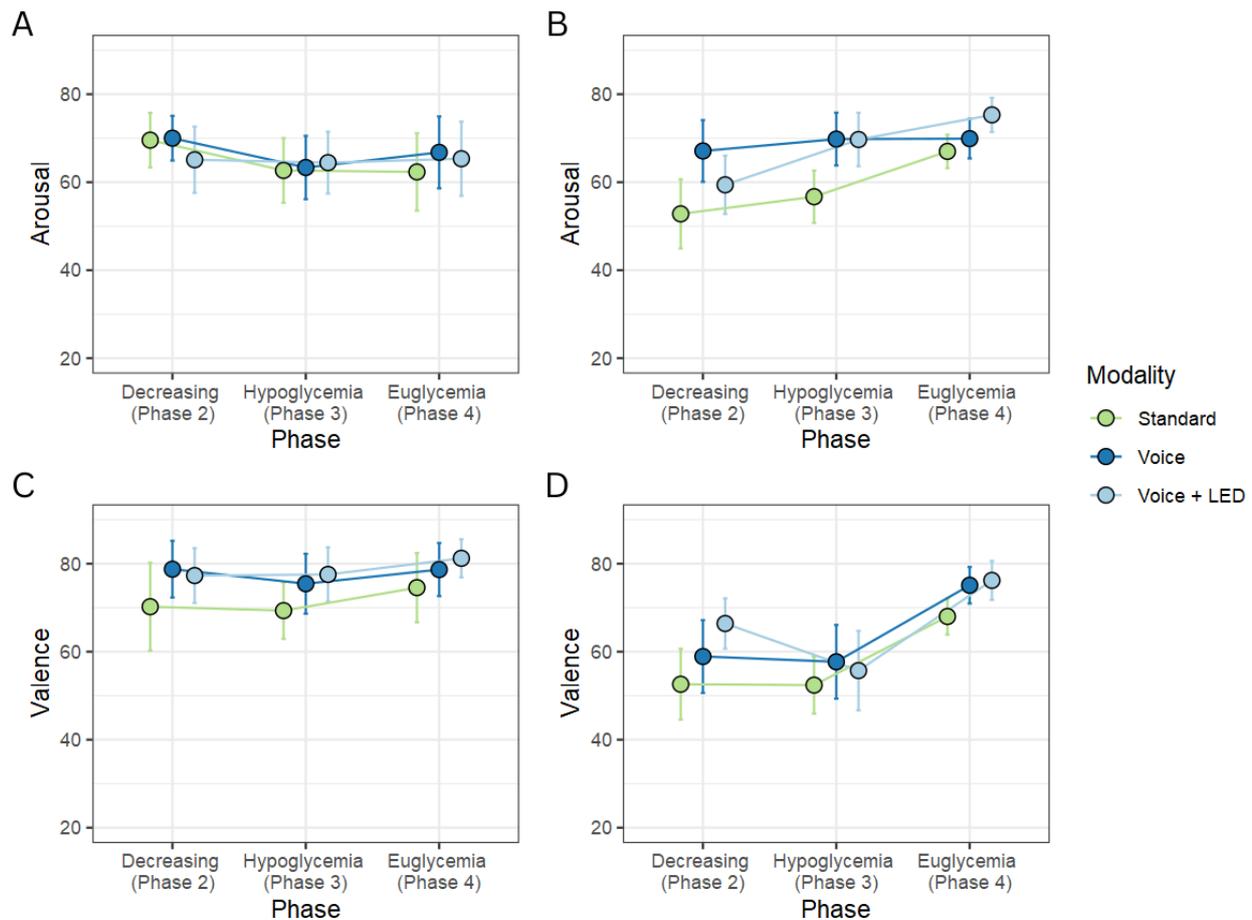

In this section, the results of the self-reported and physiological measures of emotional reaction (ie, self-reported valence and arousal and SCR) are described. A mixed-effect model was run

on all these measures, with warning modality and blood glucose phase as independent variables.

Self-Reported Arousal and Valence

According to our results, the mixed-effect models were significant for both valence and arousal in both studies ($P < .001$). [Figure 4](#) shows the means and SEs for arousal and valence.

Figure 4. Line plots of arousal and valence across warning modality and blood glucose phases across (A and C) simulated and (B and D) real-world driving. Error bars represent SEs.

In the simulated driving study, arousal was not significantly affected by either of the independent variables (modality: $F_{2,68}=0.1$; $P=.91$; partial $\eta^2=0$, blood glucose phase: $F_{2,68}=1.1$; $P=.35$; partial $\eta^2=0.03$). Valence was significantly affected by warning modality ($F_{2,68}=3.9$; $P=.03$; partial $\eta^2=0.10$) but not by blood glucose phase ($F_{2,68}=1.1$; $P=.35$; partial $\eta^2=0.03$).

In the real-world driving study, arousal was significantly affected both by warning modality ($F_{2,76}=4.3$; $P=.02$; partial $\eta^2=0.10$) and blood glucose phase ($F_{2,76}=4.1$; $P=.02$; partial $\eta^2=0.10$). Valence was significantly affected by blood glucose phase ($F_{2,76}=9.3$; $P<.001$; partial $\eta^2=0.20$) but not by warning modality ($F_{2,76}=2$; $P=.14$; partial $\eta^2=0.05$).

Physiological Arousal

According to our results, the mixed-effect models were not significant in both studies. Hence, the warning modality and blood glucose phase did not significantly affect physiological arousal measured via SCR neither in the simulated driving study (modality: $F_{2,68}=2.46$; $P=.09$; partial $\eta^2=0.1$, blood glucose phase: $F_{2,68}=0.3$; $P=.74$; partial $\eta^2=0$). nor in the real-world driving study (modality: $F_{2,76}=0.8$; $P=.47$; partial $\eta^2=0$, blood glucose phase: $F_{2,76}=0.7$; $P=.5$; partial $\eta^2=0$).

Technology Acceptance

In this section, the technology acceptance results (ie, Baldwin and Moore scales of urgency, effectiveness, and annoyance and the Van Der Laan Acceptance Scale) are described. Details are available in Table 3 [44].

Table 3. Technology acceptance measure across studies.

Measure and warning modalities	Simulated driving, mean (SD)	Real-world driving, mean (SD)
Urgency		
Standard	1.88 (1.55)	2.6 (1.26)
Voice	2.88 (1)	3 (0.82)
Voice+LED	3.12 (0.64)	3.6 (0.52)
Effectiveness		
Standard	2.25 (1.16)	3.3 (1.06)
Voice	2.75 (1.28)	3.6 (0.7)
Voice+LED	3.38 (1.06)	3.5 (0.71)
Annoyance		
Standard	2.25 (1.16)	1.7 (0.95)
Voice	0.88 (0.84)	1 (0.82)
Voice+LED	0.5 (0.76)	1.1 (1.2)
Acceptance		
Standard	3.35 (0.55)	3.52 (0.53)
Voice	3.74 (0.47)	3.88 (0.41)
Voice+LED	3.86 (0.47)	3.77 (0.61)

In the simulated driving study, the voice+LED modality elicited the highest sense of urgency and effectiveness, the least annoyance, and the highest acceptance, followed by the voice modality. In real-world driving, the voice+LED modality elicited the highest sense of urgency and least annoyance, while the voice modality elicited the most sense of effectiveness and the highest acceptance.

Preference Ranking

The average rank in the simulated driving study was 1.5 (SD 0.82) for the voice+LED modality, 2.2 (SD 0.6) for the voice modality, and 2.4 (SD 0.81) for the standard modality. The average rank in real-world driving was 1.8 (SD 0.79) for both the voice+LED and voice modalities and 2.4 (SD 0.84) for the standard modality.

In the real-world driving study, topical feedback showed that 6 participants mentioned that the light was not noticeable while driving (eg, “I have not noticed the light but at night, it certainly works better” [Participant 4]).

Discussion

Principal Findings

This study investigated the effect of warning modality (visual, vocal, and vocal with ambient lighting) on the emotional reaction and the acceptance of such a technology. Our results showed that voice warnings are more appreciated and considered more effective than standard warnings. However, the ambient lighting did affect such judgments.

Effects of Warning Modality on Emotional Reaction

Effect on SCR

No significant effect of warning modality (or blood glucose phase) on skin conductance was found. SCR measured through Empatica E4 has been previously shown to be linked with response to stimuli [45-47]. Moreover, it has been associated with blood glucose variation [48,49]. Therefore, we may consider the possibility that the measurement protocol used in this research may have experienced certain weaknesses and have affected the validity of the obtained results. Hence, we cannot consider the lack of significant results as negative evidence. Nevertheless, future research should further investigate the startling effect of the voice warning while driving, either by replicating our experimental setting, by using alternative electrodermal activity measurement tools [50], or by using other measures of emotional reaction, such as eye blinks [44].

Self-Reports

Our results showed that although in simulated driving the effect of modality on self-reported arousal was not significant, this was the case in real-world driving. In particular, higher arousal was observed during decreasing glucose and hypoglycemia for the voice and voice+LED modalities. Moreover, in the simulated driving study, the results on self-reported valence show a significant effect of modality, with voice+LED and voice warnings eliciting higher valence than a standard warning, particularly during decreasing glucose and hypoglycemia. This was not the case in the real-world driving study.

Despite the mixed results, the warning modality had a significant effect in the critical moments, that is, when the participants were about to experience or already experiencing hypoglycemia. Thus, our results showed the relevance of measuring emotional

reaction at different levels of blood glucose. While the Affective Slider is a very efficient measurement tool, it is important to note that some participants expressed a lack of confidence in self-reporting their emotions with it. Thus, future research might benefit from using alternative self-reported measures of emotion, such as the Positive and Negative Affect Schedule [51] or the Discreet Emotions Questionnaire [52].

Mixed Results

These mixed results preclude the formulation of definitive conclusions regarding the effect of modality on emotional reaction based on this study. As a sudden auditory stimulus can create a startling reaction, which can interfere with driving performance [10,33], future research should consider our recommendations and further investigate the design of a warning that is both effective and nonstartling.

Effects of Warning Modality on Acceptance and Preference

Acceptance

Our results demonstrated that the voice+LED modality tended to be the most valued regarding acceptance and preference. However, in the real-world driving study, this advantage, compared to the voice modality, seemed to decrease compared to the simulated driving study. This change might be due to the setup, where the ambient lighting was more visible in the laboratory than outdoors. Therefore, the advantage of the ambient lighting might have decreased in the real-world driving study. Thus, from the results, it is clear that the voice warning had an advantage over the standard warning, while the addition of ambient lighting (ie, voice+LED modality) did not bring a substantial advantage.

Preference

Finally, when asking participants for a posttest ranking of the warning modalities, results showed that voice (ie, both voice and voice+LED modalities) had a constant advantage over a beep with text (ie, standard modality). However, in the simulated driving study, the voice+LED modality was ranked first more often than in the real-world driving study, leading to interpret these results similar to the technology acceptance results, that is, adding ambient lighting to a voice warning was not considered substantially advantageous. These results might be influenced by the perception of the lights in daylight conditions, which differed between the simulated and the real-world driving settings. Based on the topical feedback from the participants experiencing the real-world driving setting, it might be that the contrast between the exterior and interior luminance was too low. As we did not measure the contrast in luminance between the daylight and the LEDs, future research should further investigate the use of ambient lighting as a component of in-vehicle warnings with greater control on luminance [53].

Implications

This paper involves implications both from health and automotive perceptive. First, our investigation represents a step forward in managing a real-life hazard associated with hypoglycemia. Our previous work [8] focused on designing an effective voice warning. This work compared it to a standard

warning with an unspecified auditory signal with a text, and with an addition of ambient lighting, to make the voice warning less abrupt. Our results show an advantage for a voice warning (ie, spoken) over a tone with text but not for ambient lighting. While participants showed a higher preference for adding ambient lighting in the simulated driving study, the way the ambient lighting was set in the real-world driving study was not noticeable enough to replicate the results. Other work has investigated more attention-grabbing ambient lighting, such as blinking lights [54]. Future research should investigate if different typologies of ambient light patterns could affect emotional reaction and acceptance.

Second, our investigation aims to inspire in-vehicle technology designers to develop in-vehicle health warnings using the in-vehicle VA. While there are driver-state warnings, they predominantly alarm the driver with an unspecific beep and a text on the cockpit. Future research should investigate how using the in-vehicle VA to warn the driver about dizziness or lack of attention would be accepted by drivers. Moreover, providing health-related warnings while driving fits the concept of “health-conscious” cars [55,56]. Along the lines of our investigation, there have been some attempts to develop blood glucose monitoring interfaces for the car [17,18]. However, they primarily rely on visual displays and are ill-adapted to the context of driving.

Finally, this study assumed the delivery of a hypoglycemia warning in a car with an autonomy of level 0 (ie, no automation) or level 1 (ie, with driver assistance). As cars are becoming increasingly automated, a hypoglycemia warning should be compatible with cars with a higher level of autonomy. However, the warning designed in this work is compatible with higher levels of automation. For instance, during autonomous driving, the in-vehicle VA could alert the driver that hypoglycemia has been detected and trigger the car to autonomously stop. During manual driving, the in-vehicle VA could warn the driver and trigger the car to take over (switch from manual to autonomous driving) and pull over.

Limitations and Future Research

Despite our best efforts, this investigation involved certain limitations. First, the sample size was rather small. Nevertheless, valuable insights on digital solutions can be provided with a small sample size [57-59]. Thus, although it does not allow drawing conclusions on the interaction of drivers with T1DM with in-vehicle hypoglycemia warnings, it motivates further research in this domain.

Second, emotional response to the warning was evaluated in different blood glucose states and a controlled setting (ie, simulator and closed circuit). However, the warning was not delivered when relevant (ie, only when the driver was actually undergoing hypoglycemia) or while the participant was driving on a public road unaware of the upcoming critical state. While our method allowed controlling for the blood glucose in the emotional response, it did not allow us to find the opportune moment for intervention delivery, that is, at what point of upcoming hypoglycemia is the warning most appropriate (both in terms of emotional reaction and acceptance). Future research should investigate the effectiveness of such an intervention in

a more realistic context, where the driver does not expect to be warned and is actually about to undergo hypoglycemia while on a public road.

Conclusions

This paper proposes the use of the in-vehicle VA and ambient lighting system to deliver a hypoglycemia warning, ensuring a hands-free alert. The investigation focused on the extent to

which warning modality could affect emotional response and acceptance both in a simulated and real-world environment. Although further investigations are needed, our results suggest, together with our previous work [8], that implementing multimodal warnings can improve the management of hypoglycemia in cars and also emphasize the potential of in-vehicle VA for delivering health-related warnings.

Abstract

Background: The use of chatbots in mental health support has increased exponentially in recent years, with studies showing that they may be effective in treating mental health problems. More recently, the use of visual avatars called digital humans has been introduced. Digital humans have the capability to use facial expressions as another dimension in human-computer interactions. It is important to study the difference in emotional response and usability preferences between text-based chatbots and digital humans for interacting with mental health services.

Objective: This study aims to explore to what extent a digital human interface and a text-only chatbot interface differed in usability when tested by healthy participants, using BETSY (Behavior, Emotion, Therapy System, and You) which uses 2 distinct interfaces: a digital human with anthropomorphic features and a text-only user interface. We also set out to explore how chatbot-generated conversations on mental health (specific to each interface) affected self-reported feelings and biometrics.

Methods: We explored to what extent a digital human with anthropomorphic features differed from a traditional text-only chatbot regarding perception of usability through the System Usability Scale, emotional reactions through electroencephalography, and feelings of closeness. Healthy participants (n=45) were randomized to 2 groups that used a digital human with anthropomorphic features (n=25) or a text-only chatbot with no such features (n=20). The groups were compared by linear regression analysis and *t* tests.

Results: No differences were observed between the text-only and digital human groups regarding demographic features. The mean System Usability Scale score was 75.34 (SD 10.01; range 57-90) for the text-only chatbot versus 64.80 (SD 14.14; range 40-90) for the digital human interface. Both groups scored their respective chatbot interfaces as average or above average in usability. Women were more likely to report feeling annoyed by BETSY.

Conclusions: The text-only chatbot was perceived as significantly more user-friendly than the digital human, although there were no significant differences in electroencephalography measurements. Male participants exhibited lower levels of annoyance with both interfaces, contrary to previously reported findings.

Introduction

Conversational user interfaces, also known as chatbots, have been a part of human-computer interactions since the 1960s. Most notable and one of the earliest examples is the ELIZA system, which aimed at simulating a human psychologist [1,2]. A subsequent system named PARRY was implemented in 1972, in which the conversational agent was designed to emulate a patient experiencing schizophrenia [3]. It is by no means a coincidence that the 2 earliest systems targeting the replication of human behavior through natural language processing were both derived from the field of psychiatry. The use of conversational agents has increased exponentially in the past decade [4]. With the availability of systems and the increasing need for 24-hour availability due to globalization, Radziwill and Benton [5] found that perhaps as many as 1 of 3 web-based conversations were conducted with a chatbot or a system moderated by language models, of which some have garnered more than 100 million users [4-8].

Previous research on rule-based conversational agents has shown promise with respect to the alleviation of mental health problems [4,9-11]. In a study by Oh et al [12], patients with panic disorder were randomized to support via a chatbot or support via a self-help book. The patients who were assigned to a chatbot as a support system for exercises in cognitive behavioral therapy were more likely to show symptom alleviation [12]. Digital evaluations as well as digital deliverance of mental health aid were more intensively explored following the COVID-19 pandemic [13]. In a study by Islam et al [14], the authors explored a similar design to that of Oh et al [12] and randomized a set of participants to either book or chatbot intervention for support regarding mental health issues [14]. The group of participants allocated to the chatbot intervention also significantly improved control of helplessness and social phobia scores. Some studies have shown that even a single exposure to a chatbot therapist can have a positive influence on the current state of well-being and repeated exposure can be a good complementary treatment for anxiety [9,10,15,16].

In recent years, a novel facet has been introduced into the evaluative framework for mental health chatbots: the incorporation of voice-controlled visual avatars embodying humanoid countenances colloquially referred to as “digital humans.” These digital entities harness the power of machine learning, emotion-infused linguistics, and adept emulation of facial expressions to cultivate a profound emotional rapport with their users. Research shows that human features elicit more social engagement and can trigger a stronger emotional bond [17]. This has primarily been measured through electroencephalography (EEG) with a specific focus being placed on the importance of increased α and θ wave activity as indicators of overall emotional stability and positive response

to stimuli [18-20], while β wave activity has largely been associated with less desirable states of mind such as anxiety and an active stress response [19,21].

While acknowledging the inherent complexity of brain states and wave activity, delving into the extent to which distinct brain wave frequencies exert influence during a chat session presents an intriguing avenue for investigating the emotional states of the user. In a study by Bos et al [22], the authors explored capturing vigilance and states of emotion with EEG in usability testing of chatbot technology. The study findings revealed that EEG effectively captured the facets of user experience and conversation that piqued interest. This was accomplished through the delineation of γ wave activity, predominantly linked with positivity and problem-solving. Consequently, this approach affords researchers a more objective means of apprehending user experience. A study by Ciechanowski et al [23] indicated that there is a difference in emotional response and usability preference between text-based chatbots and digital humans, with text-based chatbots eliciting more positive interactions.

Although EEG has served as a proficient tool for quantifying objective assessments of emotional responses to chatbot interventions, it is customary to use usability scales for capturing the subjective dimensions pertaining to emotions and experiences in the context of chatbot systems. While a universally accepted benchmark for conducting usability tests on chatbots remains elusive, numerous studies have gravitated toward the adoption of the System Usability Scale (SUS-10) [24-29] and the Speech User Interface Service Quality scale. SUS-10 captures the overall usability of a system independently of the platform or interface. The score ranges from 0 to 100, indicating higher usability with increasing scores [26]. A score of 68 is considered as a passing grade, while a score below 50 is considered as indicating that the system has less optimal usability. For a system to be considered as exceptionally good in terms of its design and usability, a score of 85 on average should be applied [29-31]. In the previously mentioned study by Oh et al [12], mean SUS-10 was not significantly worse or better comparing a chatbot and a book: 64.5 (SD 17.0) versus 69.5 (SD 17.2), respectively ($P=.35$). Several studies have advocated the idea that chatbots represent user-friendly alternatives to conventional analog methods or standard digital tools, such as forms [4]. Nonetheless, there is research that suggests the design flaws in a chatbot system can markedly diminish its effectiveness, potentially leading to perceptions of unhelpfulness among users [3]. Chatbots that are perceived as unhelpful, repetitive, or lacking the users’ trust tend to receive a lower SUS-10 score [32].

Many social chatbots aim to comfort, support, and advise their users [3]. Studies show that the availability of chatbot technology is what is central to its perception of usefulness

compared with human therapists. However, studies have also noted that most users prefer human therapists and are more interested in using the system as a complementary tool when a human therapist is not available [33-35]. While mental health chatbots are generally viewed positively by the user, there are many issues that can lead to decreased usability, lower SUS-10 scores, and undesirable outcomes such as irritation or worsened mental health. The propensity for misunderstanding, miscommunication, and annoyance are frequently reported in qualitative assessments of social support chatbots [33-35]. Feeling annoyed by repetitive messaging, incoherent conversations, and inability to comprehend the user's needs are frequently named as issues that increase the feeling of annoyance in users of social support chatbots [34]. The selection of an interface can wield a considerable influence on both the effectiveness and user-friendliness of a system. Users exhibit disparate reactions to chatbots depending on whether they incorporate an avatar, particularly one with humanoid attributes capable of evoking emotions. Although our understanding of chatbot usability and user preference is somewhat limited, investigations into anthropomorphic interfaces do underscore their ability to affect our emotional states [36].

The chatbot used in our study, known as BETSY (Behavior, Emotion, Therapy System, and You), uses 2 distinct interfaces: a digital human, voice-activated user interface with anthropomorphic features and a text-only user interface. Within the scope of our investigation, we aimed to thoroughly examine both interface modalities. Phase 1 of usability testing involves enlisting the participation of healthy volunteers.

The aim of this study was to explore to what extent a digital human and a text-only chatbot interface differed in usability when tested by healthy participants. We also set out to explore how chatbot-generated conversations on mental health (specific to each interface) affected self-reported feelings and biometrics.

Methods

Construction of the User Interface (BETSY)

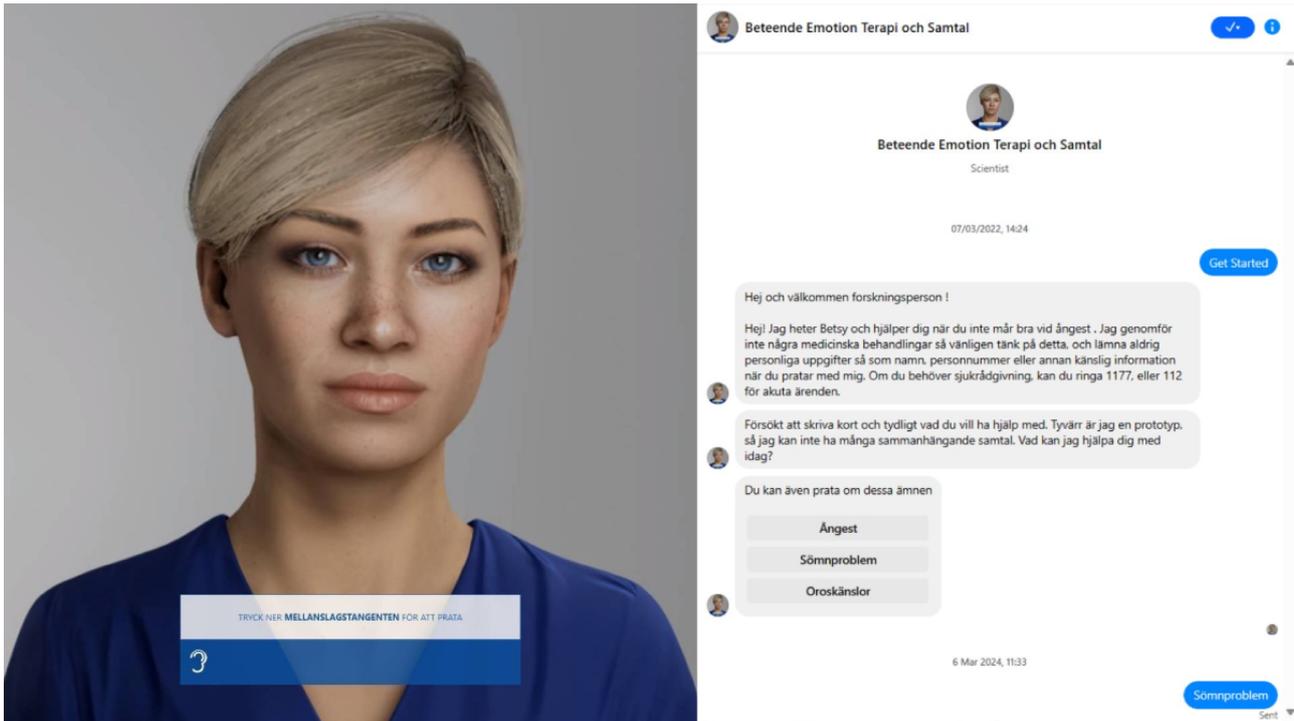

This project adopted a participatory design approach to ensure the broad involvement of health care professionals, patients, and the public. A multidisciplinary team consisting of 2

psychiatrists, 2 psychiatric nurses, 4 clinical psychologists, 1 user of health care services, and 1 engineer was assembled to comprehensively address ethical, medical, and legal considerations for a potential chatbot. Team members were selected for their expertise in digitalization and psychiatry. Before the initial workshop, where the algorithm's preliminary outline was presented, the engineer created a survey. This survey drew partly from Radziwill and Benton [5] quality attribute listing, which synthesized findings from various chatbot usability projects.

A survey was distributed to the public via the secure research platform Psytoolkit.org, offering heightened anonymity by omitting the collection of metadata such as IP addresses and locations. The survey comprised 8 multiple-choice questions and 4 open-ended free-text questions, covering demographic information, design requirements, functionality suggestions, and overall attitudes toward mental health chatbots. It was accessible for 14 days and disseminated through various social media channels. Subsequently, the collected data were analyzed to inform a series of 4 workshops conducted by the group between June 2020 and December 2020. During these workshops, the chatbot's design, encompassing appearance, content, and personality, underwent iterative development based on input from the general public and co-designer feedback, with the latter representing a patient perspective. A comprehensive account of this process will be available in a separate publication.

Two versions of the chatbot (Figure 1) were created: one enabling voice interaction with a facial expression and an avatar component, and another relying solely on text-based communication with an avatar image. The digital human was implemented using Dialogflow (Google) for conversation logic and connected to the UNEEQ platform for the human-avatar interface. Data infrastructure was hosted by Deloitte Digital and VästraGötalandsregionen/VGR-IT. In contrast, the text-only BETSY chatbot was developed on the Itsalive.io platform and deployed to a research and development account on Facebook that was closed to the public. Importantly, no personal metadata were collected during on-site testing via digital platforms. The users did not use their personal social media accounts to talk to the chatbot.

Figure 1. Two versions of BETSY (Behavior, Emotion, Therapy System, and You): digital human, voice-activated (left) and text-only (right).

Both versions of BETSY encompassed 24 topics (detailed in [Multimedia Appendix 1](#)) related to mental health, including anxiety, depression, stress, sleep, addiction, eating disorders, anger, hopelessness, helplessness, loneliness, sadness, suicidal ideation, and suicidality, among others. These chatbots were designed in the Swedish language. An assessment was conducted to evaluate the alignment of the text-only and digital human algorithms. Specifically, testers posed identical questions to both systems within various domains, with only 1 instance revealing a discrepancy when the digital human could not provide an appropriate response while the text-based bot could, indicating the need for further refinement.

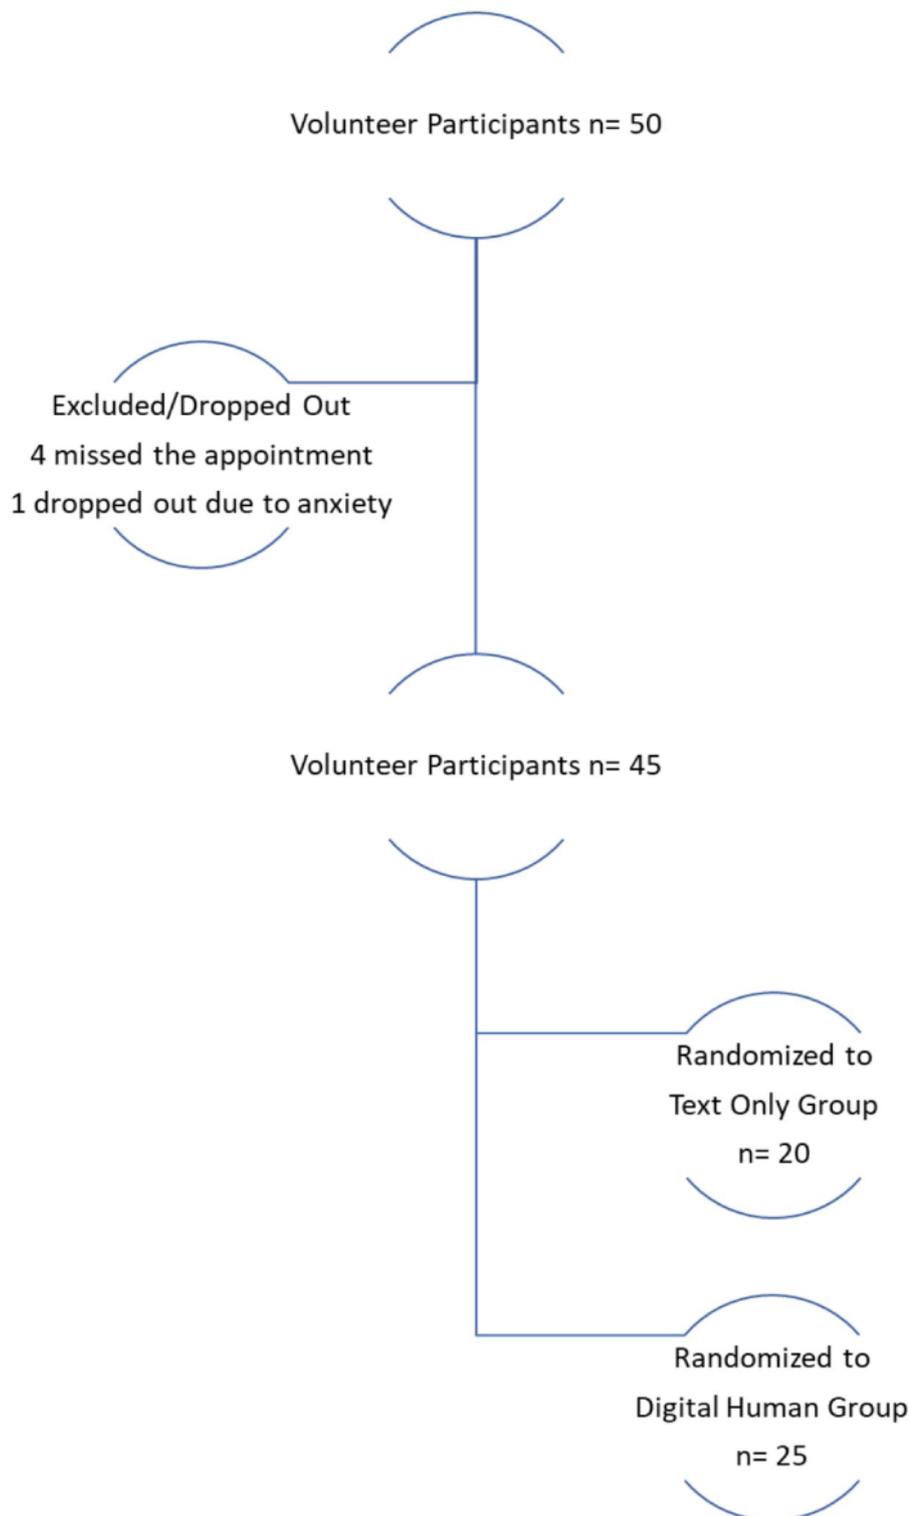

Recruitment

In this initial phase of system exploration, our focus was on evaluating the system's capabilities using volunteers who did not exhibit severe anxiety. As the system is still in its prototype stage, we exercised caution to avoid any potential exacerbation of symptoms in individuals with severe anxiety. Our recruitment

announcement, disseminated through various social media channels associated with Sahlgrenska University's official account, specified that participants should be 18 years or older, free from any current mental health disorders, and willing to physically attend the testing facility in Gothenburg, Sweden.

Participants

Of the 50 individuals who initially volunteered, 5 participants (2 men and 3 women) opted out before providing their consent ([Figure 2](#)). Subsequently, 45 individuals attended the screening at the test facility. Each participant was required to provide informed consent before undergoing the Generalized Anxiety Disorder (GAD-7) scale assessment for anxiety symptoms. Those scoring 14 or higher on the GAD-7 were excluded from the study ([Figure 2](#)). Eligible participants were then randomly assigned to one of two groups: (1) engaging in text-based conversations with the text-only BETSY or (2) participating in voice-based interactions with the digital human ([Figure 2](#)).

Figure 2. Flow chart of participation and exclusion.

The randomization process was conducted with strict double-blind procedures overseen by an independent researcher not affiliated with this project and facilitated by an automated randomization system, ensuring the impartiality of the allocation.

Prechat Procedure

The experiments were performed during the COVID-19 pandemic (June 2021-November 2021). Due to safety precautions, the participants were greeted by a tester wearing

protective gear, including a surgical R-II mask, gloves, a face visor, and hospital scrubs. Protective gear was also offered to participants upon their arrival. Participants were then placed in a sanitized room equipped with a screen, which underwent thorough sanitization with medical-grade disinfectants and a sterilizing UV lamp before and after each participant's session.

Before starting the chat with BETSY, participants were outfitted with a mobile dry-sensor EEG device to record their brain wave activity. Additionally, their blood pressure and pulse were

recorded on the left arm after a 5-minute seated rest. Systolic and diastolic blood pressure were measured using a digital sphygmomanometer, and the pulse was monitored with a pulse oximeter.

Despite relatively relaxed COVID-19 restrictions during the testing period, the tester opted not to be physically present in the room to minimize any potential risk of contagion. Each participant sat alone in the room, with the tester observing remotely via a nonrecordable streaming camera. This camera served to facilitate real-time communication and allowed the tester to monitor the participant's reactions and anticipate any need for assistance. The participants were made aware of this procedure.

Following the measurement of biometric data (blood pressure and pulse), participants were instructed to complete a questionnaire. This questionnaire covered their prior experiences with mental health chatbots as well as their demographic information, including sex, occupation, and marital status. Additionally, participants rated their overall well-being on a visual analog scale ranging from 1 (not good at all) to 10 (feeling excellent) before starting their session with BETSY. Participants were given instructions by the tester along with an accompanying sheet that provided potential chat scenarios and specified the topics within BETSY's scope. Each participant had a maximum of 30 minutes to engage with the chatbot version they were assigned to.

Chat Session Protocol and EEG Data Collection Process

EEG recording commenced simultaneously with the participant's initiation of their session with BETSY. We used a dry-sensor mobile EEG system, specifically the MUSE headband from Interaxon, which incorporates 7 sensors. These sensors include 3 frontal reference sensors and active sensors situated at Fp1, Fp2, Tp9, and Tp10.

The MUSE headband was seamlessly connected to a smartphone via Bluetooth and data collection was facilitated through the Mind Monitor app on an Android smartphone. It is noteworthy that this app neither necessitates user registration nor collects data that can identify or pinpoint individual users or their locations. Consequently, the data were recorded in an anonymous fashion and stored as a CSV file within the smartphone's document section.

Upon placing the EEG headband on the participant, they were requested to close their eyes to enable the Mind Monitor to perform calibration. After calibration was successfully established, the participant was left alone in the room to initiate a conversation with BETSY. Importantly, the EEG recording remained active throughout the entire conversation and was terminated when the participant indicated they had concluded their interaction with the chatbot.

Postchat Procedure

Upon reaching a point of satisfaction with the conversation or upon the completion of their allocated chat time, participants were directed to complete supplementary questionnaires and scales. Participants were administered the SUS-10, developed

by Lewis and Sauro [26]. The SUS-10 calculates an average score derived from a 10-item questionnaire with response options ranging from 0 to 4, resulting in a total score between 0 and 100, as outlined by Bangor et al [31].

Participants were also presented with multiple-choice questions regarding their emotional state during the chat. Additionally, in the digital human group, participants were instructed to fill out the Standardized Questionnaires for Voice Interaction Design Short Version (SUISQ-MR). SUIQ is a questionnaire tailored to assessing critical usability attributes of Interactive Voice Response, as outlined by Lewis and Sauro [26]. The original scale comprises 25 items categorized into 4 factors: user goal orientation, customer service behaviors, speech characteristics, and verbosity. SUISQ-MR, a shortened version, encompasses 9 items rated on a 7-point Likert scale, ranging from "strongly disagree" to "strongly agree." Higher scores on this scale indicate a more favorable assessment of the system's usability [24].

Furthermore, participants were provided with an open-ended questionnaire to gather their suggestions and insights regarding their session experience. It should be noted that qualitative data from this survey will be reported separately.

EEG Monitoring and Analysis

The monitoring of EEG activity entails the use of the Mind Monitor app, which captures and visually represents EEG brain wave data. The quantification of absolute brain wave values is predicated on the computation of absolute band powers. These powers are derived from the logarithm of the power spectral density calculated from the EEG data for each channel.

The frequency spectrum categories used for this analysis encompass the following bandwidths: δ (1-4 Hz), θ (4-8 Hz), α (7.5-13 Hz), β (13-30 Hz), and γ (30-44 Hz). Notably, the EEG power spectral density values acquired from the sensors typically fall within the $\{-1;+1\}$ range, which is subsequently transformed into a more intelligible $\{0;100\}$ range for text-based display purposes.

Subsequently, the collected EEG data underwent an analytical process facilitated by the Mind Monitor online graphing tool. Within this tool, the values are presented as average (dB) per session. It is imperative to note that, in the context of this study, we exclusively used absolute data for our analyses (information sourced from Mindmonitor.com and Chooseuse.com).

Statistical Analysis

All data were entered and processed in SPSS Statistics (version 28.0.1.1; IBM Corp). For group differences, means analysis was used using Pearson χ^2 asymptotic significance (2-sided) set at .05 as the significance level. For continuous outcome variables such as SUS-10, SUIQ-MR, brain wave activity, positivity, and GAD-7, linear regression analyses were used. The data were tested for kurtosis and skewness. Based on the results, t tests were performed. All results were analyzed according to group.

Ethical Considerations

All ethical decisions were guided by the Declaration of Helsinki and its subsequent amendments. The study protocol was reviewed and approved by the central ethical review board; Etikprövningsmyndigheten, Sweden (DRN 2021-02771). All precautions were taken in order to avoid any possible contagion from COVID-19. Due to the nature of the prototype, no patients were used in this initial examination of the chatbot in order to ensure that vulnerable participants would not be negatively affected by errors and flaws that might be present in a prototype-stage system.

Comparison Between Digital Human and Text-Only Chatbots

When comparing self-reported emotional states between the digital human and the text-only chatbot groups, it was observed that participants using the digital human exhibited a notably

Results

Characteristics of Participants

There were no statistically significant differences in the demographic variables between the digital human and text-only groups (Table 1). No participants were excluded due to a high GAD-7 score. The age of the participants ranged from 24 to 68 years, and as only 12 participants registered their age, this variable was consequently excluded from more advanced analyses (Table 1).

higher propensity to report feelings of nervousness versus the text-only chatbot group (Table 2). The mean GAD-7 score for the text-only chatbot group was 2.32 (SD 2.52) compared with 2.80 (SD 2.60) for the digital human chatbot group, with no statistically significant difference between the groups.

^cParticipants were asked to what extent they felt positive about talking to BETSY about mental health with scores ranging from 1 (not positive at all) to 10 (very positive).

^dBETSY: Behavior, Emotion, Therapy System, and You.

^eVAS-W: Visual Analogue Scale for Well-Being.

^fRange from 1 (not feeling well at all) to 10 (feeling very good).

^gSUS-10: System Usability Scale.

^hSUISQ-MR: Standardized Questionnaires for Voice Interaction Design Short Version.

ⁱN/A: not applicable.

Conversely, the evaluation of system usability as gauged by SUS-10 showed a significant ($P=.01$) difference between the groups. Notably, the mean SUS-10 score was higher in the text-only chatbot group at 75.34 (SD 10.01; range 57-90) compared with the digital human group at 64.80 (SD 14.14; range 40-90). In addition, the digital human group underwent assessment using SUISQ-MR: BETSY had a mean score of 4.92 (SD 0.83; range 2.83-6.75), as depicted in [Table 2](#), which is indicative of a commendable level of usability for BETSY's voice interface in accordance with the framework presented by Lewis [24].

Biometric Measures

There were no statistically significant distinctions for mean values of blood pressure or pulse between the groups either at baseline or following exposure to the interventions. Specifically, the mean pulse rate showed no discernible variations between the groups both before and after exposure, reflecting consistent values across the groups on average (data not shown).

The EEG signals collected during the study exhibited suboptimal quality, which was primarily attributed to participant movement and signal acquisition sensitivity. These challenges occasionally disrupted signal continuity during the sessions. Nonetheless, the data yielded adequate information to calculate mean values pertaining to δ , θ , α , β , and γ frequency bands, as facilitated by the web-based graphing module within the MindMonitor's platform. Only 1 significant difference was found in terms of means: the average α was significantly higher in the text-only group ([Table 2](#)).

System Usability Scale and Outcomes

Predictors of SUS-10 usability were used as a dependent variable in linear regression analysis and matched against biometric and subjective variables. Each variable was independently analyzed in a model together with SUS-10 as the dependent variable. Analysis showed that there was a significant positive relationship between average α and θ wave activity and SUS-10 in the chat-only group. A significant positive relationship was seen between SUISQ-MR scores and SUS-10 ([Table 3](#)).

Table 3. Linear regression analysis between usability and biometric variables.

Self-Reported Feelings and Gender

Furthermore, our investigation sought to discern whether significant gender disparities existed in terms of self-reported emotions. Notably, we observed a significant difference between

men and women, with men exhibiting a notably lower tendency to report feeling annoyed by BETSY in contrast to women. No other statistically significant distinctions were identified (Table 4).

Table 4. Sex difference in emotional expression toward BETSY (Behavior, Emotion, Therapy System, and You).

^cN/A: not applicable.

An analysis of feelings of closeness and positivity toward chatbot conversations was undertaken to explore differences between men and women. In mean score analyses, the results showed that men were significantly more positive toward talking

to BETSY prior to the session: 8.16 (SD 1.50) for men and 6.81 (SD 2.30) for women ($P=.34$). Conversely, there were no discernible gender-based differences concerning feelings of closeness during chatbot interactions.

Discussion

Principal Findings

This study explored how a digital human versus text-only chatbot interface affected usability and user experience in healthy participants. We also examined how chatbot-generated conversations on mental health affected self-reported feelings and biometrics. The overall sample was small and, thus, should not act as a point of reference for generalization. This study was, however, not smaller than the average study in the investigative field of mental health chatbots [9,10,12,37-41].

While the text-only system scored higher on usability, both versions of the chatbot scored average or above average with respect to overall usability [31]. The mean text-only chatbot SUS-10 score of 75.34 falls between the threshold of good (a score of 70) and excellent (a score of 80 and above) [29-31]. However, the score for the digital human (64.8) indicates that the system is perceived to be usable, but has room for improvement. Usability can be affected by many factors such as user interface design, content layout, and overall user experience [42,43].

The digital human score indicates that there may be areas for improvement in terms of all of the aforementioned aspects. It should also be noted that the SUS-10 scale does not measure a specific feature or aspect of system design, but instead provides an overall assessment of user experience [31]. Using more elaborate scales that cover more dimensions across the system is more suitable for a more in-depth analysis of the usability of chatbots. It can also be noted that the range of scores was much higher for the text-only interface (lowest score for the text-only group was 57 and the equivalent for the voice-only chatbot was 40), which indicates much poorer usability.

Taking into account the specific usability of the digital human interface, usability was considered high with an average SUIQ-MR score of 4.92. This score indicates that the voice interaction design is likely to be perceived as intuitive and useful by users. A score of 4.92 falls within the range of 4.5-5.5, which has been classified as “very good” in previous studies [24]. In addition, higher scores on the SUIQ-MR have been associated with increased user engagement and task completion rates. Therefore, a score of 4.92 can be interpreted as an indication that the voice interaction design will likely provide positive user experiences [24].

Men were more likely to score higher on positivity and less likely to report feeling annoyed by BETSY independently of the interface, which is the opposite of other studies that indicate men are more likely to be annoyed or aggressive toward female avatars [44]. In a study by Luger and Sellen [45], the authors found that higher expectations of the system lead to a higher risk of disappointment and lower scores: this could possibly explain why female participants were more agitated as their expectations might have been higher [45], however, we have no data to explore this empirically in the frame of this study. Unlike other studies with similar designs and populations [40], we did not analyze the content of the conversations. The conversations between BETSY and the participants were deleted

immediately after the session as the research question was geared toward usability and not the effect on the user's own mental health status. Much like the results from Hearst and Tory [46], the interface was the focus of this investigation. Hearst and Tory showed that a well-designed conversation tamped the choice of interface. The interface played into the perception of usability only when the system failed to respond or create barriers to conversation. In our study, we used biometric data to explore feelings of relaxation or excitement/agitation while using BETSY. Despite EEG data collection not being optimal, we were able to collect and compare some brain wave activity data in the study groups during the sessions. Even though the amplitude of brain wave activity can result in large intraindividual variation, the data were evenly distributed and there were no mean differences between the groups in our study. While we observed no significant association between scores of usability and β wave activity (more likely to be associated with frustration, agitation, or perhaps excitement), we did observe brain wave activity that is typically associated with relaxed states of mind [18-21] and this had a positive linear relationship with SUS-10 score. This indicated that the chat-only group was either more relaxed or less aroused (or both). The explanation could lie in the combination of the small sample and the fact that more individuals in the voice-only chat group reported feeling nervousness, a feeling that generally elicits higher brain wave activity and less relaxation [20,47]. With the low quality of data, combined with a limited sample, it is hard to draw any generalizable conclusions from the biometric data.

Feelings of closeness did not differ between the 2 interfaces and seem not to have been affected by the presence of anthropomorphic features. When gender was explored as a factor, there was no significant difference to what extent men and women reported feeling close to BETSY in the respective assigned interfaces. Due to the small sample size in our study, it was not possible to perform further and more elaborate designs looking at mediation of other demographic or biometric factors in a reliable way.

When devising chatbots for mental health, this study indicates that a mixed approach might be the best course of action, allowing the user to choose a preferred way of interacting with the chatbot.

Limitations

This study consisted of healthy volunteers. It is good to keep in mind that mental health issues can affect some parts of cognitive performance [48] and, thus, usability may not be equally perceived by a person in a state of emotional distress and a healthy volunteer. Further investigation and collaboration are needed in future studies to capture the usability aspects of individuals who are in an active state of distress.

The results of this study suggest that overall usability seems to be perceived as higher for the text-only chatbot interface and no significant emotional boost was present with the addition of anthropomorphic features to a digital human chatbot.

Further studies which include a larger sample of participants as well as participants who experience mild to moderate anxiety are needed to explore and further evaluate the research question

posed in this paper. In this study, the age range was limited, and the variable was incomplete. In future studies, we will strive to include more young adults and adults older than 60 years.

Large language models and application programming interface models were not available at the time this chatbot was constructed and neither were Metahuman creator or more advanced voice-cloning or voice-generating options, which would have significantly improved the anthropomorphic features of the digital human. The first iteration of the generative pretrained transformer was not available to the public and the generative pretrained transformer-3 application programming interface had a limited release during the development of this project: it was not available to our team until a year after the project was completed. With large language models, repetitiveness and limitations in terms of variability of answers would have most likely been avoided; however, the aim of our

investigation was not the general effect of the content but rather the perception of text- versus voice-driven interfaces.

Conclusions

In conclusion, the text-only chatbot was perceived as more user-friendly in terms of usability indicators for SUS-10. However, both the digital human and text-only interfaces scored average or above average in comparison to other studies performed on mental health chatbots. Although biometric data did not differ significantly, we saw significant gender differences in terms of prechat positivity and postchat annoyance, which is contrary to other studies. Male participants in our study were more likely to report higher prechat positivity toward BETSY and report less irritation postchat. SUISQ-MR also indicated that BETSY's overall usability and voice were highly ranked compared with other studies, indicating that there is great promise for mental health chatbots independently of the chosen user interface.

Acknowledgments

The authors would like to thank the participants of this study for their time and contribution to valuable knowledge. The authors also especially thank Mathias Alvidius, head of department, for contributing significantly to the possibilities of the creation of this research project. The authors would also like to express sincere gratitude to Linn Dahlén Ölander for her help in recruiting participants. SS received support from the Söderström König Foundation (SLS-974247), Stiftelsen Psykiatriska Forskningsfonden for this project. Parts of this project were funded by Innovationsfonden VGR (project VGRINN-936800) and Västra Götalandsregionen. The authors would also like to thank Peter Todd (Tajut Ltd) for third-party editorial assistance in the drafting of this manuscript, for which he received financial compensation.

Conflicts of Interest

SS receives fees for scientific consultation from Mindforce.

Abstract

Background: The use of drones in the health care sector is increasingly being discussed against the background of the aging population and the growing shortage of skilled workers. In particular, the use of drones to provide medication in rural areas could bring advantages for the care of people with and without a need for care. However, there are hardly any data available that focus on the interaction between humans and drones.

Objective: This study aims to disclose and analyze factors associated with user acceptance of drone-based medication delivery to derive practice-relevant guidance points for participatory technology development (for apps and drones).

Methods: A controlled mixed methods study was conducted that supports the technical development process of an app design for drone-assisted drug delivery based on a participatory research design. For the quantitative analysis, established and standardized survey instruments to capture technology acceptance, such as the System Usability Scale; Technology Usage Inventory (TUI); and the Motivation, Engagement, and Thriving in User Experience model, were used. To avoid possible biasing effects from a continuous user development (eg, response shifts and learning effects), an ad hoc group was formed at each of the 3 iterative development steps and was subsequently compared with the consisting core group, which went through all 3 iterations.

Results: The study found a positive correlation between the usability of a pharmacy drone app and participants' willingness to use it ($r=0.833$). Participants' perception of usefulness positively influenced their willingness to use the app ($r=0.487$; TUI). Skepticism had a negative impact on perceived usability and willingness to use it ($r=-0.542$; System Usability Scale and $r=-0.446$; TUI). The study found that usefulness, skepticism, and curiosity explained most of the intention to use the app ($F_{3,17}=21.12$; $P<.001$; $R^2=0.788$; adjusted $R^2=0.751$). The core group showed higher ratings on the intention to use the pharmacy drone app than the ad hoc groups. Results of the 2-tailed t tests showed a higher rating on usability for the third iteration of the core group compared with the first iteration.

Conclusions: With the help of the participatory design, important aspects of acceptance could be revealed by the people involved in relation to drone-assisted drug delivery. For example, the length of time spent using the technology is an important factor for the intention to use the app. Technology-specific factors such as user-friendliness or curiosity are directly related to the use acceptance of the drone app. Results of this study showed that the more participants perceived their own competence in handling the app, the more they were willing to use the technology and the more they rated the app as usable.

Introduction

Background

The health care system faces challenges such as a rural exodus, aging populations, and increasing shortages in the health care workforce; drones have the potential to increase the efficiency and capacity of the health care system [1]. The COVID-19 pandemic intensified the demand for new logistic solutions, such as fast and contactless delivery strategies [2]. It is also important to understand the attitude of the civilian population and public opinion on the use of drones [3]. In this vein, delivering medications with drones is the most identified application in health care [1,4]. There are a few studies showing that usability, lack of user skills and expertise, and negative perceptions affect user acceptance and hinder drone use [1,5,6]. Therefore, it is particularly important that all user groups are involved at an early stage. Furthermore, after a recent scoping review showed that there were no empirical studies on user acceptance of drone-based medication delivery [7], we could only find 1 study in Asia that investigated user acceptance among health care professionals in the delivery of drone-based medication [8]. The successful application of technology is predominantly determined by the type and extent of acceptance [9,10]. Acceptance in this context refers to the positive acceptance decision of an innovation by its users, which is described in the technology acceptance model (TAM; perceived usability, usefulness, immersion, and accessibility; TAM 1) [11,12]. It proposes that users tend to use a technology when they believe it will help them to perform a better job (perceived usefulness) and when they believe that the system can be handled without effort (perceived ease of use). These variables were found to correlate with the intention to use, wherein usefulness was substantially more strongly related to frequency of use than ease of use. Nevertheless, both are strong correlates of user acceptance and should not be ignored by designing and implementing successful technologies [12]. In other words, the greater the benefit of a technology and the simpler its usability, the more the users are willing to use the new system. However, some more variables that affect user acceptance such as social influences (subjective norm, image, and voluntariness), cognitive instrumental processes (job relevance, output quality, and result demonstrability; TAM 2), and psychological foundations (self-efficacy, external control, playfulness, anxiety, enjoyment, and usability; TAM 3) can be stated [13,14]. Thus, Peters et al [15] argued that this model alone does not indicate whether people would actually use a technology. In this context, basic human needs according to Ryan and Deci [16,17] and Deci and Ryan [18] play an important role. Following the Basic Psychological Need Theory [17], the more the interaction with the system satisfies basic psychological needs, the more the users will engage with a technology. Ryan and Deci [16,17] and Deci and Ryan [18], defined 3 basic psychological needs in their self-determination theory that are crucial to whether a person is proactive and engaged or passive and demotivated.

These needs include competence (ie, feeling capable), relatedness (ie, feeling connected to others), and autonomy (ie, feeling self-determined). On the basis of this, Peters et al [15] defined the Motivation, Engagement, Thriving in User Experience (METUX) model, which can be used for the evaluation and iterative design process of technologies to increase motivation, engagement, and well-being. In this case, the 3 basic needs are mediating variables between a technical product and the well-being of the users. This implies that as autonomy increases, engagement increases; as competence increases, motivation increases; and as relatedness increases, well-being increases.

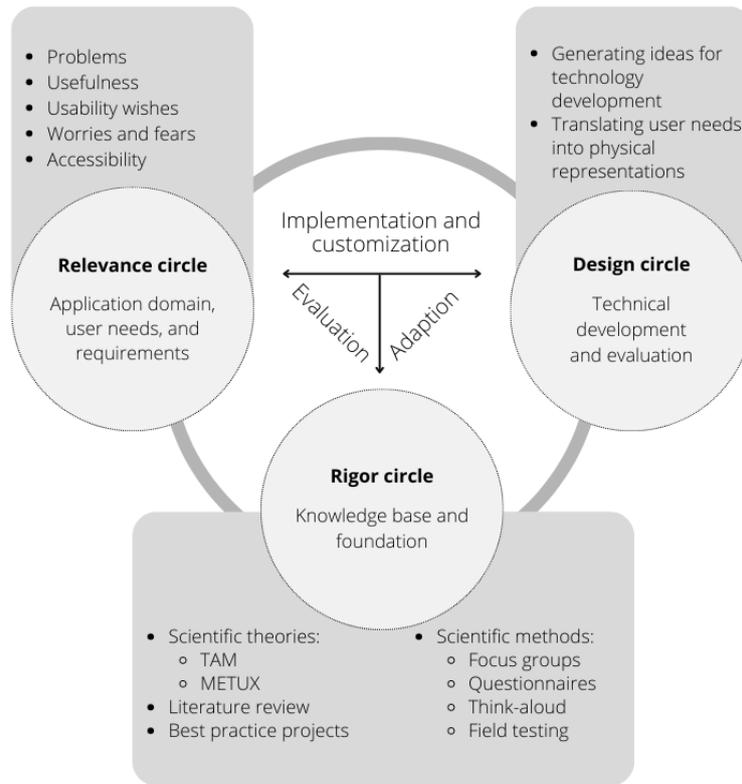

This Study

Acceptance building is a process that starts before the initial contact with the innovation and continues into the application phase, which was addressed within the pharmacy drone study (Apotheken-Drohnen-App; ADApp) [19]. This study represents a section of the whole ADApp project by investigating factors that are associated with the user acceptance of a drone-based medication delivery to be able to derive practice-relevant orientation points for participatory technology development (for apps and drones). Stephan et al [7] described that little attention is paid to the design phases of drones including the delivery process. Thus, this study used a mixed methods design and followed the methodological guidelines of the cocreative user-centered design proposed by Farao et al [20]. User-centered design is used to help consider the context of technologies as well as their implementation consequences at the design stage (Figure 1) [20,21]. Implementing technologies without user involvement may compromise the desired outcome, which in turn can lead to unmet health goals and adverse outcomes [20,22,23]. It is an evidence-based approach that involves users in developing technologies and prioritizes their needs [20,24]. In contrast to classical user-centered designs, this study used a controlled design for the first time. Traditionally, small sample groups are observed or interviewed or participate in usability tests during the testing and development phases of new technologies (usually operationalized through the think-aloud [TA] method and questionnaires). These are important approaches to get insights into key needs of the target population [25]. However, repeated measurements cause a change in the meaning of test scores, which makes it difficult to compare repeated measures. In a measurement perspective, it can be considered as bias in the measurement of change [26]. It can be inferred that conducting repeated measures with the same sample group may alter their attitudes, expectations, and behaviors in interacting with the technology. This could potentially influence their acceptance of the technology, as they become aware that the technology will adjust to their needs. Moreover, they are not unfamiliar with dealing with the app, which might influence user acceptance as well. This is indeed the purpose of a user-centered design, but it loses insights into perspectives of inexperienced users without a concrete expectation about the

changes in technology after giving feedback to it. By integrating a control group (called the *ad hoc* group), this study aimed to investigate whether the assumption of the *core* group (ie, the same sample group at all measurement time points) is

generalizable to a broader population. In this regard, a second purpose of this study was to answer the question of whether user acceptance differs between the core and ad hoc groups.

Methods

Study Design

The monocentric ADApp study aimed at an iterative and cocreative development of a pharmacy drone app with multiple measurement time points (Table 1). As this study design was embedded in the broader ADApp project, it was preceded by 2 research steps. As a first step, we conducted a scoping review of experimental studies examining the interaction between humans and drones during the delivery of drugs and defibrillators to identify research gaps and explore the scope of

research activities [7]. In the next step, problems, needs, and requirements of the users were identified and concrete scenarios were outlined, which were necessary for the implementation of a first demonstrator of the app [27]. At this point, we decided to use focus groups instead of individual interviews because it allows participants to respond to each other’s answers and gives us the most information. In this study, we conducted 3 iteration loops, where we tested the app demonstrators as well as the entire ADApp flow from order to delivery at an airport along with the user groups. The iterative process is one of the central features of the study and will be discussed in detail in the Study Setting section.

Table 1. The Apotheken-Drohnen-App design.

Goal	Methods	Participation	Time point	Reference
Knowledge	Scoping review	N/A ^a	August 2021	Stephan et al [7], 2022
Needs	Focus groups	User groups	October 6, 2021	Fink et al [27], 2023
Evaluation of functionalities	Questionnaires and think-aloud	First and second iteration loop: core group; 2 ad hoc groups	July 3, 2022	This study
Test flights	Questionnaire, think-aloud, and focus groups	Third iteration loop: core group; 1 ad hoc group	October 2022	This study

^aN/A: not applicable.

To address potential biasing effects owing to a response shift through repeat interviews with the core group, a total of 3 ad hoc groups were acquired in this study. At each of the 3

development steps, a new and naive ad hoc group was used. This unique approach of adding ad hoc groups as control groups

also allows for the generalizability of key needs identified in the development process [25].

Study Setting

Our prior work showed that a pharmacy drone app, for example, must be lean and simple; must facilitate the user's performance (eg, software integration, shipment tracking, and plannability); must enable control (eg, handover identification and data sovereignty); and must include consultation and reconciliation features. The most frequently discussed problems associated with drones were the physical contact with the drone and the drone's noise [27]. Following the focus groups, the developers designed a demonstrator of the app including communication features (eg, an extra text field for communication with the pharmacy), plannability features (eg, time slots for drone delivery), shipment tracking, and features for enabling handover security, which was tested in 3 iteration loops with users. All loops were conducted separately per the core and ad hoc groups.

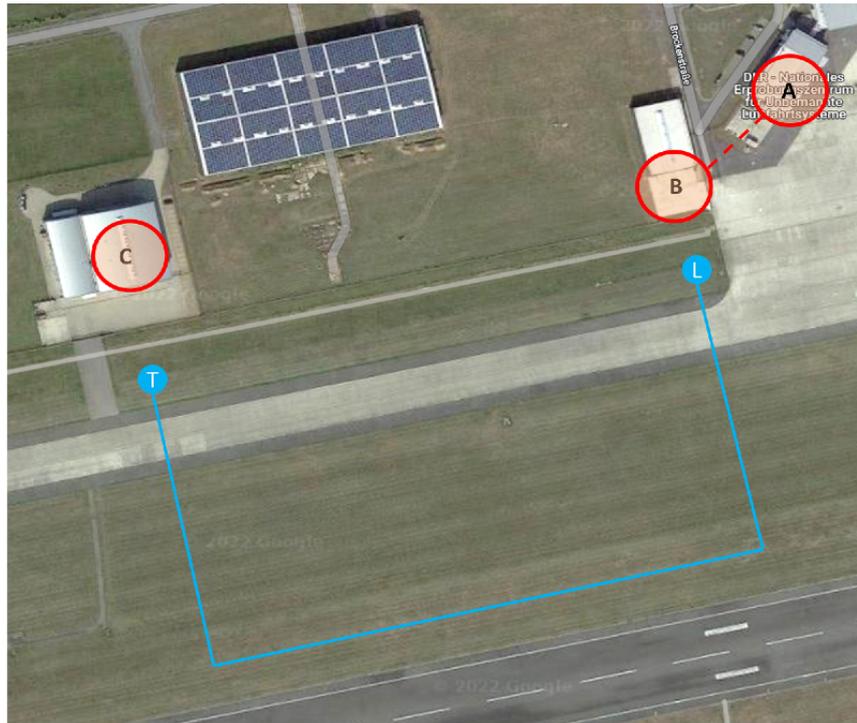

In the *first iteration loop* (conducted between March and April 2022), the usability of the app was reviewed. The app should be as easy as possible to use and allow users to create an account, add details such as delivery location, or submit an electronic prescription. The first iteration loop aimed at evaluating how intuitive the app is. For this purpose, users were shown the app and asked to think aloud while using it—without any introduction. For each participant, one experimenter prepared a protocol for taking notes. Finally, the prototypes were queried by using additional questionnaires: the Technology Usage Inventory (TUI) assessment was used to assess the intention to use, and the System Usability Scale (SUS) was used to measure usability. The basic psychological needs such as competence, autonomy, and connectedness were identified at the task level through the Technology-based Experience of Need Satisfaction (TENS) Task. After the first iteration loop, the demonstrator was adapted according to user feedback. The *second iteration loop* (conducted between June and July 2022)

was dedicated to the design of the prototype and its technical development and evaluation. The decisive factor was how intuitive the design is and whether the tasks of the app are adequately represented. The procedure was the same as that in the first iteration loop, with the exception that instead of the TENS Task, basic psychological needs were queried via the TENS Interface. To gain deep insights into the participants' thoughts while using the technology, the core and ad hoc groups were again asked to think aloud while using the app. After receiving the second round of feedback from participants, a third demonstrator was developed. However, the *third iteration loop* (conducted in October 2022) aimed at testing the overall process starting with registration, setting the delivery location, submitting a prescription, and actually receiving a delivery. As focus groups showed concerns about injuries with the drone, this study wanted to test the handover via a winch, a parachute, or dropping to reduce physical contact with the drone, but unfortunately, owing to regulations and restrictions, testing the handover was not possible [27]. Thus, the drone had to land (Figure 2). Therefore, we divided participants into 2 groups: one group tested the app, whereas the other group talked about different handover scenarios and looked at the drone from close up. After each round, the groups were swapped. Similar to that in the first and second iteration loops, the intention to use and usability was queried using the TUI and SUS. To gauge the degree to which the technology fulfills users' needs in terms of behavior, participants completed the Basic Psychological Need Satisfaction and Frustration Scale (BPNSFS). Again, the participants were instructed to think aloud while going through the tasks in the app to gain more insights into the functionality of the app. After participants submitted their prescription, they went to the location in the airport where the drone was set to land (Figure 3). After landing, participants took the *medication* (a bag of gummy bears) out of the drone. After the testing, a short discussion was held with all participants to sum up their impressions.

Figure 2. Drone landing.

Figure 3. Airport landing zone. (A) Order location, (B) reception location, and (C) drone starting point. L: landing; T: takeoff.

Participants

Participants were chosen to represent potential user groups for both the drone-based medication delivery service and the supply chain, based on their respective role characteristics: physicians, nurses, pharmacists, and interested users, especially patients with COVID-19 and relatives of patients who need palliative care. Participants of the ad hoc group were recruited with the support of the Merseburger Innovations- und Technologiezentrum (innovation and technology center) and the ADApp project team. They were contacted via email or telephone. Core group participants were recruited from the focus group that was conducted in October 2021 [27]. A total of 3 pharmacists, 2 nurses, 3 general practitioners, and 1 patient with COVID-19 were recruited from the focus groups. Owing to the underrepresentation of interested users or patients, 2 more participants were recruited with the support of the ADApp project team.

All participants were informed about the general aim and reasons of the study and the procedure. They gave written informed consent before starting the iteration loops.

Ethics Approval

The ADApp study was approved by the Ethics Committee of the Martin-Luther University Halle-Wittenberg (protocol code 2021-069; date of approval May 6, 2021).

Measures

Quantitative Measures

SUS Score

The SUS measures the user's subjective perception of the usability of a system. It is technology independent, that is, it can be used for a wide range of systems and technologies [28-30]. Overall, 10 items were divided into 5 positively and 5

negatively directed statements, each represented on a 5-point Likert scale. The answers provided the SUS item score, which were then converted into the SUS overall score. The overall score ranges from 0 to 100. To calculate the SUS overall score, the first step was to calculate the raw score minus 1 for all odd items, whereas the raw score of 5 was subtracted for the even items. For example, if for item 1, the raw score is 4, the result is a score of 3 (4-1). If for item 2 the raw score is 2, the score is 3 (5-2). In the next step, the calculated scores are summed and multiplied by 2.5 [31].

Systems can be considered usable if they achieve the benchmark score of ≥ 68 [29,31]. In preliminary works, an adjective scale was developed for a more comprehensible classification of the SUS score, which ranges from outstanding (score 90-100) to very poor (score 0-34) [32].

TUI Assessment

The TUI assessment [33] aims to measure the intention to use and is based on the TAM [12]. The intention to use a technology is a comprehensive construct based on a variety of explanatory factors. As suggested in the TAM 2 and TAM 3, the TUI considers technology-specific factors and psychological factors. The TUI therefore supplements the classic technology acceptance factors of the TAM 1, such as perceived usability, usefulness, immersion, and accessibility (technology specific) with important psychological constructs, such as technology anxiety, curiosity, interest, and skepticism. The items, with the exception of the technology anxiety and interest scale, are related to a specific technology. Each scale consists of 3 to 4 items, each of which is to be rated on a 7-point Likert scale. The ninth scale measures the intention to use a specific technology with 3 items on a visual analog scale (each 100 mm). In total, the TUI consists of 33 items and has a modular design so that individual scales can be excluded and item formulations

can be adapted to the circumstances (eg, concrete technology names). With the exception of the “immersion” scale, all scales were used this study. All answers of a scale were summed to a sum value. It starts with 1 as the lowest expression of the construct and goes up to 21 (3 items) or 28 (4 items) as the highest expression, depending on the number of items. For the intention to use scale, the distance from the right end point (full rejection) to the answer cross on the line are measured. The distance in mm is determined for all 3 items and summed. The maximum scale value to be achieved is 300. The determined scale sum values are converted into standard values (stanines). The stanines reach from 1 (strongly below average) to 9 (strongly above average) [33].

METUX Model

The “pure” usability does not necessarily predict higher use of a technology [34]. Although the SUS questionnaire focuses on usability, the TUI questionnaire also includes psychological factors. However, both neglect basic psychological needs, which are addressed in the METUX model. It aims to optimize engagement, motivation, and well-being of technologies in iterative design processes [15]. Within the model, different spheres of experience were assumed to influence well-being: interface (ie, interacting with the technology), tasks (ie, engaging with the technology), behavior (ie, the relation to the overarching technology-supported behavior), and life (ie, the overall experience outside and beyond the technology). There are different questionnaires for measuring the basic psychological needs in different spheres. The spheres adoption, interface, tasks, and behavior were tested within this study using the Autonomy and Competence in Technology Adoption Questionnaire for the first adoption process, the TENS [15] for interface and task, and the BPNSFS [35,36] for behavior. The sphere “life” was not relevant for this study. The Autonomy and Competence in Technology Adoption Questionnaire addresses the question of why people use a technology and to what extent they experience themselves as competent to use it. It consists of 2 parts: the first, self-regulation, includes 12 items; and the second, perceived competence, includes 2 items, which are represented on a 5-point Likert scale. The goal of the TENS Interface and Task questionnaires is to assess the extent to which direct interaction (via interface) with a technology and engagement in technology-specific tasks satisfies the basic psychological needs for autonomy, competence, and relatedness [15]. In the TENS questionnaires, the items are each assigned to the basic needs of competence, autonomy, and relatedness but are presented randomly in the questionnaire. All items were equally weighted, summed, and averaged per basic need. The TENS Interface questionnaire consists of 15 items with 5 items per need, whereas the TENS Task questionnaire consists of 12 items with 4 items per need. The items are each represented on a 5-point Likert scale. As the TENS questionnaires are only validated for English-speaking countries so far, a linguistic validation of the questionnaires was conducted. For this purpose, the questionnaires were translated into German by an interpreter whose native language is German and who is fluent in English. Nevertheless, both the TENS questionnaires are not standardized for the German population that has to be considered when interpreting the results.

The BPNSFS is intended to assess the extent to which a technology improves need satisfaction in relation to the behavior the technology is intended to support [15]. The BPNSFS measures the satisfaction and frustration of the basic psychological needs of autonomy, competence, and relatedness. This includes a balanced combination of subscales for satisfaction and frustration. This distinction is necessary because the absence of need satisfaction does not equate to frustration of the same [17,35]. On the basis of the original questionnaire, Heissel et al [36] identified 6 different, but intercorrelating, factors with 4 items each for the German version of the BPNSFS: Autonomy Satisfaction, Autonomy Frustration, Competence Satisfaction, Competence Frustration, Relatedness Satisfaction, and Relatedness Frustration. Each response is represented on a 5-point Likert scale. The evaluation of the BPNSFS can be handled differently; for this study, the items per basic need are summed, and the 12 items of the subscales satisfaction and frustration are summed. There exist several adaptations of the BPNSFS, which have been validated and subjected to reliability testing. These adaptations include language translations, adjustment for age (children or adults), domain (sports, work, and romantic relationships), and clinical status (HIV, intellectual impairment, and chronic pain). However, a questionnaire related to technological aspects does not yet exist. Thus, for this study, the German version of the BPNSFS was used and minimally adapted according to the wording.

Qualitative Measures: TA Method

TA has traditionally been used in psychology and education to identify cognitive processes that occur internalized in the context of problem-solving [37]. In the context of technology development, TA is equally used to gain deep insights about thinking while using a technology [38]. The advantage of the method is to capture problems and solutions as the technology is being used, as retrospective surveys can lead to incomplete information about the problems of a technology. This means TA is helpful in tracing user thinking strategies [39,40]. For this purpose, participants were instructed to think aloud constantly while using the demonstrator. If participants stopped thinking aloud, they are reminded by the experimenter to continue speaking aloud [38,39]. For understanding problems and solutions, we did not explain how the demonstrator is supposed to work. Instead, we asked them to experience the app with little direction by explaining the task they had to do: registration, set delivery location, and submit recipe [41]. Thus, during the TA situation, it was important that the experimenter interact with participants as little as possible to prevent interference with the users’ thoughts [39]. During the TA situations, the statements of the participants were digitally recorded (audio recordings) and transcribed afterward. Moreover, experimenters prepared protocols for making notes and describing events that are not verbally made by participants but important for analyzing. For example, if a participant said, “That is confusing,” the experimenter protocolled what exactly was confusing [42].

Data Analysis

Quantitative Analyses

Analyses were performed with the statistical program SPSS Statistics (version 25; IBM Corp). Bivariate correlation analyses were performed to assess the association between different user acceptance measurements of usability (SUS score), intention to use a technology (TUI factors using raw values), and psychological needs (the TENS Task and Interface as well as the BPNSFS using raw values). To investigate which factors are associated with the intention to use the pharmacy drone app, hierarchical regression analyses were performed among TUI factors as well as among all measurements. To answer the question whether TUI and SUS factors differ between the core and ad hoc groups, 2-tailed *t* tests were performed. Owing to the nature of the study design (small sample sizes), statistical analyses should not be overinterpreted; thus, the results of questionnaires were also analyzed descriptively according to the improvement of acceptance level of SUS and TUI scores.

Qualitative Analyses

The transcripts were analyzed according to the event sampling method of Berelson [43], where an utterance represents an event. Utterances are defined as a complete sentence, a sentence fragment, or any sequence of speech separated in time (eg, a pause of 2 seconds) or semantic (eg, a change in content) [39,44]. Utterances were analyzed by referring phrase analysis [39]. First, all nouns and noun phrases were identified, and utterances with the reference concept name were coded by the first author (FF). This coding shows which concepts the participants focused on during the task. After concepts have been identified, these concepts were defined by the investigator (Tables 2 and 3). The resulting coding scheme was used to code the statements of the participants. Another researcher (JS) who was familiar with the analyses analyzed randomly selected portions of transcripts (20%) to determine if there was a match. In case of disagreement, discussions were held between the 2 examiners until a consensus was reached. Cohen κ [45] was computed for all variables. The interrater reliability was $\kappa=0.654$ ($P<.001$) with a substantial agreement [46].

Table 2. Examples of the coded concepts.

Coded concept	Segment
Value and problem	“What is stupid now is this field. It does not disappear.” (Doctor, aged 48 years)
Proposal	“Would be nicer: ‘Your location and address has been confirmed.’” (Nurse, aged 51 years)
Value and conceptuality	“That black sign that irritates.” (Patient, aged 55 years)
Status	“Now I have uploaded this successfully.” (Pharmacist, aged 35 years)
Ambiguity	“Do I have to register again now?” (Nurse, aged 49 years)

Table 3. Definitions of coded concepts.

Concept	Definition
Value	Rating of usefulness, importance, or worth
Status	Information indicative of status or self-instruction
Problem	Technical inconvenience requiring action
Ambiguity	Incomprehensibility of the process, operation, or handling
Conceptuality	System of terms or concepts
Proposal	Recommendation for technical implementation

The experimenters who prepared the protocols during the iteration loops were asked to evaluate the accuracy of the definitions of coded concepts to ensure that no undefined concepts remained. After all utterances were coded, concepts were summarized for groups. The results were arranged in a table per task and discussed with the ADApp team to derive practice-relevant orientation points. To rank the participant’s points, we classified the concepts according to criteria within the ADApp team. The criteria helped us to evaluate the relevance of the concepts for developing the technology. We defined 4 criteria: safety, risk in the delivery, optimization potential, and outside the capabilities (Multimedia Appendix 1).

Results

Participants

For the 3 iteration loops, between March 2021 and October 2022, we collected data from 18 participants (mean age 43.08, SD 12.44; range 25-65 years). Owing to the relatively large amount of time required, not all participants of the core group could always participate in the iteration loops. In total, 6 participants took part in the first core group (1 general practitioner, 2 pharmacists, 1 patient, and 2 nurses); 3 participants took part in the second core group (1 nurse, 1 pharmacist, and 1 patient); and 4 participants took part in the third core group (2 nurses, 1 pharmacist, and 1 patient). Although, we tried to balance the 2 groups, it was not always possible to equalize the core and ad hoc group. Four participants

took part in the first ad hoc group (1 general practitioner, 1 nurse, and 2 relatives of patients who need palliative care); 4 participants took part in the second ad hoc group (3 patients

and 1 nurse); and 4 participants took part in the third ad hoc group (1 nurse and 3 patients). Table 4 provides detailed demographics.

Table 4. Participants' demographics.

Characteristics	Ad hoc group 1 (n ^a =4)	Ad hoc group 2 (n=4)	Ad hoc group 3 (n=4)	Core group 1 (n=6)	Core group 2 (n=3)	Core group 3 (n=4)	All (n=18)

Quantitative Results

Bivariate Correlations

Bivariate correlations showed that the more usable (SUS) the technology was, the more the participants were willing to use it (TUI; $r=0.833$). Moreover, the more they found the technology useful (TUI), the more the technology was rated as usable ($r=0.711$; SUS and $r=0.487$; TUI) and the more participants would use the pharmacy drone app (TUI; $r=0.754$). In addition, the intention to use (TUI) the app was positively correlated with curiosity (TUI; $r=0.550$). The more skeptical (TUI) the participants were, the more participants rated the app as unusable ($r=-0.542$; SUS and $r=-0.479$; TUI) and would not be willing to use it ($r=-0.446$; TUI).

Furthermore, the intention to use (TUI) the technology was positively correlated with the perceived task competence ($r=0.784$; first iteration loop) and the need satisfaction of participant's competence ($r=0.788$; third iteration loop). The more participants felt competent in handling the app in the spheres of task ($r=0.829$; ie, engaging with the app; first iteration loop) and interface ($r=0.929$; ie, interacting with the app; second iteration loop), the higher was perceived usability (SUS). However, the more participants felt competent in task ($r=0.675$) and behavior ($r=0.875$), the more they felt autonomous (ie, the app provided options and participants did not feel under pressure from the app). The more curious the participants were, the more they felt satisfied in psychological needs of competence, autonomy, and relatedness ($r=0.744$). However, the absence of need satisfaction does not equate with the presence of need frustration [17,35]. The results revealed that the more

participants rated the app as usable, the lesser they felt autonomy ($r=-0.792$; SUS and $r=-0.768$; TUI) and competence ($r=-0.751$; TUI) frustration. The more they believed the technology would be useful for them, the lesser they felt autonomy frustration ($r=-0.827$). Overall frustration shows a negative correlation with usability ($r=-0.822$; SUS and $r=-0.799$; TUI), usefulness ($r=-0.923$; TUI), and intention to use ($r=-0.730$; TUI). Moreover, the results indicated that autonomy frustration is a relevant marker for overall need frustration ($r=0.933$).

Furthermore, correlations showed that the more time participants needed to solve the task within the app, the less usable the app was rated ($r=-0.534$; SUS), the lesser they were willing to use the app ($r=-0.429$; TUI), the lesser they felt competent ($r=-0.805$), the more skepticism they had ($r=0.504$), and the older the participants were ($r=0.681$). The older the participants were, the more skeptical they were ($r=0.525$) and the lesser they believed that the technology was accessible ($r=-0.510$). Female participants showed more technology anxiety ($r=-0.505$), had more interest ($r=0.497$), and felt more related by using the app ($r=-0.800$). The results of 2-tailed t tests confirmed these differences between female and male participants (anxiety: $t_{19}=0.003$; interest: $t_{23}=0.012$; relatedness satisfaction: $t_6=0.004$).

TUI Assessment

To test whether anxiety, curiosity, interest, skepticism, usefulness, usability, and accessibility contributed to higher intention to use, we regressed participant's ratings of these variables on their intention to use and controlled for age, gender, and duration using the app. Results showed that TUI factors such as usefulness, skepticism, and curiosity explain most of the variance in intention to use the pharmacy drone app

($F_{3,17}=21.12$; $P<.001$; $R^2=0.788$; adjusted $R^2=0.751$; Table 5). Usefulness ($\beta=.499$; $P=.001$) and curiosity ($\beta=.376$; $P=.008$)

were significantly and positively associated with intention to use, whereas skepticism ($\beta=-.397$; $P=.004$) was significantly and negatively related with intention to use.

Table 5. Hierarchical regression analysis predicting intention to use the technology per the Technology Usage Inventory factors.

Model and predictor	Unstandardized coefficients, B (SE)	Standardized coefficients		R^2	R^2 change	F test (df)	P value
		β	P value				
1				0.582	0.560	26.48 (1,19)	<.001
Usefulness	14.73 (2.86)	.763	<.001				
2				0.676	0.640	18.81 (2,18)	<.001
Usefulness	13.03 (2.69)	.675	<.001				
Skepticism	-9.82 (4.29)	-.319	.03				
3				0.788	0.751	21.12 (3,17)	<.001
Usefulness	9.638 (2.51)	.499	.001				
Skepticism	-12.20 (3.66)	-.397	.004				
Curiosity	6.36 (2.12)	.376	.008				

Descriptively, anxiety, curiosity, interest, usefulness, and accessibility did not vary much between the core group and ad hoc groups, as shown in Table 6. Ad hoc groups appeared to be slightly more skeptical about the pharmacy drone app compared to the core group. This could potentially be attributed to age differences, as those in the ad hoc groups were older than those in the core group, and skepticism was positively correlated

with age (Multimedia Appendix 2). Although usability remained at slightly below average in the ad hoc groups, it increased from average to slightly above average in the core group from the first to third iteration. Moreover, the core group showed higher ratings on the intention to use the pharmacy drone app than the ad hoc groups.

^bMissing data.

The results of t tests showed a higher rating on usability for core group 3 compared with core group 1 ($t_8=-2.68$; $P=.03$). Moreover, independent samples t tests showed a higher anxiety ($t_{19}=2.88$; $P=.01$) as well as a higher skepticism toward the technology ($t_{23}=2.17$; $P=.04$) within the ad hoc group compared with the core group over all iteration loops. Moreover, the core group rated the app more usable than the ad hoc group ($t_{23}=-3.33$; $P=.003$) over all iteration loops. Although descriptive data showed a higher rating on intention to use the

pharmacy drone app within the core group (mean 90.36, SD 11.01) than the ad hoc groups (mean 76.00, SD 23.74) over all iteration loops, 2-tailed t tests became not significant ($t_3=-1.91$; $P=.07$).

SUS Score

Descriptively, perceived usability (SUS score) decreased between ad hoc group 1 (rated as marginal) and ad hoc group 3 (rated as poor). Within the core group, the usability increased from core group 1 (rated as good) to core group 3 (rated as

excellent). However, within the second iteration loop, both groups (ad hoc and core groups) rated the app more usable than during the first and third iteration loops. Moreover, the core group showed higher SUS scores than the ad hoc groups (Table 7). Results of the *t* tests indicated a significant group difference in SUS score between ad hoc group 2 and ad hoc group 3

($t_6=3.35$; $P=.01$). The results indicated lower SUS scores of ad hoc group 3 (rated as poor) than ad hoc group 2 (rated as excellent). Furthermore, independent samples *t* tests showed a significant group difference in the SUS score between the ad hoc and core groups over all iteration loops, with higher scores for the core group than the ad hoc groups ($t_{23}=-2.87$; $P=.004$).

Table 7. System Usability Score (SUS) scores (0 to 34: very poor; 35 to 49: poor; 50 to 67: marginal; 68 to 79: good; 80 to 89: excellent; and 90 to 100: outstanding [32]) in the ad hoc and core groups per iteration loop.

Group	SUS scores, mean (SD)
Ad hoc group 1	54.38 (23.22)
Ad hoc group 2	80.00 (14.43)
Ad hoc group 3	49.38 (11.25)
Core group 1	75.42 (16.84)
Core group 2	88.33 (10.10)
Core group 3	84.38 (5.54)
Ad hoc group 1 + core group 1	67.00 (21.34)
Ad hoc group 2 + core group 2	83.57 (11.57)
Ad hoc group 1 + core group 3	66.88 (20.43)
All groups	71.60 (19.75)

Overall Regressions

When regressing all factors of all usability and psychological needs, the results showed that the SUS usability score as well as the TUI factors such as curiosity and interest explained most

of the variance on intention to use the pharmacy drone app ($F_{3,16}=40.27$; $P<.001$; $R^2=.883$; adjusted $R^2=.861$; Table 8). Usability ($\beta=.845$; $P<.001$), curiosity ($\beta=.232$; $P=.02$), and interest ($\beta=.195$; $P=.04$) were significantly and positively associated with intention to use.

Table 8. Hierarchical regression analysis predicting intention to use the technology per the Technology Usage Inventory, System Usability Scale (SUS), Technology-based Experience of Need Satisfaction Task, and Basic Psychological Need Satisfaction and Frustration Scale factors.

Model and predictor	Unstandardized coefficients, B (SE)	Standardized coefficients		R^2	R^2 change	<i>F</i> test (<i>df</i>)	<i>P</i> value
		β	<i>P</i> value

Interest	2.88 (1.31)	.195	.04				

Qualitative Results

First Iteration

After the first iteration, the app received a new design according to user’s feedback. Important points after the first iteration were providing more guidance through the app with information about next steps and reasons for doing these steps (eg, the importance of setting the delivery location, clear information about how to choose the delivery location, and more precise symbols; Figures 4 and 5); adaption of conceptualizations (eg,

“location” [German: *Standort*] to “delivery point” [German: *Lieferort*]; Figure 4); automatizations (eg, transferring address data automatically to the map); minimizations (eg, reducing symbols within the map and information within each step); communication options (eg, integrating a field to formulate a message to the pharmacist); control features (eg, an order summary); and autonomy options (eg, to upload >1 prescription if necessary). However, participants missed a visualization of password requirements and a preview function of the uploaded recipe. Furthermore, users would rather preview individual

pages per click than perform 1-page scrolling. They would also desire information about payment options within the app as well as details about medication availability. This necessitates integration of the interface with the pharmacy's merchandise management system, which requires additional technical and regulatory administration. A short solution for that was to integrate a comment field at the step of ordering the medication to describe further medication wishes as well as to ask questions

to the pharmacist. Moreover, participants emphasized, at this point, the importance of shipment tracking, as Fink et al [27] described in their study. However, the most difficult step participants reported was setting of the delivery location. This was also shown in the amount of support needed while using the app (Multimedia Appendix 3). Although experimenters were instructed to not help participants, at some points the help was necessary so that the participants could finish the task.

Figure 4. User-centered app design (A) before and (B) after first iteration: delivery location.

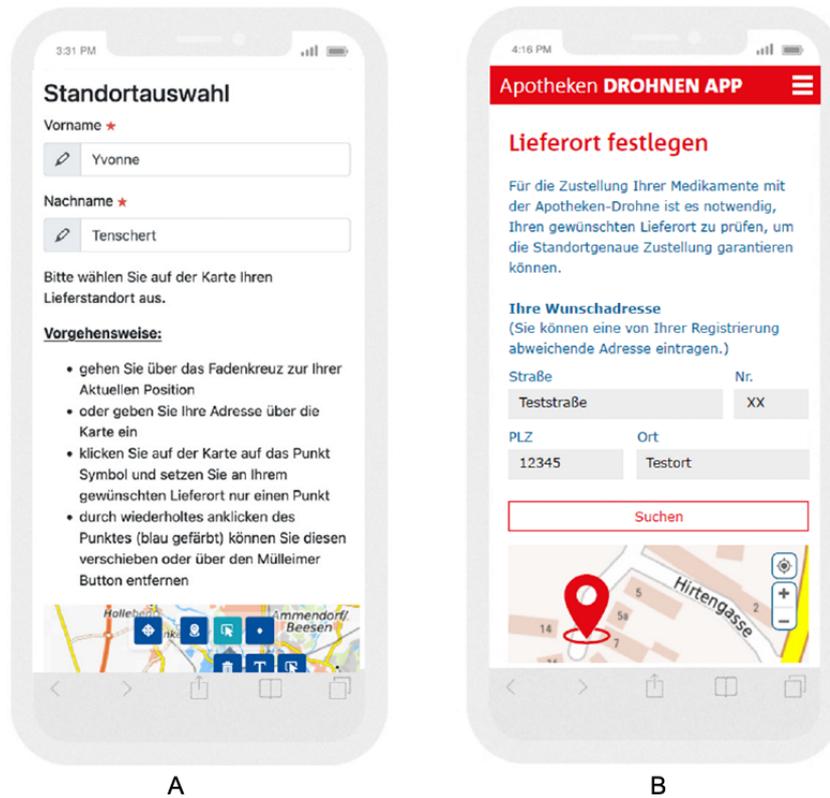

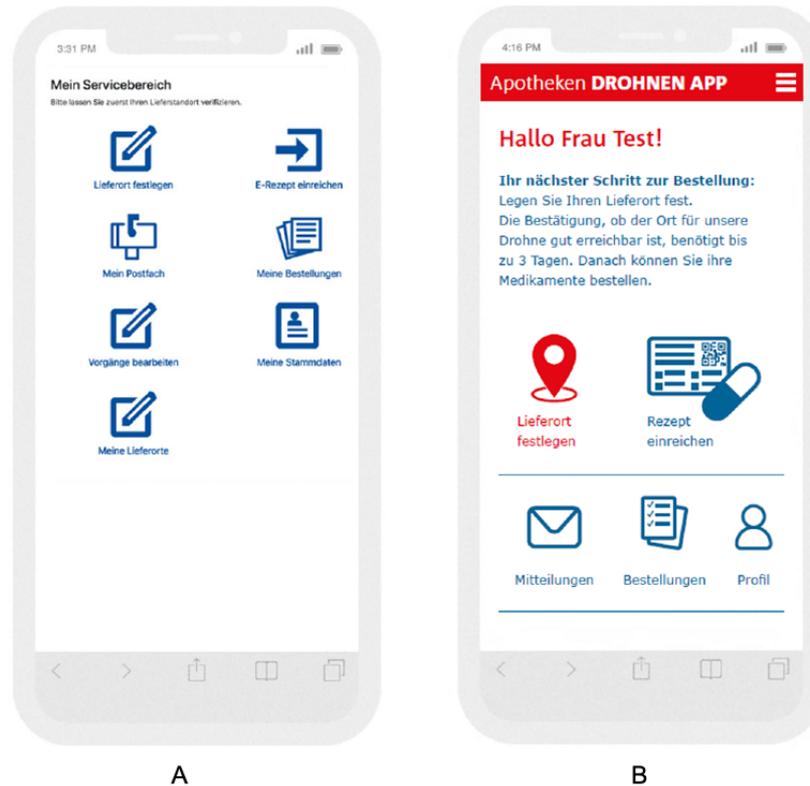

Figure 5. User-centered app design (A) before and (B) after first iteration: symbols.

Second Iteration

After the second iteration, participants in both the core group and the ad hoc group reported that registration was simplified, indicating that it was easy for them to register. Moreover, participants reported that the summary of order was clear, the texts were more comprehensible (core group), and the participants liked the option to upload >1 prescription (ad hoc group). However, participants missed a preview function of the uploaded prescription as a picture and the selection of push messages. Moreover, they suggested highlighting the icon, which is the next step to be clicked on (eg, after setting the delivery location, the icon for submitting the prescription should be highlighted), and highlighting the inbox when a new message has arrived. Important points after the second iteration were still reducing symbols within the map (eg, symbols were reduced to a minimum, and the text describing the symbols was shortened because the participants did not read the instructions above the card); more guidance through the app with information about next steps; and more transparency about how a response will be received from pharmacists (eg, integration of information about how the contact will take place, via mail or telephone), indications on password requirements (such as length, upper and lower case, and special characters), and information about shipment tracking. An important safety-relevant point was that flight slots were not up to date according to the original time. Similar to the first iteration loop, participants reported setting the delivery location as the most difficult step. They would like to have more guidance for the subsequent steps after determination of the delivery location.

Third Iteration

The core group reported that the app was more intuitive and had improved compared with the first iteration loop. They mentioned that the automated fill-in of address data in the map as well as the identification that the prescription was successfully uploaded was useful.

Important points after the third iteration were more guidance through a processing status within the app; adaption of conceptualization (eg, “mailbox” [German: *Postfach*] to “messages” [German: *Nachrichten*]); visualization of password requirements (eg, upper and lower case and special characters); automatization features (eg, automatic suggestions such as city when entering the postal code); differentiation (eg, distinction between the delivery and billing address); control (eg, adjustment of the amount of information within the app to control how much information the user wants, which might be configured via profile); push messages instead of emails because participants did not read the texts despite shortening them; a preview function of the uploaded prescription; and design features (eg, it was not clear that scrolling was necessary, thus more guidance is useful through individual pages [click to continue]). They also desired the inbox to be highlighted when new messages had arrived.

Although the app was adapted according to the participant’s feedback, the ad hoc group reported that the step of setting the delivery location remained too complex for them. They mentioned that this step was too bulky, time consuming, and not intuitive despite adjustments such as the reduction of map symbols, providing the most important information, shortening the text, and inserting address data automatically in the map. Participants of the ad hoc group felt lost and helpless during

this step. However, during discussions after thinking aloud, participants suggested that the setting of delivery comes from the operator and thus must not be made by users. They only wanted confirmation of the delivery point to ensure its correctness. Excluding this step might decrease the likelihood of user errors.

However, across all iterations, criteria emerged that were repeatedly the focus of the participants' attention: automatization (ie, easy and fast use for avoiding redundancies), minimization (ie, as little information as possible and as much as necessary), differentiation (ie, clear distinctions), control (ie, options to choose), guiding (ie, concise and understandable instructions supporting guidance through the app), conceptualization (ie,

easy and precise language), barrier-free design (ie, uniformity between different steps and intuitive visualizations), and transparency (about disclosures to be made or obtained information).

Although we could not test the handover scenarios, we have made modifications to the drone. Previous results of focus group testing within the ADApp project showed concerns about injuries caused by the drone [27]. Thus, the drone has now been given a flap underneath so that the medications can be dropped by ejection, using a parachute, or using a winch and a landing of the drone can be prevented (Figure 6). Further testing is planned to test different handover scenarios with participants to adapt the handover according to their needs.

Figure 6. Drone medication ejection.

Discussion

Factors of User Acceptance

This study aimed at investigating factors that are associated with the user acceptance of a drone-based medication delivery by using a mixed methods design to be able to derive practice-relevant orientation points for participatory technology development (for apps and drones).

First, an important point is duration handling with the app. Older participants needed more time to solve the tasks within the app. Furthermore, the longer the process took, the more the usability, intention to use the app, and feelings of competence decreased, while skepticism increased. Therefore, the duration of interaction with a technology appears to be a crucial factor for user acceptance.

Second, psychological factors such as skepticism and curiosity as well as technology-specific factors such as usefulness and usability are related with participants' intention to use the technology for a drone-based medication delivery. Regression analyses within the TUI factors revealed usefulness, curiosity, and skepticism as significant predictors for intention to use the technology, wherein usefulness explained the highest variance (49.9%), which is consistent with the findings of Gsken et al [47]. This implies a particular relevance of factor usefulness for the development of technologies in health care, especially in drone-based medication delivery. With the help of the TUI questionnaire, we can conclude that curiosity and skepticism affect user acceptance. The more the users were curious about

the pharmacy drone app and the less skeptical they were, the more the users were willing to use and interact with the technology. This is consistent with the findings of Eibfeld et al [6] who found that a positive attitude toward drones and a general technical interest are related to improved information about it.

Third, basic human needs according to Ryan and Deci [16,17] and Deci and Ryan [18] also play an important role. Results of this study showed that the more participants perceived competence in handling the app, the more they are willing to use the technology and the more they rated the app as usable. This implies that, although competence satisfaction in all iteration loops was related with usability and the intention to use, autonomy and relatedness were not related. Nevertheless, results showed that the more participants felt competent, the more they felt autonomous. Moreover, the basic psychological needs (competence, autonomy, and relatedness) were positively correlated with curiosity. In addition, the lesser participants felt frustrated on psychological needs, the higher they rated the usability, usefulness, and intention to use. Thus, following the Basic Psychological Need Theory [17], the more the interaction with the system satisfies basic psychological needs, the more the users will engage with a technology. Following the METUX model, an increase in autonomy increases engagement and an increase in competence increases motivation of using the app, which is in accordance with the results of this study [15]. Interestingly, while competence and autonomy appear to be significant factors in explaining differences in intention to use and usability, relatedness does not play a role, despite focus

group discussions emphasizing the importance of communication and consultation features within such technology [27]. One reason for this result might be the nature of the study task. Although participants used the app in a simulated context, communication aspects did not play a role in this developing step of technology. Therefore, supply studies in real-life contexts are necessary to test the impact of psychological and technological factors on real-life complex problems, which cannot be fully investigated in a simulated context such as in this study, where, for example, relatedness might hold greater significance in real-life scenarios than in simulations, as increased relatedness could potentially enhance overall well-being [15].

Fourth, overall regression analyses showed that usability, curiosity, and interest explain most of the variance on intention to use the pharmacy drone app, wherein usability showed the strongest effect (84.5%). This means, when adding all factors in one model, usability becomes the strongest predictor for intention to use the pharmacy drone app. Similar to other studies, this study found evidence for the importance of usability in using a technology [1,5]. This means that better usability of a technology leads to higher acceptance [12,33]. However, this study used a very small sample group, and the statistical results should be considered carefully. In conclusion, studies with higher sample sizes are necessary.

Taken together, the intention to use a drone-based medication delivery system is a comprehensive construct that is based on a large number of underlying, explanatory factors. This study showed that usability, curiosity, and interest had a considerable impact on intention to use, wherein usefulness, skepticism, and competence also played an important role. The failure to actively involve users in technology development can thus result in insufficient addressing of profession- and person-specific needs, thus resulting in a lack of intention to use the technology. For successful technology development, it is therefore crucial to develop an understanding of the necessary characteristics of health care technologies and to identify the determinants that ensure a high level of acceptance for improving the current supply situation [47].

In accordance with the previous scoping review [7], user feedback was collected iteratively and focused on user experience. The TA method [38] used in this process provided valuable insights that were taken into account when developing the app. In this way, important changes to the app were successfully implemented by user request such as a reduced design and automatic fill-in aids. It was found that communication with the dispatcher and shipment tracking are very important to users, which is consistent with the assumptions from the scoping review [7], and this also led to further adjustments. The changes made could be verified in the further iterations; for example, it turned out that the revision for the definition of the delivery location was not helpful: the process was adjusted based on participant feedback with more information, but this step remained too complex. In the third iteration, it became clear that the required texts were not being read at this point, leading to the ultimate decision to omit this step altogether as participants indicated that they only wanted to confirm the delivery location.

Differences in User Acceptance

A second purpose of this study was to assess group differences between a core group and ad hoc groups in user acceptance.

The results of this study indicated the importance of an ad hoc group in an iterative, cocreative process. Although within the core group, intention to use (TUI) was similar over all iteration loops (strongly above average), within the ad hoc group, intention to use varied from slightly above average to strongly above average to average. Although within the core group, the usability of the app slightly increased from “average resp. good” to “slightly above average resp. excellent,” the usability within the ad hoc group decreased from marginal to poor (SUS) and remained slightly above average (TUI). Results of *t* tests of both questionnaires showed a significant group difference between the ad hoc and core groups, with higher ratings in perceived usability for the core group. This suggests that repeated measurements induce a shift in the interpretation of test scores, potentially biasing the measurement of change [26]. Thus, this study shows that repeated measures with the same sample group might change their attitude, expectations, and behavior in dealing with the technology, which changed their ratings on usability. The core group then tended to evaluate the app better than the ad hoc group because they were not unfamiliar with dealing with the app. Thus, for naive users, the app is just not intuitive and easy enough to use. An additional explanation for this result is that the ad hoc groups were more anxious and skeptical than the core group, wherein a higher skepticism was found to be related to lower ratings on usability [47]. However, within the usability score (SUS), data showed an increase from the first to second iteration and a decrease from the second to third iteration in both groups, wherein the ad hoc groups rated the pharmacy drone app as less usable compared with the core group. One reason for the decrease from the second to third iteration could be the more complex setting during the third iteration: the participants had to run through the entire process from registration, setting the delivery location, and ordering the medication to receiving the medication. Meanwhile, the core group showed a learning effect and maybe thus rated the pharmacy drone process to be more usable from the first iteration to second iteration, and the ad hoc groups could stumble because of the complexity.

Limitations

This study shows for the first time the importance of ad hoc groups as a control group while developing and evaluating a technology in a user-centered design. When interpreting the results of this study, several methodological limitations must be considered. In terms of age and gender distribution, the sample can be classified as unrepresentative owing to the small number of participants. This is particularly evident in the statistical evaluation. Nevertheless, there is a basic tendency toward a clear effect, which is evident despite the small number of samples. The participants had a basic interest in new topics and in the topic itself. Although the risk of “positive selection” cannot be completely ruled out, it is not seen because the topic of drone-assisted medication delivery was largely unknown. Thus, the perspectives of participants who consistently reject technical systems in the context of care and delivery were as

poorly represented as those who chose not to participate in the surveys for other reasons. Reasons for this could include a general dismissive attitude toward additional effort owing to time resources, heavy workloads, or other thematic priorities.

However, it can be concluded that the results obtained to assess the acceptance of the drone app for utility purposes have revealed important insights regarding technical development and its practical use. In this context, the findings exhibit similarities to surveys conducted for other target groups in health care.

Conclusions

The study highlights the significance of understanding the essential attributes of health care technologies and the factors that lead to their acceptance in improving the current supply situation. It offers valuable insights for practitioners to develop participatory technologies and recommends ad hoc groups as a complementary approach to control the process of a user-centered design. However, larger samples and real-world contexts are required to confirm these findings.

Acknowledgments

The authors would like to thank the Apotheken-Drohnen-App team for their involvement in the participatory development of the drone. In addition, the authors would like to thank Dr Anne-Marie Lachmund for her help with proofreading.

Abstract

Background: Health care lags in digital transformation, despite the potential of technology to improve the well-being of individuals. The COVID-19 pandemic has accelerated the uptake of technology in health care and increased individuals' willingness to perform self-management using technology. A web-based service, Directlab Online, provides consumers with direct digital access to diagnostic test packages, which can digitally support the self-management of health.

Objective: This study aims to identify the facilitators, barriers, and needs of Directlab Online, a self-management service for web-based access to diagnostic testing.

Methods: A qualitative method was used from a potential user's perspective. The needs and future needs for, facilitators of, and barriers to the use of Directlab Online were evaluated. Semistructured focus group meetings were conducted in 2022. Two focus groups were focused on sexually transmitted infection test packages and 2 were focused on prevention test packages. Data analysis was performed according to the principles of the Framework Method. The Consolidated Framework for Implementation Research was used to categorize the facilitators and barriers.

Results: In total, 19 participants, with a mean age of 34.32 (SD 14.70) years, participated in the focus groups. Important barriers were a lack of privacy information, too much and difficult information, and a commercial appearance. Important facilitators were the right amount of information, the right kind of tests, and the involvement of a health care professional. The need for a service such as Directlab Online was to ensure its availability for users' health and to maintain their health.

Conclusions: According to the participants, facilitators and barriers were comprehension of the information, the goal of the website, and the overall appearance of the service. Although the service was developed in cocreation with health care professionals and users, the needs did not align. The users preferred understandable and adequate, but not excessive, information. In addition, they preferred other types of tests to be available on the service. For future research, it would be beneficial to focus on cocreation between the involved medical professionals and users to develop, improve, and implement a service such as Directlab Online.

Introduction

Background

Society is changing, and the world is becoming increasingly digital [1]. Health care lags in digital transformation, despite the potential of technology to improve the well-being of individuals [1,2]. The COVID-19 pandemic accelerated the development and use of technology in health care, also referred to as eHealth, with more digital consultations and increased use of home monitoring [3,4]. Furthermore, the COVID-19 pandemic, among others, has increased the need and willingness of individuals to perform self-management [5-7]. In patients with chronic diseases, self-management strategies are often used to support patients in dealing with treatment and lifestyle changes [8]. In addition, self-management strategies can be used to support individuals with home diagnostic tests [9]. The concept of self-management aligns with this positive health definition: "health as the ability to adapt and self-manage in the face of social, physical, and emotional challenges" [10,11].

eHealth can be used in 3 stages of laboratory diagnostic testing. The first stage is triage and advice on diagnostic testing, the second stage is the testing itself (ie, at home or a facility), and the third stage is the communication of the test results to the user. A systematic review by Versluis et al [9] showed that web-based diagnostic testing services were positively evaluated and preferred over clinic-based testing. However, most of the evaluated services only offered tests to detect sexually transmitted infections (STIs) [9].

eHealth services can support self-management, for example, with web-based services that support behavior and lifestyle changes (eg, Liva Healthcare) [12] and with websites where individuals can obtain health information (eg, Thuisarts.nl) [13]. In addition, there are multiple apps to support patients with chronic conditions such as hypertension, diabetes, or lower back pain [14-16].

In the Netherlands, a web-based service called Directlab Online (Saltro, part of Unilabs) offers individuals direct access to laboratory diagnostic tests independent of a health care provider [17]. It is a so-called direct-to-consumer platform. Directlab Online gives individuals direct digital access to diagnostic testing based on a triage that aligns with medical guidelines. Unlike the services identified in the systematic review by Versluis et al [9], Directlab Online offers a variety of diagnostic tests, for example, diagnostic tests for STIs, COVID-19, and vitamin deficiencies, as well as testing for health-related questions concerning fatigue and the prevention of heart disease. The results and the information on the website can give individuals insight into their health, which could support and motivate them to adopt healthier behaviors [12]. In addition, it supports users to be better informed about their health without the interference of a health care professional, which can lead to more efficient and accessible care [18]. Packages to test the health of individuals align with the patient-centered care approach, which can lead to a better quality of care [19]. Patient-centered care aims to empower patients to take charge of their health and actively participate in their health care [20]. Another term used is person-centered care, which is similar but

does not solely focus on disease-related aspects, aligning better with the positive health definition [21].

To completely harness the potential and significance of Directlab Online, prioritizing high-quality and user-friendly service is paramount. Delving into the barriers and facilitators individuals encounter when using the service could provide invaluable insights, facilitating the enhancement of its user-friendliness and effectiveness. For example, known factors in dermatology that could influence the uptake of a digital service are, among others, financial aspects and accessibility for a digital service [22]. In a study by Vergouw et al [23], facilitators of and barriers to digital services for older adults in primary care were researched. Nonfamiliarities with web-based environments appeared to be a barrier, and efficiency was seen as an important facilitator for using a digital service in primary care [23]. In the review of STI testing by Versluis et al [9], concerns regarding complicated language and data handling insecurities were also discovered for ordering an STI test on the web. To our knowledge, no research has been conducted on facilitators, barriers, and needs of a direct-to-consumer platform that offers direct access to multiple diagnostic tests and web-based results. Identifying the needs, facilitators, and barriers will help determine what is necessary to optimize the use and improve the implementation of those services. This can give insight into the potential future directions for developing such services.

Objectives

This study aims to identify the facilitators of and barriers to using a service such as Directlab Online and to identify the needs regarding direct digital access to diagnostic testing. To achieve this, focus groups were conducted. Half of the focus groups focused on STI test packages and the other half on prevention test packages. STI tests and prevention test packages are the most ordered test packages on Directlab Online. The focus is on potential users, that is, those who have not used Directlab Online before, because we are interested in capturing people's first impression of the service.

Methods

The Service: Directlab Online

Directlab Online is a Dutch, web-based service available for everyone, through which diagnostic tests can be ordered on the web [17]. The service was developed by a multidisciplinary innovation team of a diagnostic company (Saltro, part of Unilabs) and was launched in 2016 [24,25]. The process of using the service is presented in Figure 1. First, individuals undergo a web-based triage, based on medical guidelines, to determine whether the diagnostic tests are relevant and, if applicable, which tests are relevant. Second, individuals can order and buy associated tests. Depending on the diagnostic tests ordered, a self-sampling kit is sent to the individual's home address, or an appointment is scheduled at a blood collection center or a laboratory for collecting a blood sample. Once the laboratory receives the collected specimen, high-quality analyses are conducted. The results of the tests are communicated through a web-based, secure patient portal. Furthermore, deviating results are communicated to the patient's general practitioner but only if the patient has authorized it. The triage was based

on medical guidelines, and the diagnostic test packages were developed in cocreation with general practitioners and tested by them and laboratory specialists referred to as health care professionals. Diagnostic test packages consist of different parameters for diagnostic testing. For example, a test package for cholesterol measures the following parameters: low-density

lipoproteins, high-density lipoproteins, triglycerides, and total cholesterol. [Multimedia Appendix 1](#) provides a complete overview of the test packages that could be ordered on Directlab Online during the focus group meetings. [Table 1](#) provides an overview of the prevention and STI test packages that were part of the discussions with the focus groups.

Figure 1. Stages of using Directlab Online.

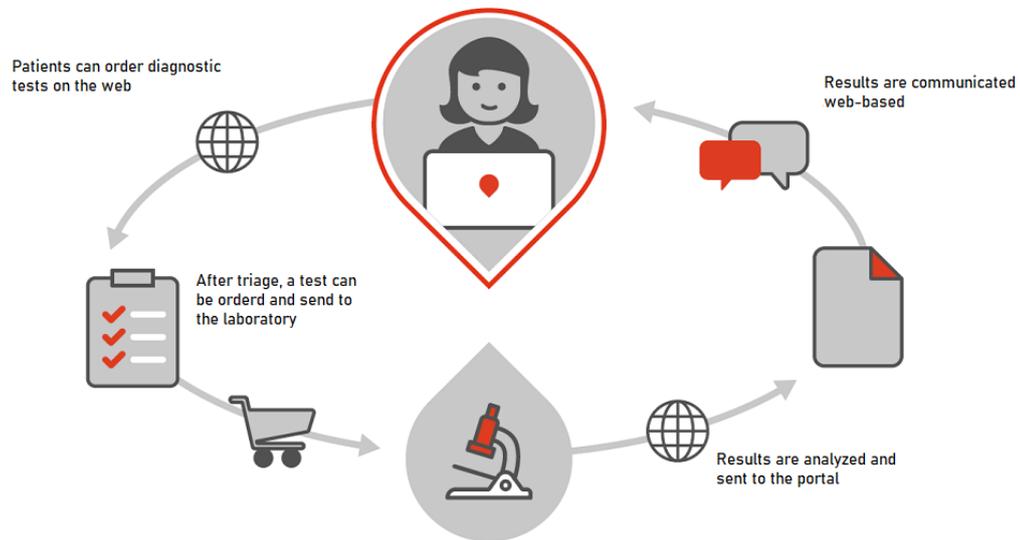

Table 1. Test packages that are available on Directlab Online.

Category	Parameters
Prevention tests	
Health checkup	Check total cholesterol ^a , low-density lipoproteins (LDL) ^a , high-density lipoproteins (HDL) ^a , triglycerides ^a , HbA _{1c} ^a , and albumin and creatinine ratio ^b
Health checkup at home ^c	Measure parameters via self-sampling of blood: total cholesterol ^d , LDL ^d , HDL ^d , triglycerides ^d , HbA _{1c} ^d , and albumin/creatinine ratio ^b
Cholesterol	Check total cholesterol ^a , LDL ^a , HDL ^a , and triglycerides ^a
Cholesterol at home ^c	Measure parameters via self-sampling of blood: total cholesterol ^d , LDL ^d , HDL ^d , and triglycerides ^d
Anemia	Check hemoglobin ^a , mean corpuscular volume ^a , ferritin ^a , and C-reactive protein ^a
Diabetes	Check glucose ^a and HbA _{1c} ^a
Healthy bones ^c	Check calcium ^a and vitamin D ^a
Healthy kidneys ^c	Check creatinine ^a , glomerular filtration rate ^a , and albumin/creatinine ratio ^b
Thyroid check	Check thyroid function via thyroid-stimulating hormone ^a and free T4 ^a
Sexually transmitted infection tests	
Chlamydia	Check for chlamydia ^e
Gonorrhea	Check for gonorrhea ^e
HIV	Check for HIV ^a
Syphilis	Check for syphilis ^a
Hepatitis B	Check for hepatitis B ^a

^aBlood sample needed for diagnostics; HbA_{1c}: hemoglobin A_{1c}.

^bUrine sample needed for diagnostics.

^cThese tests are not available any more on Directlab Online after the service update.

^dBlood sample needed for diagnostics collected by self-sampling.

^eOral, anal, vaginal, or urine sample needed for diagnostic tests.

Study Design and Participants

Focus group meetings were conducted with potential users of the service. As the Directlab Online service offers a wide variety of test packages, we focused on 2 specific categories (ie, prevention test and STI test packages). These test packages were ordered most frequently. Half of the focus groups focused on STI test packages, and the other half focused on the prevention test packages. The general inclusion criteria for the focus groups were speaking Dutch and not having used Directlab Online earlier. In addition, there were specific inclusion criteria to ensure that the sociodemographic characteristics of the participants in the focus groups were consistent with the characteristics of the target population of the test packages. Notably, a specific inclusion criterion for the focus group about STI testing was that the participants were aged between 18 and 30 years. The specific inclusion criterion for the focus groups about prevention test packages was that the participants were aged between 18 and 65 years. It is important to note that there were no specific health or disease requirements to participate. Focus group meetings were held until data saturation was reached.

Ethical Considerations

The study was declared to not fall within the scope of the Dutch Medical Research Involving Human Subjects Act by the Leiden University Medical Center Medical Ethics Committee (N21.101).

Procedure and Data Collection

The recruitment period started on October 25, 2021, and lasted until February 20, 2022. Participants were recruited via different web-based channels (eg, LinkedIn [LinkedIn Corporation] and Facebook [Meta platforms, Inc]). Individuals were invited to contact KS via email when interested. Then, KS sent them more information. In addition, questions were asked regarding their birth year and if they could understand Dutch. A few date options for web-based meetings were sent if the individual met the inclusion criteria. When individuals could participate, they received an email with the date and time, a link to the Zoom (Zoom Video Communications) platform where the meeting would be conducted (on the web), and a link to a web-based informed consent form, which they were asked to sign before participation. All participants had the right to withdraw at any moment. The focus group meetings occurred between January

10 and March 2, 2022, in the presence of MH and KS [26]. KS led the focus groups, and MH managed the time and assisted with technical issues. The focus group meetings were in a semistructured format, following a predefined topic list with open-ended questions to leave space for discussion ([Multimedia Appendix 2](#)). First, general questions were asked regarding using eHealth to see how familiar participants were with eHealth. Second, participants were provided 10 minutes to view the website of Directlab Online and navigate through the website on a computer or mobile phone; no further instructions were given. When time was up, questions were asked regarding the website in general (eg, the first impression, whether they needed help when using the website, and whether they found the website attractive). While navigating the website, they had the option to write down notes or vocalize their impressions, expressing their observations, preferences, and feelings about the website [27]. Third, participants were instructed to go through Directlab Online, do some triages, and look at their test advice. Notably, we allowed participants to navigate through the process as normal users would. Hence, they were required to peruse informational materials, undergo a triage process involving medical inquiries concerning their symptoms, and obtain guidance regarding testing. Subsequently, questions were asked regarding the triage service, facilitators of and barriers to using Directlab Online, and the participants' needs for such a service. At the end of the focus groups, they received a digital gift card of €25 (US \$27).

Data Analysis

All focus group meetings were audio recorded for subsequent analyses and were transcribed (intelligent) verbatim. When the transcripts were completed, the audio records were deleted. Two reviewers, MH and KS, conducted the qualitative data analysis according to the principles of the Framework Method [28]. The Framework Method is a systematic and flexible approach commonly used for the thematic analysis of health research semistructured interview data [29]. The method combines deductive and inductive techniques, which align with the aim of the study to identify specific issues regarding the use of Directlab Online and leave space to identify needs and opportunities that have not been formulated a priori. First, open

coding was performed independently by the 2 reviewers, KS and MH. The interview data were coded using the software Atlas.ti 22 (Atlas.ti 22 Scientific Software Development). Second, the codes were compared between the 2 reviewers. Third, the codes were grouped into categories, resulting in the analytical framework. Fourth, for identifying the facilitators and barriers, the Consolidated Framework for Implementation Research (CFIR) was used [30]. The framework is widely used for the content analysis of qualitative data regarding the factors influencing implementation success [30]. Furthermore, the framework is comprehensive and makes it convenient to systematically study a wide array of facilitators and barriers [31]. In addition, using this framework made it possible to compare the findings and transfer them to other implementation studies [32]. The CFIR is a theory-driven model and comprises five domains: (1) the innovation domain, (2) the outer setting domain, (3) the inner setting domain, (4) the individuals' domain, and (5) the implementation process [30,33]. Identified facilitators and barriers were placed within the CFIR domains. Final themes were achieved via discussion and consensus between researchers KS and MH.

Results

Participant Characteristics

Data saturation was reached after forming 4 focus groups with 19 participants. The characteristics of the participants are shown in [Table 2](#). The participants were aged 20 to 61 (mean 34.32, SD 14.70) years. The number of male (9/19, 47%) and female (10/19, 53%) participants was almost equal. The focus group meetings lasted around 90 minutes per group.

Age differed over the 2 different focus groups, as aligned with the target population of the diagnostic test packages. Overall, the experiences and choices of the focus groups regarding the website were the same. Therefore, in most cases, the focus group results were discussed together. When the results differed between the 2 groups, this was specified. Different themes around usability, facilitators, barriers, and needs emerged from the data and are elaborated in subsequent sections.

Table 2. Characteristics of the participants (N=19).

Participant	Gender	Age (years)	Focus group ^a
1	Woman	27	1
2	Woman	25	1
3	Man	24	1
4	Man	30	1
5	Woman	20	1
6	Woman	25	2
7	Woman	46	2
8	Woman	59	2
9	Man	24	2
10	Man	20	2
11	Woman	25	3
12	Man	25	3
13	Woman	30	3
14	Man	24	3
15	Man	39	4
16	Woman	58	4
17	Woman	59	4
18	Man	30	4
19	Man	62	4

^aGroups 1 and 3 focused on sexually transmitted infection packages, and groups 2 and 4 focused on prevention packages.

Facilitators of and Barriers to the Uptake of Innovation

The identified barriers and facilitators were categorized specifically into the following 3 CFIR domains: innovation domain, outer setting domain, and individuals domain. The other 2 domains of the CFIR (ie, inner setting and implementation process) did not align with the facilitators and barriers mentioned by the participants and were therefore not discussed. Table 3 provides insight into the most essential and changeable facilitators and barriers identified. Therefore, it is

not an exhaustive list of all potential barriers and facilitators that influenced the service uptake. It is notable that certain factors can be considered as a facilitator and barrier. For example, financial costs are frequently mentioned as a factor affecting the willingness to use digital health services [33]. When there are high user costs, it is a barrier; however, low costs can be considered a facilitator. The identified facilitators and barriers are explained in detail and explained per domain in subsequent sections.

Table 3. Facilitators and barriers derived from the focus groups embedded in the Conceptual Framework for Implementation Research (CFIR).

Domain of CFIR	Domain description	Results
Innovation domain		
Innovation source	The group that developed and visibly sponsored the use of the innovation is reputable, credible, and trustable.	<ul style="list-style-type: none"> The general practitioner group that developed and visibly sponsored the service was reputable, credible, and trustable, which resulted in a reliable service. Information about privacy and presenting good reviews improved reliability and credibility. Commercial appearance influenced the credibility. Furthermore, stock pictures influenced the credibility.
Innovation relative advantage	The innovation is better than other available innovations or current practices.	<ul style="list-style-type: none"> The service was easy to use, which made the service accessible. It was easy to use the service without visiting the general practitioner.
Innovation complexity	The innovation is complicated, which may be reflected by its scope and the nature and number of connections and steps.	<ul style="list-style-type: none"> Too many testing possibilities and too much information made the website less user-friendly. The search bar and filters on the website increased the user-friendliness of the website. Using multiple medical words made the service difficult to comprehend.
Outer setting domain		
Partnerships and connections	The inner setting is networked with external entities, including referral networks, academic affiliations, and professional organization networks.	<ul style="list-style-type: none"> The service was linked with academic institutions and other medical professionals, which increased the reliability of the service for users.
Societal pressure	Mass media campaigns, advocacy groups, or social movements or protests drive the implementation and delivery of the innovation.	<ul style="list-style-type: none"> Media campaigns, reviews, and blogs could help stimulate participants to use the service.
Individuals domain: subdomain patient characteristics		
Capability	The individual has interpersonal competence, knowledge, and skills to fulfill a "Role" (different characteristics of individuals).	<ul style="list-style-type: none"> If participants had experience with a similar service, they felt more confident in using the service. Otherwise, feelings of anxiety or tension could have influenced their competence, knowledge, and skills.

Facilitators and Barriers in the Innovation Domain

Innovation Source

Participants mentioned different factors that were related to the innovation source of the innovation domain. These factors mainly influenced the credibility and trustworthiness in a positive (ie, facilitator) or negative (ie, barrier) way. First, the website's commercial appearance were the most frequently mentioned barriers that influenced its reliability. For example, participants mentioned that the option to buy a gift card for a diagnostic test package did not align with a website designed for health. In addition, regarding the high prices for diagnostic test packages and the website's general appearance, they said the following:

The website said: buy this. But I want to know why this test? [Participant 4]

I found it a very commercial website; this lowers my enthusiasm. [Participant 8]

Participants did not notice that health care professionals were involved in the service and partly developed the service, while this could increase the credibility of the website.

Second, the availability of reviews was frequently mentioned as a facilitator for reliability and credibility but as a barrier in some cases. Good reviews could be considered as a facilitator, and bad reviews could be considered as a barrier to experiencing the website as reliable and trustworthy. The following was said about this view:

Yes, [...] I found it important if I go to a new website to sell or buy something to see that others used the site and what they bought. [Participant 13]

Third, 37% (7/19) of the participants mentioned the facilitator's "privacy." For the participants, it was important to know where the data were stored and for how long. However, this information was difficult to find on the website:

And then it is the question of how long data is stored and how that is important to know. [Participant 8]

I want to know, what happens to the data and how long is it stored? [Participant 16]

Participant 7 pointed out that a clear and transparent privacy statement could be a unique selling point of the service.

Finally, the most mentioned barrier in the innovation source was the presence of stock pictures on Directlab Online:

[...] those stock pictures on the website; they gave an image of unreliability. [Participant 3]

Participants mentioned that pictures of real people or famous people who used the tests could be a facilitator and positively influence the reliability and use of the service. Furthermore, they mentioned that a short video with education and instructions about diagnostic test packages could improve the triage's clarity and the diagnostic packages' content.

Innovation Relative Advantage

Participants mentioned several factors regarding why they would use this innovative service. These factors were mostly related to the accessibility of the service compared to other services or normal practice. For example, the easiness of ordering a test on the web without going to the general practitioner was a relative advantage of the service, as mentioned by a participant:

Yes, I would rather order online because going to the general practitioner [...] it takes time. [Participant 7]

Furthermore, another participant mentioned the benefit of ordering a test on the web without going to the general practitioner:

Hmm yes, I thought of a few things when I first saw the website... of the vitamin tests, STI tests, and COVID tests, I thought yes, you do not want to go to the general practitioner for that. Especially for STI testing, the threshold is high. In this way, you still test and see if you are healthy. [Participant 1]

However, the relative advantage was negatively influenced by the high costs of the tests. One participant stated:

The costs will stop people from buying anything. [Participant 17]

Innovation Complexity

Several facilitators and barriers that influenced the complexity of the service were mentioned by the participants.

First, the number of test packages and parameters available was confusing. It became clear from the focus groups that offering the "right" number of diagnostic tests was important; participants were not enthusiastic about a test package with

many separate parameters. Participants mentioned that they were optimistic about the possibility of ordering STI testing, COVID-19 testing, and some prevention tests. However, they mentioned that after the triage, they received advice to select many different test packages. Recommending many diagnostic test packages to the participants was a barrier because they were confused about which test package was important for them. Furthermore, the high amount of information provided about these test packages was experienced as challenging by approximately half (11/19, 58%) of the participants:

When I open the website, a lot of information is present. Too many tests are available. Of course, this website wants to sell tests, but... I do not know. I found the home page too complicated, too unclear. [Participant 13]

Second, the language used on the website was a factor that influenced the use of the service. The language on the home page was experienced as straightforward and was therefore a facilitator. However, when completing the triage and choosing the diagnostic package, the information was more challenging to understand. Notably, medical and incomprehensible terms were used:

I think you have a very broad target group of people who would like to use this, and I think it is written for the somewhat well-educated, reasonably well-informed citizen, shall we say [...] Offer more comfort to people by using less difficult vocabulary. [Participant 8]

Third, the participants mentioned elements of the website that influenced user-friendliness. Participants were happy with the filters in the search bar to find a particular test, as well as the search function and the website's colors:

Personally, I found the website easy to use, and what I experienced as very positive were the filters [...]. [Participant 14]

However, approximately one-third (6/19, 32%) of the participants found the website unclear—among others, due to too much text—and complicated (eg, where to find what they were looking for), and they found the home page too busy.

Facilitators and Barriers in the Outer Setting Domain

Partnerships and Connections

The service was linked to academic institutions, which increased its reliability. Mentioning partners would increase the uptake according to the participants:

Yes, mentioning partners would be nice. And famous names always attract attention. [Participant 13]

Societal Pressure

Participants mentioned that reviews and blogs could help in increasing the use of the service and its reliability:

You want to read reviews and experiences of others. [Participant 5]

Facilitators and Barriers in the Individuals Domain

The individual's skills and knowledge regarding services such as Directlab Online influenced their willingness to use the service and their perception of potentially using it. The younger participants (aged 20 to 30 years) mentioned that they had experience with this type of website, which reassured them to use this service. However, some older participants (aged ≥ 39 years) had less experience with digital services in general and mentioned some anxiety and tension when they needed to order a test. Some (4/19, 21%) preferred to go to the general practitioner for diagnostic tests. However, participants of all age groups mentioned the benefit of ordering STI tests on the web without visiting the general practitioner.

Future Needs

Different needs were identified regarding services such as Directlab Online. First, the service's purpose must be more explicit for the participants. For them, it was unclear whether the service could help them self-manage their health:

And this is what I miss on the website; what is in it for me and my health as a patient or consumer?
[Participant 19]

Second, there was a need to understand the advantages of ordering diagnostic tests on the web (eg, more accessible than going to the general practitioner for tests). Participants wanted this information to be more evident on the website. Third, after receiving their results, the participants explained that they preferred to have more information regarding how they could remain healthy or what they could do to become healthier. It could help, according to the participants, to let them know more specifically that general practitioners make the diagnostic test packages designed for the service. All participants saw the benefit of ordering STI diagnostic test packages on the web and undergoing them at home. The current offer of diagnostic test packages does not meet the wishes of all participants. There was a need for additional tests, such as tests for food allergies, testosterone levels, fertility, or urinary infections. A participant mentioned as follows:

I want a urine tract infection test; those are relatively cheap, I think [...]. [Participant 1]

Discussion

Principal Findings

This qualitative study aimed to evaluate the facilitators of and barriers to web-based direct access to diagnostic test services from the perspective of potential users. In addition, the study tried to identify the need to use such services. The study showed that a tailored amount of information could benefit the service. Participants need to use a service such as Directlab Online to ensure that the website is available for their health. The participants needed to see the benefit of a diagnostic test package. Identified barriers and facilitators were categorized using the CFIR. The study showed that a lack of privacy, information overload, and a commercial appearance were important barriers. Facilitators included providing the right amount of information on the service and involving a health care professional in developing the service. In addition, the

study showed that a tailored amount of information could benefit the use of the service. In short, we noticed that several facilitators and barriers were influencing the reliability or accessibility of the service. For example, the commercial appearance and lack of privacy information contributed to a less reliable service for the potential users, and ordering a test on the web without a health care professional influenced the accessibility.

Directlab Online is a service for users to support themselves in self-managing their health. An important quality-enhancing element for Directlab Online was that health care professionals were actively involved in developing this service. Health care professionals significantly influenced the content and information shown on the website. However, the focus groups with potential users identified needs and wishes that did not completely align with the ideas of the general practitioner. To illustrate, health care professionals preferred other types of diagnostic test packages on the web than those that the participants preferred to use. Furthermore, the general practitioners preferred detailed information on the website, whereas this information overload was not always beneficial for the participants. A study by Talboom-Kamp et al [34] regarding a web-based results portal discussed the complex balance between the general practitioner's necessities and participants' needs for the right amount of understandable information. Presenting information requires a balance between an overload of medical information and the information users need to understand test packages and results. A potential way to solve overwhelming participants with information is to not present all the information directly in one view to the participant but by offering clickable links or short videos [34].

This study used the CFIR to identify and categorize the facilitators and barriers. In another study, Versluis et al [33] performed an inventory to determine the obstacles that must be overcome and how to optimize eHealth in primary care using this framework. They found similar results to our study; costs and privacy issues were identified as important barriers. In addition, in line with other studies, the following facilitators were identified as having "experience with eHealth" and "easiness of use" [33,35]. In comparison with other studies using the CFIR to classify facilitators and barriers, similar factors were predominantly identified. A notable factor highlighted in the study by Verweij et al [36] involving patients with cancer using a digital self-monitoring system was the necessity to elucidate the service's added value, alongside concerns regarding privacy issues. However, other factors were also mentioned, such as the connection with health care professionals, which were not identified in our study. The target population (patients with cancer) could be an important explanation for this difference. The comparison with other literature revealed that, irrespective of the type of digital service or the user population, the facilitators and barriers remained quite consistent. This study's inventory could help determine what obstacles need to be overcome and how we might optimize an application such as Directlab Online.

Depending on the participants, mainly influenced by age, some would use a web-based website to organize their health. In contrast, other participants, mainly older participants, were more

at ease with visiting the general practitioner and organizing their health directly via the general practitioner [37]. In this study, the older participants preferred to visit the general practitioner, which could lead to the cautious conclusion that web-based direct access to diagnostic services is not attractive to everyone [37]. In addition, this study showed that using a service such as Directlab Online is not only related to age but also related to the user's health problem and that the type of test package was important. Participants' needs were to feel the relevance of ordering a diagnostic test package on the web instead of visiting the general practitioner. The relevance was clear for the STI test packages but unclear for other diagnostic test packages. The study results showed that it remains important to involve all end users in the service to ensure that the service supports the needs of the target population [38]. Directlab Online was developed with general practitioners, and the elements that they found important were integrated into the service. While this study provided insight into the facilitators and barriers of potential users, it appeared that these things were not the same. It is important for a reliable and proper service that both perspectives of all stakeholders should be included in (further) development of such services. Finally, the facilitators and barriers to using a service such as Directlab Online found in this study could be used to optimize this service and other comparable services.

Strengths and Limitations

There is a lot of direct access to diagnostic testing services available, mainly when it entails STI diagnostic test packages. However, not many of them have a scientific basis or are developed by medical professionals. This is the first study that examined the facilitators of and barriers to a service that provides more diagnostic test packages than only STI tests and which is developed in cocreation with health care professionals. Another strength of the study was that the CFIR was used to analyze the facilitators and barriers mentioned in the focus groups. Embedding the facilitators and barriers in this framework made the comparison with other research easier. In addition, the domains identified by the CFIR can help to find the right implementation strategy [33,39].

This study focused on potential users because we were interested in their first impression of the service. The rationale was that, in the real world, such a service could be visited by many new

users [40]. Previous experiences have not biased the impression of potential users. However, this could also be a limitation because participants who did use Directlab Online before could have another opinion regarding the service. This made the results less generalizable. Another limitation is that the mean age of participants was relatively low, making it more difficult to generalize the results to the general Dutch population. However, all participants, independent of age, mentioned the benefit of ordering STI tests on the web. The service showed benefits for participants who were ashamed to visit a general practitioner for a diagnostic package and for participants who wished to order tests in an accessible, nonbinding manner.

Future Research

Directlab Online is a service developed for a wide range of users. However, this study showed that it is important to include end users to ensure that the service aligns with the population's needs. Cocreation with end users and medical professionals could be a solution to solve disbalances in wishes and needs between them and to improve an eHealth application [38]. For future research, organizing cocreation sessions and analyzing their results could be beneficial to improve the service. Finally, in future research, information about the influence of the diagnostic test's result on the user's lifestyle could be analyzed. Namely, this could result in a preventive role for a service such as Directlab Online to improve the health of a population.

Conclusions

According to participants, information provision, comprehension, and the overall appearance of the website were the most important elements that influenced the use and uptake of a direct-to-consumer website for diagnostic test packages. Barriers, such as the commercial appearance and lack of privacy information, negatively influenced reliability and accessibility. The study showed that it is important to include relevant stakeholders in creating an eHealth intervention because there was a disbalance between the users' needs and what the involved general practitioners considered necessary. Future research could take a quantitative approach to further identify the needs regarding test packages and to identify the demographics of users and the influence of test results on the behavior of users. Directlab Online offers opportunities for more web-based self-management of health.

Acknowledgments

The authors would like to thank all participants for their input and contributions during the focus groups. Funding for this research was provided by Unilabs.

Conflicts of Interest

During the research, KS and EPWATK were employees at Unilabs.

Abstract

Background: The emergence of smartphones has sparked a transformation across multiple fields, with health care being one of the most notable due to the advent of mobile health (mHealth) apps. As mHealth apps have gained popularity, there is a need to understand their energy consumption patterns as an integral part of the evolving landscape of health care technologies.

Objective: This study aims to identify the key contributors to elevated energy consumption in mHealth apps and suggest methods for their optimization, addressing a significant void in our comprehension of the energy dynamics at play within mHealth apps.

Methods: Through quantitative comparative analysis of 10 prominent mHealth apps available on Android platforms within the United States, this study examined factors contributing to high energy consumption. The analysis included descriptive statistics, comparative analysis using ANOVA, and regression analysis to examine how certain factors impact energy use and consumption.

Results: Observed energy use variances in mHealth apps stemmed from user interactions, features, and underlying technology. Descriptive analysis revealed variability in app energy consumption (150-310 milliwatt-hours), highlighting the influence of user interaction and app complexity. ANOVA verified these findings, indicating the critical role of engagement and functionality. Regression modeling (energy consumption = $\beta + \beta_1 \times \text{notification frequency} + \beta_2 \times \text{GPS use} + \beta_3 \times \text{app complexity} + \epsilon$), with statistically significant *P* values (notification frequency with a *P* value of .01, GPS use with a *P* value of .05, and app complexity with a *P* value of .03), further quantified these bases' effects on energy use.

Conclusions: The observed differences in the energy consumption of dietary apps reaffirm the need for a multidisciplinary approach to bring together app developers, end users, and health care experts to foster improved energy conservation practice while achieving a balance between sustainable practice and user experience. More research is needed to better understand how to scale-up consumer engagement to achieve sustainable development goal 12 on responsible consumption and production.

KEYWORDS

mobile health; energy consumption in health care smartphone apps; dietary tracking apps; optimization and sustainability in mobile health; user engagement and experience; Android apps performance; digital health technologies; app; apps; applications; digital health; energy; consumption; sustainable; sustainability; environment; environmental; use; smartphone; smartphones; electricity; electrical; mobile phone

Introduction

Background

Nations worldwide and researchers from various disciplines are increasingly focusing on sustainable and energy-efficient techniques for energy production. The works of Bhaskar et al [1], Muthanna et al [2], and Ashfaq et al [3] exemplified the innovative approaches being developed in this domain, highlighting the significance of renewable energy applications, unmanned aerial vehicle path scheduling in the Internet of Things, and secure energy trading with machine learning and blockchain technology, respectively. In today's health care scene, smartphones stand as crucial companions, seamlessly connecting the realms of technology and wellness promotion. The surge in popularity of mobile health (mHealth) apps reflects a broader movement toward adopting energy-smart habits in all facets of mobile computing. This trend underscores the

pivotal role of crafting sustainable software to lessen our ecological footprint, a goal echoed by the strides made in green computing and energy-saving innovations [4-6]. These apps mark a transformative step toward digital health, empowering people to proactively manage their health journeys. The growing focus on energy efficiency and the adoption of eco-friendly use habits emphasize the significance of these apps. Research by Choi et al [7] and Pop et al [8] shed light on the essential role that energy-efficient software plays in prolonging the lifespan of devices and mitigating environmental impacts, heralding a significant shift in digital health practices. The fusion of wearable technologies with these apps further highlights the importance of designing with energy mindfulness at the forefront, ensuring that our pursuit of health does not lead to unsustainable energy use. Table 1 illustrates the relationship between the popularity of mHealth apps and their user review scores. Apps with the highest user satisfaction were selected in this study to be assessed for energy efficiency.

Table 1. Correlation between app popularity, where popularity is determined by the number of downloads.

App name	Downloads (in millions)	User review (out of 5)
Ate Food Journal	2	4.4
Calorie Counter	5	4.2
Lifesum	10	4.6
My Plate	8	4.4
MyFitnessPal	45	4.4
Noom	15	4.2
Ovia	3	4.0
PlateJoy	1	4.6
Spokin	4	4.2
Yummly	20	4.6

Problem Statement

Even though mHealth and nutrition apps have become increasingly popular, there is a dearth of research on how much energy they are consumed on Android devices and practical guidance on what can users do about it. Almasri and Gouveia [9] studied the gap in sustainable practice using Android apps and highlighted the need given their popularity and potential for energy-saving practice and given the global priority and commitment toward creating sustainable smartphones to achieve sustainable development goal 12.

Objective

The objective of this study is to assess the energy consumption of popular mHealth and nutrition apps and identify key areas where improvements can be made.

Literature Review

mHealth Apps and Energy Consumption

The widespread use of mHealth apps in our everyday routines has underscored the need to better understand energy consumption. Awais et al [10] examined the direct link between the complexity of these apps and their energy demands. Their

findings indicate that apps with advanced features, such as real-time monitoring and personalized recommendations, can consume up to 30% more energy compared with simpler apps. Additionally, Sahar et al [11] provided an in-depth analysis of how unnoticed background activities, such as continuous data syncing and location tracking, play a significant role in draining smartphone batteries. Their study revealed that background activities could account for up to 40% of an app's total energy consumption, underscoring the importance of both developers and users to understand the app architecture and appreciate the influence it plays on energy use.

User Behavior and Energy Efficiency

Understanding energy efficiency warrants an understanding of user behaviors around app use. Personal relationships, belief in one's abilities as presented by Rahman et al [12] (self-efficacy), and the collective confidence in our shared power to effect change are key to embracing and consistently using mHealth technologies [13-15]. How individuals use mHealth apps has a significant impact on energy consumption patterns. Al Nidawi et al [16] showed that regular app use, including entering data and syncing, significantly increases energy consumption. Acer et al [17] highlighted how notifications, a common feature in mHealth apps, significantly boost energy use.

Strategies for Energy Optimization

Isuwa et al [18] showed that using adaptive brightness settings and energy-saving modes can extend the battery life of mobile devices by up to 20%. Furthermore, Benkhelifa et al [19] explored the potential of leveraging software-defined networking for energy optimization in mobile cloud computing, resulting in a decrease of up to 25% in energy use.

Technological Advancements and Energy Consumption

Emerging technologies play a nuanced role in the story of mHealth apps' energy consumption, presenting a mix of hurdles and breakthroughs. On the one hand, advancements in app development frameworks, as outlined by Kelényi et al [20], opened fresh opportunities for energy efficiency. On the other hand, the growing complexity of those apps, as pointed out by Porter [21], introduces significant obstacles to keeping energy use in check. The potential of artificial intelligence (AI) in optimizing energy consumption for sustainability has been highlighted in a recent article by Ericsson [22]. Their research indicates that AI features, while enhancing app functionality, can lead to a 25% increase in energy consumption if not optimized properly.

Cross-Platform Analysis of Energy Consumption

Khan et al [23] conducted a comparative analysis of power consumption in mobile devices to inform the development of energy-efficient mobile apps. Their study introduced a methodology for assessing and evaluating power use, providing valuable insights and guidelines for developers aiming to create more sustainable mobile apps. Ciman and Gaggi [24] analyzed smartphone energy consumption using different sensors, including either only app, or by using GPS, accelerometer, compass, camera, or microphone. They found that cross-platform frameworks significantly increase energy consumption compared with native apps. They suggested that power consumption should be considered when choosing between native implementation and using a framework or between different frameworks for mobile app development.

Energy Consumption Metrics and Measurement Techniques

Ergasheva et al [25] explored metrics of energy consumption to evaluate the energy efficiency of apps. They introduced metrics, such as energy-per-function, which quantifies the energy consumed for each app function, and energy-per-user interaction, which measures the energy used per user interaction, providing a more granular understanding of app energy consumption. Pathak et al [26] used advanced methods for tracking app energy consumption in real time, offering insights into the variables that drive energy use. They developed a real-time energy monitoring framework that captures detailed energy use data at the component level, enabling developers to identify energy hotspots within the app. This approach allows for more targeted energy optimization strategies, focusing on the most energy-intensive components and interactions.

Methods

Ethical Considerations

The approach we took was a quantitative analysis study measuring energy use in popular US-based health and nutrition apps. This study did not require ethics board approval as it involved the quantitative analysis of publicly available data related to the energy consumption of mHealth apps. No human subjects were directly involved, and no personal or sensitive data were collected during the study. This approach aligns with the institutional guidelines and adheres to regional and local policies regarding research involving nonhuman subjects, ensuring that all analyses remain within ethical boundaries as per the existing frameworks.

Selection of mHealth Apps

The selection of mHealth apps was based on Almasri and Gouveia's [27] criteria and insights from Kelényi et al [20].

Popularity and User Base

Apps with a vast number of downloads and positive feedback from users were selected.

Functional Complexity

Apps featuring a spectrum of functionalities were selected, from the simplest to the most complex, aiming to understand how different features influence energy use following the concept by Isuwa et al [18].

Energy Consumption Potential

Apps known or suspected to be high on energy use, including features such as continuous data syncing or GPS tracking, based on preliminary evaluations and what developers have documented (Benkhelifa et al [19]), were selected.

Measurement of Energy Consumption

Overview

Ergasheva et al [25] and Pathak et al [26] both introduced metrics such as energy-per-function and energy-per-interaction, offering detailed insights into app energy efficiency by measuring energy use for specific functions and user interactions. The process unfolded in 3 key steps as given below.

Baseline Measurement

We first set a baseline for energy consumption for each app when it was not in use, providing a benchmark for comparing energy use during more active scenarios.

Feature-Specific Scenarios

We then measured energy use in scenarios that trigger specific features of the apps such as logging meals or syncing with wearable technology. This step was crucial for pinpointing and measuring the energy footprint of distinct functionalities within the apps. The flowchart depicted in Figure 1 outlines the sequential steps taken from the collection of energy consumption data to the identification of high-impact features and a review of the data collection methodology. Figure 2 exemplifies a snapshot of the Trepr Profiler (Qualcomm), a tool used for real-time performance monitoring of the apps under study. The

graphs depict central processing unit frequency and graphics processing unit load over a session, demonstrating how various app features and user interactions can influence energy

consumption. Such detailed monitoring is indispensable for identifying high-energy-demand periods, thereby informing our strategies for app optimization.

Figure 1. Flowchart of the energy consumption analysis methodology.

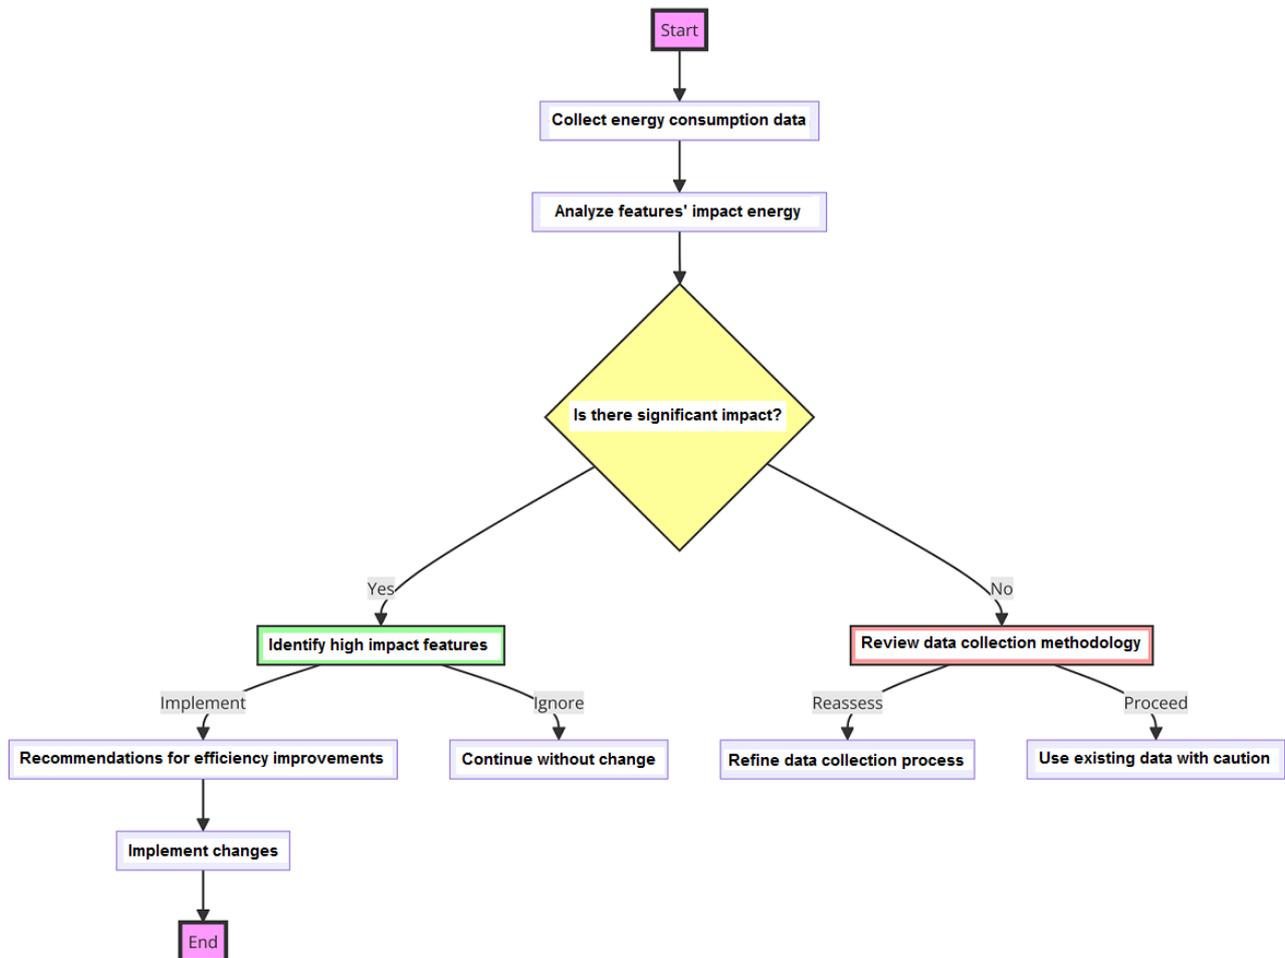

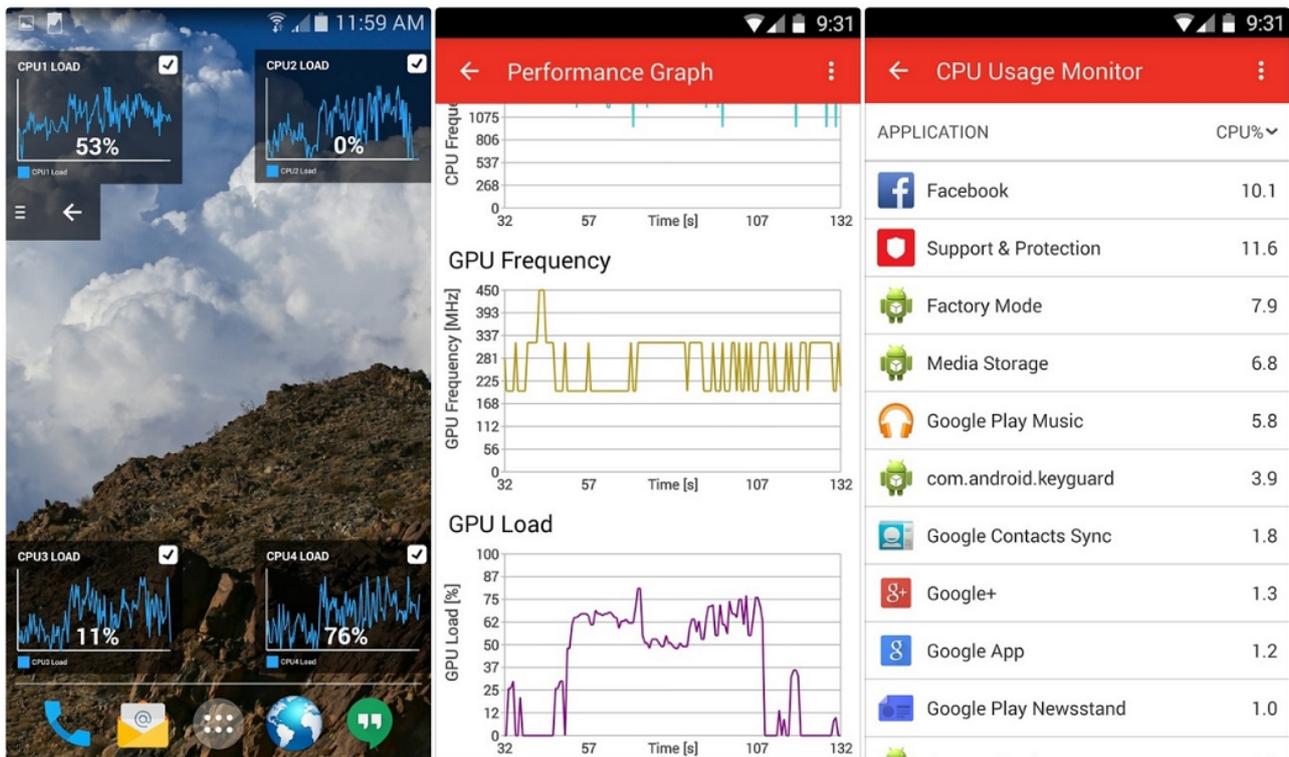

Figure 2. Example of real-time performance monitoring using Trepro Profiler. CPU: central processing unit; GPU: graphics processing unit.

User Interaction Patterns

Finally, by simulating a range of real-life user interactions, from minimal to extensive use, we were able to depict how different use patterns impact the app's energy consumption.

Data Analysis

Overview

This study examined data on energy consumption and the potential of behavior change interventions to cut energy use, drawing inspiration from Internet of Things-enabled tactics designed to boost energy efficiency consistent with recent findings that underscore the effectiveness of behavioral strategies in curbing energy use across different contexts [28,29]. We conducted our statistical analysis using MATLAB software (MathWorks), and our analysis approach included descriptive statistics, comparative analysis, and regression analysis.

Descriptive Statistics

Energy consumption for each app across various scenarios was quantified in milliwatt-hour (mWh) using real-time energy monitoring tools. This analysis provided insights into energy consumption patterns and fluctuations.

Comparative Analysis

ANOVAs were used to compare energy data across different apps and scenarios, identifying significant differences attributable to app features or user interactions.

Regression Analysis

Building regression models enabled us to measure how certain factors, such as how often notifications pop up or GPS tracking is used, impact energy use. This analysis helps understand the layers of what drives energy consumption in mHealth apps.

Results

Energy Consumption Patterns

Table 2 maps out a comparative analysis of the 10 popular mHealth apps. It elucidates each app's market presence, user experience, and estimated energy consumption, laying a foundation for understanding the interplay between app features and energy efficiency. We found a notable range in how much energy these apps use, with some consuming up to 3 times more energy than their counterparts in similar conditions. This disparity stemmed from various factors, such as the complexity of the app's features, how efficiently it runs in the background, and how often and in what ways users interact with the app. In our analysis, we conducted a descriptive statistical examination to highlight the energy consumption patterns of the selected apps. Our findings reveal a variance in average energy use, with apps consuming between 150 mWh and 310 mWh under typical use scenarios. The SD in energy consumption underscores the variability, ranging from 15 mWh to 31 mWh, which is indicative of how user interactions and background processing contribute to energy expenditure. The minimum and maximum energy use values further allocate the range of energy efficiency among these apps, from 135 mWh to 341 mWh, reflecting the impact of app features and optimization on battery life.

Table 2. Detailed comparative analysis of top mobile health apps.

App name	Popularity (downloads)	User review (out of 5)	Average energy use (CPU ^a)	Feature complexity	Integration with wearables	Notification frequency	Support for multiple diets
Yummly	>5M ^b	4.3	Low	Medium	No	Low	Yes
My Plate Calorie Counter	>5M	4	Medium	Medium	No	Medium	Yes
MyFitnessPal	>50M	4.6	High	High	Yes	Medium	No
Spokin	>50K ^c	3.9	Low	Low	No	Low	No
PlateJoy	>500K	4.2	Low	Low	No	Low	Yes
Ovia	>1M	4.1	Medium	Low	No	Medium	No
Lifesum	>10M	4.5	Medium	High	Yes	High	Yes
Noom	>10M	4.4	High	High	Yes	High	No
Calorie Counter	>10M	4.7	High	High	Yes	High	Yes
Ate Food Journal	>100K	4.2	Low	Low	No	Low	No

^aCPU: central processing unit.

^bM: million or more.

^cK: hundred thousand or more.

Table 3 illustrates the comparative energy consumption patterns of 10 popular mHealth apps under various use scenarios. This visualization underscores the substantial disparities in energy use, driven by factors such as app feature complexity, background processing efficiency, and user interaction methods. It highlights the critical need for targeted energy optimization strategies to mitigate the significant energy demands of

feature-rich apps. The apps that demanded the most energy were those packed with sophisticated features such as live syncing with wearable tech and ongoing background updates. On the flip side, the more straightforward apps that relied on manual inputs and had fewer background processes were much kinder to battery life.

Table 3. Comparative energy consumption patterns of 10 popular mobile health apps.

App name	Use scenario and energy consumption (milliwatt-hour)		
	Baseline	GPS use	High use
Ovia	1	4	22
Calorie Counter	3	5	18
My Plate Calorie Counter	5	8	16
Yummly	5	10	20
Lifesum	4	9	17
Noom	3	7	15
My Fitness Pal	2	5	23
Ate Food Journal	1	6	13
PlateJoy	2	8	11
Spokin	3	6	10

Additionally, our research highlights how the use of notifications and alerts plays a significant role in energy consumption. Apps that leaned heavily on notifications to keep users engaged were more likely to use more energy, primarily due to the frequent lighting up of screens and the data exchanged over network services. It was found that on average, using an mHealth app for an hour each day could drain approximately 15% to 20% of a smartphone's battery life, depending on the app's complexity and background activity. This observation points to the critical need for fine-tuning notification strategies, and finding a sweet

spot that maintains user interest without unnecessarily draining the battery.

Impact of App Features on Energy Use

Our findings suggest that certain app functions are linked to the amount of energy they use. GPS tracking—used for recording outdoor meals or activities—along with frequent data synchronization and sophisticated graphical interfaces, emerged as the main factors driving up energy consumption. GPS tracking was particularly notable for its high energy use, relying heavily on constant location services and data exchange. The

research also brings to light how user behavior affects energy use, specifically how long and how often people use the apps. Apps designed to keep users engaged for longer periods, whether through fun gamification features or detailed dietary logging, were seen to consume more energy overall. This finding points to the need for thoughtfully crafting user engagement methods to avoid unnecessary energy consumption. Our findings are consistent with existing research. Choi et al [7] reaffirmed the considerable effect of screen brightness and network use on energy consumption. Our findings highlight the intense energy demands of certain features in mHealth apps, such as GPS tracking and frequent synchronization, areas not deeply researched by previous studies. While earlier research underscored the significance of hardware and system optimizations for lowering energy use, our research emphasizes the paramount role of optimizations at the app level where user-centered design and behavior will be critical. By concentrating on the architecture and capabilities of mHealth apps, developers have a profound opportunity to enhance the energy efficiency of their creations, as well as by involving both users and practitioners alike who can guide what features remain paramount for impactful and sustainable technology practice.

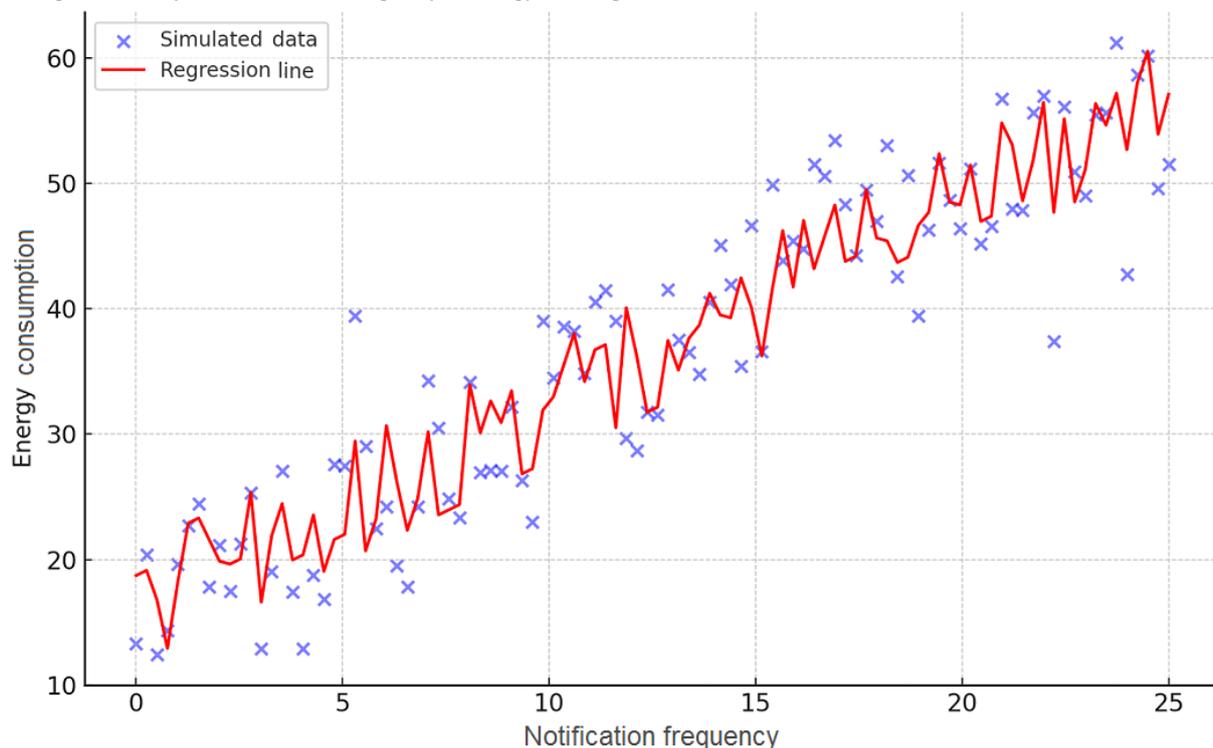

Insights From User Engagement and Energy Efficiency

Our regression analysis showed the relationship between user engagement, app features, and energy consumption. The analysis featured a key insight: while increased user engagement typically leads to higher energy consumption, strategic app design can mitigate this effect. Specifically, our findings highlight how certain app features, such as notification frequency, GPS use, and complexity level, influence the energy efficiency of mHealth apps. Assuming a linear relationship between these factors and energy consumption, our regression model is represented by the equation:

$$\text{Energy consumption} = \beta_0 + \beta_1 \times \text{notification frequency} + \beta_2 \times \text{GPS use} + \beta_3 \times \text{app complexity} + \varepsilon$$

where β_0 is the intercept, indicating the baseline energy consumption in the absence of the examined features. β_1 , β_2 , and β_3 are coefficients quantifying the impact of notification frequency, GPS use, and app complexity on energy consumption, respectively, and ε represents the error term, accounting for variability not explained by the model. Figure 3 clarifies this relationship, presenting a regression analysis that demonstrates the impact of notification frequency on energy consumption.

Figure 3. Regression analysis of notification frequency on energy consumption.

Our simulated analysis yielded the following equation:

$$\text{Energy consumption} = 9.55 + 1.62 \times \text{notification frequency}$$

The coefficients derived from our analysis which provide insights into the relative influence of each feature on energy consumption start with the intercept ($\beta_0=9.55$) representing the baseline energy consumption. Then, each unit increase in notification frequency ($\beta_1=1.62$) corresponds to a 1.62-unit

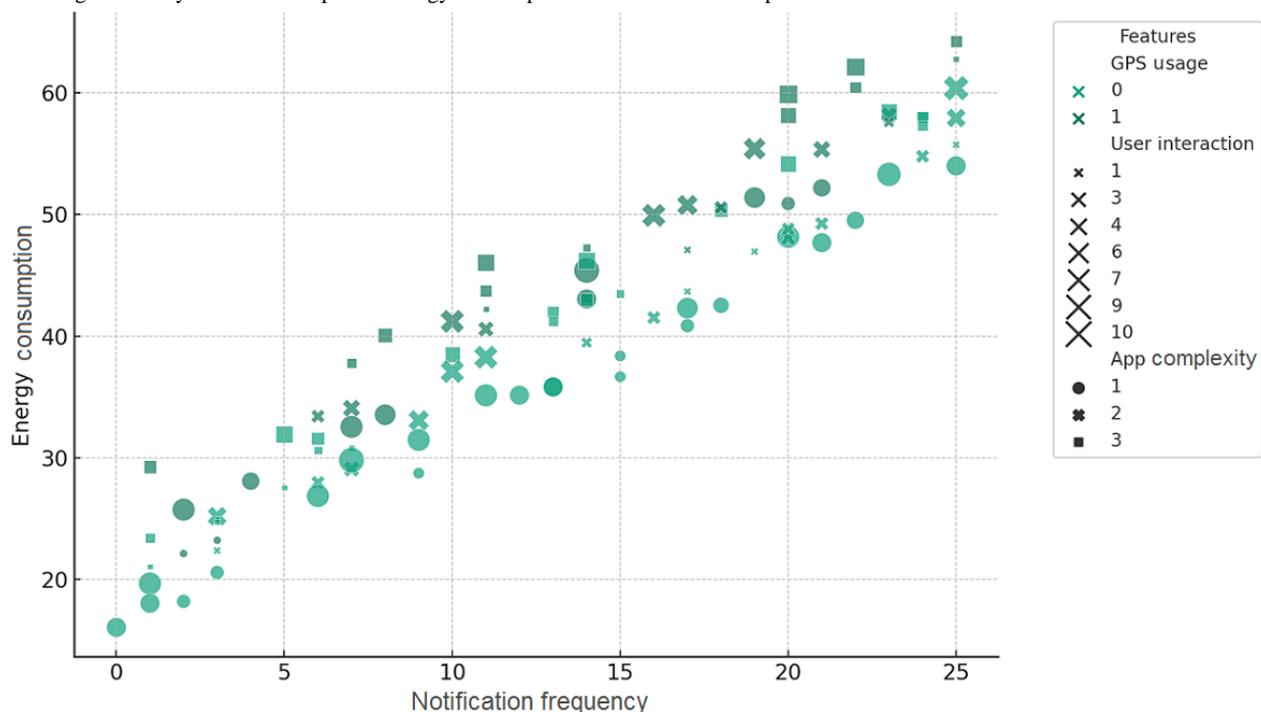

increase in energy consumption, emphasizing its significant role. Besides, GPS use ($\beta_2=5.00$) suggests that activating GPS functionality contributes an additional 5 units to energy consumption, highlighting the substantial energy demand of location services. Finally, the app complexity ($\beta_3=3.00$) shows that higher complexity levels increase energy consumption by 3 units, indicating the impact of advanced features and functionalities. The statistical significance of each coefficient

was evaluated through P values, confirming the strength of our findings. The P value for notification frequency is .01, indicating a highly significant relationship with energy consumption. The P value for GPS use is .05, suggesting an impact on energy consumption at the 5% level. The P value for app complexity is .03, demonstrating its significant effect on energy consumption.

For example, apps that adopt flexible synchronization schedules and energy-conscious notification strategies are more likely to succeed in keeping users engaged without a corresponding spike in energy use. This finding is also critical for developers aiming to refine the user experience while staying true to the principles of energy efficiency. Furthermore, we include an “integrated

analysis approach” to examine the compounded effects of app features on energy consumption. This analysis builds upon our original regression model by openly considering the interactions between different app functionalities and their collective impact on energy use. To convey this concept, in Figure 4, we present an integrated analysis, contrasting the specific energy demands of app features against user interaction patterns, highlighting the potential for energy optimization. This visualization highlights the synergy between GPS use, notification frequency, app complexity, and their aggregate effect on energy use. Through this analysis, we aim to guide developers in identifying which combinations of features escalate energy demand and how thoughtful integration can mitigate such effects, fostering more energy-efficient app designs.

Figure 4. Integrated analysis of feature-specific energy consumption and user interaction patterns.

Discussion

Principal Findings

Finding the right equilibrium among app functionality, user satisfaction, and energy efficiency is critical for sustainable practice. Our research analysis enriches our understanding of the nuanced relationships within mHealth app use and highlights the broader consequences and opportunities for innovation in the digital health domain, underscoring the importance of a balanced approach to app development that honors both human and environmental considerations.

The diverse energy use among various mHealth apps, especially those dedicated to diet and meal tracking, reveals how an app is built and how users interact with it. Features, such as GPS tracking and constant data updates, significantly increase energy consumption, emphasizing the urgency for app creators to weave energy efficiency into the fabric of app development. User behaviors are also critical—including how often users interact with the app, respond to notifications, or use specific features.

Behavior change modalities also need to be introduced to address user habits and smarter app configurations.

Our study findings bring forth the question of the need to identify modalities or to balance between incorporating features that boost user engagement and satisfaction and the essential task of reducing energy consumption. Such modalities are important to prolong battery life and lessen the ecological impact of mHealth app use.

Implications for Developers and Users

This study highlights for developers the crucial role of weaving energy efficiency into every stage of the app development cycle. This means going beyond just streamlining code and choosing low-power software development code libraries. It also means crafting app features and user interactions in ways that naturally lead to less energy use. Developers are urged to embrace smart algorithms that dynamically tweak app functions according to real-time energy use and battery status, ensuring the apps are as energy-efficient as possible without sacrificing the quality of the user experience.

On the user side, the research points out how a little awareness about how apps are set up and used can go a long way in reducing energy consumption. Users have the power to drive energy savings by tweaking their app settings, such as reducing how often apps search for new content or turning off unnecessary background activities. It is paramount to use apps that are designed from the ground up to be energy conscious with efficient battery life and for the purpose of encouraging a greener approach to leveraging digital health tools.

Broader Implications for Digital Health Technology

This research adds a valuable perspective to the conversation about making digital health technologies more sustainable, emphasizing the collective responsibility of consumption and production, including developers, users, health care professionals, and stakeholders, to put energy efficiency at the forefront. As mHealth apps play a more prominent role in enhancing health and nutrition outcomes and managing diseases, understanding and optimizing their energy use becomes essential for ensuring digital solutions can grow sustainably, and consumers and producers are both responsible for sustainable practice as well.

Moreover, the insights gathered here highlight the exciting possibilities of interdisciplinary studies that merge knowledge

from software engineering, behavioral science, and environmental sustainability. This approach could lead to the creation of comprehensive guidelines and best practices for crafting mHealth apps that are not only effective but also energy efficient. By working together across fields, there is a tremendous opportunity to drive forward app innovations that serve the dual purpose of advancing health care while respecting our planet.

Conclusion

The mHealth apps within the mHealth sector consume energy, especially when app functionalities are governed by how we interact with these apps. It is a challenge for developers and users to find the right mix of features that drive engagement and health and nutrition benefits while also becoming cognizant of reducing energy use.

For developers, this means weaving energy efficiency more deeply into the fabric of app creation, from concept through to coding. This can be done by embracing flexible technologies and applying forward-thinking design philosophies that marry efficacy with energy savings. For users, it is about becoming more aware of how the choices they make in app settings and their daily use can affect energy consumption, moving toward a more conscious and deliberate use of these digital tools.

Abstract

Background: Early users found Engagement and Visualization to Improve Symptoms in Oncology Care (ENVISION), a web-based application designed to improve home management of hospice patients' symptoms and support patients' and family caregivers' well-being, to be generally useful and easy to use. However, they also raised concerns about potential challenges users with limited technological proficiency might experience.

Objective: We sought to concurrently accomplish two interrelated study aims: (1) to develop a conceptual framework of digital inclusivity for health information systems and (2) to apply the framework in evaluating the digital inclusivity of the ENVISION application.

Methods: We engaged ENVISION users (N=34) in a qualitative study in which data were collected via direct observation, think-aloud techniques, and responses to open-ended queries. Data were analyzed via theory elaboration and basic qualitative description.

Results: Accessibility, relevance, and impact were identified as 3 essential considerations in evaluating a health system's digital inclusivity. Study findings generally supported ENVISION's digital inclusivity, particularly concerning its perceived relevance to the work of family caregivers and hospice clinicians and its potentially positive impact on symptom management and quality of life. Limitations to ENVISION's digital inclusivity centered around issues of accessibility, particularly operability among individuals with limited technological knowledge and skills.

Conclusions: The Accessibility, Relevance, and Impact conceptual framework of digital inclusivity for health information systems can help identify opportunities to strengthen the digital inclusivity of tools, such as ENVISION, intended for use by a broad and diverse range of users.

Introduction

Background

Hospice is a health care delivery model and a philosophy of care focused on reducing pain and promoting quality of life among patients who are terminally ill and their families [1]. In the United States, hospice care is most often provided in patients' homes [2]. While more intensive staffing is available during acute medical crises, routine home hospice care consists of only periodic visits from nurses, nursing aides, social workers, chaplains, and others operating under the direction of a hospice physician [3]. A total of 3- to 4-hour-long weekly home visits may be typical for an established patient. Thus, responsibility for the overwhelming majority of home hospice care falls to patients' family members and friends (referred to as *family caregivers*), who are typically unpaid and often lack formal health care training [4-6].

Hospice family caregivers are commonly tasked with in-home management of patients' symptoms, including pain, shortness of breath, anxiety, and fatigue. Recent population-based research indicates that >78% of family caregivers who assist with symptom management in the last month of a patient's life report difficulty doing so [7]. These findings are consistent with those of numerous other studies highlighting the reality that symptom management challenges are a significant source of stress for many hospice family caregivers [8-11]. These challenges,

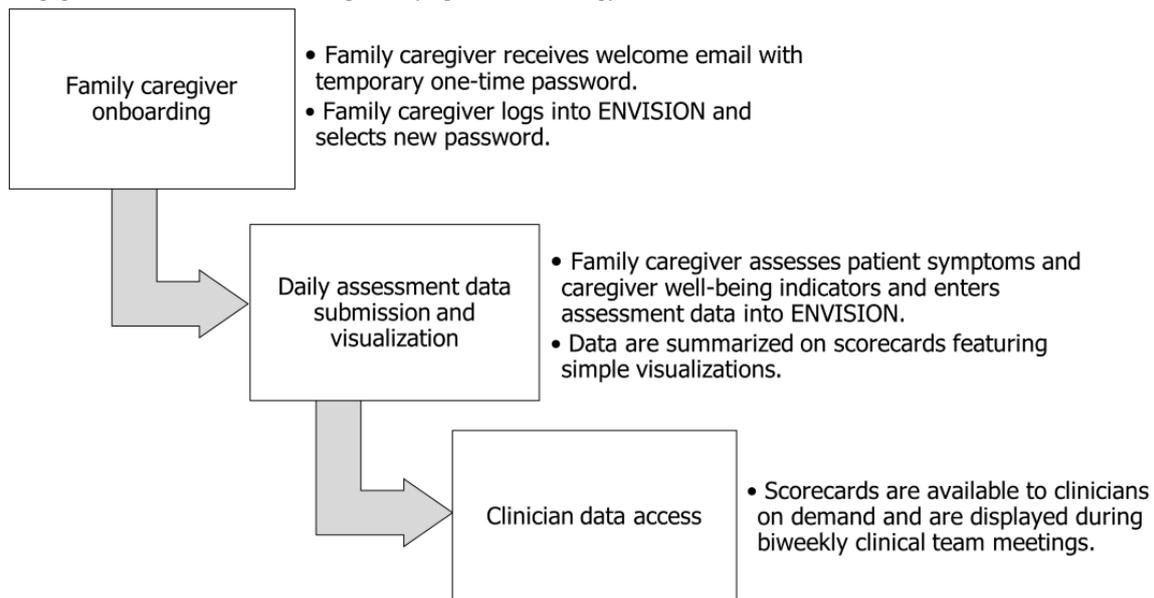

coupled with lack of a standardized processes for real-time symptom reporting and monitoring in home hospice care, commonly result in suboptimal home management of patients' symptoms [12].

Engagement and Visualization to Improve Symptoms in Oncology Care

Engagement and Visualization to Improve Symptoms in Oncology Care (ENVISION) is a secure, web-based application designed to improve home management of hospice patients' symptoms and support patients' and family caregivers' well-being by improving the exchange of information between family caregivers and hospice clinicians [13]. It uses daily symptom and well-being data entered on the internet by family caregivers to create simple visualizations summarized in a patient and caregiver scorecard (Figure 1), allowing hospice clinicians to quickly identify areas of concern. These scorecards are displayed during biweekly hospice interdisciplinary team meetings and are available on demand to hospice clinicians outside of regularly scheduled meetings. A workflow diagram illustrating ENVISION's use is provided in Figure 2. Optional views, including longitudinal graphs of individual or combined symptoms, are also available to clinician users. Although ENVISION was initially developed specifically for advanced cancer care, its use has been expanded to include care for hospice-eligible individuals experiencing any life-limiting illness.

Figure 1. Mobile version of the application Engagement and Visualization to Improve Symptoms in Oncology Care (ENVISION), showing a sample patient and caregiver scorecard.

Patient	
Pain	None
Tiredness	Moderate
Drowsiness	Mild
Nausea	Mild
Lack of Appetite	None
Shortness of Breath	None
Depression	Mild
Anxiety	Moderate
Insomnia	None
Problems with Wellbeing	Mild
Caregiver	
Depression	None
Anxiety	Mild
Insomnia	None
Problems with Wellbeing	None

Figure 2. Engagement and Visualization to Improve Symptoms in Oncology Care (ENVISION) workflow.

Digital Inclusivity

ENVISION was created over several years with significant involvement of hospice family caregivers, clinicians, and administrators. While early research broadly supported ENVISION's usefulness and ease of use, it also raised concerns about potential barriers to use that might be experienced by family caregivers with limited technological skills or resources [13]. These concerns echo those voiced as part of an ongoing discussion in health care regarding digital inclusivity [14], broadly defined as "the ability of individuals and groups to access and use information and communication technologies [15]."

Digital inclusivity, particularly as it pertains to digital health technologies, is a salient concern on multiple social levels [16]. Individually, users vary with regard to their level of digital literacy and their ability to personally take advantage of available technological resources [17]. For example, an individual may struggle to discern differences between trustworthy and untrustworthy sources of health information, may have functional limitations (for example, vision or hearing impairment), or may be unable to afford home internet access. Similarly, families and other social groups differ in their degree of collective technological resources, a reality evident when less technologically equipped individuals benefit from the digital knowledge and skills of family members and friends. A family member assisting a patient in accessing their health care portal would be one example [18]. Communities can also be considered more or less digitally inclusive based on the adequacy of the infrastructure (such as home broadband connectivity or public Wi-Fi networks) available to meet residents' technological needs [15].

Study Aims

Our initial aim in conducting the study described herein was to better understand early ENVISION users' concerns regarding the application's digital inclusivity. However, in planning our study, we struggled to identify an existing conceptual framework

to guide our research, given our plan to explore digital inclusivity as a quality of an individual application (rather than, for example, a community). Thus, we added a second study aim: to engage ENVISION users in a process of theory elaboration, resulting in a conceptual framework of digital inclusivity for health information systems. In this way, we sought to inform future ENVISION enhancements while contributing to the broader emerging science of digital inclusivity in health care. Thus, our finalized study aims were as follows: (1) to develop a conceptual framework of digital inclusivity for health information systems and (2) to apply the framework in evaluating the digital inclusivity of the ENVISION application.

Methods

Setting, Participants, and Recruitment

As part of ENVISION's ongoing, iterative, user-centered design [19], we recruited hospice family caregivers and clinicians (nurses, physicians, social workers, and chaplains) to participate in a qualitative research study [20]. We partnered with the university's Institute of Clinical and Translational Sciences' Recruitment Enhancement Core to recruit hospice family caregivers via flyers, targeted email blasts, social media posts, and listing of the study on a public-facing website. Family caregivers were eligible for inclusion if they were aged ≥ 18 , able to speak and read English, and current or former (within the prior year) family caregivers of a patient receiving services from a Medicare-certified US hospice agency. We recruited hospice clinicians via social media posts and email blasts from professional hospice organizations, targeted emails to prior research partners, and presentation of the study opportunity at scheduled meetings of hospice agencies with which we had established partnerships. Hospice clinicians were eligible for study inclusion if they were aged ≥ 18 , able to speak and read English, and currently employed or affiliated with a Medicare-certified US hospice agency.

Data Collection

All consenting participants met online individually with a research team member for approximately 30 to 45 minutes via a university-managed, Health Insurance Portability and Accountability Act-compliant Zoom (Zoom Video Communications) account [21]. At the start of each call, the researcher provided assistance in using Zoom's screen share feature, which the researcher later used to observe the participants completing a series of structured tasks in the ENVISION application. In addition, the researcher provided instruction in the think-aloud technique [22,23], explaining that the participants would be asked to verbalize their thinking as they navigated the application and completed specific tasks. The researcher also informed the participants that they would be asked to answer a series of open-ended questions about their perceptions of the application and its potential use in hospice care. Finally, the researcher confirmed the participants' understanding and began recording the session with the participants' knowledge and permission.

Structured Tasks

During the recorded Zoom session, family caregivers were sent a personalized email with a brief welcome message, a link to the ENVISION website, and a temporary one-time password (an automatically generated alphanumeric string of characters). As their first observed task, family caregivers were asked to navigate to the ENVISION website, enter the site using their email address and one-time password, and choose a new password. They were then asked to recall a typical caregiving day and enter corresponding symptom and well-being data for the patient and themselves into the ENVISION application. Next, they were asked to navigate to the patient and caregiver scorecard, which summarized the data they had just entered, and answer questions that required them to interpret simple data visualizations (labeled rectangles filled with different shades of orange ranging from none or white to dark or bright orange to reflect greater symptom intensity). Finally, they were asked to exit the application. After completing these structured tasks, they were asked a series of open-ended questions, including, for example, "What made it easy to use ENVISION?" "What made it challenging?" and "Which symptom(s) would be most important to communicate to the hospice team? Why?"

Hospice clinicians were also observed navigating to the ENVISION website, entering the site using their email address and temporary password, and selecting a new password. Because the researcher had entered them into the system as a clinician when generating their welcome email, clinicians were taken to a screen that included a list of fictitious patients' names and medical record numbers upon logging into the system. When they reached this screen, clinicians were asked to navigate to a specific patient's information (this required them to locate and click on the patient's name, but they were not given these specific instructions). Clicking on the patient's name took them to a screen that included a daily patient and caregiver scorecard that featured visualizations similar to those shown to family caregivers. This page also included a simple line graph that allowed clinician users to view the intensity of one or more symptoms or well-being indicators over time by clicking a box

next to the appropriate symptoms or indicators (users were not provided with these specific instructions). While on this page, clinicians were asked questions that required them to interpret the colored boxes on the patient and caregiver scorecard; select and deselect specific symptoms on the longitudinal graph; and interpret trends, including symptom co-occurrence over time, shown via the graphed data. Finally, they were asked to exit the system and answer a series of open-ended questions, including, for example, "How, if at all, would having [information provided via ENVISION] affect how you do your job?" and "Describe how you would access ENVISION. For example, would you use a desktop computer, tablet, or smartphone? Would you use the application from the hospice agency office, patients' homes, or elsewhere?"

Data Preparation

In preparation for data analysis, we contracted with a third-party service to transcribe audio files of participants' recorded Zoom sessions verbatim. We then imported the resulting transcripts into NVivo qualitative analysis software (Lumivero). Complete copies of all audio and video files of participants' recorded Zoom sessions and corresponding field notes were stored in a secure Box folder made available to all institutional review board-approved research team members throughout data analysis.

Data Analysis

Our analysis was broadly informed by the work of organizational management researchers Fisher and Aguinis [24], who described a process they referred to as theory elaboration, defined as "the process of conceptualizing and executing empirical research using preexisting conceptual ideas or a preliminary model as a basis for developing new theoretical insights by contrasting, specifying, or structuring theoretical constructs and relations to account for and explain empirical observations." As part of this process, we engaged in vertical contrasting, which entailed adapting an existing conceptual framework (described in detail in the next paragraph) developed for one level of analysis to examine a phenomenon at another level. In doing so, we sought to determine which aspects of the framework functioned similarly on both levels of analysis and which functioned differently. We also engaged in construct specification, seeking to refine the constructs articulated in the original framework and to introduce new constructs when the existing constructs failed to capture important aspects of the phenomenon under investigation (in our case, ENVISION's digital inclusivity). At times, this involved construct splitting, a process whereby we split existing constructs into more specific dimensions if more conceptual specificity was needed to capture important aspects of ENVISION's digital inclusivity. Finally, we engaged in structuring, or identifying relationships between and among constructs, remaining open to new relation structures.

To accomplish these analytic activities (ie, contrasting, specifying, and structuring), 2 researchers (KTW and AKD) first reviewed all study transcripts, video files, and field notes. They then met to develop an initial codebook based on the elements of an existing framework: *Building Digital Communities: A Framework for Action* [15], created by the Institute of Museum and Library Services, the University of

Washington Technology and Social Change Group, and the International City or County Management Association. As its name suggests, this framework was created to promote digital inclusivity at the community level. Consistent with this purpose, it articulated 13 principles for community-wide digital inclusivity, including access principles (which addressed community infrastructure needs), adoption principles (which focused on community members' facilitators and barriers to use), and application principles (which specified areas where deployment of digital technologies would be likely to enhance community members' lives). The original framework's principles and corresponding definitions are provided in [Multimedia Appendix 1](#).

We originally envisioned development of the initial codebook as a relatively straightforward process in which most, if not all, constructs articulated in the original framework would be initially retained and then refined in subsequent analytic steps. However, it soon became apparent that some of the original principles had limited applicability in the context of an individual application and should, therefore, be de-emphasized or excluded in the early stages of our analysis. For example, the application principles outlined in the original framework identified specific community sectors, such as education and public safety, where the deployment of technologies was deemed likely to benefit community well-being. However, digital health tools are, by definition, intended for deployment in health care (and, in the case of ENVISION, more specifically in hospice care). Thus, we omitted them from the initial codebook, feeling confident they would neither enrich our understanding of ENVISION's digital inclusivity nor ultimately represent constructs comprising our adapted conceptual framework.

After completing the initial codebook, KTW and AKD independently coded approximately 15% of the study transcripts, consulting video recordings and field notes as needed for context or clarification of transcribed data. KTW and AKD then met to make substantive modifications to the codebook to enhance its goodness of fit with the data. Examples of changes made at this stage included specifying that *affordability* referred to ENVISION's initial and ongoing costs and should, thus, be

re-labeled as *affordability and sustainability* (construct specification) and dividing *design for inclusion* into *perceivability*, *operability*, and *comprehensibility* (construct splitting), as the available data suggested that these were conceptually meaningful distinctions. We then used the modified codebook to code the entire data set, meeting afterward to compare individual coding decisions (resolving discrepancies via discussion and arriving at consensus), finalize our code definitions, and group related codes into broader categories that comprised our resulting conceptual framework and shed light on ENVISION's strengths and limitations with regard to digital inclusivity.

Ethical Considerations

All research activities were reviewed and approved by the Washington University in St Louis Institutional Review Board (#202105172).

Individuals interested in study participation were provided with contact information for our study coordinator, who screened potential participants for eligibility, obtained verbal informed consent for those interested in participating, and coordinated all subsequent research activities including participant payments of US \$40 sent via check to the mailing address of the participants' choice.

Results

Overview

A total of 34 individuals participated in our qualitative research study, enabling the concurrent achievement of 2 interrelated study aims: (1) to develop a conceptual framework of digital inclusivity for health information systems and (2) to evaluate the digital inclusivity of the ENVISION application (participant characteristics are summarized in [Table 1](#)). In the following sections, we present our study findings, beginning with a brief overview of our conceptual framework and its essential elements. We then provide an in-depth description of the framework, illustrating its specific constructs with examples from our evaluation of ENVISION's digital inclusivity.

Table 1. Summary of participant characteristics (N=34).

The Accessibility, Relevance, and Impact Conceptual Framework of Digital Inclusivity for Health Information Systems

Our analysis resulted in the development of a conceptual framework of digital inclusivity for health information systems that comprises 3 essential elements: accessibility, relevance, and impact (Figure 3). Per the Accessibility, Relevance, and Impact (ARI) framework, in evaluating a health information system's accessibility, the availability and affordability or sustainability of access to the internet (for web-based applications); necessary devices (eg, computers, smartphones, and tablets); and the application or system itself must be considered. Also relevant are a system's perceivability (the extent to which it can be used by individuals with different sensory abilities, such as visual or hearing impairments),

operability (the extent to which it can be used by individuals with different physical abilities or technological proficiencies), and comprehensibility (the extent to which users can understand and accurately interpret the system's content). A health information system's relevance is also key to its digital inclusivity. Digitally inclusive systems are useful (ie, they fulfill a clear purpose); trustworthy (ie, they are viewed as credible); and aligned with users' values, beliefs, customs, and preferences (ie, they are congruent). Finally, the framework suggests that the evaluation of a health information system's digital inclusivity requires consideration of its impact, that is, the extent to which it improves (or would be expected to improve) users' lives (benefit) and the presence or absence of protection from web-based threats (eg, malware and data breaches) associated with the system's use (safety).

Figure 3. The Accessibility, Relevance, and Impact (ARI) conceptual framework of digital inclusivity for health information systems.

Evaluating ENVISION's Digital Inclusivity Using the ARI Framework

Accessibility

Data describing ENVISION's availability referenced the presence or lack of internet access, technological devices, or

otherwise referred to potential users' ability to retrieve the application. Study participants' feedback and experiences related to availability were generally positive. Family caregivers either did not comment on ENVISION's availability or were positive in their responses; no family caregivers identified availability-related barriers to accessing the application. Although hospice clinicians also expressed generally positive

perceptions of ENVISION's availability, some clinicians noted potential limitations. For example, one clinician stated that the application would be inaccessible for some, including "people without internet, without computers." Another explained, "Keep in mind that your patients or family members...may not have access to technology." With regard to the application's availability to clinicians, one participant emphasized the importance of integrating any new tools with the existing electronic health record:

Sometimes more tools are better, but sometimes more tools take more time...If this could be embedded into our current [EHR], I could find that helpful. To log out and then log in to something else or to toggle between two applications, I think, would be more cumbersome.

Data describing ENVISION's affordability and sustainability referenced the cost of ENVISION itself or other resources (eg, internet access and technological devices) required to access and use the application. Participants who commented on ENVISION's affordability and sustainability expressed generally positive perceptions. Family caregivers, many of whom likely assumed the application would be included in routine hospice care and thus free of charge to patients and families, did not directly raise the issue. Two clinicians (one of whom also occupied an administrative role) noted the importance of making the application affordable and sustainable for hospice agencies, stressing the issue of cost-effectiveness, and linking the application to clinically relevant outcomes. When asked if they would recommend routine use of ENVISION in hospice care, they replied as follows:

I think you'd have to look at...cost, [but] this program will definitely improve outcomes for symptom management.

Data describing ENVISION's perceivability referenced the extent to which the application could be used by individuals with different sensory abilities, particularly with regard to vision. Participants' comments regarding the perceivability of ENVISION varied. Some suggested that the font size was too small:

The print would have to be a little larger. I think, in general, anything to do with [older adults] should be larger.

Others stated the opposite, describing ENVISION's text and images as "not too small." One participant who did not cut and paste the one-time password from their welcome email into the log-in screen noted that "for people [who] are...visually challenged, [entering] the password [could be] a bit of a headache." A clinician described ENVISION as a "wonderful option for patients and family members" but suggested that it not be required, as some may not be "able to see and hear...and all those sorts of things."

Data describing ENVISION's operability referenced the extent to which it could be used by individuals with different physical abilities or technological proficiencies. Participants provided mixed feedback on ENVISION's operability. Overall, for family caregivers, logging into the application for the first time (which

required them to enter their email address and a one-time password emailed to them during the call) was more challenging than using it once they logged in. One family caregiver stated as follows:

If you're not a computer-savvy sort of person, [logging in the first time] could be a challenge.

This was particularly the case for users (family caregivers and hospice clinicians) who did not cut and paste their one-time password from their welcome email into the log-in screen:

I have to write [the one-time password] down because I won't remember it.

Another user provided a specific suggestion related to this issue:

Do you know, with this system, can you instruct people to copy the initial password and paste it in, just to make it easier for people?

After entering the system, however, family caregivers could easily enter symptom and well-being data into ENVISION, describing this process as "pretty simple" and "really easy." One family caregiver stated, "That took less than 30 seconds," while another explained as follows:

I think it was really easy. I really liked how there's a definition [of each symptom or wellbeing indicator]...It's comparable to other applications I use for work...I think that would be pretty straightforward for the general population, too.

Although this user saw the information symbol (lowercase "i" with a circle around it) located next to each symptom and well-being indicator and knew to click on it for more information, others required prompting before being able to do so. Ultimately, however, 100% of the users who expressed a desire for more information about a symptom or well-being indicator were able to successfully obtain that information by clicking on the information symbol independently or after receiving the following verbal prompt from the researcher: "Is there anything on the screen that might give you more information about that?"

Clinicians' comments regarding ENVISION's operability with regard to logging into the system and navigating the application generally mirrored those of family caregivers. They described the overall application as generally operable while emphasizing that it might be challenging for individuals to use if they were physically unable to type or "[could not] even use a smartphone" (the issue of family caregivers' ability to independently use the application is further described when discussing *congruence* under the *Relevance* section, as numerous clinicians expressed concern that they would be tasked with training and assisting technologically challenged family caregivers with ENVISION's use, requiring significant amounts of their already limited work time). Most of the unique data about ENVISION's operability for clinicians focused on using the interactive graphs that enabled longitudinal viewing of symptoms and well-being indicators (these graphs were available only to clinician users). To choose which symptoms or well-being indicators appeared on the longitudinal graphs, clinician users needed to click a box next to the appropriate symptoms or indicators, which multiple users failed to do without prompting or considerable thought.

For example, one clinician user's think-aloud data included the following:

I'm guessing maybe—I was looking at it on my computer—the little check boxes underneath the graph might affect the graph, I guess...Now, let's see...[begins clicking on boxes and noting changes to the graph].

Another suggested that the application be modified to include “some education on what that graph is and how to utilize it.” Other clinician users appeared to interact with the graph more intuitively and were observed easily manipulating it. One such clinician stated as follows:

I didn't have any problem with it. I'm middle-aged and...pretty computer-literate. I didn't have any problems with it at all.

Data describing ENVISION's comprehensibility referenced the extent to which users could understand and accurately interpret the application's content. ENVISION's comprehensibility was determined to be mixed. Overall, family caregivers could easily comprehend ENVISION's content, successfully entering symptom and well-being indicators and accurately interpreting the data visualizations (labeled boxes shaded in different intensities to reflect symptom and indicator intensity) featured on patient and caregiver scorecards. Several described the content as easy to understand, using words and phrases such as “straightforward” and “written in plain English.” Among family caregivers, comprehensibility challenges were limited to understanding the definition of specific symptoms or well-being indicators; however, most of these challenges were resolved when the users clicked on the information symbol and were shown a definition. Users commonly clicked on the information symbol next to “well-being,” expressing confusion about what it entailed (eg, “Is that mental well-being or is that physical?”). Differentiating between “tiredness” and “drowsiness” was also challenging for numerous family caregivers. Among the comprehensibility challenges that were not resolved by clicking on the information symbol, nonspecificity (eg, uncertainty whether they were being asked to report on generalized anxiety or anxiety specific to the hospice experience and confusion about the insomnia indicator: “Is that insomnia [as in] you can't sleep, or is it just that you know you have to get up because you have to check [on the patient]?”) was by far the most common. Clinicians recommended that longitudinal graphs be labeled with complete descriptions of symptoms and well-being indicators rather than shortened descriptors (eg, use “shortness of breath” rather than just “breath”). However, this may have been more of a design preference than an issue related to comprehensibility. One family caregiver recommended that features beyond the patient or caregiver name and uploaded photograph be included to remind the family caregiver when they were being asked to report on the patient's experience or their own:

You could say, “Now we're...addressing you, not the patient” or however you would want to say it...Make it clearer which page is for the patient and which is for the caregiver.

Relevance

Data describing ENVISION's purpose referenced its perceived usefulness. Most users identified a clear and important purpose for ENVISION in their respective roles. Family caregivers repeatedly emphasized the importance of reporting symptoms and well-being indicators to the hospice team (patient pain was most commonly cited as a high-priority symptom to communicate). Feedback on the importance of the general well-being indicator, however, was mixed among family caregivers. Some family caregivers selected it as the most critical piece of data to communicate, while others saw it as redundant:

I feel that was a culmination of all the options that you gave me to begin with. If I'm already addressing each one of those issues individually...maybe I didn't necessarily need to rate it separately.

One caregiver was unclear why caregiver insomnia was included as a well-being indicator:

If I had insomnia, how would the healthcare provider help me with that?

With a few exceptions, clinician participants could readily identify a purpose for ENVISION in their clinical role, evident from representative statements as follows:

I think it would help me do my job better due to it being so precise, and I go back to the [patient and caregiver scorecard]. It's a lot easier for me to see what's going on with that patient the way that was presented than what I'm doing now in a chart, where I have to click and copy and paste and go here and there and everywhere [to] different notes and things like that.

A chaplain explained how using ENVISION would enhance spiritual care:

[ENVISION might help me decide] how soon I might want to make another visit. Because if the person is very spiritual and prayer or listening to hymns or singing [helps] with pain or anxiety, [using ENVISION would allow me to] see if maybe another visit might be something that they might appreciate sooner than later.

One chaplain user, who expressed generally positive perceptions of ENVISION's relevance, suggested that the application would be improved by the inclusion of an indicator for “some type of spiritual distress.” With regard to the graph's usefulness, clinician feedback was generally positive. One clinician explained as follows:

[ENVISION] would be helpful to identify patterns without having to go back and read your notes, and it would also be helpful to measure how long a pattern's been happening when it might be hard to conceptualize that just through memory.

More general comments described ENVISION as “a really cool tool and a really good idea [that would be] really useful” and “really helpful.” Another stated as follows:

I would be eager for [ENVISION]. I think it would be great for patients' families [to feel] like they have another method of communicating with us.

A clinician described the patient and caregiver scorecards as follows:

I think they are very helpful. It's easy, quick to identify, and you can see exactly what the problems are.

A few clinicians specifically commented on including caregiver well-being indicators in addition to patient data, noting its usefulness:

What I really appreciate is that...it indicates an attention to continued review about how the caregiver is doing, and that isn't always done.

A hospice physician stated as follows:

I think having access to this would really help, so I can get the patient perspective. As a hospice physician, a lot of times I'm getting just a third-party review from the nurse. I don't necessarily get this drilled-down of a rating scale on what's going on.

Two clinician users were more negative than positive regarding ENVISION's purpose. One (the more ambivalent of the 2) user stated as follows:

I think it's helpful, but is it necessary? I don't know.

The other user explained their reservations about the application:

[My] knee-jerk response to [ENVISION] is why the heck would I be looking at a computer and not talking to [the family caregiver]? I have no idea why we would add a layer between the hospice nurse and the [patient and family]...I'm struggling with the whole concept...I'm a [age in the 60-69 range]-year-old nurse, and I'm covering two different teams...[Even] with 21 patients, I would still want to have direct conversations with my patients and families. I would want them to feel like they have no barriers whatsoever to either calling the office or calling my work cell phone and saying, "Guess what's happening this morning?"

Data describing ENVISION's congruence referenced the degree to which the application was aligned with users' values, beliefs, customs, and preferences. When discussing ENVISION's congruence, participants commented on qualities such as the application's goodness of fit or described what they liked and disliked about it. Overall, family caregivers generally reported ENVISION to be aligned with their values, beliefs, customs, and preferences. None of the family caregivers reported perceived or anticipated challenges with daily symptom and well-being data entry. Two family caregivers mentioned specific symptoms that seemed at odds with their expectations or understanding of hospice care. One questioned why the hospice team would need to know whether they (the family caregiver) were experiencing insomnia (as previously described), and the other thought asking about patients' lack of appetite might be problematic, as they understood decreased appetite to be a normal part of the dying process rather than something that

required a clinical response: "I was just told, 'Don't try to make her [eat].'" Other data suggested that this family caregiver's concern might have been warranted, as one caregiver cited "lack of appetite" as among the most important symptoms to communicate to the hospice team, explaining that a hospice patient "needs to eat." While cultural congruence was infrequently discussed regarding the ENVISION application, the few comments provided were positive and related to cultural norms that might reduce the likelihood of unscheduled contacts with the hospice team in the absence of a tool such as ENVISION:

In an ideal world, every clinician would call [the family caregiver of a patient whose pain medications were increased] the next day to check in to see if this is working better, but I know that's not going to be the case. A lot of caregivers actually wait a full week until the...nurse comes back, and I'm like, 'Oh, don't do that. Let them know that it's working. Let them know if it's not working. Because [patients] don't need to suffer like that.' There are cultural values that limit how people communicate, and that's especially true in, like, Latino populations and other people who have been marginalized before who don't know that they're also an authority in this, in the reporting of patients' symptoms.

Congruence pertaining to clinician data primarily related to clinicians' preferences and experiences as busy professionals with limited time to engage in additional work tasks. These data primarily addressed the provision of technical support or data entry reminders to family caregivers using ENVISION, something clinicians were almost universally disinclined to take on. In addition, the previously described response from the hospice nurse with a strong preference for nontechnologically mediated communication ("Why we would add a layer between the hospice nurse and the [patient and family]?") was identified as a likely example of perceived incongruence with the clinician's personal values (ie, an aversion to technology or belief that more traditional forms of communication are more effective or personal). Conversely, perceptions of ENVISION as a tool to increase efficiency were strongly related to perceptions of the application as a good fit for clinicians' workflow. For example, one clinician emphasized the timesaving value of ENVISION's patient and caregiver scorecards:

It doesn't seem like there's a lot of information on [the scorecards] that doesn't need to be there, so that's helpful...Whenever I'm reading people's [medical] records, I'm just like, "Where is the information I'm looking for?"

Descriptions of the application as "a quick snapshot" and as allowing clinicians to quickly identify symptoms in need of attention were common.

Data describing ENVISION's credibility referenced the degree to which users perceived the application as trustworthy. Participants rarely commented on ENVISION's credibility. Furthermore, 100% of the data segments labeled with the code "credibility" were also labeled with the code "safety" and were found to pertain more directly to security issues than to the

perceived trustworthiness of the application. Thus, to avoid duplicate reporting of findings, these data are described in the context of ENVISION's safety, which is discussed in the section describing findings related to ENVISION's impact.

Impact

Data describing ENVISION's benefit referenced the ways in which the application might improve users' lives. Both family caregivers and clinicians cited potential benefits of the ENVISION application, primarily centered around better symptom management and increased awareness of opportunities to improve patients' and family caregivers' quality of life. Much of the information labeled with code "benefit" was also labeled with the code "relevance" due to perceived improvement in individuals' ability to complete tasks associated with their respective roles, whether as family caregivers or hospice clinicians. For example, a hospice clinician indicated that ENVISION "would be a good communication tool [so] that...all the team is getting the same information in real time." Another stated, "It could allow for efficient follow-up and getting the care needed to the patient probably in...a faster manner." Several clinicians predicted that ENVISION use would increase patients' and family caregivers' satisfaction with the care they received. A clinician explained as follows:

It would make the patients and families feel like the hospice team is more competent, that we actually work together as a team, because we would know going in [to the home] what has been going on with them for the past few days or since we've been there. I do get that a lot. Patients are like, 'I don't want to go over it again. Don't you guys talk to each other?'

Another clinician described ENVISION as potentially empowering:

When your patients and families are allowed to have input, it makes them feel empowered and a part of the care. I could see how [ENVISION] would be beneficial for the patients or their families to utilize.

One clinician user identified benefits from 3 perspectives:

From the caregiver's perspective, I think it's helpful to have some sense of feeling like you have an outlet to discuss what symptoms you're having so that you can actually get help from the interdisciplinary team. I think it's helpful from the patient's perspective to kind of have a sense of control over how their symptoms are being managed...I think it's helpful from the provider's perspective for...symptom management, changes in medications, gauging how they're working, as well as helping guide that family with new symptoms that are showing up and education as well as prognostication.

Comments describing potential drawbacks of the application were less frequent and often co-coded with other digital inclusivity elements. For example, clinicians worried that family caregivers with limited technological skills might feel frustrated when interacting with the application. Clinicians also worried that family caregivers would find it burdensome to enter daily symptom assessment data:

[Having daily symptom and well-being data] would be sweet. That might be a big ask for some caregivers. One more thing to do.

However, no family caregivers cited daily data entry as likely burdensome. Clinicians also cautioned against using ENVISION data to reduce or "change the care that we otherwise would attempt to provide."

Data describing ENVISION's safety referenced the presence or absence of protection from online threats associated with the application's use, such as malware or data breaches. ENVISION's safety was rarely addressed. When the users did address it, they tended to focus on password-related hassles rather than concerns that using the application made them susceptible to digital threats. One exception was that clinicians emphasized the need for any application used in hospice to be Health Insurance Portability and Accountability Act compliant, as that would likely be required for adoption into routine care.

Discussion

Principal Findings

We developed a conceptual framework of digital inclusivity for health information systems and then applied the framework in evaluating the digital inclusivity of ENVISION, a symptom monitoring tool for home hospice care. Our analysis identified accessibility, relevance, and impact as essential considerations in assessing a health system's digital inclusivity; all 3 were incorporated into our newly created ARI framework. Study findings resulting from our application of the ARI framework generally supported ENVISION's digital inclusivity, particularly concerning its perceived relevance to the work of family caregivers and hospice clinicians and its potentially positive impact on symptom management and quality of life. Limitations to ENVISION's digital inclusivity centered around issues of accessibility, particularly operability among individuals with limited technological knowledge and skills.

The ARI framework is informed by and extends prior knowledge. It incorporates constructs from several existing models, most notably the community-oriented framework on which it was explicitly based [15]. Both frameworks place a strong emphasis on accessibility, including availability, affordability, and more standard accessibility features, conceptualized in the ARI framework as perceivability, operability, and comprehensibility (these closely mirror principles detailed in the widely referenced Web Content Accessibility Guidelines 2.0, authored by the World Wide Web Consortium) [25]. The ARI framework also echoes some of the principles highlighted in usability heuristics for user interface design given by Nielsen [26] (eg, the match between the system and the real world) and Technology Acceptance Model elaborated by Davis [27] (eg, usefulness and ease of use). In building on prior research, the ARI framework synthesizes relevant constructs from numerous bodies of existing work, setting the stage for meaningful assessment of the digital inclusivity of individual tools. In addition to providing a valuable synthesis of existing models pertinent to digital inclusivity, the ARI framework incorporates constructs uniquely relevant to the context of health information systems. It

identifies patients and families, clinicians, and institutions as unique yet interdependent user types, each with potentially different cultures, responsibilities, needs, and concerns. Furthermore, it is grounded in data derived from home hospice care, a clinical context that highlights the extent to which patients and families are increasingly required to be both care providers, via family caregiving [28] and disease self-management [29], and care recipients, via patient- and family-centered models of care [30].

Importantly, the salience of specific constructs highlighted in the ARI framework will likely fluctuate over time. For example, limited internet availability may become less problematic in the United States, where the federal government's recent infrastructure investments are predicted to significantly expand rural internet availability [31]. Similarly, while health information systems' operability will likely continue to be important, tools requiring basic technological skills to operate may become more broadly operable due to demographic shifts, as the proportion of potential users who are digital natives (people who grew up regularly using digital technologies [32]) is expanding. Other issues, such as cost-related barriers to accessing digital health tools, seem likely to retain their importance over time, particularly in light of increased recognition of income inequality and other social determinants of health [33].

Limitations

Study findings should be interpreted in light of numerous limitations. First, our study sample was disproportionate in terms of having higher number of non-Hispanic, White, and female individuals. All family caregivers who participated in the study had at least some college education or trade school experience, and all could speak and read English. Furthermore, while our sample reflected some variability regarding functional abilities (eg, some participants reported mild visual impairment requiring corrective lenses), no participants reported significant physical disabilities. Additional research with more diverse participants, including individuals with varying degrees of literacy and functional ability, is needed to refine the ARI framework and better understand and ultimately enhance ENVISION's digital inclusivity. Notably, the ARI framework is in its infancy, and additional development and testing will likely be needed to maximize its potential impact on the field. In particular, noted conceptual links between relevance and the benefit subcategory of impact highlight the need for ongoing attention to issues of construct validity. With regard to ENVISION's potential for clinical adoption, recommended next steps include pilot testing in real-world scenarios, followed by more definitive efficacy testing to determine its effect on outcomes identified by users as areas of potential impact, such as symptom management and quality of life. In addition, in developing the ARI framework, we opted to include some elements of digital inclusivity even in the absence of data from the ENVISION evaluation supporting their inclusion if existing literature or expertise among team members suggested that they were essential to the concept of digital inclusivity. For example, although participants rarely discussed safety, it was retained from the original framework in light of the large and growing number of digital security threats in existence and noted

disparities in individuals' knowledge of cybersecurity [34]. Thus, while the ARI framework is primarily grounded in data derived from our evaluation of ENVISION's digital inclusivity, some exceptions apply. Finally, we emphasize that all study participants used ENVISION in a hypothetical manner, interacting with data either from memory (as was the case for family caregiver participants) or from fictitious patients and caregivers (as was the case for clinician participants). We cannot conclude with certainty that individuals using the application in real-life situations would have similar experiences or provide feedback mirroring that provided by the study participants. The hypothetical nature of participants' application use also limited their ability to provide feedback on certain aspects of ENVISION, such as the application's actual costs, including the labor and other resources required to support and sustain its use. Additional research is needed to determine ENVISION's costs and its benefits to home hospice patients, family caregivers, and clinicians.

Conclusions

Our evaluation of ENVISION identified many ways by which the tool is digitally inclusive. Although specific users' experiences and feedback varied, ENVISION was determined to be generally accessible by individuals with the skills and resources required to access and operate typical web-based applications. This overall assessment was most explicitly reflected in users' comparisons of ENVISION's operability to that of applications that they regularly encountered in their work and personal lives. User data were most positive regarding ENVISION's relevance, with nearly all family caregivers and clinicians readily identifying multiple use case scenarios for the application in home hospice care. Although individuals participating in the study interacted with hypothetical patient and family caregiver data, most predicted numerous, meaningful, positive outcomes of ENVISION use, including improved symptom management and patient and caregiver well-being.

User data also provided insights into ways in which ENVISION's digital inclusivity is limited. While most Americans can access the internet from home, this capability remains limited among older adults, racial and ethnic minority groups, and individuals residing in rural communities and low-income households [35,36]. As an entirely web-based application requiring daily use, ENVISION would largely be inaccessible to individuals without high-speed internet access at home or nearby. Moreover, individuals with limited technological skills may be unable to use the application without training and support, which many hospice agencies lack the resources to provide. Minimally, our findings suggest that support would be needed to assist first-time users in logging into the system and creating a new password, as this proved to be the most challenging aspect of operating ENVISION for many users. Adoption of password alternatives (eg, biometrics, physical hardware, etc) may be considered as this technology evolves [37]. In addition, offering support in using existing tools to enhance accessibility (eg, the zoom-in feature or magnifying applications on mobile phones to enhance character visibility) may be needed. Incorporation of existing principles (eg, the usability heuristics by Nielsen) [26] into future design efforts would likely enhance operability and is thus supported by study

findings. With regard to relevance, ENVISION may be a poor fit for family caregivers and clinicians who prefer face-to-face (or telephone) contact over more technologically mediated communication. Clinicians' concerns that the application might lead to decreased face-to-face contact might be assuaged by presenting ENVISION as a tool to supplement, not substitute,

in-home patient and family care. Finally, findings clearly indicate that ENVISION must provide clinicians with a net gain in terms of efficiency, consistent with existing research highlighting time constraints as the most significant professional challenge for hospice clinicians [38].

Acknowledgments

The Engagement and Visualization to Improve Symptoms in Oncology Care (ENVISION) application was created in partnership with the software engineering and user experience team at PlatformSTL. Funding for ENVISION and this study was provided by the BJC HealthCare and Washington University in St Louis Healthcare Innovation Lab and the Washington University in St. Louis Institute for Informatics, Data Science, and Biostatistics through the Big Ideas Data-Driven Innovation Competition (principal investigator: KTW) and by the Foundation for Barnes-Jewish Hospital (principal investigator: PW). All works made for hire are the exclusive joint property of Washington University in St. Louis and BJC HealthCare. The Recruitment Enhancement Core in the Network Capacity component of the Washington University Institute of Clinical and Translational Sciences is supported by the National Center for Advancing Translational Sciences of the National Institutes of Health (UL1TR002345). The paper's content is solely the authors' responsibility and does not necessarily represent the official views of the National Institutes of Health or any other funding entities.

Authors' Contributions

All authors contributed to the writing of the article and provided substantive feedback on its content. KTW designed and directed the study and led data analysis and interpretation of findings. DPO and GD contributed to data analysis and interpretation of findings. AKD served as the study coordinator, collected data, and contributed to data analysis and interpretation of findings. PGL, PW, and JJB contributed to the study design and interpretation of findings.

Conflicts of Interest

None declared.

Abstract

Background: Family caregivers of people with dementia are critical to the quality of life of care recipients and the sustainability of health care systems but face an increased risk of emotional distress and negative physical and mental health outcomes.

Objective: The purpose of this study was to examine the usability, acceptability, and preliminary effectiveness of a technology-based and caregiver-delivered peer support program, the Caregiver Remote Education and Support (CARES) smartphone or tablet app.

Methods: A total of 9 adult family caregivers of people with dementia received the CARES intervention, and 3 former family caregivers of people with dementia were trained to deliver it. Quantitative data were collected at baseline and at the end of the 2-week field usability study. Qualitative data were also collected at the end of the 2-week field usability study.

Results: The field usability study demonstrated that a 2-week peer-delivered and technology-supported mental health intervention designed to improve burden, stress, and strain levels was experienced by former and current family caregivers of people with dementia as acceptable. Current family caregivers rated CARES as above average in usability, whereas the caregiver peer supporters rated CARES as marginally usable. CARES was associated with non-statistically significant improvements in burden, stress, and strain levels.

Conclusions: This field usability study demonstrated that it is possible to train former family caregivers of people with dementia to use technology to deliver a mental health intervention to current family caregivers of people with dementia. Future studies would benefit from a longer trial; a larger sample size; a randomized controlled design; and a control of covariables such as stages of dementia, years providing care, and severity of dementia symptoms.

Introduction

Background

Family caregivers of people with dementia are critical to the quality of life of care recipients and to the sustainability of health care systems. Family caregivers provide US \$257 billion in unpaid care to people living with dementia but face an increased risk of emotional distress and negative physical (eg, heart disease and hypertension) and mental (eg, depression and anxiety) health outcomes [1,2]. While positive gains are reported in the caregiving role, caregivers are more likely than their noncaregiving peers to report stress, burden, and strain. Approximately 46% of family caregivers of people with dementia are classified as having high levels of burden [1,2]. Burden is defined as the psychological, physical, emotional, and social challenges that family caregivers experience in response to the demands of providing care [3]. Caregivers with high levels of burden report more physical and psychological symptoms, use prescription medications and health care more frequently, and provide poorer quality of care to recipients, leading to an increased likelihood of premature institutional care [4,5]. In addition, 59% of family caregivers of people with dementia rate the emotional stress of caregiving as high or very high, and 38% rate the physical stress of caregiving as high or very high [1,2]. Stress is defined as individuals' emotional or physical responses to the challenges of caregiving, such as fatigue [6,7]. The stress of providing care to a family member with dementia increases caregivers' risk of health complications, increases their susceptibility to diseases such as hypertension, and negatively affects their quality of sleep [1,2]. Family caregivers have also reported greater levels of strain compared to caregivers of people without dementia. Strain is defined as caregivers' perception of the challenges of caregiving and their state of well-being [7]. Family caregivers who perceived themselves as having higher strain levels due to caregiving responsibilities were at a higher risk of death than those who perceived little or no strain [1,2].

Technology-Based Interventions for Caregivers

While psychosocial interventions have been shown in fully powered randomized controlled trials to reduce caregiver burden and delay nursing home admission for the care recipient, a recent meta-analysis by Walter and Pinquart [8] found that current interventions had a disappointingly small to moderate effect on caregiver well-being, burden, depression, and anxiety [4,8-10]. In addition, uptake of these interventions in the real world is limited due to caregiving obligations (between 69 and 117 hours of informal care are provided to people with dementia per week), geographical distance from the intervention, requirements to meet in person, and failure to address the personalized needs of the family caregivers.

Technology-based interventions may offset these challenges through improved accessibility of psychosocial interventions at any time or location [11,12]. A scoping review on existing technology-based peer support interventions for family caregivers found that web-based programs include websites that offer educational materials with the option to contact other informal caregivers, web-based portals with psychoeducation

and peer-to-peer contact, asynchronous e-learning platforms, internet support forums and chat rooms, videoconferencing support groups facilitated by a health professional, and live virtual reality support groups facilitated by psychologists [11]. Online informal peer support groups for informal caregivers have shown high levels of engagement. Technology-based interventions enable caregivers to participate even if they are unable to leave the person with dementia unsupervised. For example, during the COVID-19 pandemic, telephone-, videoconference-, and chat room-based online support groups were the only media accessible to caregivers, a benefit due to the 24/7 nature of supporting a family member with dementia and the consequential challenges in accessing support [11,13]. Online informal peer support groups are an effective method of asynchronous web-based delivery when offered in combination with a structured psychosocial and educational intervention by skilled clinical professionals [11]. However, while some studies such as that by Han et al [14] have shown significant reductions in depression, stress, and helplessness, others such as the study by Marziali and Garcia [15] have shown only moderate effects in reducing burden and depression and increasing caregiver knowledge.

Significance of Technology-Delivered Caregiver Peer Support

To date, technology-based interventions have relied on a skilled workforce of geriatric mental health professionals. However, there are insufficient numbers of adequately trained geriatric mental health care providers [16]. As such, task shifting services from skilled clinical professionals to community members provides an emerging workforce of peer support workers (ie, interventionists without formal mental health education but with life experiences similar to those of the people they serve) [17]. Although the need for traditional clinical professionals remains, peer support services for individuals with mental health conditions have been shown to increase service accessibility without impacting service quality [17]. However, there is limited knowledge of caregiver-delivered peer support.

The use of caregiver-delivered digital peer support may promote the uptake of psychosocial interventions, reduce burden, and delay nursing home admission. Social and behavioral theories such as social support, experiential knowledge, and the helper therapy principle highlight how peer supporters have the unique ability to offer acceptance, understanding, and validation to the individuals they work with [18]. Because of their shared lived experiences, peers are often viewed as more credible and trustworthy than other health care providers and, therefore, encourage increased digital health engagement. Individuals are motivated to achieve their mental health goals (eg, reductions in burden, strain, and stress) because of the reciprocal accountability offered and modeled by their peers. Former family caregivers of people with dementia have the knowledge and skillset to deliver trained peer support to current family caregivers and could potentially benefit emotionally from the delivery of support. While there are positive outcomes associated with the end of caregiving, when family caregivers of people with dementia become former family caregivers, the detrimental effects of previous caregiving fail to improve [19]. Many former dementia caregivers experience persistent sleep disturbances,

depression, anxiety, increased physician office visits, declining health, and feelings of guilt and regret [20]. Despite evidence that former caregivers who pursue new caring roles benefit emotionally, payers and health care providers have not hired and trained former caregivers to provide evidence-based digital interventions [20].

Research Aims

The purpose of this study was to examine the usability, acceptability, and preliminary effectiveness of a technology-based and caregiver-delivered peer support program, the Caregiver Remote Education and Support (CARES) smartphone or tablet app. In this study, 3 former family caregivers of people with dementia (caregiver peer supporters) were trained in the delivery of caregiver peer support and delivered the CARES intervention and app to 9 current family caregivers of people with dementia (caregiver participants) in a 2-week field usability study.

Design of the CARES App

The CARES app and intervention were adapted from the PeerTECH smartphone or tablet app and developed to facilitate the examination of the usability, acceptability, and preliminary effectiveness of the first technology-based and caregiver-delivered peer support program in a 2-week field usability study. The PeerTECH system was designed using universal design principles and for lay interventionists (not skilled) to deliver fidelity-adherent evidence-based interventions. The PeerTECH system has been successfully used with Certified Peer Specialists, home health aides, and Certified Older Adult Peer Specialists [21]. Certified Peer Specialists are people with a mental health diagnosis who are hired, trained, and certified to provide peer support services to individuals with a similar diagnosis [22].

PeerTECH was built on the stress-vulnerability model. According to the stress-vulnerability model, the outcomes of a mental health condition are connected to biological vulnerability, stress, and protective factors (eg, peer support) [23]. PeerTECH was designed to empower individuals to address the stress and vulnerability that lead to worsening medical, psychiatric, and social health conditions. Peer specialists are trained to deliver evidence-based practices through the PeerTECH app to help participants decrease stressors and increase protective factors.

The PeerTECH app was codeveloped with peer specialists and includes 2 features developed through community-engaged research. The first is a peer-facing smartphone or tablet app that guides peers in delivering evidence-based health self-management skill development interventions. The app includes prompts to share their lived experiences of health

challenges and solutions (ie, peer support) and structured intervention delivery through scripted, evidence-based training on topics such as coping skills, psychoeducation, medical management, social skills, and self-advocacy. The second feature is a participant-facing app that offers self-management support through features such as a library of self-management resources (eg, peer-led videos) and a secure messaging feature to connect with their assigned peer specialists and reinforce goals [21].

Similar to PeerTECH, the CARES app includes 2 features: a peer-facing smartphone or tablet app and a participant-facing smartphone or tablet app ([Multimedia Appendix 1](#) for illustrations of the CARES app). The content of the CARES app, similar to that of PeerTECH, was designed according to the stress-vulnerability model to help participants decrease stressors and increase protective factors. The CARES app and intervention were adapted from the PeerTECH app by a team of researchers with expertise in peer support to guide caregiver peers in the delivery of evidence-based mental health interventions and designed according to the techniques and principles of peer support and acceptance and commitment therapy (ACT). The participant-facing CARES app offers a library of resources designed to educate participants on psychological skills (eg, mindfulness) that empower them to manage difficult thoughts (eg, acceptance) and engage in activities and behaviors that are guided by their life values and boost their well-being (eg, setting goals and identifying values) [24]. Caregiver peer supporters were trained and educated on topics such as values, goal setting, acceptance, avoidance, and negative thoughts and connected with their assigned participants via a secure messaging feature to reinforce ACT principles, share their lived experience of caregiving challenges, and share practices to enhance caregivers' wellness and mental health in relation to caregiver-related stressors [25]. The mutual practice of goal setting, for example, can help link caregivers' values to concrete plans for behavior change [26]. [Figure 1](#) illustrates the CARES app.

The participant-facing app includes access to direct messaging with an assigned caregiver peer supporter, goals, wellness, surveys, and a resource library (see the bottom right of [Figure 1](#)). The caregiver peer supporter app allows caregiver peer supporters to message assigned participants directly (see the bottom left of [Figure 1](#)), view participants' goals and wellness plans, and view their progress in the library resource feature. The principal investigator (PI) had access to data on the participants' and peer supporters' rate of engagement with library resources, messaging, and goals and wellness features (see the top of [Figure 1](#)).

Figure 1. Caregiver Remote Education and Support app.

Description of the CARES App

Fundamentally, CARES is a peer-instructed and mediated caregiver support program that uses a smartphone app-based mechanism for communication. The CARES app consists primarily of two features: (1) a former family caregiver (caregiver peer supporter)-facing app on a smartphone or tablet that includes the option to message or video chat with the current family caregivers (participants) they have been assigned to provide caregiver peer support (Figure 2) and (2) a participant-facing app that offers the option to review an on-demand library of educational resources and a HIPAA (Health Insurance Portability and Accountability Act)-compliant text and video chat feature to communicate with their assigned caregiver peer supporter (Figure 3). The participants and caregiver peer supporters also have the option to set goals and

create wellness plans. Figure 4 shows the features seen by both the participants and caregiver peer supporters.

Figure 2A depicts the home page of the caregiver peer supporter-facing CARES app. The home page includes the option to select the individual's availability to offer caregiver peer support to their assigned participants (Figure 2B), set goals, and access information on their assigned participants and chats. Figure 2C shows the options to message and video chat with the assigned participant and track their goals and wellness plan.

Figure 3 depicts the home page of the participant-facing CARES app. The home page includes the option to send messages to the assigned caregiver peer supporter, video chat directly with the assigned caregiver peer supporter, set goals, create a wellness plan, and access a library of resources (Figure 5).

Figure 2. Screenshot A depicts the home page on the caregiver peer supporter facing CARES application. The homepage includes the option to select the individual's availability to offer caregiver peer support to their assigned participants (see Screenshot B), set goals, and access information on their assigned participants and chats. Screenshot C provides options to message and video chat the assigned participant and track their goals and wellness plan.

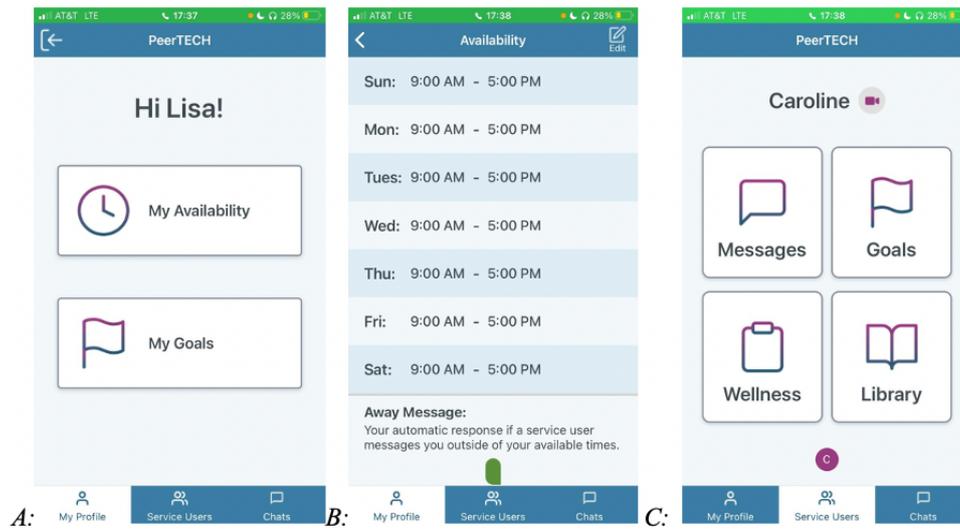

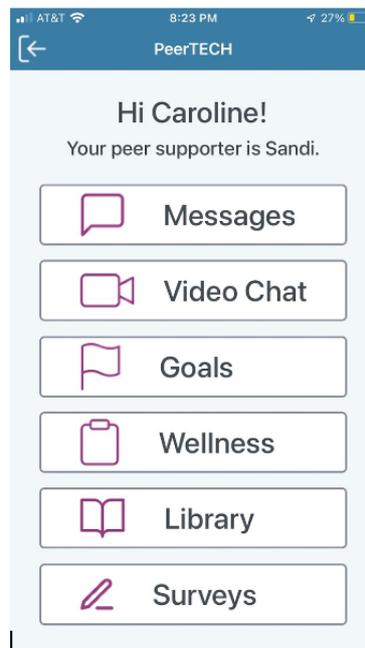

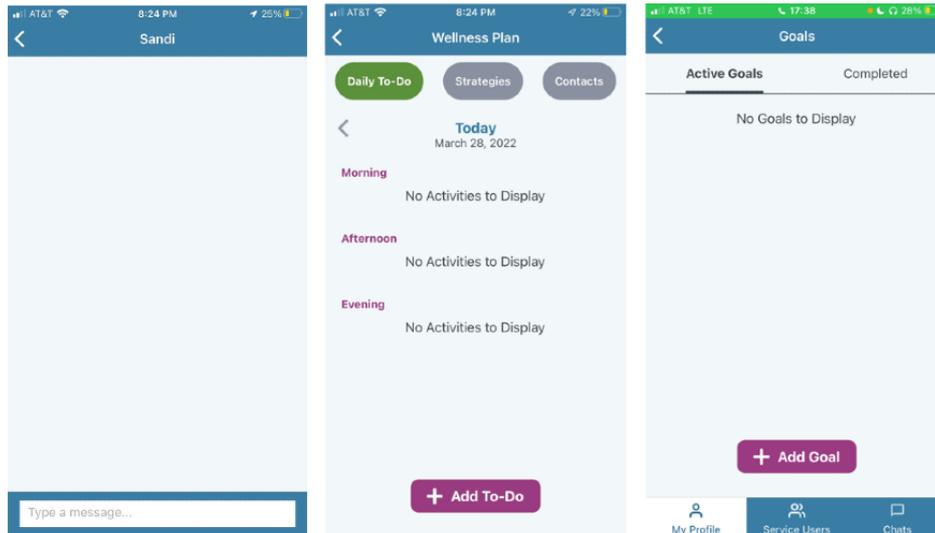

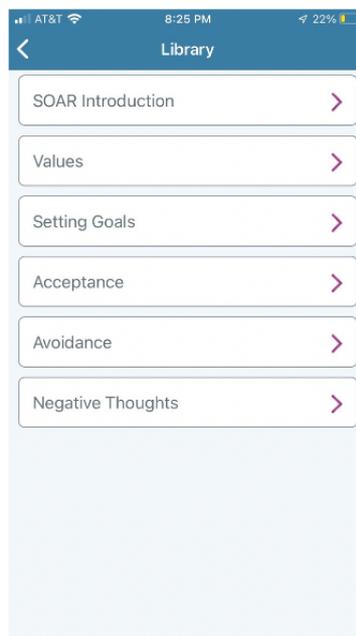

Figure 3. Caregiver Remote Education and Support participant-facing app.

The left panel in Figure 4 depicts the messaging option provided within the CARES app. Within the messaging section of the app, participants and their assigned caregiver peer supporters can send each other text-like messages. The panel in the center depicts the wellness plan. Within the wellness plan section,

participants and caregiver peer supporters can add activities and strategies they wish to complete to enhance their wellness. The panel on the right depicts the goals section. Within the goals section, participants and caregiver peer supporters can set goals for themselves.

Figure 4. Caregiver Remote Education and Support features on both the participant- and caregiver peer supporter-facing apps.**Figure 5.** Caregiver Remote Education and Support library of resources.

Description of the CARES Resource Library

The CARES app includes a resource library with materials related to the principles of peer support and evidence-based practices and skills, such as ACT, to manage stress and promote mental health and well-being. CARES educational resources are designed to be reviewed by a participant and caregiver peer supporter together or individually (Figure 5). Each resource includes a combination of videos and text.

Figure 5 depicts the library of resources found in the CARES app. Each topic includes a scripted curriculum with evidence-based practices to improve mental health and well-being.

Methods

Overview

A field usability study was conducted in April 2022 to evaluate the usability, acceptability, and preliminary effectiveness of CARES as an assistive tool for guiding former family caregivers of people with dementia (n=3) in fidelity-adherent delivery to current family caregivers of people with dementia (n=12). The purpose of a field usability study is to assess the feasibility and acceptability of technology in users' natural and conceptual environments [27]. Through field usability studies, researchers gain an understanding of the problems users encounter while using the system and gain insights into how individuals use the product [27]. The field usability study was conducted for 2 weeks to provide caregiver peer supporters and participants with the time to use and assess the CARES app and establish a peer connection. The field usability study was a first step in

assessing the usability and acceptability of CARES, the study design, and the training. Caregiver peer supporters provided 5 to 7 hours of peer support per week, including video chats, messaging, and supervision. Each caregiver peer supporter was assigned 4 participants. In total, 17% (2/12) of the participants dropped out of the study due to a delay in the start date, and 8% (1/12) of the participants were excluded for not using the app and failing to initiate the field usability testing process, resulting in a final sample of 9 current family caregivers and 3 caregiver peer supporters. Study measures of burden, stress, and strain levels were administered via Qualtrics (Qualtrics International Inc) at baseline and at the end of the 2-week field usability study. Study measures on usability and acceptability were administered in an hour-long HIPAA-compliant videoconference semistructured interview at the end of the 2-week field usability study. All assessments were conducted by the PI.

Ethical Considerations

The Committee for the Protection of Human Subjects at the Dartmouth Health Institutional Review Board approved the project (FP00002112). Participants provided their written informed consent. Participants were compensated for taking part in the study. Current family caregivers received US \$20 for the baseline assessment, US \$20 for the completion of the 2-week CARES field usability study, and US \$20 for the completion of the semistructured interview conducted after the 2-week field usability study. Caregiver peer supporters received US \$120 for the 6 hours of training, US \$30 per hour for the 2-week field usability study, and US \$30 for the completion of the semistructured interview conducted after the 2-week field usability study.

Participants

A total of 12 participants were recruited from the Dartmouth-Hitchcock Aging Resource Center, memory cafés, and senior centers across New England and via dementia caregiver Facebook support groups to participate in the study with the goal of recruiting between 10 and 20 participants. Previous research has found that 10 users report approximately 80% of usability problems and 20 users report approximately 95% of usability problems for a given product [28]. The pilot study included 9 current family caregivers of people with dementia. Participants were eligible if they (1) were a current family caregiver of an individual with dementia, (2) were aged ≥ 18 years, (3) spoke and read English, and (4) provided voluntary informed consent for participation in the study. The study also included 3 former family caregivers of people with dementia. Participants were eligible if they (1) were a former family caregiver of an individual with dementia, (2) were aged ≥ 18 years, (3) spoke and read English, (4) were willing to use technology to deliver an intervention, and (5) provided voluntary informed consent for participation in the study. All participants were excluded if they (1) had a chart diagnosis of dementia or documented cognitive impairment as indicated by a Mini-Mental State Examination score of < 24 ; (2) had major visual, hearing, or motor impairment; (3) had a terminal illness expected to result in death within 1 year; or (4) were patients with ≥ 2 emergency room visits or hospitalizations in the previous 6

months or determined by the clinical team to be psychiatrically or medically unstable.

Measures

The usability of the CARES app was evaluated using the System Usability Scale (SUS). The SUS is a widely used, valid, reliable 10-item scale that assesses system usability [29]. Sample questions include “I think that I would like to use this system frequently” and “I thought the system was easy to use.” Response options range from 1 (*strongly disagree*) to 5 (*strongly agree*). Scores range from 0 to 100, with higher scores indicating better usability [30]. A mean SUS of ≥ 68 is indicative of an above-average user experience [30]. A system with an SUS score of > 70 is considered acceptable. Scores of > 85 are considered “excellent,” scores between 71 and 84 are considered “good,” and scores between 51 and 70 are considered “OK” [30].

Caregiver burden was assessed using the Zarit Burden Interview–Short Form. The Zarit Burden Interview–Short Form is a 12-item scale that evaluates caregivers’ physical burden, financial burden, interpersonal burden, and health [3]. The Zarit Burden Interview–Short Form is a valid scale for evaluating burden in caregivers of community-dwelling individuals with dementia [3]. Sample questions include “do you feel that because of the time you spend with your relative that you don’t have enough time for yourself” and “do you feel that you have lost control of your life since your relative’s illness.” Response options range from 0 (*never*) to 4 (*nearly always*). Scores range from 0 to 48, with higher scores indicating higher levels of burden.

The Modified Caregiver Strain Index is a 13-item scale that was used to assess strain and its consequences on caregivers’ overall health. The Modified Caregiver Strain Index is a stable and reliable measure of strain among long-term caregivers [7]. Sample questions include “caregiving is inconvenient” and “I feel completely overwhelmed.” Response options include “yes, on a regular basis,” “yes, sometimes,” and “no.” Scores range from 0 to 26, with higher scores indicating higher levels of strain.

Caregiver stress was assessed using the Caregiver Self-Assessment Questionnaire (CSAQ). The CSAQ is an 18-item scale that assesses the stress levels of family caregivers [31]. The CSAQ is a valid scale for individuals caring for people with dementia [31]. Sample questions include “during the past week or so, I have felt that I couldn’t leave my relative alone” and “during the past week or so, I have been satisfied with the support my family has given me.” Response options for questions 1 to 16 include “yes” or “no.” Caregivers are considered to have high levels of stress if they respond with “yes” to ≥ 10 questions. Question 17 asks the caregiver to rate their level of stress from “not stressful” to “extremely stressful” on a scale from 1 to 10. Caregivers are considered to have high levels of stress if they score ≥ 6 on question 17.

A semistructured interview was administered to assess the acceptability of the CARES app from the perspective of the participants. The interview questions were informed by the Consolidated Framework for Implementation Research (CFIR).

The CFIR is a meta-theoretical framework that guides implementation research and is used to systematically assess potential barriers to and facilitators of implementing an intervention [32,33]. Previous studies on the feasibility of web-based tools and interventions have used the CFIR to guide qualitative analysis, identify aspects of implementation feasibility, and determine areas of improvement and adaptation to better meet the needs of users (eg, see the study by Lawson et al [34]). The PI used the CFIR Interview Guide Tool to develop the interview questions. Interview questions covered CFIR domains such as intervention characteristics (what key attributes of the intervention influence the success of implementation), patients' needs and resources (the extent to which patient needs and barriers to and facilitators of meeting those needs are accurately known), implementation climate (shared receptivity of involved individuals to an intervention and the extent to which the use of that intervention will be supported), self-efficacy (individuals' beliefs in their own capacity to successfully implement the intervention), and evidence strength and quality (individuals' perceptions of the quality and validity of the intervention) [32]. Interview guide questions included the following: "what would you change about the CARES system and intervention?" "How well does the intervention align with your values and norms?" "What barriers will family caregivers of people with dementia face to delivering or participating in the intervention?"

Procedures

Recruitment

The PI (CCP) met with staff members at the Aging Resource Center to discuss the purpose of the study and the recruitment process. Together, they identified potential groups within and outside the Dartmouth-Hitchcock Aging Resource Center to recruit both former family caregivers of people with dementia to be trained in the delivery of the CARES app and current family caregivers of people with dementia to receive the CARES intervention. If the potential participants met the inclusion criteria, they were contacted via email and provided with a description of the study. Participants were told that the study was for an honors psychology thesis that aimed to assess the usability, acceptability, and preliminary effectiveness of a technology-based and caregiver-delivered peer support program, CARES, intended to help current family caregivers of people with dementia manage burden, strain, and stress levels. If they were interested in the study, they agreed to meet with the PI via HIPAA-compliant videoconferencing software or telephone for a baseline interview. The baseline interview lasted approximately 20 to 60 minutes. For the baseline interview, the PI read through the informed consent forms and answered participants' questions regarding the content of the study. After the baseline interview, participants who provided informed consent for the study were sent a copy of their informed consent form; sent a link to a baseline survey on Qualtrics with questions on demographic information and their current burden, stress, and strain levels; and provided with information on how to download and log in to the CARES app.

Training

Once 3 former caregivers of people with dementia were recruited, they completed 6 hours of CARES training over 2 days through HIPAA-compliant videoconferencing software. The CARES training was adapted from the Digital Peer Support Certification [35]. Fortuna et al [35,36] found that a combination of educational training (the Digital Peer Support Certification) and management of the PeerTECH system increased peer support specialists' capacity to use features of the digital peer support technology [35]. The training was based on adult learning theory and experiential learning theory. Adult learning theory suggests that adults learn best when they use past lived experiences and past developed skills and knowledge to enhance their learning process [37]. Experiential learning theory consists of four principles: (1) concrete experience, (2) observation and reflection, (3) abstract conceptualization, and (4) active experimentation [38]. In the CARES training, former caregivers were taught new skills; asked to reflect on and connect new knowledge and skills to past experiences and situations; and, finally, asked to practice the new skills they had learned. Techniques such as reinforcement, summation, and teach-back were used in the CARES training to promote the mastery of peer support skills [35].

The CARES training focused on instructing the former caregivers on the basic principles and competencies in the delivery of digital peer support and evidence-based practices to manage stress. The training included an overview of the following topics: peer support, health and aging, engaging older service users with technologies, teaching older adults how to use technology, life review, acceptance, mindfulness, coaching and making a plan of action, recognizing negative thoughts, the art and science of adult learning theory, and the role of family and caregivers in technology. Facilitated group discussions were paired with a PowerPoint (Microsoft Corp) presentation. The PowerPoint presentation was provided to all caregiver peer supporters at the end of the training. After the 6-hour training, participants who provided informed consent for the study were sent a copy of their informed consent form, a link to a baseline survey on Qualtrics with questions on demographic information, a copy of the caregiver peer support training, and information on how to download and log in to the CARES app. The PI was available for technological support from Monday to Saturday between the hours of 9 AM and 5 PM.

Fidelity

Over the course of the 2-week field usability study, a member of the research team tracked the CARES app messages between the caregiver peer supporters and assigned participants to evaluate whether the caregiver peer supporters were providing peer support in line with the training.

Informed Consent

Before the 2-week field usability study, the participant was provided with a description of the study, shown the CARES app, and read aloud the consent form word for word. Participants were evaluated according to the study criteria. If the participant was eligible and provided informed consent to take part in the study, they then completed the baseline survey on Qualtrics.

Quantitative Analyses

Descriptive statistics were used to describe the demographic characteristics of the study sample and the results of the SUS. A paired-sample 2-tailed *t* test was conducted to assess the difference between the baseline and 2-week burden, stress, and strain level scores for statistical significance. All incomplete survey responses were excluded from the analyses. Descriptive statistics and analyses were computed using the SPSS software (version 26; IBM Corp).

Qualitative Analyses

Interview data were analyzed using the rigorous and accelerated data reduction (RADar) technique. The RADar method helps streamline the process of qualitative data analysis through its ability to organize, reduce, and analyze data in user-friendly software packages such as Excel (Microsoft Corp) [39]. In accordance with the RADar methodology, the interview transcripts were formatted into an all-inclusive Excel spreadsheet. The Excel spreadsheet column headings included participant number, question, response, code, and notes. One researcher assigned codes to each response. A priori codes and themes related to the CFIR framework were identified. These codes included the acceptability of CARES, user needs and resources, intervention characteristics key to the success of the implementation, self-efficacy, quality and validity of the intervention, and receptivity of users. Codes were derived from

the interview data by carefully reviewing the transcribed text. The all-inclusive data table was then reduced to include only content that answered the overarching research questions and was of primary interest to the analysis. The remaining text and codes were then organized into themes that applied the CFIR framework and were adjusted to best fit the content covered in the qualitative interviews. The percentage of each theme was determined by dividing the frequency with which the theme was present in the interview quotes by the total number of interview quotes.

Results

Overview

Table 1 presents the sociodemographic characteristics of the sample at baseline. The sample of current family caregivers (9/12, 75%; the participants) had a mean age of 67.3 (SD 15.1) years and was predominantly female (6/9, 67%) and White (9/9, 100%), and most of them (4/9, 44%) cared for a spouse. The sample of former family caregivers (3/12, 25%; the caregiver peer supporters) had a mean age of 68.3 (SD 11.0) years and was predominantly female (3/3, 100%) and White (3/3, 100%). One of the caregiver peer supporters had experience caring for a parent with dementia (1/3, 33%), one had experience caring for a spouse with dementia (1/3, 33%), and the other had experience caring for a sibling with dementia (1/3, 33%).

Table 1. Sociodemographic characteristics of study participants (N=12).

Characteristics	Participants (n=9)	Caregiver peer supporters (n=3)
Sex, n (%)		
Male	3 (33)	0 (0)
Female	6 (67)	3 (100)
Age (years), mean (SD; range)	67.3 (15.1; 42-87)	68.3 (11.0; 61-81)
Race (White), n (%)	9 (100)	3 (100)
State, n (%)		
Connecticut	1 (11)	1 (33)
Florida	1 (11)	0 (0)
Massachusetts	2 (22)	1 (33)
New Hampshire	3 (33)	0 (0)
Vermont	2 (22)	1 (33)
Smartphone owner, n (%)		
Yes	9 (100)	3 (100)
No	0 (0)	0 (0)
Relation to relative with dementia, n (%)		
Child	3 (33)	1 (33)
Parent	1 (11)	0 (0)
Sibling	1 (11)	1 (33)
Spouse	4 (44)	1 (33)

A total of 3 participants were excluded from the study. In total, 33% (1/3) of these participants did not complete the 2-week CARES app field usability study and interview session. A total

of 67% (2/3) of these participants did not complete the 2-week CARES app due to a delay in the 2-week field usability study with one of the caregiver peer supporters. The caregiver peer

supporter delayed the start of their 2-week field usability study because the CARES app was not functioning on their smartphone. The remaining 9 participants and all 3 caregiver peer supporters completed the CARES intervention.

Usability of CARES

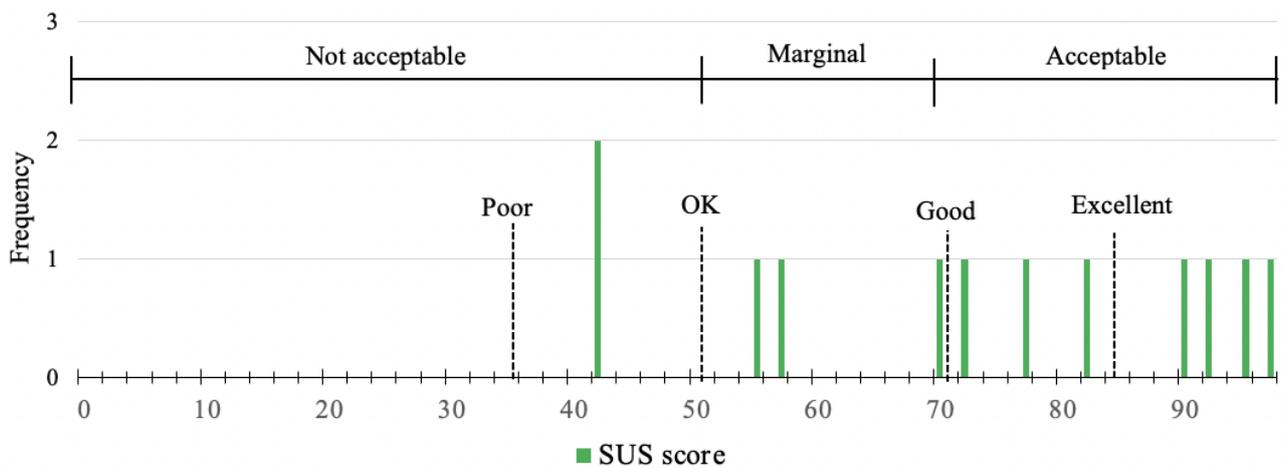

Overall, participants reported above-average system usability on the SUS, with a mean score of 72.92 (SD 19.77) and a range from 42.50 to 97.50. Most participants found CARES to be an acceptable (8/12, 67%) and good or excellent (7/12, 58%) system. Specifically, the current family caregivers receiving support reported above-average system usability, with a mean score of 76.94 (SD 19.03) and a range from 42.50 to 97.50. Caregiver peer supporters reported marginal usability, with a mean score of 60.83 (SD 20.21) and a range from 42.50 to 82.50 on the SUS. One current caregiver and one caregiver peer

supporter rated CARES as below OK. The distribution of the acceptability and adjective ratings as indicated by Bangor et al [30] are shown in Figure 6.

On average, participants sent 27 (SD 6.88) messages, with a range from 15 to 36, to their assigned caregiver peer over the course of the 2 weeks. All participants engaged weekly with the app. On average, participants reviewed 44% of the library resources over the course of the intervention, with a range from 0% to 100%.

Figure 6 shows the distribution of participant and interventionist (N=12) responses to the SUS. The x-axis marks the individual SUS scores, and the y-axis marks the frequency of the scores. Acceptability ranges and adjective ratings are informed by the work by Bangor et al [30].

Figure 6. Distribution of results of the System Usability Scale (SUS) for study participants and interventionists.

Barriers to and Acceptability and Facilitators of Using CARES

Overview

Regarding the acceptability of the CARES app and intervention, 24 codes and 6 themes related to the acceptance of CARES

were identified. The 6 themes were improving the CARES app and intervention, acceptability of the CARES app features and design, value of the caregiver-peer relationship, barriers and limitations of CARES, caregiver needs and preferences, and caregiver challenges. The themes are listed in Table 2.

Table 2. Themes from qualitative analysis of the semistructured interviews.

Theme	Description	Participant quotes
Improving the CARES ^a app and intervention	The participants and caregiver peer supporters provided input on how to improve the CARES app features and study protocol.	<ul style="list-style-type: none"> • “If you’re dealing with some kind of messaging app...there’s no point if there’s no notification because nobody will think to go check it.” [participant 5] • “One of my concerns was that a couple of the people didn’t understand what they were supposed to be doing, or how to interact with the app. I think that there needs to be a little bit more explanation upfront before we start interacting with [participants].” [caregiver peer supporter 14]
Acceptability of the CARES app features and design	Most participants and caregiver peer supporters found the CARES app to be acceptable for providing support to caregivers of individuals with dementia.	<ul style="list-style-type: none"> • “I knew that right after, like the first couple of messages back and forth, I was like, this is a great idea. Because it’s convenient. It’s easy. It’s, you know, nonjudgmental. It’s just what you want from a support thing.” [participant 7] • “I think that it’s like a personal support group. That’s what it is. And it’s in your pocket, because it’s on your phone and it’s delivered in an app, you don’t have to leave your home, you don’t have to try to arrange coverage to somebody to sit with, you know, your loved one, so that you can sneak out for an hour and then worry the whole hour that you’re out about what’s going on at home.” [caregiver peer supporter 13]
Value of the caregiver-peer relationship	Participants specifically highlighted their appreciation of the caregiver-peer relationship.	<ul style="list-style-type: none"> • “You really felt like you had somebody to reach out to in the times when things were really stressful and really felt overwhelming. It just was somebody that you could connect with that knew how you were feeling.” [participant 7] • “...knowing that there’s somebody out there who is thinking about me and my situation.” [participant 10]
Barriers and limitations of CARES	This refers to challenges that users face in using the CARES app and delivering the CARES intervention.	<ul style="list-style-type: none"> • “The only barrier I see is, if somebody doesn’t have access to an iPhone.” [participant 8] • “I’m so busy doing the caregiver stuff, and all the other sort of managing, so that if I have any time to myself, I would want to be doing other things that, you know, that didn’t involve caregiving. So I wouldn’t be apt to wanting to take the time out of those personal times.” [participant 10]
Caregiver needs and preferences	Most participants and caregiver peer supporters found that the CARES app met the needs and preferences of family caregivers of people with dementia.	<ul style="list-style-type: none"> • “I think that a lot of caregivers will love [CARES] too. You know, the doctors are doctors, they’re doing the medical part of it. They don’t even think about the emotional part that the caregiver is going through.” [caregiver peer supporter 14] • “It’s more I know that I have to take care of myself in order to be a better caregiver. And I can’t do that if I’m not feeling good about myself. And yet, I didn’t know how to do that...So I think I think [my peer supporter] was really good the way that she, she validated my feelings and, and was out there for me.” [participant 6]
Caregiver challenges	Participants highlighted the overall challenges of caring for a family member with dementia.	<ul style="list-style-type: none"> • “My daughters were very concerned about me not getting out enough on my own.” [participant 9] • “One of the biggest struggles that I have is finding people that understand what I’m going through...it’s very difficult to find somebody that I could connect with that had been through what I was going through, and that I felt comfortable really voicing my feelings to. So I think the idea behind the app is like, great, actually because, I mean, it’s like somebody that’s always there that knows exactly what you’re feeling and what you’ve been through.” [participant 7]

^aCARES: Caregiver Remote Education and Support.

Improving the CARES App and Intervention

The most prevalent theme was improving the CARES app and intervention. This theme comprised 3 subthemes: improving the study, improving the app features, and technological difficulties. Improving the CARES app and intervention constituted 26% of the themes discussed in the interviews. The participants and caregiver peer supporters provided input on how to improve the CARES app features and study protocol. For example, a few participants noted problems receiving notifications when their assigned peer sent them a message through the app. Participant 5 mentioned the following:

...if you’re dealing with some kind of messaging app...there’s no point if there’s no notification because nobody will think to go check it.

Some participants found aspects of the app difficult to maneuver. At times, the video chat would not connect properly, and the library resources would appear blank. Caregiver peer supporter

13 thought that the home page of the CARES app should clarify the content of the library resource feature to increase interaction with the materials contained within the library:

...you don’t know that the resources are there, they’re offering them to you, but you can’t find them. It’s like you’re going on a board game, and you don’t know where to get off.

Other participants provided ideas on how to enhance the app. For example, caregiver peer supporter 15 suggested that the app include the option to communicate via telephone along with video chat and messaging as building rapport can be “very difficult to do with texting.” Other participants suggested adding a support group–like feature where participants could connect with multiple peers rather than just 1. Participant 5 suggested the following:

...having kind of a group chat or a message board, where you could just be like, okay, just, you know,

like, venting for a second or whatever, that could be really kind of an expansion from beyond just the one on one.

The caregiver peer supporters also provided feedback on how to improve the peer support training. The caregiver peer supporters thought that clarification of the peer supporter and participant roles and expectations would have improved the participant-peer interaction and relationship. For example, caregiver peer supporter 14 stated the following:

...one of my concerns was that a couple of the people didn't understand what they were supposed to be doing, or how to interact with the app. I think that there needs to be a little bit more explanation upfront before we start interacting with [participants]

Both participants and caregiver peer supporters recommended holding a training specifically on the features of the CARES app. Caregiver peer supporter 13 said the following:

I think that it would have also been beneficial to download the app, and then on part of the training, you walk through it with us, and we...just play with it...like hands on learning.

The caregiver peer supporters suggested that the training should include additional practice using the CARES app and suggestions on how to initiate relationships with their assigned participants. Participants proposed that, in the future, a researcher should explain the features available on the CARES app and clarify their expectations for both the caregiver peer and the participant. Finally, participants recommended that future studies should match peers with participants based on their relationship to the individual with dementia they are caring for.

Acceptability of the CARES App Features and Design

The second theme, acceptability of the CARES app features and design, constituted 25% of the themes discussed in the interviews. Overall, most participants and caregiver peer supporters found the CARES app to be acceptable for providing support to caregivers of individuals with dementia. All participants agreed that the main purpose of the app was to connect caregivers with peers with a similar lived experience. Most participants interacted most with the messaging feature. Participant 5 mentioned the following:

I think the main point, or the main feature, is the connection to peers.

Participants and caregiver peer supporters emphasized the convenience and accessibility of the CARES app. For example, participant 7 said the following:

I knew that right after, like the first couple of messages back and forth, I was like, this is a great idea. Because it's convenient. It's easy. It's, you know, non-judgmental. It's just what you want from a support thing. And it's also sort of on your own terms, though, because you get a message. So like, if you didn't want to respond instantly, you can kind of gather your thoughts, and you have time to respond, unlike a regular back and forth support group where

if somebody asked me a question, I kind of have to have an answer...So. I think this was better, because I had a few minutes to really think through what she was asking me...and I had a minute to kind of gather my thoughts, and then I could just type it back.

Participant 5 mentioned that, in contrast to in-person support groups where caregivers may “struggle with getting away even for an hour out of an apartment or their house for an hour,” they “like the fact that they can [use CARES] over an iPad or an iPhone...I think that definitely makes it more accessible and easy.” Caregiver peer supporters agreed that the CARES app was an appropriate tool for current caregivers of people with dementia. Caregiver peer supporter 13 shared the following:

I think that it's like a personal support group. That's what it is. And it's in your pocket, because it's on your phone and it's delivered in an app, you don't have to leave your home, you don't have to try to arrange coverage to somebody to sit with, you know, your loved one, so that you can sneak out for an hour and then worry the whole hour that you're out about what's going on at home.

However, while all participants found the messaging feature of the CARES app beneficial, only some of the participants used the library resources (specifically the mindfulness, values, and negative thinking information). The “goals” and “wellness” features of the app were the least used by participants.

Value of the Caregiver-Peer Relationship

The third theme, the value of the caregiver-peer relationship, constituted 15% of the themes discussed in the interviews. Participants specifically highlighted their appreciation of the caregiver-peer relationship. Most participants emphasized that the purpose of the CARES app was the caregiver-peer connection. Participants found that their assigned caregiver peer supporters were knowledgeable, understanding, and validating. Participant 7 mentioned the following:

...you really felt like you had somebody to reach out to in the times when things were really stressful and really felt overwhelming. It just was somebody that you could connect with that knew how you were feeling.

They also shared the following:

...it was also nice, because the person that I was connecting with chose to be connected with somebody. So it wasn't like you felt like you were burdening somebody else with your feelings.

The caregiver peer supporters also found value in the caregiver-peer relationship. Caregiver peer supporter 13 said the following:

I think it's a great way to connect with caregivers. And it's easy because you can just type a message and somebody picks up that message at that point, and it's like having a support system at your fingertips...So I think when it works correctly, it would be a great effective tool for caregivers...because I found that caregivers in general, you know, they're

not healthcare professionals. And they're expected to be in that role as part of the healthcare team. And they don't even know like, who to call, like, do I call you when my husband is running a fever and needs care?...I feel for these people that are just like plunked down in this role. And they don't have anyone. Even [one participant] said, I feel great, just knowing that you're there. And you provided this emotional support for me. And it's nice to know that you can reach out to someone that gets it. And that's exactly what it is...You know, it's a lifeline for people.

Participants and caregivers found that participants appreciated the intervention “knowing that there's somebody out there who is thinking about me and my situation” (participant 10). The caregiver-peer connection was central to the CARES intervention.

Barriers and Limitations of CARES

The fourth theme, barriers and limitations of CARES, constituted 12% of the themes discussed in the interviews. Participants highlighted 2 main barriers and limitations: access to technology and time constraints. First, participants recognized that some caregivers may not have access to a smartphone or tablet or may not have adequate internet connection. Participant 8 mentioned that “the only barrier I see is, if somebody doesn't have access to an iPhone.” Other participants noted that older adults may not be comfortable using technology. Time constraints and competing priorities were cited as other barriers that participants might face when using the CARES app. For example, participant 10 shared the following:

I'm so busy doing the caregiver stuff, and all the other sort of managing, so that if I have any time to myself, I would want to be doing other things that, you know, that didn't involve caregiving. So I wouldn't be apt to wanting to take the time out of those personal times.

Finally, many participants and caregiver peer supporters thought that a 2-week period did not provide enough time to fully explore the features of the CARES app and peer relationship. For example, participant 7 said that “well, I didn't really check it out as much as I wanted to, because two weeks is not a lot of time.”

Caregiver Needs and Preferences

The fifth theme, caregiver needs and preferences, constituted 11% of the themes discussed in the interviews. Overall, most participants and caregiver peer supporters found that the CARES app met the needs and preferences of family caregivers of people with dementia. Specifically, participants found that the CARES app and intervention provided social and emotional support. Participant 6 shared the following:

I think sometimes it's important for people who are caregivers to just be able to say how they're, how they're feeling.

Caregiver peer supporter 14 mentioned the following:

I think that a lot of caregivers will love [CARES] too. You know, the doctors are doctors, they're doing the

medical part of it. They don't even think about the emotional part that the caregiver is going through.

For many participants, the CARES app and intervention provided individualized care and support. For example, participant 6 shared the following:

...it's more I know that I have to take care of myself in order to be a better caregiver. And I can't do that if I'm not feeling good about myself. And yet, I didn't know how to do that. Because I'm so tied up, so wrapped up in this. So I think I think she was really good the way that she, she validated my feelings and, and was out there for me.

However, participants also stressed that caregiver peer supporters should have a general understanding of individuals' backgrounds and access to resources when providing support. For example, participant 5 mentioned the following:

...there's a wide range of resources that people have. I've seen this in the caregiver group I am a part of. Some people have planned well, and can afford help and support and some people don't have that, and they have no family around...The support person...should have an awareness of saying...you need to just hire somebody to come in for an hour every day.

Caregiver peer supporters need to have an awareness of participants' available resources and priorities when providing support. Finally, most caregiver peer supporters also felt that CARES met their needs and preferences as former caregivers. For example, caregiver peer supporter 13 shared the following:

I always feel purposeful when giving back. That's most of the reason that I do coaching...I always feel a feeling of purpose. And there's a lot of emotional support and a feeling of gratification that comes from giving that emotional support, because you have the lived experience that you can share with these other caregivers. And if you don't have that experience, you don't get it like you can be in that role, but you don't truly get what they're going through.

Caregiver peer supporters felt a sense of purpose while delivering the CARES intervention.

Caregiver Challenges

Finally, caregiver challenges was an emerging theme that constituted 5% of the themes discussed in the interviews. In their interviews, the participants highlighted the challenges of caring for a family member with dementia. Topics included difficulty taking time for oneself, frustration, anxiety about the unknown and upcoming changes, guilt, and the inability to find people who understand their situation. For example, participant 9 mentioned the following:

...my daughters were very concerned about me not getting out enough on my own.

Participant 6 said the following:

I just wish with this disease they could say, well, in six months you may experience this and another six months you may experience that.

Participant 2 stated the following:

...there are certain days you just feel more on top of things than others.

Some participants shared how the CARES app and intervention addressed their challenges:

But one of the biggest struggles that I have is finding people that understand what I'm going through. Because if you have not provided care for somebody with dementia, you really don't understand like you can try to understand you can have the knowledge. But if you don't have the experience, it's very difficult to find somebody that I could connect with that had

been through what I was going through, and that I felt comfortable really voicing my feelings to. So I think the idea behind the app is like, great, actually because, I mean, it's like somebody that's always there that knows exactly what you're feeling and what you've been through. [participant 7]

Others did not voice whether CARES attended to the specific challenges they faced as caregivers.

Preliminary Effectiveness of CARES

Participants' decreases in burden, strain, and stress levels were not significant. However, we were not powered to find significance; rather, the purpose of this study was feasibility and acceptability. Non-statistically significant improvements were observed in all measures. The results of the baseline and 2-week posttreatment assessment for the 9 participants who completed the CARES intervention are shown in [Table 3](#).

Table 3. Changes in outcomes from before to after the field usability study (2 weeks) for study participants (N=9)^a.

Measure	Participants, n (%)	Pretest assessment, mean (SD)	Posttest assessment, mean (SD)	<i>t</i> test (<i>df</i>)	<i>P</i> value	Effect size (Cohen <i>d</i>)
ZBI-12 ^b	9 (100)	22.44 (10.04)	21.44 (11.34)	1.25 (8)	.25	0.42
MCSI ^c	9 (100)	11.22 (6.62)	11.00 (7.44)	0.41 (8)	.70	0.13

^aA 2-tailed paired *t* test was used to assess statistical significance.

^bZBI-12: Zarit Burden Interview–Short Form.

^cMCSI: Modified Caregiver Strain Index.

^dCSAQ: Caregiver Self-Assessment Questionnaire. The CSAQ total is the average number of “yes” responses on the CSAQ, and the CSAQ stress score is the mean score on question 17 of the CSAQ, which asked participants to rate their level of stress on a scale from 1 to 10.

Discussion

Principal Findings

The purpose of this study was to evaluate the usability, acceptability, and preliminary effectiveness of the CARES app and intervention. The pilot study demonstrated that a 2-week peer-delivered and technology-supported mental health intervention (CARES) was acceptable for both former family caregivers of people with dementia who delivered peer support and current family caregivers of people with dementia who received peer support. Current caregivers reported above-average usability of CARES, and former caregivers reported marginal usability. The pilot study demonstrated that it is possible to train former caregivers in peer support and the delivery of CARES and integrated psychoeducation and mental health interventions using technology. CARES was associated with non-statistically significant improvements in burden, stress, and strain levels.

The usability of the CARES app was demonstrated using the SUS. Most caregivers found the CARES app to be an acceptable and good system with above-average usability. The CARES app allowed peer caregivers to provide individualized support and provided caregivers with access to evidence-based mental health resources on topics such as mindfulness and acceptance. The usability of CARES was also demonstrated through

participants' capacity to use the smartphone and tablet app, completion of library resources on the app, and use of the messaging chat feature. Overall, most participants and caregiver peer supporters agreed that the CARES app and intervention were an acceptable tool to support family caregivers of people with dementia. However, participants and caregiver peer supporters identified areas in which the usability and acceptability of the app could be improved, and the caregiver peer supporters specifically reported marginal usability of the CARES app. Caregiver peer supporters may have reported below-average usability because of latency in messaging and other technological difficulties using the app. Future studies should examine the cause of differences in usability scores between current and former family caregivers and update the CARES app accordingly.

Participants suggested that improvement of technological features would strengthen the app's ability to achieve its purpose of connecting caregivers with peers. Some participants and peers faced technological difficulties while using the app. For example, at times, the app would not notify participants of new messages. This created a barrier in participants' and peers' ability to communicate efficiently and effectively. Participants also provided suggestions on how to improve the app features. For example, participants suggested adding a telephone feature to the app. Participants believed that adding a telephone feature would allow caregivers to communicate via the medium of their

preference and, therefore, increase their comfort level with technology and the caregiver-peer relationship. Participants also suggested adding a feature through which they could connect with more than one caregiver with a similar lived experience and suggested adding more caregiver-specific resources to the library resource page.

Despite technological limitations, most participants and peers found that the CARES app was an acceptable support intervention for family caregivers of people with dementia. Participants identified the caregiver-peer connection as the principal feature of the CARES app. Participants labeled the message-based support as convenient, easy-to-use, accessible, and individualized. The caregiver peer supporters were described as knowledgeable, understanding, validating, and supporting. Participants felt that the shared lived experience offered by the former caregivers better matched their needs and preferences for emotional and social support compared to professional medical and health care workers. On the other hand, the former family caregivers felt a sense of purpose and gratification while delivering the CARES intervention.

These findings suggest that technology- and peer-based interventions are usable and acceptable to family caregivers of people with dementia and that a smartphone app is a promising tool to support the mental and emotional health and well-being of family caregivers outside of an in-person or clinical setting. Task shifting informal caregiver digital mental health services to community members with lived experience has the potential to provide acceptable mental health interventions to family caregivers of people with dementia while addressing the current barriers and challenges with respect to accessing support. While it is estimated that nearly 153 million older adults will have dementia worldwide by 2050, mental health services for caregivers and their family members are limited due to an insufficient number of adequately trained geriatric mental health care providers [16,40]. Peer-delivered and technology-supported interventions have the potential to provide mental health services to family caregivers of people with dementia that are easily accessible and effective [36]. While caregiver psychosocial interventions have faced limitations due to time commitments, geographical location, requirements to meet in person, and failure to address the individualized needs of the caregiver, former and current family caregivers of people with dementia reported that the CARES app and intervention addressed the unique needs and experiences of consumers.

The results of the study support the hypothesis that former family caregivers of people with dementia have the knowledge and skillset to deliver trained peer support to current family caregivers. In previous studies, peers have been reported to be particularly effective at engaging participants in interventions. By sharing a lived experience, peers have the ability to develop alliances with participants and are viewed as more credible than traditional clinicians and providers [21]. With the use of technology-based messaging and support, participants were able to provide individualized support to caregivers at any time and location.

However, there are barriers and limitations to consider when using and delivering the CARES app and intervention. First,

the CARES app is not accessible to caregivers who do not have a smartphone or adequate internet connection. In addition, time constraints may limit caregivers' ability to interact with the app and their assigned peer. Offering peer support to family caregivers of people with dementia may place stress on the interventionists. Caregiver peer supporters involved in the study should be offered mental health support while delivering the intervention. Finally, participants and peer supporters suggested that the abrupt ending of the 2-week field usability study may leave caregivers without the resources and support systems they came to rely on to manage well-being. Future studies should provide caregiver participants with additional caregiver support resources at the end of the CARES field usability study.

This study is not without limitations. First, one member of the research and intervention development team conducted a qualitative analysis of the interview data and identified codes and themes, which may have biased the results. In addition, member checking was not used to validate the findings and assess the accuracy of the qualitative results. Second, caregivers' input was not included in the initial development of the CARES app. Stakeholder engagement in the early stages of intervention development is essential to ensure that the modality and components are relevant to the community [41]. Future studies will incorporate caregivers' feedback to further improve and adapt the CARES app and intervention. Third, some participants and caregiver peer supporters experienced technological difficulties with the CARES app. For example, 22% (2/9) of the participants and 33% (1/3) of the caregiver peer supporters were unable to receive notifications and, therefore, had delayed responses to messages. Another caregiver peer supporter experienced challenges sending messages and, consequently, had to delay the start of their 2-week field usability study. These technological difficulties could have impacted the results of the field usability study and SUS. Fourth, the participant response rate was not tracked during the recruitment process. Future studies should track the response rate to improve recruitment procedures and decrease bias (eg, nonresponse bias). Fifth, data on the frequency of use of CARES app features such as video chat, goal setting, and wellness plans were not tracked across participants. This information will be helpful for further understanding the acceptability and usability of CARES. Sixth, the caregiver peer supporters were not assessed regarding whether they had learned the topics presented in the training, and the competence of the training was not assessed. Therefore, it is unknown whether the training sufficiently educated caregivers on the delivery of peer support. Seventh, the fidelity of caregiver peer support was not systematically evaluated through audio interactions; rather, message data determined high fidelity to the peer support model. Future research will assess message and audio interactions to determine fidelity to the caregiver peer support model of care through audio recordings on the app. Caregiver peer supporters' deviation from the training may have biased the results. Eighth, the participant eligibility criteria were broad and included all family caregivers of individuals with dementia aged ≥ 18 years. Criteria such as whether the caregiver lived with their care recipient and the number of hours spent caring for their relative with dementia could impact the acceptability, usability, and effectiveness of the CARES app and intervention. Future studies should

investigate the influence of differing caregiver roles and responsibilities on CARES. Finally, demographic information on factors such as education and income level was not collected, which may have affected the results and the perceived usability of the app.

While the aim of this study was to evaluate the usability of CARES and assess the acceptability and potential barriers to using the CARES technology, future studies would benefit from a larger sample size and a longer trial duration. In the qualitative interviews, participants shared that they wished they had a longer period to explore the app and the caregiver-peer relationship. While the length of the study and sample size were consistent with a field usability study, longer trials would allow participants to further assess the usability and acceptability of the app and whether it meets their needs and preferences as caregivers [42]. A longer trial would also more accurately reflect the length and fluctuation of the dementia caregiving experience. Future studies would also benefit from a randomized controlled design (eg, an intervention group with CARES and caregiver peer support vs a control group) and a control of covariables influencing the outcomes to evaluate the effectiveness of the CARES training, intervention, and app in reducing burden, strain, and stress in family caregivers of people with dementia. For example, future studies should examine the influence of age; relationship to the individual with dementia receiving care; stage of dementia; years providing care; severity of dementia symptoms; severity of the family caregiver's stress, strain, and burden levels; and the use of other caregiver support treatments and interventions on the effectiveness of the CARES app.

Future studies should also assign caregivers to peers based on dementia diagnosis or relationship to the individual with dementia. Matching caregivers with peers based on shared caregiver lived experiences may moderate the effectiveness of the CARES intervention. Future research would also benefit from a more diverse group of participants. Recruitment procedures should focus on recruiting a sample of participants representative of the demographics of the greater caregiver population. This includes recruiting more caregivers of color and caregivers who identify as male or nonbinary. Finally, future work should address the benefit of caregiver peer support for the family caregivers both delivering and receiving the mental health intervention. Caregiver peer support may have bidirectional effects. The caregivers providing support may see improvements in their mental health and well-being along with those of the participants they are supporting. As indicated by the study interview data, caregiver peer supporters felt a sense of purpose while delivering the intervention. Future studies should further assess the potential bidirectional influence of the CARES app and intervention.

Conclusions

This pilot study demonstrated that it is possible to train former family caregivers of people with dementia to use technology and deliver the CARES mental health intervention to current family caregivers of people with dementia. These findings provide preliminary evidence that a peer-delivered and technology-supported intervention designed to improve burden, stress, and strain levels is feasible and acceptable.

Abstract

Background: Studies evaluating the usability of mobile-phone assessments in older adults are limited.

Objective: This study aims to identify design-based barriers and facilitators to mobile app survey completion among 2 samples of older adults; those in the Framingham Heart Study and a more diverse sample from a hospital-based setting.

Methods: We used mixed methods to identify challenging and beneficial features of the mobile app in participants from the electronic Framingham Heart Study (n=15; mean age of 72 years; 6/15, 40% women; 15/15, 100% non-Hispanic and White) and among participants recruited from a hospital-based setting (n=15; mean age of 71 years; 7/15, 47% women; 3/15, 20% Hispanic; and 8/15, 53% non-White). A variety of app-based measures with different response formats were tested, including self-reported surveys, pictorial assessments (to indicate body pain sites), and cognitive testing tasks (eg, Trail Making Test and Stroop). Participants completed each measure using a think-aloud protocol, while being audio- and video-recorded with a qualitative interview conducted at the end of the session. Recordings were coded for participant usability errors by 2 pairs of coders. Participants completed the Mobile App Rating Scale to assess the app (response range 1=inadequate to 5=excellent).

Results: In electronic Framingham Heart Study participants, the average total Mobile App Rating Scale score was 7.6 (SD 1.1), with no significant differences in the hospital-based sample. In general, participants were pleased with the app and found it easy to use. A large minority had at least 1 navigational issue, most committed only once. Most older adults did not have difficulty completing the self-reported multiple-choice measures unless it included lengthy instructions but participants had usability issues with the Stroop and Trail Making Test.

Conclusions: Our methods and results help guide app development and app-based survey construction for older adults, while also giving consideration to sociodemographic differences.

Introduction

Adults aged 65 years and older are increasingly using tablets and smartphones and engaging with a range of technologies [1]. Technology use can reduce social isolation [2] and enhance communication with family members and health care providers, thereby, increasing well-being. Further, digital technologies have the potential to improve the health of older adults by facilitating symptom monitoring and self-care management as well as monitoring cognitive and mobility decline. However, older adults often lack confidence in their ability to use technology [3] and report needing assistance with new electronic devices and mobile apps [4]. They face unique challenges with technology including poor eyesight, hearing loss, fine motor skill and sensory limitations, and cognitive decline. These challenges make it essential to understand how technologies can be made more useful to older adults. Perceived value, usefulness, and impact on quality of life are important predictors of technology adoption in this age group [5,6]. In addition, a design that minimizes user frustration will enhance the use and lower the risk of leaving older users out of the technology revolution.

Older adults are often not well represented in user testing of technology [7] due to the restricted age range of research studies, physical or sensory impairments, or because technology studies may be less appealing to them. There are a growing number of smartphone apps that include opportunities for self-management of specific diseases and cognitive self-assessment but the quality and usability of the apps are often unknown especially among groups of older adults and adults from diverse race and ethnic populations [8,9]. In addition, health care providers and hospital systems are increasingly requesting that patients complete previsit health questionnaires electronically, which help with care efficiency and are preferred by providers [10,11]. However, older adults are less likely to access and use patient portals and may have unique needs influencing their use [12-14].

Usability information provides practical recommendations that can help increase patient responsiveness to electronically collected data. For example, studies that have evaluated the usability of mobile apps that assess fall risk demonstrated the importance of simple instructions and clear feedback such as a color change to indicate task completion [6,15,16]. A mobile app designed for older adults with heart failure to report Patient Reported Outcomes Measurement Information System (PROMIS) measures demonstrated that these adults successfully returned the PROMIS data and an additional survey indicated high levels of usability [17].

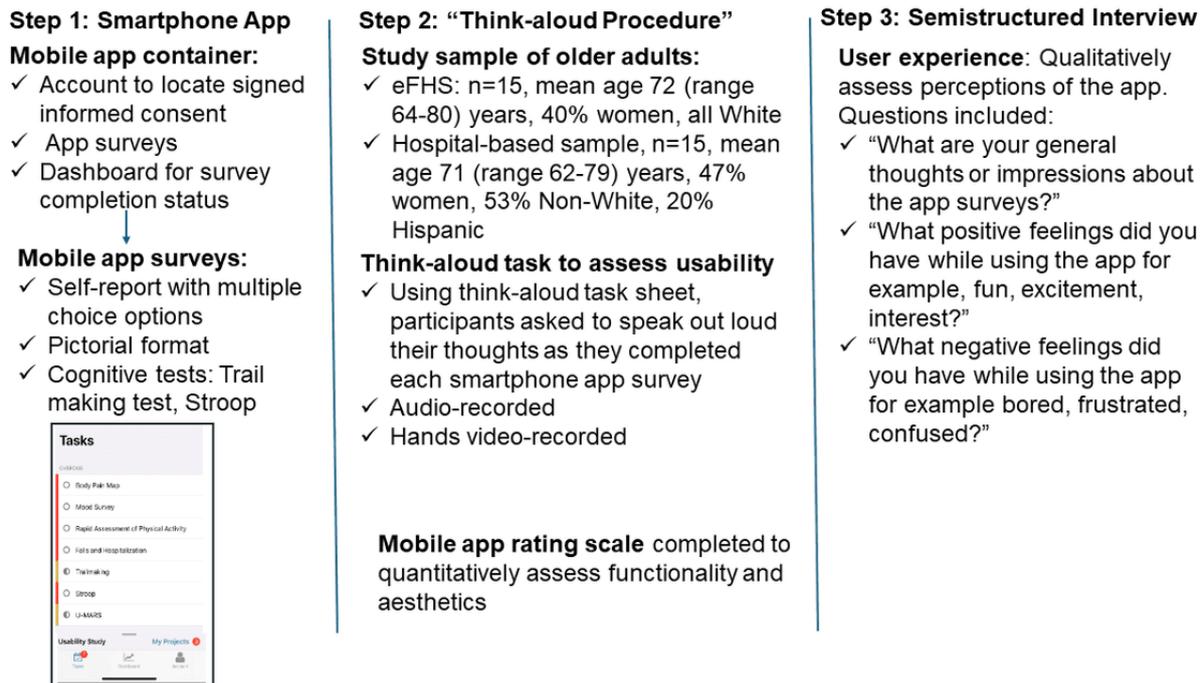

We designed a smartphone app for use by community-dwelling older adults who are participants in the Framingham Heart Study (FHS). The smartphone app consists of surveys with different response formats (eg, multiple choice, pictorial, and tasks). The aim of this study is to identify design-based barriers and facilitators to mobile app navigation and survey completion through usability testing. We also sought to understand whether participant feedback differed depending on the response format of each measure. Because FHS participants were White, we enrolled a diverse sample of older adults at a second site to understand if any additional barriers to mobile app survey completion were observed given that digital literacy and preferences for using technologies can vary across older adults of different races and ethnic backgrounds [12,18]. Importantly, little is known about the usability of mobile apps for racially or ethnically diverse populations [8].

Methods

Study Design

The study used mixed methods to conduct 1 usability testing session followed by a postsession interview with enrolled participants (Figure 1). Usability testing methods included using the “think-aloud” protocol while conducting a series of surveys and tasks on the smartphone app. This was followed by a semistructured interview using an interview guide, to solicit information on barriers encountered in the session.

Figure 1. Overall study design.

Study Sample

The study sample was drawn from 2 sites: the FHS Offspring study and a hospital-based site. The FHS Offspring participants were recruited in 1971 and are invited back to the research center for examination every 6 to 8 years [19]. The tenth examination of the FHS Offspring participants occurred from 2019 to 2022 and included a mobile health component called the electronic Framingham Heart Study (eFHS). For this study, we enrolled eFHS participants who were English-speaking, owned a smartphone (iPhone or Android), attended Offspring exam 10 before the eFHS began, and enrolled in eFHS between July and September 2022. The eFHS research technician assisted the participants with registration, informed consent, and app download. Because most of the eFHS sample had iPhones and were less racially and ethnically diverse, we recruited participants from a second site who were not part of eFHS. The second site was a hospital in an urban area with a racially and ethnically diverse patient population. At the second site, inclusion criteria were age 60 years and older, English speaking, and able to attend a study session between December 2022 and April 2023. Participants were recruited through flyers placed in clinic waiting rooms and community centers, participation in prior research studies, and through patient registry lists. Non-White and Hispanic/Latino patients were oversampled from patient registry lists. As with eFHS, the research technician assisted the participants with registration, informed consent, and app download on a study iPhone. Participants at both sites were using the app for the first time. We enrolled 15 participants at each study site to ensure the representation of men and women, iPhone and Android users, and older people below and above 75 years. In addition, the number of unique challenges identified with the study design proposed appears to asymptote 15 participants [20]. While eFHS participants were not compensated for their time in the study (because FHS

participants have not been compensated for participation in the parent study), participants from the hospital-based cohort were provided a US \$100 card for participating upon completion of the session.

Ethical Considerations

The institutional review board at Boston University Medical Campus approved the eFHS study (H-36586) and this study (H-42659). The institutional review board at the University of Massachusetts Chan Medical School approved the hospital-based study (approval number 00000567).

Measures

Study App

A mobile app hosted a compendium of different types of survey assessments and tasks that users could click on to complete. CareEvolution’s MyDataHelps Designer platform was used to build the smartphone app surveys for iPhone (iOS 10.0 or higher) or Android (version 7.0 or higher) devices. The MyDataHelps mobile app container includes an account where participants can locate their signed consent form, tasks (app surveys), and a dashboard. The dashboard was created in the app to provide the participant with survey completion status and encouragement with a thank you message. Investigators and CareEvolution industry partners internally tested the app surveys and tasks with attention to consistency inspection, and user-centered design principles to ensure clear instructions, easy navigation, and simple words and sentences [21].

Because the goal of the study was to assess usability, we included a variety of app-based surveys and tasks with different response formats (Multimedia Appendix 1). First, we tested several self-report surveys with multiple choice options including (1) the short form of the PROMIS measure of mood (anxiety and depression, 8-items) [22] and cognitive function

(4-items) [23] that included 5 response options that ranged from “never” to “always” for the mood assessment and “not at all” to “very much” for the cognitive function assessment; (2) falls and hospitalizations with yes/no response options and a calendar wheel to ascertain the date of a fall occurrence; and (3) rapid assessment of physical activity [24] to report the frequency of physical activity and the level of intensity (light, moderate, and vigorous), assessing frequency, intensity, and time, with yes/no response choices. The hospital-based site did not complete the PROMIS measure of mood. Second, we tested a pictorial format measure to collect data on chronic pain, based on a modified version of the Michigan body pain map measure [25]. Participants were shown an outline of a human body and were asked to click on the different places of the body where they are currently experiencing chronic pain, defined as pain lasting 3 months or longer. The app first displays the image of the front of the body and next the back of the body. If the participant is not experiencing chronic pain, a box was provided so that the user can indicate “no chronic pain.” The third and final smartphone tasks tested were 2 commonly used cognitive tests. The Trail Making Test [26,27] is a timed assessment that requires the user to consecutively tap dots in alternating order between numbers and letters by first tapping the number “1” followed by tapping the letter “A” and then “2” followed by “B” until the user reaches the number “7.” Correct answers result in the appearance of lines between the dots, resulting in a “trail.” Finally, we assessed the Stroop [28] on the smartphone that requires the user to complete a series of 4 increasingly more difficult tasks responding as quickly and accurately as possible to changes in color and instructions. Because the Stroop requires the user to be able to see colors (yellow, green, red, and blue), persons with color blindness are not eligible for this task. A practice session was provided for each set of the 4 tasks with the ability to repeat the practice session should the user desire to do so [29]. At the end of the testing session, participants completed the Mobile App Rating Scale (MARS) on the smartphone to assess app functionality and aesthetics including ease of use, navigation, visual appeal, performance, graphics, and layout [30]. Items were rated by the participant using a 5-point Likert scale from 1=inadequate to 5=excellent.

Demographic data were not collected within the study app. For eFHS participants, these data were collected as part of Offspring exam 10. Sociodemographics such as age, gender, and employment were assessed via the research study coordinators and entered into a secure web-based software platform, REDCap (Research Electronic Data Capture; developed initially at Vanderbilt University, now collaborative support from the REDCap consortium) at the hospital-based site.

Procedure

Study sessions were conducted in person at the FHS Research Center. eFHS participants were asked to complete the above assessments using their own smartphones, but hospital-based participants used a study smartphone (iPhone 7). In addition, they were also asked to navigate to different areas of the MyDataHelps app container (account, tasks, and dashboard). While doing these tasks, participants were asked to “think your thoughts” out loud, including feelings (positive like “fun” and negative like “frustrating”). Prior to beginning the usability

testing, the research technician demonstrated the “think-aloud” procedure using the text app on a smartphone and then asked the participant to demonstrate the think-aloud procedure using the same app verbalizing every movement, feeling, and decision. Once the participant was ready to begin, the research technician encouraged the participant to use the think-aloud task sheet (Multimedia Appendix 1) that included a list of app-based tasks. Participants were asked to speak out loud their thoughts, feelings, and actions as they completed each task. The participant was audio-recorded, and the participant’s hands were video-recorded throughout the think-aloud procedure. The participant also completed the MARS [30] on the smartphone after the think-aloud procedure. The technician was present to audio- and video-record the think-aloud procedure and to encourage participants to speak their thoughts out loud. The technician was explicitly trained not to assist the participant with the app unless the participant was irrevocably stuck.

After completion of the think-aloud procedure, the research technician conducted a 15-20-minute interview using open-ended questions and reflective listening to obtain participant feedback on their experiences using the app. Interview questions are available in the Multimedia Appendix 1 and include questions such as “What are your general thoughts or impressions about the app surveys?”; “What positive feelings did you have while using the app for example, fun, excitement, interest?”; and “What negative feelings did you have while using the app for example bored, frustrated, confused?” In addition, the interviewer asked the participants to what extent family, friends, and people of their own age would be able to use and enjoy the app and their thoughts on how to ensure the app would be acceptable to people of different cultures. The research technicians (AD, NA, and AH) are coauthors of this work.

Research Technician Training

In total, 4 interviewers were trained (by BB and JF), 3 were bachelor level and 1 was PhD level. Training consisted of learning the think-aloud procedure and also how to conduct the post think-aloud interview. Building rapport and communication skills (open-ended questions and reflective listening) were part of the training. Training included didactics and role plays and trainees were required to complete 3 sessions with “mock” participants, supervised by 1 or both trainers before being cleared to do the protocol with study participants. Feedback on study participants was provided to research technicians on an ongoing basis, by viewing the audio and video tapes together. The audiotaped portion of the think-aloud procedure and interview was professionally transcribed (Daily Transcription).

Process of Coding the Sessions

Investigators developed a coding sheet and accompanying coding manual for use by teams of coders when coding the video- and audio-recordings of the think-aloud procedure and postinterviews. The coding sheet included general items (eg, navigation between surveys, tapping in the wrong area to advance to the next task, and unclear instructions for surveys) as well as assessment-specific variables (clarity of instruction, understanding concepts, navigating within a survey, and “look and feel” eg, font size, line spacing, and color). For training

purposes, all coders reviewed 3 participant recordings together and resolved any coding discrepancies before separating into the 2 coding teams to code in pairs. In order to maintain coding reliability over time, the 2 teams (team one: JF, JM; team 2: BB, DDM) independently coded the same participant recordings on 5 occasions throughout the coding process and came together to review the coding sheets for any discrepancies across teams to ensure all coders were following the coding guidelines. The average percent agreement between coders ranged from 80.5% to 98% across the 5 recordings that were coded in common by the 2 teams.

Statistical Analysis

Descriptive statistics of the 2 study samples used mean and SD for continuous variables, and numbers and percentages for nominal variables. For the comparison of continuous variables, 2-tailed *t* tests were applied, and chi-square tests or Fisher exact tests were used to compare nominal variables between the samples. The percent agreement between coding teams was calculated by the ratio of the number of discrepancies divided by the number of items in the coding sheet. For the MARS, all items used a 5-point Likert scale and the mean score for each domain (functionality and aesthetics) was calculated separately and an overall MARS score was computed for each of the 2

study samples. In addition, we calculated the mean score of each item within a domain (eg, layout, graphics, and visual appeal).

Results

Study Sample

In eFHS, 15 participants signed informed consent (mean age of 72, SD 4.2, range 64-80 years; 6/15, 40% were women; 1/15, 100% non-Hispanic, White). All eFHS participants owned a smartphone with 9 of 15 (60%) of the eFHS study sample participants owning an iPhone (Table 1). In the hospital-based site, 77 were contacted, 19 declined to participate, 3 deferred enrollment to a later date, and 15 participants signed informed consent (mean age 70.6, SD 6.2, range 62-79 years; 7/15, 47% women; 3/15, 20% Hispanic/Latino; and 8/15, 53% non-White). In the hospital-based sample, 1 participant did not own a smartphone, and among smartphone owners, 6 of 14 (42.9%) owned an iPhone. More than half of the participants at both sites had a college education or advanced degree. While nearly 90% (13 of 15 participants) of eFHS participants reported their health to be very good to excellent, only one-third (5 of 15 participants) of the participants at the hospital-based site did ($P=.003$).

Table 1. Participant characteristics.

Characteristics	eFHS ^a (n=15)	Hospital-based sample (n=15)	<i>P</i> value
Age (years)			.48
Mean (SD)	72 (4.2)	70.6 (6.2)	
Range	64-80	62-79	
Women, n (%)	6 (40)	7 (46.7)	.71
Non-White, n (%)	0 (0)	8 (53.3)	.002
Hispanic, n (%)	0 (0)	3 (20)	.22

Income <US \$55,000, n (%) ^c	4 (31)	5 (33)	.89
Subjective health, very good or excellent, n (%)	13 (86.7)	5 (33.3)	.003

^aeFHS: electronic Framingham Heart Study.

^bAll offspring participants owned a smartphone (iPhone or Android); 1 hospital-based participant did not own a smartphone.

^cIncome of 2 participants in eFHS sample was unknown.

In the eFHS sample, the average length of time of the think-aloud procedure was 25.5 (range 12.4-44.0) minutes and the postprocedure interview time on average was 18.7 (range 12.4-20.9) minutes. Two participants declined the interview (think-aloud times were 28.5 and 33.35 minutes, respectively). At the hospital-based site, the average length of time of the think-aloud procedure was approximately 11 minutes longer (mean 36.5, range 24.1-55.1 minutes) while the postprocedure

interview time was similar to eFHS with an average of 18.5 (range 10.6-35.1) minutes. No participant at the hospital-based site declined the post think-aloud interview.

Barriers to App Use Identified During Think-Aloud and Postprocedure Interview

Table 2 presents the themes identified from the think-aloud task and postprocedure interview along with sample participant quotes.

Table 2. Barriers and facilitators identified during the think-aloud and postprocedure interview.

Domain or survey type	Theme	Sample quotes
General structure, satisfaction	<ul style="list-style-type: none"> Information about security of app Use to raise awareness of health Everyone could learn from it 	<ul style="list-style-type: none"> “The more I do, the easier it gets” “I just think it’s gonna help me monitor my health and go from there. I like technology that helps me and doesn’t just amuse me or keep going and if this helps me stay healthy, stay fit, it makes sense.”
Ease of use	<ul style="list-style-type: none"> Easy, simple, fun Questions easy to answer Confusion related to not paying attention and not reading the app instructions carefully enough Font color yellow difficult to see Font could be bigger 	<ul style="list-style-type: none"> “The app spells everything perfectly clear after you read it a couple times to get it” “I wasn’t really paying attention to what I was reading. That was mostly my problem.”
Navigation	<ul style="list-style-type: none"> Navigating within and between surveys was easy More detail on getting back to the home screen and using “next,” “cancel,” and “done” 	<ul style="list-style-type: none"> “The more I did it, the more I was able to figure out how to get from one place to another.” “You might want to give a little more detail about some of the sections, like what happens when you cancel, what happens when you hit done.”
Multiple-choice survey formats	<ul style="list-style-type: none"> Surveys were interesting and simple except physical activity survey with lengthy definitions and confusing response choices 	<ul style="list-style-type: none"> “It was easy the questions were simple and it was easy to find the answers.”
Pictorial format	<ul style="list-style-type: none"> Body pain map did not include all areas that can be a real problem Checkbox worked differently than response choices for other surveys Hard to find the “no pain” box—small font 	<ul style="list-style-type: none"> “Well, on the pain thing, I think they should have something near the anus. Because that can be a real headache. And then, of course, for women, it would also include, uh, the uterus.”
Cognitive tasks: Trail Making Test and Stroop	<ul style="list-style-type: none"> Stroop was confusing Difficulty understanding practice session versus testing session Confusion over 4 increasingly challenging sets of tests within the Stroop task TMT^a had difficulties with instructions and navigation but the eFHS sample did not 	<ul style="list-style-type: none"> “The all underling thing was a little confusing to me. I think because I was trying to get through it quick. I lost track of whether underline the word or is it the color or is it this color or the word?” “The trail-making one I liked”
Friends or family	<ul style="list-style-type: none"> Fear of technology; Little interest in learning how to use technology Learning curve for older people 	<ul style="list-style-type: none"> “I think they would find it very useful I think it’s very useful, just for like, the cognitive part of it.”
Different cultural backgrounds	<ul style="list-style-type: none"> Need the app to be available in different languages 	<ul style="list-style-type: none"> “I come from the Indian community, and we place a lot of value on education, you know, I think this is the kind of thing that, you know—I would—we do—I would like to be quizzed, and this is a quiz.” “For example, I came from Burma. Burma used to be very underdeveloped country, and, also, still lots of problem. But they are very good at technology.”

^aTMT: Trail Making Test.

General Structure of the App

In general, participants were pleased with the general structure of the app. However, a few participants had not used an app previously and they said it was “not intuitive” but “once you run through it a few times it isn’t a problem.” Participants generally thought that the app had the right amount of surveys (and that additional surveys would make them bored). Participants suggested that a progress indicator be inserted to let users know the status of survey completion. One participant

also raised the importance of conveying information regarding the security of the app.

Ease of Use

Overall, participants found the app “easy to use,” “simple,” and “fun.” One participant said that it looked and functioned similarly to apps he was already familiar with, such as a social security app. A small minority of participants, however, wanted increased font size and more user-friendly colors. One participant was frustrated with the functionality of the app, but he blamed it on using an old phone. There were some

suggestions for modifications, such as tailoring the app by age group and disability, so it is not so “one size fits all.” Another participant suggested removing the free text space (which was needed for 1 question) or adding a digital keyboard so it is more intuitive that the person is supposed to type. For example, upon completion of the Stroop task, there was a query (“did you encounter any issues during the task?”) that permitted the participant to freely type in a response.

Navigation

A large minority of participants reported at least 1 navigational issue, including navigating within and between surveys and also clicking the incorrect area in the app to navigate to the next screen (eg, navigating to “done”). The vast majority of these errors were committed only once. Participants suggested making the buttons look more like buttons or having them flash when you are supposed to press the button, “...making it extremely obvious what you are supposed to hit.” Participants also suggested that more details should be added, such as what will happen after you hit a button (eg, after “cancel” or “done” is pressed), and more information about what the “icons at the bottom of the app” mean (eg, dashboard). A few participants mentioned that the app should avoid having to scroll to see more information, and instead put all of the information on one page if possible or continue to the next page.

Response Choice Formats

Multiple-Choice Formats

Participants reported that most of the multiple-choice surveys were easy and interesting to complete, with only a few sporadic usability errors by a few participants. For the most part, participants reported that the instructions were easy to understand, with one exception, which was “The Rapid Assessment of Physical Activity” survey, which included lengthy definitions of physical activity levels (eg, mild, moderate, and vigorous activity) which were needed to answer the subsequent questions. Participants were confused by the content and format of the definitions. With regard to the latter, both physical activity intensity level and physical activity frequency in a single question (eg, “I do some light or moderate physical activities but not every week,” yes or no).

Pictorial Format

For the pictorial format assessment, (modified version of the Michigan Body Pain map), a small minority of participants noted the checkbox for response worked differently than the other surveys; instead of seeing a checkmark in the response box, the response box if selected was highlighted in color and was confusing for some. Some participants also noted that the map did not include all body areas where pain was present. For some participants, the “no chronic pain” response box was difficult to find due to the small font, and the small font used to label the body parts was also difficult for several participants (but necessary to eliminate scrolling to see the entire body outline). There were no participants who reported difficulty understanding the instructions or concepts. Only a couple of participants did not realize that they had to press “next” to go to the next page to view the back of the body to indicate pain areas there. One participant said that bowels and reproductive

areas give people his age a lot of issues and that these areas should be added to the body pain map.

Cognitive Testing Formats

In terms of the formats used for cognitive testing, most older participants had some difficulty with the process of completing these measures. In terms of the Stroop, some participants had difficulty understanding that they were in the practice session versus the test session. Participants also thought that they needed to do the testing quickly and were confused if they did not read the instructions for each of the 4 test sets, as each had different instructions. Most participants did not take advantage of the opportunity to repeat the practice session when asked by the app, even when they were confused by the task. The yellow font color for the Stroop was also problematic for a few participants. One participant suggested that voice and animation be used to explain the instructions for the Stroop. For the Trail Making Test, the eFHS sample did not report any difficulties with instructions or navigating within the task, and seemed to have a good understanding of the concepts included in the task. However, a large minority of the hospital-based sample had difficulties in all 3 of these areas. There were no difficulties reported on the look and feel of the task (eg, font, line spacing, and color).

Relevance for Friends, Family, and Different Cultures

Participants noted that they knew older people who engaged with technology and others who were not interested in the “electronic age,” did not use a computer or smartphone, and had no interest in learning. One participant said that she had a friend aged 90 years or older who would easily be able to interact with the app and another friend of the same age who would have more difficulty. Participants noted older adults may have a fear of technology, be less confident using technology, and need assistance or a training session given that, for older people who have not used computers or technology, using the app would “be like a foreign language to them.” Participants provided their thoughts on using the app in older adults of different cultural backgrounds. Many noted that the current version of the app is available only in the English language and would need translation to other languages. One participant was from a country that they felt embraced technology, and another participant reported her culture valued education and felt like the app included an educational-like component like a “quiz” which would be viewed positively by her culture.

Satisfaction With the App

The mean total MARS score (7.6, SD 1.1), mean functionality score (3.8, SD 0.6), and mean aesthetics score (3.8, SD 0.6) in the eFHS sample did not significantly differ from the hospital-based sample (Figure 2). With the exception of ease of use, the individual items of the functionality and aesthetics scores (performance, navigation, interactions such as taps, swipes, layout, graphics, and visual appeal) did not significantly differ between the 2 samples (Figure 3). Ease of use may have differed as participants at the hospital-based site used a study iPhone whereas eFHS participants used their own smartphone. The performance item was rated the highest with a mean of 4.5 in both the samples. The mean overall star rating was 3.5 (SD

0.7) in the eFHS sample and 3.7 (SD 0.96) in the hospital-based sample indicating participants rated the app above average. In addition, during the interview, participants noted that the app could be used to raise awareness of health and people could learn from it, even though that was not the original purpose of

the app. Some participants liked the app because it enabled one to “express yourself” through the surveys. Finally, a few participants suggested making the app “more entertaining” by adding narration.

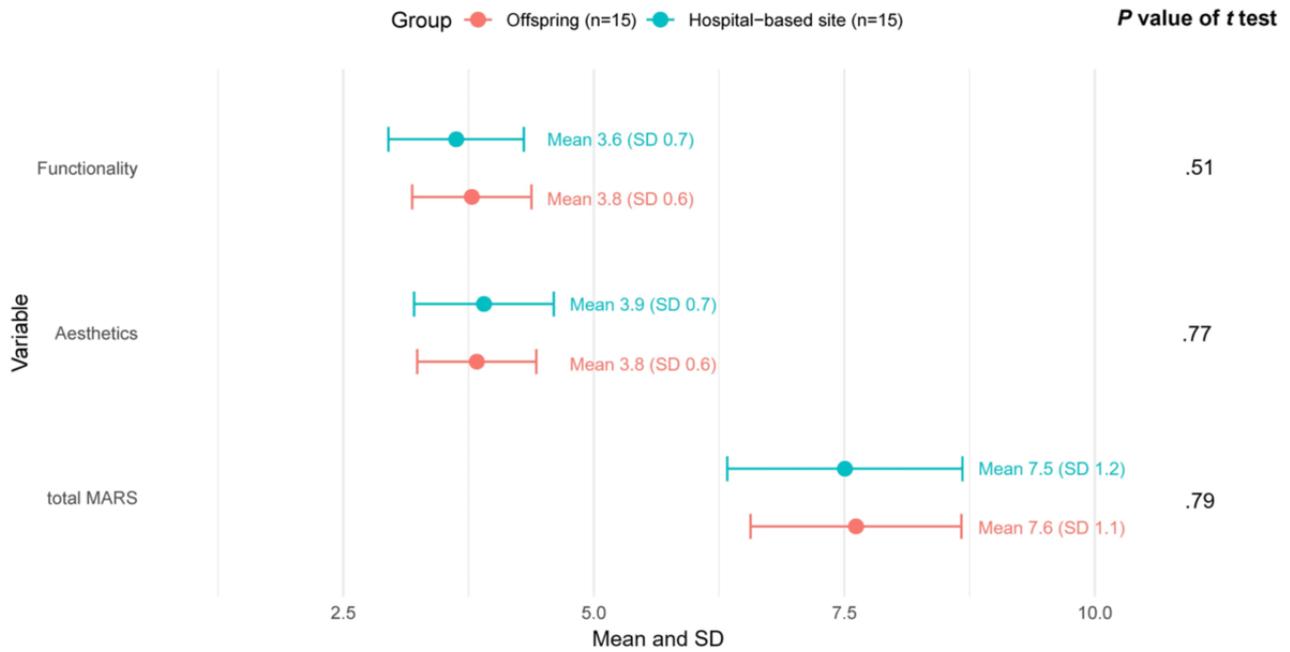

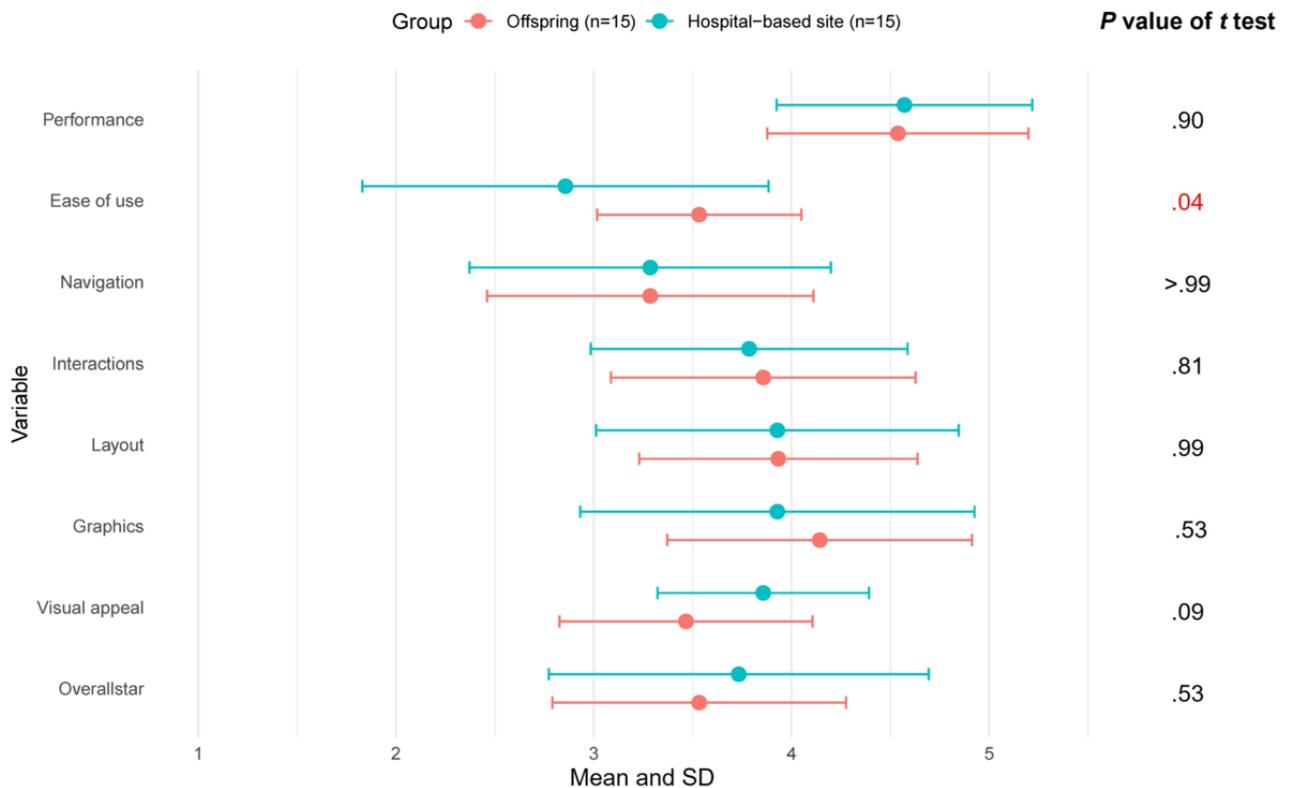

Figure 3. MARS (Mobile App Rating Scale) scores by study sample: individual items within the Functionality and Aesthetics domains.

Discussion

We tested the usability of a smartphone app designed to collect health information using complementary approaches in a community sample of older adult participants of the Framingham Offspring Study, and to understand generalizability we also tested older adults from a more diverse hospital-based sample. In general, participants liked the structure of the app and found the app was simple, fun, and easy to use. However, a large minority reported navigation issues that mostly occurred once with the ability to learn and figure out how to move within and between app-based surveys. A small minority of participants verbalized a preference for larger font sizes or more user-friendly colors. We observed that most older adults did not have difficulty with the multiple-choice app-based surveys unless the survey included lengthy instructions. Finally, most older adults experienced challenges with the app-based cognitive tasks especially the Stroop which required participants to read and understand a series of 4 increasingly more challenging tests with the Stroop task. Of importance, some participants noted that the app could be used to raise awareness of health and one could learn from it. Our observations confirm those of others that the involvement of older users can result in positive feelings among older adults, dispel stereotypes associated with older users, and the insights gained from older users can be used to enhance the quality of the design [31]. For example, our participants suggested using voice instructions and animated tutorials. To enhance usability, app designers and investigators should consider training that includes tutorials within the app provided by an older adult guide to boost confidence when designing smartphone apps for use by older adults.

This work has several implications for tailoring technology for older adult users. First, a guide within the app explaining the purpose of the app and highlighting key app functions including such functions as “next,” “back,” and “done” would enhance usability. Older adults are more likely to engage with technology that they perceive as useful [5]; therefore, having a clear understanding of the goals of technology is critical. Further, the addition of basic training in smartphone use in older adults less proficient with technology was associated with fewer errors and less cueing during a smartphone app-based health prevention program and may result in improved engagement [32]. In our sample, older adults who had not used an app before did not find it intuitive but after running through it a few times did not find it a problem. Our results support recently published app design guidelines for older adults advocating for initial training, if possible face-to-face, along with video instructions that are contextualized and provide step-by-step instructions to support older users [33]. Training may boost confidence and make the experience as frictionless as possible lowering the potential for abandonment. Second, streamlining and simplifying instructions may enhance understanding by inviting older adults to read them attentively. Participants in our study noted confusion that they attributed to not paying attention or related to the need to slow down and read directions more than once. Consistent with our observation, others have noted the need for clear and simple instructions when designing mHealth apps for older adults [6]. Some participants also requested features they enjoyed in their

use of other apps. Gamification of functions, where possible, such as a flashing “done” button or a countdown to the start of the next task may improve engagement. Finally, consider voice narration and animated guides throughout the app surveys where features other than straightforward multiple-choice questions and responses will be encountered.

Our study may have important insights to help address the continued digital disparities observed in older adults. Older adults are increasingly using the internet and smartphones [34]; however, connection to the internet decreases across ages with nearly half of young adults almost constantly connected versus 8% of adults aged 65 years and older [4]. Other key digital health behaviors are also lower in a nationally representative sample of older adults including using health apps, using a digital device to track health or a health-related goal, and digitally communicating with a health care provider [35]. Digital technologies were lifesaving during the COVID-19 pandemic as the rapid transformation from in-person visits to televisits permitted access to health care in a setting that provided social distance and did not expose vulnerable older adults to the virus. Similarly, the ability to participate in digital interventions may provide several benefits, such as improved memory and independent living [36], physical functioning, physical activity [37], depression, and anxiety [38]. Including older adults in technology design and conducting usability testing may address digital health inequities by addressing digital health literacy and creating programs that are user-friendly to this population [39]. They may also improve implementation beyond pilot studies and achieve the needed sustainability of technology solutions [40] for chronic disease management and home care options for older adults and, at the same time, maybe one step in addressing digital disparities. We plan to use the smartphone app more widely in the Framingham cohorts as a tool to monitor health. We will be able to provide critical information on the characteristics of those who enroll and use the technology, as well as those who choose not to.

Our study had several strengths. There is no “best” method to assess usability [21]; therefore, we used both qualitative and quantitative methods. We tested older users with mean age of 70 years and older in both samples often not included in studies testing technology and included older adults from diverse race and ethnic backgrounds. The study sample included a range of older users. Participants without a smartphone or experience with app use and both iPhone and Android users were included. This strategy allowed us to uncover errors with the app beyond what would be observed with “regular” users and permit greater guidance in app redesign to benefit older users.

In addition, participants with health issues were included. Some older adults with health conditions or geriatric syndromes such as frailty have higher levels of nonuse of information communication technologies and more negative views on usefulness and usability [41]. Our study also had some limitations that merit comment. Participants at the hospital-based site used an iPhone only. This may have been a limitation if the participants were Android owners or had a different iPhone version; however, this is also a strength as we were able to include participants who were not smartphone owners. Our observations focus on the first interactions with the app-based

surveys. It is beyond the scope of the study to examine other aspects of use such as efficiency (how quickly the survey or task is completed once the design is learned) and memorability (how easy to use after a period of not using the app) that may have important implications to research study designs. Continued engagement with technology changes over time in older adults but the factors related to continued technology use are unclear and require further investigation [42]. Our study took place in Massachusetts, and therefore, may not be generalizable to other geographic areas. Participants with color blindness were not eligible for the Stroop task and were excluded from testing. Therefore, results may not be

generalizable to this group of older adults. FHS participants who enroll in eFHS are healthier and have higher levels of education than participants who chose not to enroll.

Our study of a diverse sample of older adults testing several different smartphone app survey types and response formats provides a guide to investigators and clinicians that can be used for future app development and app-based survey construction for older adults. Many older users are able to interact with and enjoy technology. Further work to enhance engagement among older users and diminish digital disparities in this group is needed if the potential of technology to improve well-being, functioning, and health in older adults is to be realized.

Abstract

Background: A survey conducted by McKinsey & Company reported that, as of May 2022, as many as 26% of Indonesians had recently started to engage actively in physical activity, 32% undertook regular physical activity, and 9% exercised intensely. The Fourth Industrial Revolution has spurred the rapid development of mobile fitness apps (MFAs) used to track people's sports activities. However, public interest in using these apps for any length of time is still relatively low.

Objective: In this study, we aimed to determine the effect of incentives (eg, self-monitoring, social support, platform rewards, and external influence) on the use of MFAs and the moderating effect of gender on users' continuance usage intention.

Methods: The study used a mixed methods approach. Quantitative data were collected through a web-based questionnaire and qualitative data from interviews with 30 respondents. The quantitative data, collected from 379 valid responses, were processed using covariance-based structural equation modeling. The qualitative data were processed using thematic analysis. The MFAs included in this research were those used as sports or physical activity trackers, such as Apple Fitness, Strava, Nike Run Club, and Fita.

Results: The results of the data analysis show that 3 groups of incentives, namely, self-monitoring, platform rewards, and external influence (with the exception of social support), affect the perceived usefulness of these apps. Gender was also shown to moderate user behavior in relation to physical activity. The study showed that women were more likely to be motivated to exercise by social and external factors, while men paid greater attention to the tracking features of the app and to challenges and rewards.

Conclusions: This research contributes to the field of health promotion by providing guidance for MFA developers.

KEYWORDS

incentive; fitness; mobile fitness apps; gender; continuance usage intention; Indonesia; mobile phone

Introduction

Background

According to the World Health Organization [1], regular physical activity (PA) is a key factor in the prevention and management of noncommunicable diseases. The Global Status Report on Physical Activity [2] reported that 1.4 billion individuals aged >18 years do not meet the levels of PA

recommended to promote and protect health. In 2016, it was reported that, globally, 23% of all men and 32% of all women aged ≥ 18 years were not sufficiently physically active to stay healthy [1]. This means that approximately 1 in 3 women and 1 in 4 men are not sufficiently active and do not meet the global recommendation of at least 150 minutes of moderate-intensity PA or 75 minutes of high-intensity PA per week [3]. In August 2022, McKinsey & Company released the results of a survey conducted with 1041 Indonesian respondents in which 26% of

the respondents stated that they had started to engage actively in personal training, 32% reported that they had been playing sports regularly, and 9% indicated that they had increased the intensity of their sports or fitness activities [4]. These data indicate that the level of Indonesians' interest in, and awareness of, sports, fitness, and personal training is significantly higher than the global average. This conclusion is supported by the increased use of mobile fitness apps (MFAs) in Indonesia, with 29 million users in 2022 [5].

MFAs use several types of incentives, which include self-incentives, peer incentives, and platform incentives [6-9]. In the MFA context, self-incentives involve a self-monitoring (SM) system in which users monitor and track their own behavior [10,11]. Peer incentives are focused on social support (SS), which includes informational, emotional, and material support or the protection provided by fellow users of the app [12]. In the context of MFAs, platform incentives usually take the form of rewards or awards resulting from gamification features [13]. Users who collect a large number of rewards are usually considered to have a higher status on the MFA and feel more satisfied with their use of the app [14,15].

According to Zhu et al [16], very few studies have examined the role played by gender differences in the use of health and fitness apps. Yin et al [17] stated that achievements in sports motivate men more, while social relationships motivate women more. Previous research on MFAs has explored their design [18] and evaluation [19-22], as well as user adoption intentions [23]. In addition, several studies have discussed continuity in the use of MFAs [24-27]. Chiu et al [25] integrated the expectation-confirmation theory (ECT) with the investment model to analyze the continuous use of MFAs. However, research investigating the various types of MFA incentives has been shown to have several limitations [17,26] because the effects of each incentive have mostly been explored separately [28-30]. Per McKinsey & Company's 2022 survey among Indonesian citizens [4], 87% of the respondents intended to continue using their personal training and fitness apps. The market analysis and demographics of this study apply only to MFA users in Indonesia.

Research Question

This research adopted the self-determination theory (SDT) and the ECT. The SDT, as postulated by Ryan and Deci [31], states that there are 3 main psychological needs that drive human behavior: autonomy, relatedness, and competency. If these psychological needs are met, intrinsic motivation will increase and make it easier to maintain certain behaviors [31]. Teixeira et al [32] show that the SDT can be applied to behavioral interventions that relate to exercise or PA. While the SDT has the ability to predict the intensity of a behavior based on the influence of incentive factors [17], the ECT is generally used to predict the continuity of a behavior [25]. The combination of the SDT and the ECT was chosen to analyze the relationship between the incentive factors that affect the use of MFAs and continuity in using them. Thus, the research question is "How do the incentives promoted by MFAs influence users' continuance usage intention (CUI)?" This research can provide guidance for MFA developers by helping them to evaluate their apps.

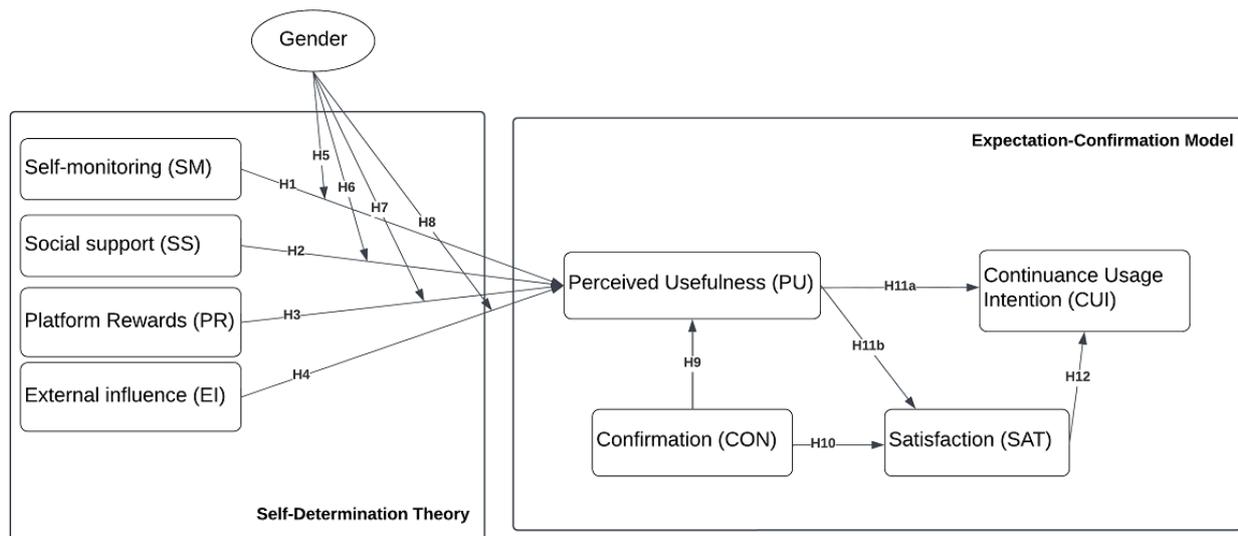

Methods

Research Model

Overview

The model used for this research is based on 2 theories and 1 moderating effect, namely, the SDT and the ECT, with the moderating effect of gender. Significant studies reporting on the use of these 2 theories include those by Yin et al [17], Huang and Ren [26], Chiu et al [25], and Li et al [33]. Yin et al [17] found that incentives are compatible with the SDT in motivating users' PA behaviors. The SDT approach described by Yin et al [17] is the theoretical basis for this research because it analyzes incentives offered by MFAs collectively and uses gender as a moderating variable. The relationship between perceived usefulness (PU) and incentives was also analyzed by Huang and Ren [26]. This research suggests that technology functions in MFAs, such as SM, self-regulation, and goal attainment, have an indirect effect on CUI through PU; for instance, Chiu et al [25] and Li et al [33] found that users' CUI was significantly predicted by ECT. Our research model, which includes 9 variables and 13 hypotheses (described in the following subsections), is presented in [Figure 1](#).

Figure 1. Proposed conceptual model.

The Influence of SM on PU

SM, which is classified as one of the self-incentives in MFAs, includes managing and tracking one's own behavior [17]. These actions enable users to observe their own progress and evaluate their performance against previously set goals [34]. PU refers to the extent to which a person feels that technology can improve their performance of certain tasks [35]. In this study, the task was identified as increasing the user's PA, while, for MFA users, PU implies that using the MFA will enhance their personal training intensity [36,37]. Bhattacharjee [38] argues that when users confirm their initial expectations of the main functionality of a mobile app, they will begin to perceive the app as useful for improving their task performance and thus continue to use it. Huang and Ren [26] measured PU relating to the effectiveness and performance of PA through the use of 4 technological functions of the MFA, one of which is SM. Therefore, we examine the following hypothesis:

- H1: SM has an influence on PU.

The Influence of SS on PU

SS is classified as one of the peer incentives in MFAs [17]. Web-based SS is seen as an important factor affecting the physical and mental health of individuals, such as sports activity and increased well-being [12,39]. Humans have a tendency to behave in ways that are consistent with people in their own social networks, and this can be exploited in the context of mobile health (mHealth) [29]. Chen and Pu [40] conducted research on social incentives by developing the HealthyTogether mobile game, which allows users to participate in PA together and send messages to one another. The authors showed that users significantly increased their PA when using HealthyTogether compared to when they were exercising alone [40]. Edney et al [6] built the Active Team app, which is an MFA with social and gamification functions. The primary outcome of their study was a change in the total daily minutes of moderate to vigorous PA at 3 months, as measured objectively using an accelerometer [6]. Therefore, we propose the following hypothesis:

- H2: SS has an influence on PU.

The Influence of Platform Rewards on PU

The platform rewards include gamification elements, such as badges, points, and leaderboards [17]. The gamification element in MFAs can provide two types of information: (1) the user's PA progress and (2) a comparison of the user's PA with that of other users [41]. From this information, MFA users can observe their progress and experience greater satisfaction as they recognize their own personal training achievements. This leads to higher user competency satisfaction and increased behavioral motivation [13,42]. Yin et al [17] found that platform rewards have a positive relationship with users' PA. This finding is supported by Plangger et al [13] and Huang and Ren [26], who analyzed the effect of the goal-attainment technology function of MFAs, in which users can set their own goals, which are then achieved by undertaking PA. These achievements are then categorized as platform rewards. Huang and Ren [26] also found that this technology function had a positive effect on PU. Therefore, we propose the following hypothesis:

- H3: Platform rewards have a positive influence on PU.

The Influence of External Influence on PU

External influence (EI) is one of the extrinsic motivations identified in the SDT, which means that behavior is motivated through influences that do not depend on internal factors [43]. Huang [28] proposed this variable to explain how PA can be promoted through external factors. One example is companies providing incentives to MFA users as part of their corporate social responsibility initiatives [28]. Several studies discuss EI and PA. One example of EI referred to in this study is the name or *image* of a sponsor of an activity [44]. Low and Pyun [45] explain that sponsorship that gives a good impression to customers or users will produce behavior that tends to be positive. In the context of sporting activities, Huang [28] explains that sponsor characteristics play an important role in participation in a sporting activity. Therefore, because an MFA is a tool that can measure a person's PA, we intend to explore the following hypothesis:

- H4: EI has an influence on PU.

The Influence of Gender on SM and PU

According to Mao et al [7], MFA incentives are not always equally effective for women and men. This is because women and men have different ways of thinking [17]. Yin et al [17] conducted research that assumed that gender would influence the effectiveness of SM incentives, making them more effective for men than for women. This assumption was based on the belief that men generally pay more attention to their own achievements than women [46]. Surprisingly, Yin et al [17] show that gender does not affect the effectiveness of SM in MFAs. This finding relates to the concept of self-regulation, which is strongly driven by self-efficacy [47]. Individuals who decide to use MFAs are generally believed to have high self-efficacy in carrying out PA [17]. Therefore, we plan to test the following hypothesis:

- H5: Gender influences the relationship between SM and PU in MFA users.

The Influence of Gender on SS and PU

With regard to SS, Yin et al [17] explain that SS is one of the factors that most helps to fulfill the relatedness needs described in the SDT. According to Wang et al [9], social ties and commitment are more important for women than for men in shaping their attitudes toward the sharing of information. In considering gender, Yin et al [17] found that women tend to be more influenced by their relatedness needs than men. Women are also believed to be driven more by collective goals, such as pleasure or interpersonal harmony [48,49]. In the context of health apps, Kimbrough et al [50] found that women are usually more affected by environmental conditions and social relationships than men. Thus, we propose the following hypothesis:

- H6: Gender influences the relationship between SS and PU among MFA users.

The Influence of Gender on Platform Rewards and PU

Men tend to focus more on themselves and tend to be more independent than women [46,51]. Men also tend to focus more on completing or achieving individual goals that demonstrate their performance and abilities [46,51]. Relatedly, Vilela and Nelson [52] showed that men tend to be more motivated by their own achievements than women when using information system products. This is due to the general behavioral characteristics of men, who are generally more aggressive, pragmatic, and self-oriented in their behavior compared to women [52]. When specifically applied to incentives and CUI, Yin et al [17] also found an influence between gender and the effectiveness of platform reward incentives. The authors assumed that this is caused by the behavioral characteristics of men, who generally make decisions more rationally and pay greater attention to their own behavior. Thus, we propose the following hypothesis:

- H7: Gender influences the relationship between platform rewards and PU among MFA users.

The Influence of Gender on EI and PU

Sun and Zhang [53] state that women have a higher awareness of the environment than men. Leong et al [54] and Li et al [33] also found that men tend to be less easily influenced by external advice or support. Similarly, Venkatesh et al [55] concluded that women tend to be more influenced by EI, while men are usually less affected by external facilitation in their use of technology. This was confirmed by Weman Josefsson et al [56], who showed that men participate in challenges organized by the community to compete, while women participate for social and autonomy reasons. Hence, we propose the following hypothesis:

- H8: Gender influences the relationship between EI and PU among MFA users.

The Influence of Confirmation of Expectations on PU

Confirmation of expectations refers to the perceived level of conformity between the information system product or service expectation and actual performance [38]. Bhattacharjee [38] explains that PU refers to the individual's perception of the anticipated benefits from the use of IT products or services. The ECT implies that the confirmation of a user's expectations has a positive effect on their perception of the PU of an IT product or service [25,57-59]. According to the cognitive dissonance theory [60], IT users may experience psychological conflict if their initial expectations are not confirmed by their actual use experience [61]. Conversely, if users' initial expectations are confirmed or met, they may display higher investment behavior and reduce their preference for alternative apps [25]. Hsu and Lin [62] state that confirmation of expectations is positively related to the perceived quality of the IT product or service used, with the result that users tend to ignore quality alternatives. Therefore, we propose the following hypothesis:

- H9: Confirmation of expectations has an influence on PU.

The Influence of Confirmation of Expectations on Satisfaction

Chiu et al [25] proposed that confirmation of user expectations affects satisfaction with the app as well as its PU. Satisfaction can be interpreted as an individual's evaluation of their initial experience with a product or service [38]. Chiu et al [25] explain that before downloading an app, users generally have expectations of it, based on detailed information received from the app provider and on ratings and reviews from other users. After using the app, the user gains experience and evaluates the performance of the app based on previously established expectations. In line with the expectation-confirmation model, Chiu et al [25] assume that users' perceptions of postuse benefits and the confirmation of previous expectations determine their satisfaction in using IT products and services. Therefore, we propose the following hypothesis:

- H10: Confirmation of expectations has an influence on satisfaction.

The Influence of PU on CUI

PU refers to the user's perception of the benefits expected from using an IT product or service [61,63]. According to Bhattacharjee [38], expectations based on the user's direct

experience have an important role in forming their IT CUI. Chiu et al [25] state that many studies conducted in various contexts [59,64,65] empirically support a positive relationship between PU and CUI. Wu et al [66] show that when users find the mHealth app useful, they show a higher level of satisfaction and tend to use it continuously. Thus, we define the following hypothesis:

- H11a: PU has an influence on CUI.

The Influence of PU on Satisfaction

According to Chiu et al [25], PU also has a strong and positive impact on satisfaction. The authors state that the more benefits users receive from health and fitness apps, the greater their satisfaction [25]. When a user has used an app for an extended period of time, the user will evaluate its performance and form either a confirmation or a disconfirmation of judgment with regard to their expectations [62]. Disconfirmation of expectations affects user satisfaction and creates negative perceptions of the usefulness of MFAs. Conversely, users' positive perceptions of usefulness increase their satisfaction with an app. Therefore, we propose the following hypothesis:

- H11b: PU has an influence on satisfaction.

The Influence of Satisfaction on CUI

Satisfaction can be identified as a significant factor influencing consumer behavior [25]. Bhattacharjee [61] strengthens this definition by explaining that user satisfaction is an important determinant of postadoption behavior relating to IT products and services. In other words, users with higher levels of satisfaction will exhibit greater levels of use of IT products and services than those who are less satisfied [25]. Wu et al [66] confirm that satisfied users are more likely to continue using an app because dissatisfied users can easily switch to other technologies at no additional cost. The relationship between satisfaction and CUI has been identified as one of the strongest relationships in the expectation-confirmation model [63]. Therefore, we propose the following hypothesis:

- H12: Satisfaction has an influence on the CUI of MFA users.

Research Procedure

This study used a mixed methods approach that integrated a quantitative approach, based on a questionnaire, with a qualitative approach, using interviews. The only inclusion criterion for respondents in this study was that they used MFAs. We modified a questionnaire that has been established in

previous studies [12,15,16,24,25,28,33,66-70]. Before distributing the questionnaire, a readability test was conducted to validate how easily the questionnaire could be understood by respondents. The readability test was carried out both face-to-face and internet-based, using Google Meet, with 8 people who met the research criterion (ie, they all used MFAs). This readability test was carried out between February 5 and 10, 2023. We then used the results of the readability test to refine the questionnaire.

Once the questionnaire had been refined, we conducted a pilot study from February 20 to 25, 2023, aiming to measure the validity and reliability of the questionnaire by distributing it to 31 selected research respondents. The results of the pilot study were used to check the value of Cronbach α , which, in this pilot study, was 0.832, well over the required value of >0.7 .

Research Instruments

The instruments used in this study were a web-based questionnaire and semistructured interview questions. The questionnaire first asked questions regarding the demographics of the respondents, and it then presented statements regarding the research model being tested. Each of the 8 variables exclude the gender variable in the study was assessed by 3 or 4 measurement items, and each indicator was represented by a statement to which participants responded on a Likert scale ranging from 1=*strongly disagree* to 5=*strongly agree*. The questionnaire used in this study is available in [Multimedia Appendix 1](#), and a list of the interview questions is available in [Multimedia Appendix 1](#).

Ethical Considerations

This research was approved by Faculty of Computer Science (approval number S-7/UN2.F11.D1.5/PPM.00.00/2024).

Results

Participant Demographics

We distributed the research questionnaire on the web through various social media platforms such as WhatsApp, Line, Twitter, Instagram, and Telegram. These social media platforms are widely used by Indonesians. The questionnaire distribution was carried out between February 27 and March 20, 2023. [Table 1](#) provides a demographic summary of the respondents. Of the respondents, 75.5% (286/379) were aged between 17 and 25 years, 72.3% (274/379) were women, 25.1% (95/379) were privately employed, and 51.5% (195/379) lived in Greater Jakarta.

Table 1. Respondents' demographics (n=379).

Variable	Respondents, n (%)
Age (years)	
17-25	286 (75.5)
26-35	74 (19.5)
36-45	14 (3.7)
>45	5 (1.3)
Gender	
Woman	274 (72.3)
Man	105 (27.8)
Occupation	
College student	201 (53)
Employee of state-owned enterprise	8 (2.1)
High school student	15 (4)
Privately employed	95 (25.1)
Unemployed	19 (5)
Entrepreneur	23 (6.1)
Housewife	2 (0.5)
Civil servant	3 (0.8)
Other	13 (3.4)
Domicile	
Greater Jakarta	195 (51.5)
Java island	137 (36.1)
Outside of Java island	47 (12.4)

After collecting both the quantitative and qualitative data, we processed the quantitative data using covariance-based structural equation modeling. Using covariance-based structural equation modeling, data processing is carried out in several stages: specification and identification of the research model, estimation of the research model, testing the feasibility of the research model, modification of the research model, and hypothesis testing.

To validate the quantitative data results, we also collected qualitative data by conducting semistructured interviews with

30 respondents. The interviews were conducted both offline and on the web and took 30 to 45 minutes each. The qualitative data analysis was carried out thematically on the basis of the defined hypotheses.

Measurement Model

The factor loading values of all variables and indicators met the Cronbach α standard of >0.7 [71]; thus, the model feasibility test could be carried out. This study yielded average variance extracted values >0.5 as well as Cronbach α and composite reliability values >0.7 [71] (Table 2).

Table 2. Average variance extracted, Cronbach α , and composite reliability values.

Variable	Average variance extracted	Cronbach α	Composite reliability
Self-monitoring	0.968	0.705	0.920
Platform rewards	0.773	0.927	0.872
External influence	0.865	0.816	0.834
Social support	0.638	0.854	0.835
Confirmation of expectations	0.975	0.763	0.885
Perceived usefulness	0.709	0.888	0.848
Satisfaction	0.669	0.889	0.889
Continuance use intention	0.640	0.812	0.842

Structural Model

Next, we tested the structural model with the goodness-of-fit criteria, which included the relative chi-square index, goodness-of-fit index, root-mean-square error of approximation,

root mean square residual, normal fit index, comparative fit index, and the Tucker-Lewis Index [71]. The goodness-of-fit values are presented in Table 3, and the R^2 values are shown in Table 4.

Table 3. Goodness-of-fit values.

Goodness-of-fit criteria	Cutoff value	Value	Description
Relative chi-square index	<2	1.956	Good fit
Goodness-of-fit index	≥ 0.9	0.900	Good fit
Root-mean-square residual	≤ 0.05	0.048	Good fit
Normal fit index	≥ 0.9	0.913	Good fit
Comparative fit index	≥ 0.9	0.955	Good fit
Tucker-Lewis Index	≥ 0.9	0.948	Good fit
Root-mean-square error of approximation	≤ 0.08	0.050	Good fit

Table 4. R^2 values.

Variable	R^2	Effect size
Perceived usefulness	0.349	Weak
Satisfaction	0.511	Medium
Continuance use intention	0.714	Strong

Hypotheses Testing

This study used a 2-tailed significance test; thus, the condition for accepting the hypothesis was $P < .05$ [71]. Table 5 presents

the results of hypotheses 1 to 4 and 9 to 12, only one of which (H2) was rejected.

Table 5. Hypotheses testing results.

Hypothesis	Estimate (95% CI)	P value	Result
H1: SM ^a →PU ^b	0.319 (0.244 to 0.394)	.001	Accepted
H2: SS ^c →PU	0.060 (-0.019 to 0.143)	.12	Rejected
H3: PR ^d →PU	0.136 (0.044 to 0.219)	.007	Accepted
H4: EI ^e →PU	-0.101 (-0.166 to -0.033)	.006	Accepted
H9: COE ^f →PU	0.323 (0.251 to 0.388)	.001	Accepted
H10: COE→satisfaction	0.541 (0.435 to 0.632)	.002	Accepted
H11a: PU→CUI ^g	0.280 (0.200 to 0.363)	.002	Accepted
H11b: PU→satisfaction	0.218 (0.069 to 0.355)	.003	Accepted
H12: Satisfaction→CUI	0.683 (0.560 to 0.813)	.001	Accepted

^aSM: self-monitoring.

^bPU: perceived usefulness.

^cSS: social support.

^dPR: platform rewards.

^eEI: external influence.

^fCOE: confirmation of expectations.

^gCUI: continuance usage intention.

According to Awang [72], the test for moderation is not significant when the difference in chi-square values between the constrained model and the unconstrained model is <3.84. Table 6 presents a summary of the results of the hypothesis

testing using the moderating effect of gender. On the basis of the difference in the chi-square values between the constrained model and the unconstrained model, it can be concluded that all difference values were >3.84 and therefore meet the

requirements for calculating the significance of the moderating effect, meaning that H5, H6, H7, and H8 were all accepted.

Table 6. Summary of moderating variable hypothesis testing, with gender as the moderating effect.

Path	Chi-square constrained model	Chi-square unconstrained model	Difference (<i>df</i>)	Result
SM ^a →PU ^b	1318.671	1043.151	275.520	H5 accepted
SS ^c →PU	1627.823	1043.151	584.672	H6 accepted
PR ^d →PU	1395.076	1043.151	351.925	H7 accepted
EI ^e →PU	1796.875	1043.151	753.724	H8 accepted

^aSM: self-monitoring.

^bPU: perceived usefulness.

^cSS: social support.

^dPR: platform rewards.

^eEI: external influence.

Qualitative Interviews and Validity of the Hypotheses

This research shows that the incentives offered in MFAs in the form of SM (eg, distance walked or run, number of calories expended, time taken, and heart rate) influence users' motivation to undertake PA. The acceptance of H1 is thus in accordance with the findings of Yin et al [17] and Stragier et al [73]. Yin et al [17] state that the user's PA level correlates positively with the amount of SM they do. The majority of interviewees felt that the SM feature provided encouragement for their PA:

So I feel happy because I have exercised, more enthusiasm. [Interviewee 6]

In addition, the interviewees believed that MFAs documented or tracked their progress in PA, which helped them to maintain or even improve their exercise consistency:

So that I can compare with previous progress and so that in the future I can look back at my history. Like pace, I also remember what date I did sport. [Interviewee 9]

An example of a feature that can be implemented is one that displays a summary of the user's performance while exercising, together with visualizations in the form of trends and graphs. Some apps also display comments that describe the user's sports activity performance, based on their activity level. Users can take advantage of these insights to increase their PA levels in their next sports activity.

However, H2 was rejected in this study. H2's rejection aligns with the findings of Sun and Jiang [74] and Kim et al [75]. According to Kim et al [75], social comparison and the user's level of PA are not directly connected. Social comparison here is defined as the relationship between the level of PA and the variable self-efficacy, or a person's belief in their own capabilities [75]. The rejection of H2 indicates that the community or social ecosystem around MFA users does not have a significant impact on motivating the users to exercise. On the basis of the interviews, the SS feature in the app does not have an important effect on PA levels because users do not feel compelled to exercise when using the SS feature:

There is no motivation from the engagement side, more from tracking my own progress. [Interviewee 9]

In addition, nearly one-third of the interviewees (9/30, 30%) admitted that they used the SS feature only to document sports activities that had already been completed.

H3 was accepted in this study. The acceptance of H3 aligns with the studies by Bojd et al [41], Payne et al [42], Plangger et al [13], Goes et al [76], and Hamari and Koivisto [77]. Bojd et al [41] found that the gamification element in MFAs can provide two types of information: (1) the user's PA progress and (2) a comparison of the user's PA with that of other users. Furthermore, when MFA users are able to observe their progress, they feel more satisfied and recognize their own PA competency, which will drive higher user competency satisfaction and behavioral motivation [13,42]. Goes et al [76] and Hamari and Koivisto [77] also highlight the gamification element in MFA, which tracks the user's effort, progress, and achievement of personal goals. According to Goes et al [76], the public nature of user-acquired gamification elements, such as levels, badges, or leaderboards, can generate users' social status on the MFA platform, which encourages social comparison and competitive motivation among users. On the basis of the interviews, MFA users want to take part in challenges (an example of implementing gamification) on the app because they want to obtain limited edition rewards and measure their own capabilities in sports activities:

Gamification keeps me motivated and helps me see my activities historically during physical activity based on the badge I have earned. [Interviewee 21]

Furthermore, the interviewees acknowledged that the rewards they obtain can be used as a benchmark of their capacity in the sports activity against which to build new achievements:

I feel happy when I get an achievement because it shows an improvement in my sport. Even though I don't I have specifically targeted certain achievements, but if I can surpass the previous achievements, it means that my sport has improved. The goals that I have set are higher than before. [Interviewee 17]

Therefore, it would be better if the MFA included challenges that were personalized as well as recommendations that were based on the user's type of sports activity, the user's sports activity goals, and the user's own sports activity history. An example of such a feature could be that, based on the user's history, if they have only managed to run a distance of 3 km, then, to improve their performance, other MFA users could recommend a 4-km challenge.

Huang [28] found that sponsor characteristics play an important role in triggering user behavior. Sponsorship referred to circumstances where the use of a sponsor's product occurred naturally as part of a sponsored event [78]; for example, with an MFA whose function is to promote PA, sponsorship of athletic apparel would be perceived as highly congruent, whereas sponsorship of a cold remedy would reflect low congruence. The H4 finding is in line with the study by Yang et al [79], who stated that the level of involvement of a brand produces a positive association with the brand and strengthens the positive effect of an evaluation impacting one's behavioral intention toward an app. From the interviews, it was found that interviewees were encouraged to take part in a challenge or activity if the activity was associated with the party (public figure, company, etc) that organized it:

For a club other than Strava, I think it's cool if you participate, for example, it's like unique. There's definitely a challenge made by Strava every month, so it's not as special as other clubs. The limited edition is more about Heart Month, New Year, and others. I want to take part because it would be a shame if I didn't follow. [Interviewee 9]

We found that not many interviewees took advantage of EI incentives, but those who did participate focused more on the challenges than on the organizers or the external community. If a user felt capable of taking part in a challenge, they would try to do so:

Actually, I see from the challenge, if I feel capable, then I want to join. [Interviewee 7]

Thus, we argue that it would be better if MFA developers or providers developed challenges for their apps that are created by communities, organizations, and figures with high functional congruence.

With regard to H5, H6, H7, and H8, the results show that, in every case, gender has a moderating effect on the relationship between the variables investigated. This study showed that gender influences the relationship between SM and PU (H5). These results are supported by the studies by Gabriel and Gardner [46] and Sun et al [51], who found that men tend to make decisions based on rationality, while women tend to be more perceptual. According to Gabriel and Gardner [46] and Sun et al [51], men are generally more focused on personal goals that demonstrate their individual performance and abilities, while women are usually less conscious of their own goals and performance. This finding is supported by van Elburg et al [80], who state that men focus more on practical goals and achieving goals when using an mHealth app. We found that our female interviewees usually used the metrics in MFAs for tracking their PA only as monitoring information:

I only look at the pulse. [Interviewee 1]

However, the men usually used these metrics as targets for self-development:

To find out whether in sports we have reached the desired target or not. On the other hand, if our sports performance is good, this can also be seen through the information displayed on Apple Watch. Thus, the Apple Watch can be a helpful tool in determining whether our performance has reached the expected level or not. [Interviewee 12]

Moreover, this study found that gender influenced the extent to which SS incentives affected users' PU (H6). The results of the interviews showed that most female respondents felt more motivated by their social community or by the SS feature provided in the MFA they used. By contrast, the male users used the SS feature, such as sharing their sports activity progress, for personal documentation purposes:

Just so you know. Only for review, not to share with other friends. [Interviewee 28]

Other male respondents stated that this was the case simply because the app posted their activity automatically:

Because it has to be posted on the Strava application. [Interviewee 8]

Many male respondents had never used this feature, indicating their lack of interest in the SS feature:

I have never tried it. [Interviewee 18]

However, the female respondents all expressed interest in the SS feature available in MFAs and felt more motivated to exercise due to this feature:

I also become motivated to exercise when I see my friends after posting their sports results. [Interviewee 11]

Some of the female respondents commented that the SS feature of MFAs motivated them to exercise by creating a sense of competition:

If I just wake up in the morning and get a notification that my friend has finished exercising, I feel left behind because I just woke up but he has finished exercising. Section it motivates, really. [Interviewee 9]

Relatedly, Li et al [33] found that women pay greater attention to social relations and are more willing to accept support from those around them. By contrast, Leong et al [54] found that men usually ignore external advice or support due to their sense of independence. These findings are supported by Yin et al [17], who found that SS had a more positive effect on PA in women than in men.

This study also showed that gender influences the relationship between platform rewards and PU (H7). The interviews showed that male respondents were generally more motivated by the challenges, badges, and awards offered by the MFA they were using:

Makes me more enthusiastic for the next run, and I use it to keep track of whether I should improve or maintain, for example, I can rank third so I feel I have to improve my performance. [Interviewee 16]

However, the female respondents usually followed or used this feature only for their own satisfaction and without specific targets or motivations:

There is no specific goal to get rewards, but I feel happy and proud of myself if I get them. [Interviewee 13]

According to Yin et al [17], in the context of PA, men usually pay more attention to meeting their needs for autonomy and competence, such as badges, awards, and so on. This was also demonstrated by Vilela and Nelson [52], who stated that men tend to be more aggressive, pragmatic, and self-oriented. Therefore, they are motivated by the need for achievement when using information system products [52]. Similar findings were identified by Forman et al [81], who showed that the gamification element has a more positive effect on men than on women by arousing their competitive and achievement-oriented motivation. Brandts et al [82] also support this finding and explain that task-based goal setting increases task completion and performance only for men.

This study also showed that gender affected the impact of EI on the user's PU of MFAs (H8). The results of the interviews confirmed that there are 2 main reasons a person will participate in PA supported by the MFA: the match between the organizer of the activity and the user and the match between the user's capabilities and the activity or challenge created. Comparing these 2 reasons, we found that the women were more likely to do something because of a match with the organizers, in contrast to the men, who usually focused more on their own ability to participate in an activity:

If Strava doesn't have motivation, if it's a club other than in my opinion, Strava is cool if you join, it's like unique. What Strava makes is there every month, so it's not as special as other clubs to participate on Strava. [Interviewee 29]

According to Huang [28] and Yang et al [79], the reason female MFA users participate in sports activities is that they experience a special feeling because these sports activities are created by a special club. Huang [28] and Yang et al [79] explain that the sponsorship characteristics of a sports activity and high brand involvement play important roles in triggering the behavioral intention of MFA users and their behavior in general. H8 is also supported by the findings of Weman Josefsson et al [56], who explain that men tend to be more influenced by winning rewards than women, who tend to participate more for autonomous and social reasons.

Furthermore, H9 was confirmed in this study. The acceptance of H9 is in accordance with previous research conducted by Bhattacharjee [38], Huang et al [15], Chiu et al [25], Wang et al [9], Cai et al [83], and Wu et al [66]. Wu et al [66] found that PU and user satisfaction are directly influenced by confirmation of expectations, namely, the realization of the expected benefits of using mHealth. This result is supported by Chiu et al [25],

who state that PU of the MFA is reflected in the user's enhanced exercise capacity and satisfaction, as evidenced by their increased enjoyment of exercising. Thus, it is to be expected that, after the initial experience, the confirmation level of the user's expectations will have a positive effect on their PU [9,15,38,83]. One of the expectations of a respondent who used an MFA was that they would experience changes and improvements in their PA or exercise, and these expectations were indeed successfully confirmed:

Because when I want to download Strava I want to be diligent in exercising, and it is proven that I exercise more often because I can track my sports progress. [Interviewee 23]

H10 was also accepted by this study, and this result is in accordance with the studies by Bhattacharjee [38], Huang et al [15], Chiu et al [25], Wang et al [9], Cai et al [83], and Wu et al [66]. Wang et al [9] found that confirmation of expectations positively affects user satisfaction with IT products and services. The results of the interviews confirmed that interviewees felt satisfaction when using MFAs:

From a user point of view, everything has been fulfilled in my opinion. What I need so far has been achieved. [Interviewee 24]

In my opinion, the features are quite complete, because that's all I really need. The application also provides a reminder if you have passed one day without exercising and automatically arranges for the workout that can be fulfilled the next day to be even tougher. [Interviewee 10]

This study also showed that PU influences CUI. Acceptance of H11a is in accordance with the studies by Bhattacharjee [38], Huang et al [15], Chiu et al [25], Huang and Ren [26], Wang et al [9], Cai et al [83], Wu et al [66], and Cho et al [24]. Cho et al [24] reported that, in the context of MFAs, perceived benefits were associated with managing health-related information. The interviews confirmed that interviewees would continue using the MFAs if they helped them to be more active in their exercising, and they could track their sports activity progress effectively:

I will continue to use it because in my opinion it is also effective and looks simple. [Interviewee 10]

As long as device is connected to the Apple Watch, will still use it. The ability to track different types of exercise separately is one of the advantages of the Apple Watch. This makes me still choose to use the Apple Watch in the future, as long as it meets my sporting needs. [Interviewee 12]

The study's acceptance of H11b is in accordance with the studies by Bhattacharjee [38], Huang et al [15], Chiu et al [25], Wang et al [9], Cai et al [83], and Wu et al [66]. Cai et al [83] explain that PU is reflected in user satisfaction when exercising using an MFA. The more benefits users obtain from the MFA, the greater their satisfaction [25]. Wang et al [9] also found that satisfaction was a partial mediator between CUI and PU. We found that the level of user satisfaction with an MFA was based not only on its meeting users' sports activity expectations but

also on the convenience and effectiveness of the features, the user interface, and the user experience that supported the user's sports activities:

I will continue to use Strava, because I am comfortable with Strava. [Interviewee 14]

I will continue to use it, because in my opinion it is also effective and the appearance is not a hassle. [Interviewee 10]

What makes me satisfied is the user interface, which is easy to use, and the user experience is simple. [Interviewee 19]

Finally, the effect of satisfaction on CUI was confirmed in this study. The acceptance of H12 is in accordance with the studies by Bhattacharjee [38], Huang et al [15], Chiu et al [25], Wang et al [9], Cai et al [83], and Wu et al [66]. Wu et al [66] found that satisfied users are more likely to continue using an app because dissatisfied users can easily switch to other mHealth technologies. User satisfaction is an important determinant of the postadoption behavior of users of IT products and services [38]. This is supported by Chiu et al [25], who state that user satisfaction with the use of IT products and services is very important for fostering long-term use of IT. The main reason for user satisfaction with an MFA is that the features are complete and meet user needs, with the result that they come to depend on the MFA for their exercise routines:

Because I really like it and I have become very dependent on this application for sports. I don't want to exercise if there is no access to this application. [Interviewee 9]

This application has fulfilled my daily needs. [Interviewee 15]

Discussion

Principal Findings

The findings from this study extend previous research by examining the incentive system in MFAs [17,26] and the use of the ECT in the context of mHealth [25,33,38,62,66]. It also expands the understanding of the moderating effect of gender on incentive-based systems [68]. We found that MFAs and the incentives they offer have a strong influence on users' sports activity behaviors and on their intention to continue using the app. The results of this study indicate that the most influential feature of an MFA is the SM incentive feature. MFA users often do not feel like exercising or engaging in PA if the activity is not being tracked by their app. The SM feature was also found to have a greater impact on male users than on female users. This finding regarding gender differs from the results of a study by Yin et al [17], who stated that no gender trend was evident

in the effectiveness of the SM feature. Furthermore, in contrast to the study by Yin et al [17], we found that SS had little effect on the PA of MFA users. The results of the qualitative interviews indicate that this is because the social circle of Indonesian MFA users is relatively small, and this small social circle affects the effectiveness of the SS feature.

MFA service providers should evaluate how different app features impact users of different genders to effectively motivate users to keep using their app in the long term. In addition, users feel more satisfied when their expectations regarding the use of an app are met. App developers can increase the PU of their MFA by using the users' social communities (eg, by creating social profile features, group exercises, sporting events organized by recognized organizations or communities, and personalized challenges or awards based on the user's sports activity history). App developers can improve the accuracy of the tracking feature, whether through a smartphone or a smartwatch, with the goal of providing users with more in-depth statistics and data. For user convenience, app providers should also develop tracking features that start automatically.

Limitations

The respondents to both the quantitative and qualitative studies were predominantly aged 17 to 25 years and female; thus, other moderating variables could be considered in a future study. The weak effect size for PU in Table 4 indicates that the differences or relationships between some variables were not significant. This suggests that there are other variables that might influence PU, which were not considered in this study. In future research, another variable that could be considered is PA. This could serve as a metric to determine whether using MFAs with specific incentives increases users' PA [17].

Conclusions

The results of the study show that SM, platform rewards, and EI can all influence the PU of MFAs. However, no relationship was found between SS and the PU of MFAs. Indonesians generally consider MFAs to be useful because these apps allow them to track their sports activities and also offer rewards and awards. The confirmation of a user's initial expectations also affects their perceptions of the usefulness of MFAs. PU and confirmation of expectations also affect user satisfaction with MFAs, which in turn influences the user's desire to continue using the MFA. In addition, gender was shown to influence user behavior when using MFAs. In future research, the scope of EI incentives could be expanded by considering financial reasons for exercising, other people's recommendations, and job demands, among other factors. We suggest considering tangible benefits as additional incentives to determine whether quantifiable benefits, such as assets or money, can increase a person's motivation to exercise.

Abstract

Background: Young adults in the United States exhibit some of the highest rates of substance use compared to other age groups. Heavy and frequent substance use can be associated with a host of acute and chronic health and mental health concerns. Recent advances in ubiquitous technologies have prompted interest and innovation in using technology-based data collection instruments to understand substance use and associated harms. Existing methods for collecting granular, real-world data primarily rely on the use of smartphones to study and understand substance use in young adults. Wearable devices, such as smartwatches, show significant potential as platforms for data collection in this domain but remain underused.

Objective: This study aims to describe the design and user evaluation of a smartwatch-based data collection app, which uses ecological momentary assessments to examine young adult substance use in daily life.

Methods: This study used a 2-phase iterative design and acceptability evaluation process with young adults (aged 18-25 y) reporting recent alcohol or cannabis use. In phase 1, participants (8/15, 53%) used the data collection app for 14 days on their Apple Watches to report their substance use patterns, social contexts of substance use, and psychosocial risk factors (eg, affect). After this 14-day deployment, the participants completed a user experience survey and a semistructured interview to record their perspectives and experiences of using the app. Formative feedback from this phase informed feature modification and refinement of the app. In phase 2, an additional cohort (7/15, 47%) used the modified app for 14 days and provided feedback through surveys and interviews conducted after the app use period.

Results: Analyses of overall app use patterns indicated high, consistent use of the app, with participants using the app for an average of 11.73 (SD 2.60) days out of 14 days of data collection. Participants reported 67 instances of substance use throughout the study, and our analysis indicates that participants were able to respond to ecological momentary assessment prompts in diverse temporal and situational contexts. Our findings from the user experience survey indicate that participants found the app usable and functional. Comparisons of app use metrics and user evaluation scores indicate that the iterative app design had a measurable and positive impact on users' experience. Qualitative data from the participant interviews highlighted the value of recording substance use patterns, low disruption to daily life, minimal overall burden, preference of platforms (smartphones vs smartwatches), and perspectives relating to privacy and app use in social contexts.

Conclusions: This study demonstrated the acceptability of using a smartwatch-based app to collect intensive, longitudinal substance use data among young adults. The findings document the utility of smartwatches as a novel platform to understand sensitive and often-stigmatized behaviors such as substance use with minimal burden.

KEYWORDS

smartwatches; substance use; ecological momentary assessment; mobile health; mHealth; human-centered design; feasibility studies; mobile phone

Introduction

Background

Young adults exhibit some of the highest rates of substance use across all age groups in the United States [1], including alcohol use (50.2% or 17.5 million people), cannabis use (25.9% or 9 million people), vaping nicotine (24% or 8.3 million people), and prescription psychotherapeutic drug use (7.3% or 2.5 million people). Substance use can be associated with significant long-term effects on individuals' health and well-being [2]. As such, there is an urgent need to understand, detect, and mitigate substance use among young adults.

There has been much prior work within the substance use domain in determining various psychological, social, and environmental factors that impact young adults' substance use behaviors. These studies [3-6] highlight the value of collecting mood, affect, situational, and social context data to assess how they affect substance use patterns in this population. In recent years, this domain has shifted from relying on cross-sectional surveys and retrospective data toward using ecological momentary assessments (EMAs) on a daily level to detect relevant within-person trends. With recent advances in ubiquitous technologies and the surge of interest in accessible and affordable health care, there has been an increasing focus on understanding substance use and associated consequences through technology-based solutions. Thus, in the aforementioned studies [3-6], smartphones have been the primary device of choice.

In addition to having adaptable interfaces that support EMAs, smartphones also have extensive sensors that show potential to unobtrusively detect substance use in young adult populations. Prior work in the ubiquitous-computing community has described apps that seek to collect and analyze data to predict drinking episodes. Several studies have investigated the efficacy of inferring alcohol use through a smartphone user's gait [7-9], as well as device use and movement features [10,11]. Smartphone sensors also exhibit potential in detecting cannabis use behaviors from users' gait using accelerometer and gyroscope data [12], as well as from a combination of time features and GPS, accelerometer, SMS text messaging, and smartphone logs [13].

Systems that are capable of capturing behaviors, experiences, and sensor data in real time provide researchers a deeper understanding of the various contexts in which young adults engage in substance use. Although smartphones have been successful in collecting such data and are thus widely used in substance use research, a recent review of EMA protocols determined that compliance for substance use-related EMAs deployed on participants' smartphones was lower than acceptable levels [14]. Hence, there is a need to explore novel interfaces and establish their utility in collecting granular substance use data with high compliance and low perceived burden.

Smartwatches offer a user experience that is distinct from that of a smartphone. The persistent, wearable nature of this device can enable users to observe cues (such as notifications, sounds,

and vibrations) and perform quick interactions in diverse situations, such as when the smartphone is out of reach or an inconspicuous use of technology is required to minimize social disruption [15,16]. Moreover, smartwatches offer extensive health-sensing features that allow individuals to track and understand health behaviors. Thus, in recent years, there has been wide adoption of smartwatches: globally, approximately 202 million individuals own smartwatches [17], with 1 in 5 Americans using a smartwatch or fitness tracker [18]. This uptake of smartwatches by consumers has propelled researchers to investigate how smartwatches can be used as instruments of behavioral health studies. In fact, there have been several efforts to investigate whether illnesses and disorders could be recorded or managed through smartwatch-based tools such as those for managing attention-deficit/hyperactivity disorder [19] and posttraumatic stress disorder [20], aiding students with intellectual and developmental disabilities [21], assessing mobility among older adults [22], and managing chronic disorders [23]. In addition, there has also been interesting work in terms of detecting substance use behaviors, such as smoking, using these devices; for example, Skinner et al [24] used the accelerometer and gyroscope data in the Android Wear-based LG G Watch to detect signature hand movements of cigarette smoking.

Smartwatches and fitness trackers have met with resounding success in the health monitoring and self-management market [25,26]. Individuals use these devices to monitor and manage their fitness, sleep, mental health, and menstrual cycles through various apps. *Given their wide adoption for assessing health behaviors, especially by young adults [26], we argue that smartwatches may be well suited to understand substance use trends and patterns in this population.* In fact, Carreiro et al [27] highlight the significant potential yet underuse of wearables in combining detection and interventions for substance use. Importantly, the authors emphasized that wearable-smartphone combinations (such as smartwatches) are especially suitable for understanding and addressing substance use among adolescents and young adults. Recently, several studies pioneered the use of wearable sensors in understanding substance use and associated factors [28-30]. In these studies, participants noted several perceptions that suggested their preference for smartwatch-type interfaces over research-grade sensors for detecting and understanding substance use. Participants noted that these smartwatch interfaces were easy to integrate into their lives, offered various auxiliary features (such as screens, clock faces, and fitness-tracking capabilities), and drew minimal attention from strangers [28,29]. These aspects of smartwatches address many barriers that participants often face while using sensors and wearables in research studies. However, despite their potential and rapid uptake, these devices have rarely been used to assess substance use-related health behaviors in young adults.

Objectives

There is a critical need to better understand and assess substance use behaviors and trends in real-world settings, and this need has so far been addressed by using smartphones for collecting self-report and sensor data. However, the engagement and compliance rates of smartphone apps in this domain are less

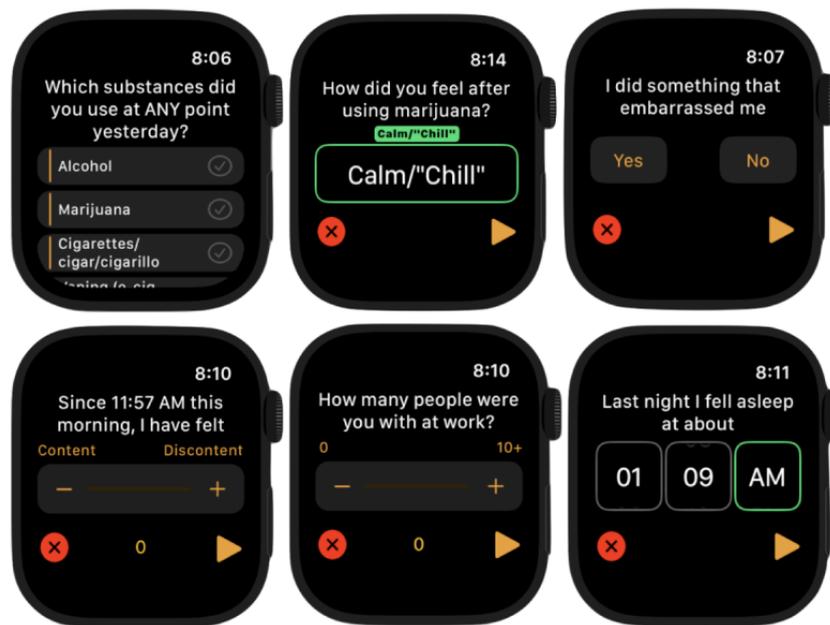

than ideal, indicating a need to explore the suitability of other interfaces to collect such data. Therefore, this study aims to address this need by assessing the feasibility and acceptability of using smartwatches to collect EMA and sensor data to understand young adult substance use. Our use of smartwatches for this study is motivated by several reasons. First, in recent years, there has been wide adoption of commercially available smartwatches, specifically for health assessments and interventions. Second, smartwatches offer a novel user experience, built-in health sensor data capture, and popularity within young adult populations, thus offering the potential to collect richer, more granular data to understand young adults' substance use with minimal burden. Finally, existing research in the substance use domain suggests that smartwatches may be especially suitable for understanding young adults' substance use behaviors [27].

Methods

System Design and Development

Designing apps for smartwatches requires approaches and techniques that vary significantly from those required for typical

Figure 1. Screenshots of ecological momentary assessments on an Apple Watch interface depicting the variety of interface elements used to elicit responses from participants.

Iterative Application Design: Phase 1 and Phase 2

Our fundamental approach to app design and development was based on the principles of human-centered design, an approach that heavily incorporates users' experiences and perspectives throughout the design process. It is a nonlinear process that iterates continually between various stages of understanding users, defining the problem domain, generating ideas, prototyping or developing solutions, and testing. This process helps build mobile health (mHealth) systems that are usable, effective, and accessible [32,33].

The creation of the smartwatch app went through continual iterations of user evaluation and development to produce an

smartphone app experiences. Smartwatch apps offer a seamless and intuitive experience when they are responsive; involve simple tasks; and make use of features that draw users to the device, such as haptic notifications, glanceable content, intuitive gestures, and a focused core functionality [31].

The primary requirement of the interface concerns ensuring that it provides an experience that results in highly granular and robust data collection, while keeping the perceived burden of interaction low. To address this challenge of high response rates and low study burden, we designed our questionnaire so that each question would take <5 seconds to answer. We expected that keeping the questions concise and interactions intuitive would help maintain low perceived burden and survey fatigue. Examples of these EMA components on the smartwatch (ie, an Apple Watch) are depicted in Figure 1. A companion app on the user's iPhone uploaded all user responses and sensor data to our database.

experience that enables robust data collection while also ensuring that the app is easy to use, minimally invasive, and considerate of users' privacy and security concerns. Thus, we incorporated feedback from participants (8/15, 53%) in phase 1 of the feasibility study, so that participants (7/15, 47%) enrolled in the next phase were able to evaluate a refined app that provided a better user experience. During the initial rounds of testing and development, the app required confirmation from the database for each EMA question, causing a 1- to 2-second delay. This delay generated negative feedback from phase 1 participants. They reported that this delay between questions was frustrating and prompted them to assume that their responses were not recorded. To correct for this delay, we

eliminated the step of waiting for the database confirmation before moving to the next screen.

Participants and Procedures

Our methodology for the feasibility study was informed by two main objectives: (1) to fully capture participants' experience using the smartwatch app and their perspectives on its usability; and (2) to collect data that accurately reflect users' lived experiences with substance use, social contexts, affect, behaviors, and experiences. Hence, for this study, we used a mixed methods design with 3 key components: a 14-day in situ data collection period, where participants used the app to answer short EMAs regarding their behaviors and experiences; a poststudy survey that sought to quantitatively capture the usability of the app through various dimensions; and a semistructured interview that sought to capture more nuanced perspectives on participants' experiences with the app.

To be eligible, participants needed to be aged 18 to 25 years, report past-week alcohol or cannabis use, own and use both an iPhone (with iOS version 15 or newer) and an Apple Watch (with watchOS version 8 or newer) to deploy and use the smartwatch app, and be a current student at the local university.

Participants were recruited through convenience sampling, using study flyers posted on the university campus, social media posts, and the university's StudyFinder website. Potential participants were asked to email the study team if they were interested, after which they were sent a link to the screener survey as well as more details about the study. Informed consent to participate in the study was also obtained at this stage.

Eligible participants were immediately directed to a baseline survey in which they provided demographic information, typical substance use behavior, and technological use behaviors. The screener and baseline surveys were collected and managed using REDCap (Research Electronic Data Capture; Vanderbilt University) [34]. After completing the baseline survey, participants were scheduled for a web-based visit with the research staff who explained the research activities, guided them through app installation, and informed them about the compensation structure. Of the 25 eligible participants who completed the baseline survey, 15 (60%) scheduled and attended the web-based visit. After the completion of the 14-day data collection period, participants were requested via email to upload their HealthKit (Apple Inc) data, complete the usability survey, and schedule a second web-based visit for the semistructured interview.

Of the 15 participants who used the app, 12 (80%) completed all research activities. All study activities were conducted virtually between August 2021 and May 2022.

Measures

EMA Data

The types of data we collected from the user through the EMAs related to (1) mood and general affect [35]; (2) experiences of stress; (3) sleep duration; (4) types and amounts of substances used; (5) feelings of intoxication [36,37]; (6) substance use-related consequences [38]; and (7) social context, such as location and social environment. The questions for self-reports

explored a wide range of constructs and were sourced from prior research and findings that established their validity and reliability [35-38]. All constructs used in this app were motivated by a wealth of research indicating various associations with substance use [5,39-45]. A full list of all aforementioned EMA items is included in Table S1 in [Multimedia Appendix 1](#) [35-38]).

Participants were sent 5 survey prompts per day at 11 AM, 4 PM, 7 PM, 10 PM, and 1 AM, which were available only for specific time windows or *sessions* every day (11 AM-3 PM, 4 PM-6 PM, 7 PM-9 PM, 10 PM-midnight, and 1 AM-3 AM, respectively). A brief overview of the initial design and development of this app is provided in prior work [46]. For every item, participants had the option of skipping the question if they did not wish to respond.

In the 11 AM session, participants were asked about their experiences and behaviors that occurred at any time on the previous day, and these data were grouped as *prior day* data while analyzing responses. Participants were also asked (in all sessions) about their experiences and behaviors that occurred since their last response, and these data were categorized as *periodic* data during analysis (Table S1 in [Multimedia Appendix 1](#)).

Sensor Data

In addition to self-report questionnaires, we also collected sensor data: location (GPS), physical activity, and health data streams. The health data streams serve various purposes: physical exercise, exercise intensity, and the types of exercise are all factors that have significant benefits in reducing substance use, decreasing depression symptoms associated with substance use, and improving the abstinence rate among those using illicit substances [44,45]; sleep has a bidirectional relationship with substance use in young adults, with sleep patterns and duration being significant predictors of cigarette, alcohol, and cannabis use; and the type of substance use is a significant predictor of total sleep duration as well as sleep patterns (eg, weekend oversleep) [43]. Although the limited sample size in this study hinders us from assessing whether these data streams can be effectively leveraged to unobtrusively detect substance use behaviors, the feature is incorporated into the app to examine preliminary associations, as well as for use in future studies with an anticipated larger sample size.

User Experience Evaluation

For the usability survey, we used the System Usability Scale (SUS) [47] to assess the perceived usability of the Apple Watch app, and we used an adapted version of the Mobile Application Rating Scale: User Version (uMARS) [48] and various other items to assess the acceptability of the interface and the EMAs sourced from prior work [49,50]. Both the SUS and uMARS surveys have high reliability and validity and have been extensively used to evaluate digital systems and mHealth systems, respectively.

In the semistructured interview, we queried the participants on whether the app impacted their substance use or substance cravings; whether the app influenced their awareness of substance use patterns; whether they had any concerns about

using the app in various social contexts; and whether they had any privacy concerns regarding their substance use data, location data, or HealthKit data. All interviews were conducted via Zoom (Zoom Video Communications, Inc) and were recorded and transcribed using Zoom's live transcription service powered by Otter.ai. The interview script is provided in Textbox S1 in [Multimedia Appendix 1](#).

Analysis

Only deidentified data were used during the analysis of app use data and interview data, blinding the authors to the identity of the participants while reviewing the results.

For our analysis, we focused on analyzing participants' EMA responses, app use patterns, and user perspectives to determine the feasibility and acceptability of the smartwatch app. To understand the effect of the iterative design improvements, we compared various measures between participants from both phases, treating them as separate groups during analysis. These findings are discussed in the *Results* section.

Ethical Considerations

All study activities and methods were approved by The Pennsylvania State University Institutional Review Board (17735) in the northeastern region of the United States in a state in which medical cannabis was legal, but recreational cannabis use was not legal at the time of data collection. A certificate of confidentiality was secured to protect participant responses concerning underage and illegal substance use behavior. All 15 participants provided informed consent before taking part in the study.

Participants were compensated for the study through Amazon gift cards and followed an established structure. Participants were compensated US \$5 for completing the baseline survey, up to US \$33 for the EMA data collection period, and US \$10 for completing the user experience survey and semistructured interview. For the in-the-wild data collection period, participants were compensated US \$2 per day if they completed both the

11 AM session and 1 other session during the day, but they were compensated only US \$1 if they completed only the 11 AM session. Participants who did not complete the 11 AM session were not compensated for the day. If participants answered even 1 EMA during the 14-day period, they were compensated US \$5.

Results

Quantity and Description of EMA Data Set

Participants ranged in age from 20 to 25 (mean 22.20, SD 1.86) years, and all were college students (undergraduate students: 10/15, 67% and graduate students: 5/15, 33%). Two-thirds (10/15, 67%) of the participants identified as female, while one-third (5/15, 33%) identified as male. Of the 15 participants, 5 (33%) identified as Asian, 1 (7%) as Black or African American, and 7 (47%) as White, while 1 (7%) participant preferred not to answer the question about race. Only 1 (7%) of the 15 participants identified as Hispanic or Latinx. Additional participant demographics are reported in Table S2 in [Multimedia Appendix 1](#).

Overall, the 15 participants provided 4796 responses to EMA questions over 210 days. On average, the app collected 320 (SD 151; range 110-652) responses across all participants across all days of the study. Our data consisted of 45 prior-day (collected only at session 1) substance use reports, with a majority of reports mentioning alcohol use (alcohol: n=39, 87%; cannabis: n=12, 27%). We also collected 67 periodic substance use reports, which were reports collected in sessions 1, 2, 3, 4, or 5. Of these 67 periodic substance use reports, a majority included alcohol use, and a small portion included cannabis use, vape (e-cigarette or Juul e-cigarette) use, and cigarette use (reports of periodic alcohol use: n=49, 73%; reports of periodic cannabis use: n=13, 19%). [Table 1](#) details all instances of substance use reported by the participants. Of the 15 participants, 3 (20%) did not report any substance use during the study.

Table 1. App use and substance use reports by participants.

Phase and participant	Total days participated (n=14), n (%)	Total sessions completed (n=70), n (%)	Days compliant (n=14), n (%)	Total EMAs ^a answered, n	Longest consecutive use of app (days; n=14), n (%)	Prior-day substance use reports (n=45), n (%)	Periodic substance use reports (n=67), n (%)
Phase 1							
P1	10 (71)	18 (26)	5 (36)	224	9 (64)	1 (2; alcohol)	1 (1; alcohol)
P2	8 (57)	27 (39)	7 (50)	271	8 (57)	2 (4; alcohol)	2 (3; alcohol)

P15	9 (64)	21 (30)	4 (29)	215	9 (94)	1 (2; alcohol)	1 (1; alcohol)

^aEMA: ecological momentary assessment.

When analyzing the intensity of substance use, we found that participants reported an average consumption of 3.44 (SD 3.09; min=1, max= \geq 10) alcoholic drinks, with more positive (mean 3.82, SD 2.05; range 0-6) than negative consequences related to alcohol use (mean 0.33, SD 0.66; range 0-3), while participants reporting prior-day cannabis use reported consuming an average of 8.92 (SD 2.23; min=3, max= \geq 10) hits, with an average of 2.667 (1.370; range 1-6) positive consequences and no negative consequences related to cannabis use.

Periodic substance use reports also included measures that asked participants to describe how they felt after consuming alcohol or cannabis. For alcohol use, the options provided were *buzzed*, *tipsy/happy*, *drunk*, and *wasted*. Most reports of alcohol use described participants feeling *buzzed* (12/28, 43%), followed by feeling *tipsy/happy* (9/28, 32%) and feeling *drunk* (7/28, 25%). For cannabis use, the options provided were *calm/chill*, *relaxed*, *high*, and *stoned*. Most reports of cannabis use described participants feeling *calm/chill* (3/7, 43%) or *high* (2/13, 29%). Cannabis use reports also included the manner in which the substance was consumed. A majority of responses reported cannabis use through pipes (7/13, 54%) or vapes (5/13, 38%).

Participants were also asked about various aspects of their health daily. In session 1, participants were asked about prior-day stress levels and sleep duration. In all sessions, participants were asked about their mood since the last response.

Of the 149 self-reports received for session 1, a total of 148 (99.3%) self-reports contained responses related to stress. In 96 (64.9%) of these 148 self-reports, participants reported that stressful events did not occur. When asked to rate their prior-day stress levels on a scale ranging from 1 to 100, on average, participants reported a stress level of 33.920 (SD 22.181; range 0-90). With respect to sleep, the app collected 147 self-reports, where participants were asked when they went to sleep the prior day and when they woke up on the current day. On average, participants reported 7.290 (SD 1.859; range 0-11.167) hours of sleep. Finally, participants were asked to report their mood through 8 bipolar items, which garnered 3167 self-reports.

Overall, the data collected through the app consisted of a broad range of substance use behaviors and experiences, as well as a variety of health behaviors. This suggests that *participants are willing and able to share substance use data through smartwatches*, along with a variety of measures that have

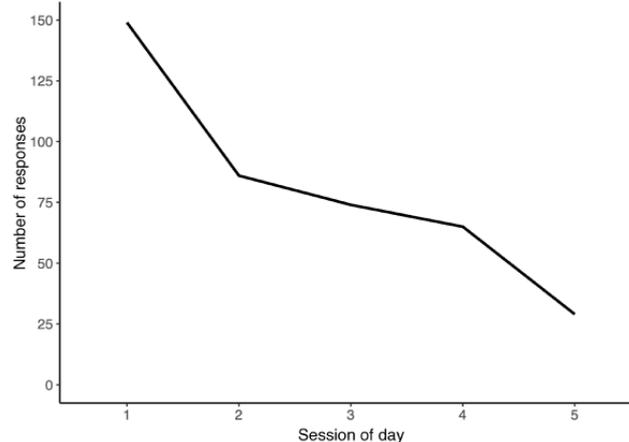

historically been associated with substance use in young adult populations.

App Use

We first examined how regularly participants used the app to answer EMAs. Of the 15 participants, 6 (40%) responded to at least 1 prompt on all 14 days of the study. Most participants (11/15, 73%) responded on ≥ 10 days. On average, participants provided data on 11.73 (SD 2.60) days out of the 14 days of the study. For participants completing all activities of the study, the average number of days participated was even higher: 12.24 (SD 2.14). [Table 1](#) lists EMA completion details across each participant.

We had 403 sessions with ≥ 1 EMA response. On average, participants provided data for 26.80 (SD 12.15) sessions. We instructed participants to complete the first session every day along with at least 1 other session. Using these criteria, the overall compliance rate was 59% (8.2/14). On average, participants were compliant for 8.20 (SD 3.67) days out of the 14 days of the data collection period.

Figure 2. Variations in responses by session.

A null model allowed us to calculate the intraclass correlation coefficient (ICC) of whether a participant responded. The ICC was 0.135, which meant that only 13.5% of the variation in responding stemmed from between-person differences, which indicated that a large proportion of the variation arose due to within-person changes. Thus, a random intercept model was created by adding the session of day as a predictor. This model significantly explains more of the variance in participants' responses than the null model and hence is a better fit to the data ($\chi^2_4=181.6$; $P<.001$). Using this model, we found that the session of day had a highly significant effect on whether the participant would respond. The odds and odds ratios calculated using this model indicated that the probability of a participant responding in session 1 was approximately 0.73. Compared to session 1, sessions 2, 3, 4, and 5 were respectively associated with a 76.47%, 82.29%, 85.88%, and 95.68% decrease in odds of a participant responding. In other words, *the probability of a participant answering in a particular session decreased significantly across the day*. Model details are described in [Table S3](#) in [Multimedia Appendix 1](#).

Finally, we also examined consecutive app use—the longest consecutive *streak* of days where participants used the app to provide responses. The longest streak was 14 days: 6 (40%) of the 15 participants used the app every day during the study. The average streak across all participants was 10.00 (SD 3.96) days, indicating sustained engagement with the app for a majority of the study duration.

Contextual Variations in App Use

In this part of our analysis, we wanted to determine whether there were certain times and contexts in which participants were less likely to respond to prompts than others. Toward this effort, we explored how app use patterns varied with time, substance use, and social environments.

In our data set, the response rate varied across sessions ([Figure 2](#)). Session 1 (11 AM-3 PM) had the most responses, and app use fell as the day progressed, with the lowest responses being collected during session 5 (1 AM-3 AM). To understand whether the session of day had a significant effect on whether the participant would respond, we used multilevel modeling (using the *lme4* package in R).

A random slope model did not significantly improve the fit of the model ($\chi^2_{14}=22.9$; $P=.06$) and thus was not included for further analysis.

We used a similar method to understand whether the likelihood of reporting substance use varied across the day. The results of our null model calculated an ICC of 0.515, indicating that 51.5% of the variation in reporting substance use stemmed from between-person variances. The results from our model revealed that only session 5 had a significantly higher probability of participants reporting substance use compared to session 1 (estimate=1.70, SE 0.67; $P=.01$). The odds ratio for session 5 indicated that the odds of a participant reporting substance use in session 5 were approximately 5.49 times higher than the odds of a participant reporting substance use in session 1. This model proved to be a significantly better fit to the data than the null model ($\chi^2_4=11.3$; $P=.02$), that is, participants were more likely to report substance use later in the day. Model details are described in [Table S4](#) in [Multimedia Appendix 1](#).

We also explored whether participants were able and likely to respond even when under the influence of substances.

Specifically, we analyzed how participants' responses differed after they reported substance use (compared with reports with no substance use). For this analysis, we used repeated measures correlations to determine within-individual association for paired or repeated measures data using the *rmcorr* package in R. We found no significant moment-level associations of substance use reports with responses in subsequent sessions, that is, whether a participant reported substance use in a specific session had no significant impact on their response to the first ($r=0.02$, 95% CI -0.08 to 0.13 ; $P=.65$), second ($r=0.01$, 95% CI -0.09 to 0.11 ; $P=.83$), third ($r=0.03$, 95% CI -0.07 to 0.13 ; $P=.56$), or fourth ($r=-0.03$, 95% CI -0.14 to 0.06 ; $P=.46$) session after the reported substance use. Random intercept multilevel models confirmed this result: reporting substance use in a specific session was not a significant predictor of whether a participant responded to the first, second, third, or fourth sessions after the session in question. Similarly, we saw no significant associations between social environments (people and places) and participants' likelihood of responding.

To summarize, our findings suggested that *participants were likely to respond to EMA prompts in a variety of social contexts and after consuming substances*. However, we found a time effect, where participants were more likely to respond to prompts earlier in the day.

Differences in Use Patterns Between Design Phases

To investigate whether the improvements made to the smartwatch app had any effect, we compared 5 metrics between phase 1 and phase 2 participants with respect to the total number of EMAs answered, the total number of sessions completed, the total number of days participated, the total number of days compliant, and the longest consecutive use of the app. Before running the analysis, we used the Shapiro-Wilk test to check whether the metric values were distributed normally across the phases. The distributions of counts from participants in phase 2 for the total number of days participated ($W=0.77$; $P=.03$), the total number of EMAs answered ($W=0.74$; $P=.02$), and the longest consecutive use of the app ($W=0.77$; $P=.02$) were all significantly nonnormal. Thus, to test for differences between the phases for these 3 variables, we used a nonparametric test, the Wilcoxon rank sum test. For the remaining variables, we used the independent 2-tailed *t* test (the Welch 2-sample *t* test) to examine whether the differences were significant.

Our analysis showed that, on average, the total number of days participated among phase 1 participants (mean 10.88, SD 2.95) was lower than that among phase 2 participants (mean 12.71, SD 1.89); however, this difference was not significant ($W=17$; $P=.21$; $r=-0.32$). Similarly, the group means were higher for phase 2 participants compared to those for phase 1 participants in terms of the total number of EMAs answered (phase 1: mean 304.38, SD 155.84; phase 2: mean 337.29, SD 154.78; $W=21$; $P=.86$; $r=-0.05$), the total number of sessions completed (phase 1: mean 25.50, SD 14.55; phase 2: mean 28.29, SD 9.64; $t_{12}=-0.44$; $P=.67$), the total number of days compliant (phase 1: mean 7.38, SD 3.93; phase 2: mean 9.14, SD 3.39; $t_{13}=-0.94$; $P=.37$), and the longest consecutive use of the app (phase 1: mean 8.88, SD 3.94; phase 2: mean 11.29, SD 3.86; $W=17$; $P=.21$; $r=-0.33$), but none of the differences between the phases were significant.

Although we did not see statistically significant increases in app use metrics after improving the app, the systematically higher engagement in terms of days used, EMAs answered, days compliant, and longest consecutive use suggests that the changes were a step in the right direction.

User Evaluation

For our analysis of the user experience survey deployed after the participants finished their 14-day data collection period, we primarily focused on reporting various measures of usability, describing notable user perceptions, and comparing usability metrics between phase 1 and phase 2 participants to evaluate the effect of app improvements on overall user experience.

SUS Scores

Of the 15 participants who used the app, 12 (80%) completed all research activities. The average SUS score for all 12 participants was 63.54 (SD 18.78). As a comparison point, Bangor et al [51] found that the mean SUS score from 964 usability tests across various interface types was 70. However, a usability study of fitness trackers found that the average SUS score for an Apple Watch interface was 61.36 [52]. While slightly higher than average in terms of smartwatch interface, this score does provide the opportunity to understand pain points within the app. The mean score for each SUS measure is depicted in Table 2.

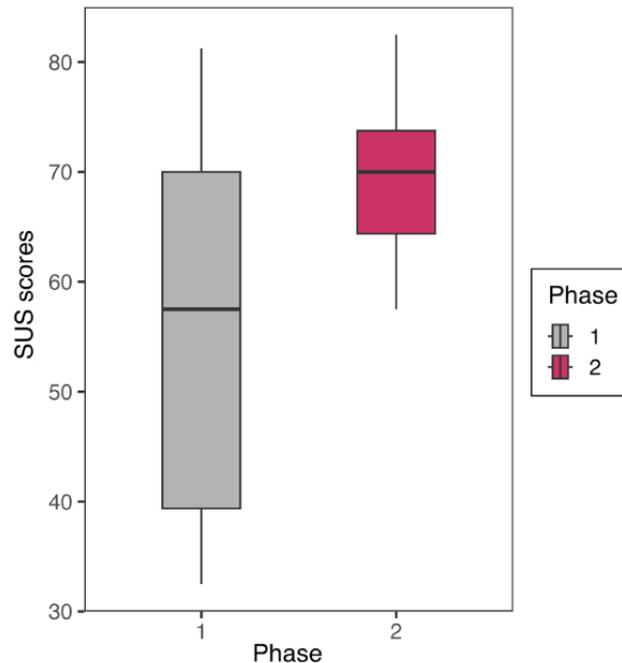

Table 2. Summary of itemized System Usability Scale (SUS) scores presented overall (combining the results of participants from both phases) and by study phase. Notably, phase 2 participants reported higher mean SUS scores than phase 1 participants, but this difference was not significant.

Measures	SUS items, mean (SD)										Total SUS score, mean (SD)
	1	2	3	4	5	6	7	8	9	10	
Overall	2.83 (1.11)	2.5 (1.17)	3 (1.28)	1.83 (0.94)	3.33 (1.30)	2.67 (1.44)	4.33 (0.49)	3 (1.35)	3.67 (1.07)	1.75 (0.96)	63.54 (18.78)
Phase 1	2.17 (1.17)	3 (1.26)	2.83 (0.98)	1.5 (0.84)	3.33 (1.63)	3.33 (1.63)	4.17 (0.40)	3.33 (1.63)	3.33 (1.21)	1.83 (1.16)	57.08 (22.77)
Phase 2	3.5 (0.55)	2 (0.89)	3.17 (1.60)	2.17 (0.98)	3.33 (1.03)	2 (0.89)	4.5 (0.55)	2.67 (1.03)	4 (0.89)	1.67 (0.82)	70 (12.55)

Before comparing overall mean SUS scores between the phases, we first used the Shapiro-Wilk test to check whether the SUS scores were distributed normally across the phases. The results of this test and an examination of skew and kurtosis values indicated that the SUS scores were distributed normally overall and by phase. Thus, to compare the means, we used the

independent *t* test (the Welch 2-sample *t* test). *Although participants in phase 2 reported higher mean SUS scores than those in phase 1, this difference was not statistically significant* (phase 1: mean 57.08, SD 22.77; phase 2: mean 70.0, SD 12.55; $t_8=-1.21$; $P=.26$). A box plot depicting differences in the SUS scores between the phases is shown in Figure 3.

Figure 3. Box plot of System Usability Scale (SUS) scores by phase of study. Mean SUS scores were higher in phase 2, after we had made changes to the app to correct for delay issues. However, the difference in SUS scores between the phases was not statistically significant.

uMARS Scores

All uMARS items were rated on a scale ranging from 1 to 5. Both the average functionality and aesthetics scores for all 12 participants were 3.88 (SD 0.55) and 3.89 (SD 0.52) respectively, indicating that participants found both measures acceptable (mean ≥ 3).

In terms of overall mean scores, participants in phase 2 rated app functionality as *good* (mean ≥ 4), while those in phase 1 rated app functionality as *acceptable*. Participants from both phases rated aesthetics as *acceptable*. Mean functionality scores were higher in phase 2 (phase 1: mean functionality score=3.58, SD 0.61; phase 2: mean functionality score=4.17, SD 0.31; $t_7=-2.11$; $P=.07$), but mean aesthetics scores were slightly higher in phase 1 (phase 1: mean aesthetics score=3.94, SD 0.71; phase 2: mean aesthetics score=3.83, SD 0.28; $t_7=-2.11$; $P=.07$).

Notably, the scores for the performance domain of the functionality metric from phase 2 participants exceeded those from phase 1 participants (phase 1: mean performance score=2.33, SD 0.52; phase 2: mean performance score=4.17, SD 0.75; difference in scores between the 2 phases=1.84). Using the Wilcoxon rank sum test, we found that phase 2 participants rated the app significantly higher on the performance scale than phase 1 participants ($W=1$; $P=.006$; $r=-0.79$). There were no significant differences between the phases for the ease of use, navigation, and gestural design domains of uMARS functionality scores. Similarly, none of the aesthetics domains

(layout, graphics, and visual appeal) had any significant differences in ratings between the phases.

EMA-Specific Participant Perceptions

Along with ratings of established usability scales, we also asked participants specific survey questions about EMA usability, touching upon the constructs of the ease of use, enjoyment, the speed of answering EMAs, EMA length, interruptibility, and notions of trust and privacy.

Most of the participants (8/12, 67%) either agreed or strongly agreed that the EMAs were easy to fill. However, there were discrepancies between the phases. Most participants in phase 2 (5/6, 83%) agreed or strongly agreed that the EMAs were easy to fill, while 3 (50%) of the 6 participants in phase 1 either disagreed or strongly disagreed with this statement. Similarly, all participants in phase 2 (6/6, 100%) agreed or strongly agreed that they were able to complete the EMAs quickly, while 4 (67%) of the 6 participants in phase 1 disagreed with this statement. Of the 12 participants, 8 (67%) did not think that the EMAs were too long, and among the 4 participants who did think so, a majority ($n=3$, 75%) were phase 1 participants.

To examine perceived burden and fatigue, participants were asked about the number of days after which they felt tired of answering the EMAs. On average, participants in phase 1 reported fatigue after 6.40 (SD 3.44; range 3-12) days, while participants in phase 2 reported fatigue after 9.17 (SD 3.13;

range 4-12) days. This difference among the phases was not statistically significant ($t_8=-1.39$; $P=.20$).

Overall, most of the participants felt that the app was acceptable and simple to use. A higher proportion of participants in phase 2 felt so compared to those from phase 1. None of the participant ratings of ease, speed, or fatigue were significantly different across the phases, but the higher ratings in phase 2 suggest that the app changes were a step in the right direction to improve app usability and address critical issues.

Interview Themes

Overview

In this subsection, we present our main findings from our analysis of the semistructured interviews that were conducted after the 14-day data collection period. For the analysis of the interview data, we used inductive thematic analysis to identify common themes using a qualitative interpretivist approach. The primary author conducted the initial analysis and then discussed the themes and codes with the other authors to ensure the validity of the primary findings and to reduce bias.

Overall, participants agreed that their experience using the smartwatch app to answer EMAs was easy, novel, and acceptable, but they also brought up certain key issues with app responsiveness and commented on the suitability of the smartwatch interface for this specific use case.

General App Perceptions

When asked about their overall experience using the app to answer EMAs, most of the participants shared that the app was generally easy to use. A participant recalled that using the app was quickly incorporated into their day, while noting that this was not disruptive to their routine:

I mean it kind of turned into, like, an everyday routine where, like I just expected it at certain times and I used to take time out and do it. [P6]

This sentiment was echoed by another participant:

Since it is only like 3 to 5 minutes, I didn't think that's a very disruptive time point, like I could do it in between class or, if I was at dinner [or] lunch and I remembered, I'd typically do it then. [P4]

Although not disruptive to their daily lives, this participant shared that using the app was different to how they normally used their smartwatch:

Disruptive? Not really. I don't normally look at my watch for more than a couple of seconds, so that was a little different, but overall it wasn't really that disruptive. [P4]

Other participants also noted how completing the EMAs only took a few minutes (generally <2-3 min), unless lagging or responsiveness issues occurred.

Advantages and Challenges of Using Smartwatch Interfaces

Participants presented varied perspectives when it came to the elements of the smartwatch interface; for instance, some of the

participants found advantages and preferred the fact that the smartwatch provided a small screen and a personal experience:

I think that's the one benefit that the watch did have, is that it's such a small screen that it's hard for anyone to, you know, look at what you're doing, on such a small screen. So the watch definitely had a benefit in kind of, like, protecting your privacy. [P8]

By contrast, participants also noted that the small screen and the wearable experience presented a hindrance, with a participant sharing the challenges they faced in using the watch to answer EMAs:

Well, so for me, just having, just turning my arm and touching my watch is, I don't know if it's a range of motion thing, It's just not the most natural thing to me and so just having to be in this position, looking at my watch, touching stuff, I don't particularly like that. [P3]

This participant indicated that a bigger screen would provide a more comfortable experience:

Just having a larger screen to be able to do everything on, I think it'd be a lot easier. [P3]

Personal preferences factored greatly into how easy and intuitive participants found various aspects of the app experience. When asked about their perspectives on the various formats in which the questions were presented, such as sliders, checkboxes, and radio buttons, the responses were similarly varied. Some of the participants found all question formats easy to answer:

I think all of the formats were very straightforward and in terms of them, like, how they worked, I think they all worked just fine. There was no issue transitioning between the different formats. [P8]

Others reported issues with the radio button and checkbox formats:

I think the multiple select got harder because just, like, being able to see all the options and then be able to click next on an Apple Watch screen [that] is kind of tiny, so in that sense, yes [was a difficult format to answer]. [P7]

Similarly, a participant faced challenges with the slider format:

Think the [slider] one, because I think I had to press, if I'm like, you know, perfectly energetic [on the MDMQ] then I had to go all the way plus plus plus plus plus, it was like, a lot of plusses. Other than that, the rest was great. [P12]

App Responsiveness and Lagging Issues

Phase 1 participants frequently shared their experiences with recurring lag issues, noting that it lengthened app use time and caused disruptions and general frustration:

Overall, it was pretty easy and straightforward, but it did start to get frustrating switching between different survey prompts. It would get, like, frozen a lot. So I would click to go to the next prompt, I guess, and it would get frozen, so surveys that were supposed

to take 2 minutes ended up taking upwards of 10 minutes because it would get frozen. [P8]

A lot of the buttons weren't the most responsive, so you had to click them a couple of times before it would actually do anything. And sometimes I had to restart my watch because it just wouldn't have responded. [P3]

As mentioned in the *Iterative Application Design: Phase 1 and Phase 2* subsection in the *Methods* section, we identified that this delay was caused by the data-uploading mechanism, which was corrected for phase 2. As a result, phase 2 participants did not report this frequent lag between questions in their interviews.

Comparisons to iPhone Platform

Several participants believed that having the option to answer the EMAs on both the iPhone and the Apple Watch would offer an easier and more seamless experience and provided the strengths of both devices to support this sentiment. A participant offered some context where such a system would prove useful for them:

So I know in the evening, sometimes, especially when I'm just, like, sitting on my couch, laying down, watching TV, I'll take my watch off to charge for the night, but I'll still have my phone with me. So, I'm not gonna get those alerts, if I'm not wearing my watch. So, it's nice to be able to switch, then, to the different interface on my phone, to use that. [P14]

Another participant shared a similar perspective:

I guess, that [having the option to complete surveys on both devices] would be okay, because that way you can at least see the surveys, do on your watch, in case your phone is not in your hand, you still have the watch, you're wearing your watch, you have the option of both. [P11]

By contrast, a participant shared a scenario where using a smartwatch would prove easier than using a smartphone:

Usually you have to open up the phone and then you have to take off your mask [to unlock it using facial recognition]. With the watch, you don't have to do anything, you just, you know, do with the 1 finger, which makes it a lot easier and better. [P12]

Similarly, another participant noted as follows:

I check my watch more than I check my phone. I feel just time wise, and yeah, I feel like it'd be harder to use the phone. Like take my phone out and use it. [P14]

However, most of the participants agreed that the larger screen size would provide a smoother experience while answering EMAs, with a participant sharing their perspective on how having a bigger screen would benefit their experience:

Just cause it's a little bigger, and you can just, like, do it on your phone while walking or something, and like on your watch you can't really do that. [P10]

Self-Monitoring Substance Use

Several participants shared how using the app provided a valuable self-tracking experience that helped them think about their substance use patterns. Although this was not an intended use of the app, participants found a tangible benefit in keeping track of their substance use to answer the EMAs accurately:

It makes you cognizant of your usage, and it makes you cognizant, while looking at the questions, as to what, you know, could be impacted [by substance use]. [P11]

A participant shared how answering the EMAs helped them evaluate their substance use:

I think it just forced me to kind of analyze...like, I'd mainly only drink on the weekends, so it made me [think about] how I spend my weekends and how much I was using a substance in a specific time frame. So it made you kind of take a step back and analyze that, which is always, I think, shocking to people, how much or how little they may have been using a substance. [P8]

Answering frequent EMAs about their substance use helped participants increase their awareness of their substance use patterns and behaviors.

A participant also shared an interesting perspective of how useful they found the self-monitoring aspect of using the app and how they experienced a lack of incentive to track their substance use after the 14-day data collection period ended:

I think, just being aware of, like, how many drinks I was consuming. Yeah, because if I don't have to track it, I don't remember how much I drink. So, because I was able to be like oh, like the next window is at 7 o'clock, like, my next notification at 7, like that. I've had to remember that I've had, you know, 2 drinks to put it in that notification. [P14]

Other participants noted how they already mentally keep track of their substance use, but using the app made them reevaluate their use:

It definitely increased my awareness, but I felt like I already knew. If I had work or most of the school days, like, I won't be doing anything like that [substance use], but, more on the weekends. Like, oh, maybe I shouldn't do this tonight, or something like that. [P7]

Participants used the EMAs to reflectively track their substance use. These interactions augmented their existing self-monitoring practices to periodically and contextually evaluate their substance use behaviors.

Use of the App in Social Settings

All participants reported that they used the app in public and social settings and were comfortable doing so; for instance, a participant shared how their friends felt when they saw the participant using the app:

Yeah, like I thought it was totally fine. All my friends knew I was taking, [and] like I didn't care that they

knew. But when I was out at the bars, I was fine taking the surveys, and I don't know if other people knew that I was using my watch, or whatever. But all my friends knew, and they thought it was cool. [P14]

Another participant also spoke about their use of the app in such settings:

Yeah, like, if I got the notification when I was at school, like in class or something, or like walking to class, I would take it then. [P7]

This indicates that the app is able to effectively collect data in various social settings. This finding is especially meaningful, given the sensitive and often-stigmatized nature of the substance use data that the app collects. The convenience and comfort with which participants are able to share information indicates that using the smartwatch in this way is potentially unintrusive in various social contexts and environments.

Several participants offered insight into how they did not have concerns regarding privacy or security while interacting with the app and shared how the smartwatch platform helped in this aspect:

No [I did not feel uncomfortable using the app in public or social settings]. I mean, the watch screen is so small, I don't even think anyone realized what I was doing, that I'm on it. [P7]

The small screen of the watch ensured that the participants' activities while using the app remained private from their peers and other people in their vicinity and thus helped their perception of the security of their data.

Discussion

App Feasibility and Acceptability

Overall, the app collected 4796 responses to EMA questions from 15 participants over the course of a 2-week-long study. Participants demonstrated high and consistent use of the app, responding on an average of 11.73 (SD 2.60) days and consistently using the app for an average of 10 (SD 3.96) days. Our analysis of app use patterns indicates that participants respond in a variety of contexts: after they consume substances and among different social contexts. The interview data supported these findings: participants were able to quickly incorporate using the app into their daily life and easily provide substance use data, and they were comfortable using the app in diverse social settings. Together, these findings demonstrate that it is indeed feasible to use a smartwatch app to collect substance use data.

With respect to app use, the decrease in participants' responses across the day was an interesting finding. We speculate that the higher response rate in session 1 might be due to the longer availability compared to other sessions (4 h vs 2 h). Participants were also specifically asked to complete session 1 each day and were compensated accordingly. However, our findings also indicate that participants were more likely to report substance use at night, in session 5 (1 AM-3 AM), than in session 1 (11 AM-3 PM), which coincides with substance use patterns among young adults. Together, these results suggest that there are

certain time periods that may be better suited to obtaining specific insights into substance use behaviors. Morning and noon may be suitable periods to understand prior-day substance use behaviors, mood, and experiences, while late night might be better suited to understand evening drinking behaviors. As such, there is an opportunity to develop better informed and less burdensome methods for collecting substance use data. Future work should try to replicate our findings regarding the temporal variation of EMA completion rates for substance use.

In terms of user evaluations, the average SUS score for the 12 participants who completed the survey was 63.54 (SD 18.78). Participants in phase 2 reported higher mean SUS scores than those in phase 1 (phase 1: mean 57.08, phase 2: mean 70.00). For context, an SUS score of 70.00 is considered average and acceptable, but it is to be noted that this subjective qualification of SUS scores does not consider smartwatch interfaces. If we factor the interface into our assessment of participants' SUS scores, we can estimate that overall and in phase 2, participants rated the app above average in usability. Furthermore, in terms of mean uMARS scores, participants from phase 2 rated app functionality as good (mean ≥ 4), while those from phase 1 rated app functionality as acceptable. Although not significant, these findings suggest that the performance improvements to the app had a large and measurable impact on participants' perceptions of usability. Indeed, the improvement also had an impact on app use: on average, the total number of days participated, the total number of EMAs answered, the total number of sessions completed, the total number of days compliant, and the longest consecutive use of the app were all higher among phase 2 participants than among phase 1 participants.

These findings not only establish the user acceptability of smartwatches to collect substance use data but also indicate that app performance, specifically responsiveness to user inputs, is critical for user acceptance. Given the limited computational capability of smartwatches, it is particularly important to aim for responsive design by default. Modifications to improve app responsiveness resulted in better perceived usability and user satisfaction, along with systematically higher user evaluation scores and app use metrics. Thus, supporting quick, responsive interactions is a critical consideration when designing EMAs for smartwatches. Researchers and practitioners interested in using these devices as platforms for intensive data collection must focus on efficient, quick, and simple interactions to ensure sustained use as well as acceptable compliance and response rates.

Smartwatches and Substance Use

Our data consisted of 45 prior-day and 67 periodic substance use reports which contain alcohol, cannabis, cigarette/cigar/cigarillo, and e-cigarette/vape use data. Participants were able to share data on a range of variables associated with substance use through the smartwatch.

Furthermore, our interview data highlighted a key benefit that participants found through regularly using the app: tracking and reflecting on their substance use. Using the app to provide substance use data encouraged participants to contemplate on their substance use by requiring them to recollect aspects of their use (when, how much, with whom, etc). Even without a

feature that displays the patterns of use, participants noted how the task of recollecting and entering substance use data helped to make them more aware of patterns within their substance use as well as cognizant of the contexts in which they consume various substances. While the benefits of self-monitoring substance use are not limited to the smartwatch interface, it is promising that a smartwatch app is able to successfully promote such experiences.

An aspect of the smartwatch interface that might have helped participants share substance use data confidently is the privacy that it affords through a smaller, more discreet screen. Participants reported how they felt comfortable using the app in social and public settings, saying that the small screen ensured that others in their vicinity would not be able to discern what the participants were doing on their smartwatch. Nevertheless, some participants thought that a larger screen, such as a smartphone screen, might be useful in certain contexts. Participants also noted that some question formats, such as those that require scrolling, are harder to complete on a small screen. Importantly, participants preferred having the option to complete a survey on a smartphone or a smartwatch, depending on what is most convenient at a given time and place. Future studies using smartwatches for health assessments and interventions should ensure that the proposed systems can work comfortably across diverse contexts. One way to accomplish this is by supporting interchangeable use of the app on different devices: smartphones *as well as* smartwatches. Users can then choose which device is most appropriate for their current activity and social environment and use the app correspondingly.

On the whole, our analysis of app use, surveys, and interview data indicate the feasibility and acceptability of using smartwatches in this domain, demonstrating that users are able and willing to use a smartwatch to share substance use data. Participants shared data on a range of substances, experiences, and behaviors and identified aspects of the smartwatch interface that enabled them to do so comfortably. Participants found that comprehensively self-monitoring their substance use through the app was a useful and important feature. Our findings also provide insight into which aspects of the smartwatch interface elicit responses as well as those that do not: while the small screen affords users privacy while relaying sensitive information such as substance use data, it can provide challenges for certain EMA formats and in certain contexts.

Limitations

This study has a number of limitations that are important to discuss, given their potential impact on our findings. First, the study had a small sample size, which we considered to be acceptable, given that the goal of the study was to establish the feasibility and acceptability of a smartwatch-based app for collecting substance use data. However, we acknowledge that the reported findings may not be generalizable to the larger population of young adults who consume substances. Reproducing this study with a larger, more diverse sample can

offer a wider perspective on the use of smartwatch-based apps to collect longitudinal, intensive data in this domain. The findings concerning significance should be interpreted with caution, given our small sample size and unstable estimates. Furthermore, participants were already smartwatch owners, which might have had an impact on the perceptions of usability. Thus, understanding the perspectives of novice smartwatch users using the app can help us investigate the effect of novelty on user experience. Finally, most participants in our sample were not binge drinkers or did not exhibit high-intensity substance use. The user experience of the app might differ with participants and circumstances that arise from heavy or hazardous substance use behaviors that are not adequately represented in our sample. Future work focusing on users who exhibit such patterns of substance use can help build more robust systems that cater to a wider range of people who use substances.

Next, we detail limitations associated with our app. Developing data collection apps on the Apple system has the constraint of being platform dependent (limiting the devices on which the apps can be deployed); however, developing for a single ecosystem was the first step in testing the general feasibility of a smartwatch-based data collection app. Implementing the data collection app on multiple ecosystems and running studies with various devices and apps was outside the scope of this study. However, our design and development process focused considerably on creating a reproducible and well-documented codebase so that cross-platform or platform-agnostic implementation can be achieved at a later stage.

Conclusions and Future Work

In recent years, there has been wide adoption of smartwatches for health assessments and interventions. This paper focuses on ascertaining the feasibility and acceptability of using a smartwatch app to collect substance use data from young adults. Our data indicate that it is feasible and acceptable to use smartwatches to collect data about sensitive and stigmatized behaviors, including substance use. On the basis of these findings, we also discuss considerations for future smartwatch apps for health and well-being data collection. These findings have important implications for researchers aiming to leverage smartwatches as an mHealth platform for effective assessments and interventions. In the future, we plan to conduct a larger study, with a randomized between-participants experiment design, to compare app use and user perceptions between smartphones and smartwatches. This future study will help us understand which device results in better compliance, better engagement, and lower perceived burden within the context of substance use data collection. We also intend to use the health sensor data from this larger study to explore whether they can be used to unobtrusively detect substance use or associated behaviors. Finally, we aim to incorporate analyses such as the impact of battery life on app use to gain a nuanced understanding of how smartwatch capabilities impact user experience.

Abstract

Background: Health outcomes are significantly influenced by unmet social needs. Although screening for social needs has become common in health care settings, there is often poor linkage to resources after needs are identified. The structural barriers (eg, staffing, time, and space) to helping address social needs could be overcome by a technology-based solution.

Objective: This study aims to present the design and evaluation of a chatbot, DAPHNE (Dialog-Based Assistant Platform for Healthcare and Needs Ecosystem), which screens for social needs and links patients and families to resources.

Methods: This research used a three-stage study approach: (1) an end-user survey to understand unmet needs and perception toward chatbots, (2) iterative design with interdisciplinary stakeholder groups, and (3) a feasibility and usability assessment. In study 1, a web-based survey was conducted with low-income US resident households (n=201). Following that, in study 2, web-based sessions were held with an interdisciplinary group of stakeholders (n=10) using thematic and content analysis to inform the chatbot's design and development. Finally, in study 3, the assessment on feasibility and usability was completed via a mix of a web-based survey and focus group interviews following scenario-based usability testing with community health workers (family advocates; n=4) and social workers (n=9). We reported descriptive statistics and chi-square test results for the household survey. Content analysis and thematic analysis were used to analyze qualitative data. Usability score was descriptively reported.

Results: Among the survey participants, employed and younger individuals reported a higher likelihood of using a chatbot to address social needs, in contrast to the oldest age group. Regarding designing the chatbot, the stakeholders emphasized the importance of provider-technology collaboration, inclusive conversational design, and user education. The participants found that the chatbot's capabilities met expectations and that the chatbot was easy to use (System Usability Scale score=72/100). However, there were common concerns about the accuracy of suggested resources, electronic health record integration, and trust with a chatbot.

Conclusions: Chatbots can provide personalized feedback for families to identify and meet social needs. Our study highlights the importance of user-centered iterative design and development of chatbots for social needs. Future research should examine the efficacy, cost-effectiveness, and scalability of chatbot interventions to address social needs.

Introduction

Background

Unmet social needs (eg, food insecurity, housing insecurity, transportation challenges, and economic instability) are strongly associated with poor health outcomes [1], perpetuating health inequities [2,3] and informing social determinants of health. Children are especially at risk when families face unmet social needs [4,5]. Driven by recent recommendations, there has been a rapid uptake of social need screening [2,6]. Although screening can be relatively straightforward, linkage to resources to address social needs is a major challenge [7,8].

Typically, clinicians provide families who are identified with a social need with a resource sheet. Families are then responsible for follow-up. Most clinics do not have social workers or other staff to help families access services and overcome barriers, such as language or cultural differences, financial constraints, transportation issues, limited internet access, or lack of awareness about available resources. Thus, families are often left to navigate complex social services independently, which can result in significant difficulties in obtaining much-needed assistance and support [9]. This passive provision of information is rarely effective. It is imperative to develop scalable strategies that screen for social needs and effectively link to services.

Digital health technology could improve both screening and resource referral to assist vulnerable populations [10]. Currently, electronic health records (EHRs) help facilitate screening, and patient portals help with bidirectional communication [2]. However, this does not eliminate the need to maintain lists of resources and the need to link individuals to matching resources. Semiautonomous intelligent and conversational digital health technologies, such as chatbots (conversational agents or dialogue systems), can help address these gaps. By using machine learning algorithms and natural language processing, chatbots can deliver personalized feedback and health recommendations to a wide range of users via interactive, user-friendly interfaces that are designed to maintain human conversation [11,12]. The capacity of the technology to reach and assist a large number of users simultaneously offers a cost-effective and efficient method for delivering personalized health services [13,14]. Chatbots have been used for health care communications, including health information seeking, health screening, and health care support, and to improve adherence to recommended care [15-20]. A previous study [21] described a chatbot to screen adults with low and high health literacy for social needs in emergency departments. The authors reported that the performance of the chatbot is comparable to that of traditional screening, and there is a greater interest from lower literacy participants for a chatbot. At a broader scale, chatbots show promise to facilitate social need screening and provide personalized resources to families outside of the traditional clinic setting via speech or text and could improve access [22,23] and further contribute to increased understandability and personalization while addressing social needs [21,24].

The DAPHNE (Dialog-Based Assistant Platform for Healthcare and Needs Ecosystem) chatbot project has been initiated to address unmet social needs via a conversational interface for

low-income or resource-limited families, who often have trouble with a complex web of social challenges that include food insecurity, inadequate housing, and financial difficulties [25]. These vulnerable groups typically experience lower incomes, higher rates of unemployment, and diminished access to quality health care services. In the Nationwide Children's Hospital (NCH) primary care clinics, approximately 10% of families are identified to have at least 1 unmet social need [4], with >16% facing food insecurity (based on current data from our ambulatory patient population). This emerging need for social support has been the main motivation of our study. In this paper, we report our findings from the iterative design, prototype development, and evaluation of the DAPHNE chatbot for social need screening and resource referral. In this stage of development, we focus on food insecurity, the most frequently endorsed unmet social need, which has a significant impact on health care costs [26,27].

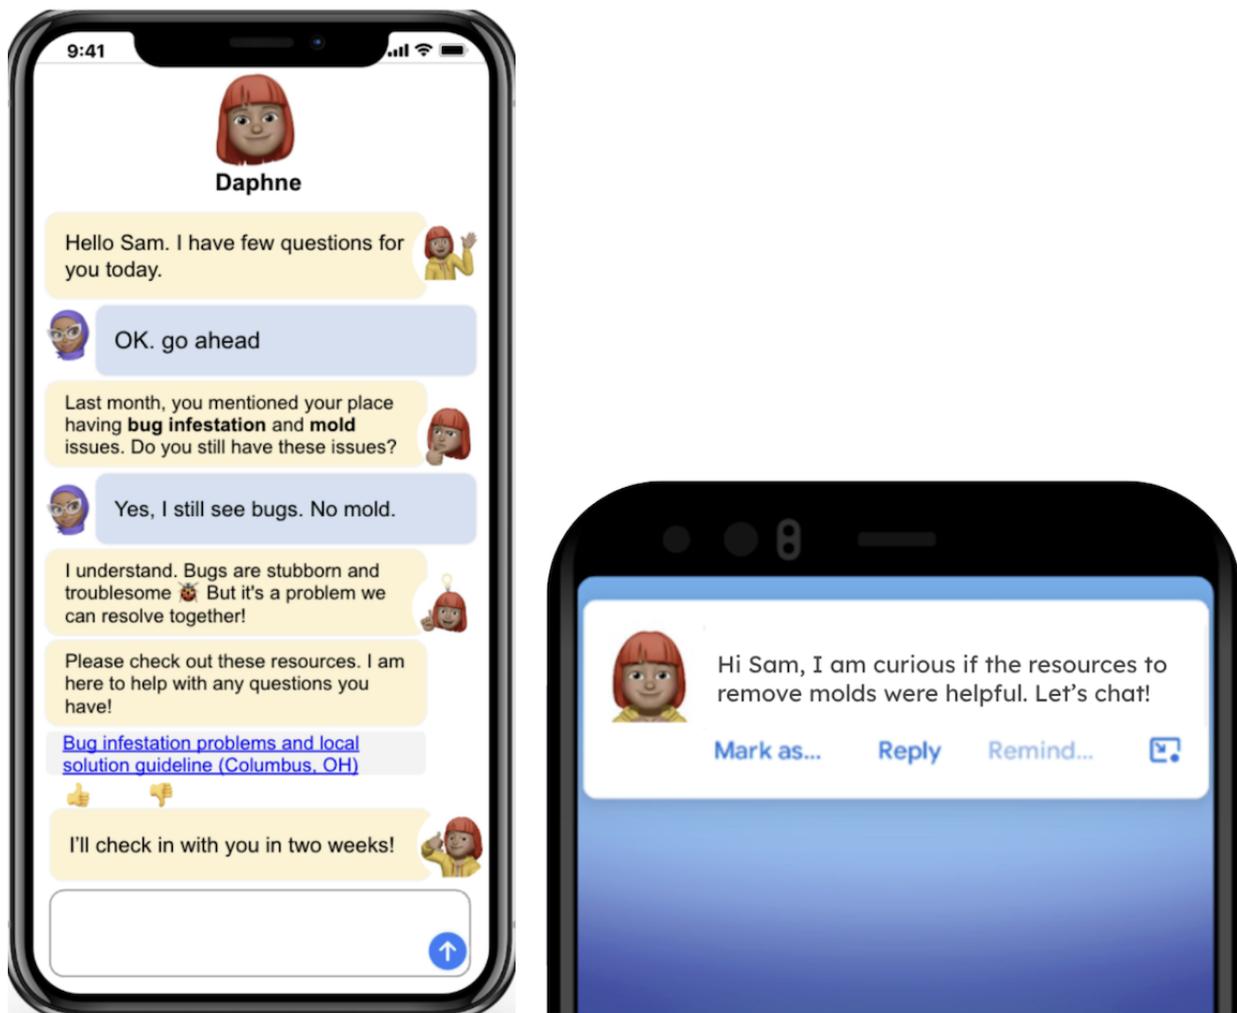

DAPHNE Chatbot

DAPHNE is a web-based application available via a computer or an iOS- or Android-based mobile device over a web browser. Figure 1 presents the initial wire-frame concept. The DAPHNE conversational interface prototype was designed using Adobe XD (Adobe Inc), Expo (650 Industries, Inc), and JavaScript (Oracle Inc) with a secure text-to-speech and speech-to-text service for voice interaction using Amazon Web Services (Amazon.com, Inc). Conversational flow was designed to be rule based. We opted for a rule-based design over pretrained language model or hybrid model at this stage to ensure greater transparency, predictability, and control in system responses, which is crucial for accurately identifying needs and retrieving specified resources.

The architecture, including data storage, conversational intelligence, information search, and referral services, uses Amazon Web Services and Microsoft Azure (Microsoft Corp) backend services. DAPHNE leverages application programming interfaces (APIs) provided by community resource platforms to access resource databases. These platforms, such as FindHelp.org, 211.org, and Cap4Kids.org, provide information about community resources categorized by geographic region. DAPHNE's architecture is designed to be integrated with EHR, enabling the communication of social need screening results to health care providers such as social workers, community health workers, and care teams. Its functionalities are listed in Textbox 1. In the scope of this study, the resource database of DAPHNE was locally created for testing purposes, without leveraging real-time API connection to the community resource platforms. In addition, the prototype was limited to screen 1 social need to reduce complexity during the testing.

Figure 2 outlines the chatbot ecosystem framework. Within the scope of this study, we are focusing on iterative design and the evaluation of engagement using conversational interface (Figure 2A). In the next phases, DAPHNE will have backend cloud services and API connection to enable access to web-based resource databases (Figure 2B) and provider dashboard to track engagement, control content (Figure 2C), and integration to medical records to report back social determinants of health monitoring (Figure 2D).

Figure 1. Initial wire frames and mock-ups.

Textbox 1. DAPHNE (Dialog-Based Assistant Platform for Healthcare and Needs Ecosystem) chatbot functionalities and descriptions.

Profile page

- Users create their account and set up profile details, including name, zip code, family type and size, and income level. The information is to be used for resource-finding queries.

Avatar

- Users can create an avatar to personalize their chatbot experience. For the prototype, we used Apple's Memoji to create an avatar that dynamically reflects emotions [28].

Language selection

- Users can select their preferred language. The prototype included the following languages: Somali, Nepali, and Spanish.

Audio narration

- Users can use the text-to-speech and speech-to-text features to enable audio entry and engagement and listen to the responses.

Multimodal input

- Users can use voice input (using speech to input), assistive buttons with prepopulated responses to select, and text entry with a free-text form to interact with the chatbot.

Social need screening

- DAPHNE uses the following standardized questions [4] to guide the screening process:
 - Food: within the past 6 months, you worried that your food would run out before you had money to buy more.
 - Housing: do you think you are at risk of becoming homeless?
 - Transportation: in the past 12 months, has lack of transportation kept you from medical appointments or from getting medications?
 - Utility: in the past year, has the utility company shut off your service for not paying your bills?

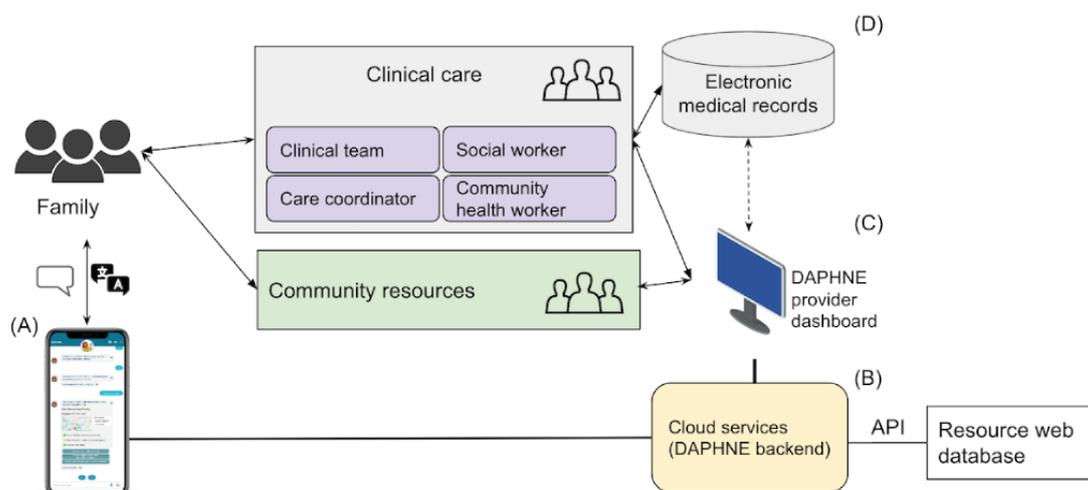

Interactive resource sharing

- DAPHNE can search the resource databases and present matching resources based on user response and ask follow-up questions.

Check-in and reminder notifications

- DAPHNE can send notifications. Scheduled check-in: it can collect information about whether the resource shared was useful. Reminder: it can set and send reminders asking whether the user would like to engage in another time. (Refer to Figure 1 for a reminder notification example.)

Figure 2. Conceptual framework of the chatbot ecosystem: (A) Conversational interface, (B) Backend cloud services and API connection, (C) provider dashboard, and (D) integration to medical records. API: application programming interface; DAPHNE: Dialog-Based Assistant Platform for Healthcare and Needs Ecosystem.

Methods

Study Design and Participants

The research was reported as a three-stage study: (1) understanding family needs and perception toward chatbots, (2) designing the chatbot, and (3) evaluating its feasibility and usability. We used stepwise, user-centered, iterative, and participatory development and improvement processes to ensure the proposed technology meets needs and expectations. [Figure 3](#) presents the design, development, and evaluation stages.

Study 1 aims to understand families' ability to meet social needs and access essential resources and perceptions toward using chatbots to find resources. We conducted a cross-sectional web-based survey. A total of 201 adults in US households participated. Participants were living together with spouses, children, and significant others and self-reported an annual household income of ≤US \$29,999 as of August 2023. The participants were recruited through a web-based platform designed for academic and market research, Prolific [29]. We followed a convenience sampling approach, inviting available

participants via the survey tool. Survey details are available in [Multimedia Appendix 1](#).

Study 2 focuses on iterative design, which includes the stages of ideation, prototyping, and refinement [30,31]. We held internet-based sessions with an interdisciplinary group of stakeholders. The sessions focused on answering the following research questions to understand design preferences and needs: “What are the pain points in current practices of social need screening and resource sharing?” “Why should we use or not use technology to facilitate this process?” and “How can we design and use a chatbot to connect with families in primary care settings in order to address social needs effectively?” The interdisciplinary stakeholder group (n=10) was formed internally at the NCH, including an epidemiologist (n=1, 10%), a primary care physician (n=1, 10%), a nurse (n=1, 10%), the director of clinical social work services (n=1, 10%), a community health worker (n=1, 10%), a public health scientist (n=1, 10%), an industry partner leader (n=1, 10%), a community partner leader (n=1, 10%), a family advocate (n=1, 10%), and an information system expert (n=1, 10%). Stakeholder group members were recruited within the NCH network (including primary care clinics) in September 2022.

Figure 3. Study process diagram.

Study 3 is a mixed methods evaluation of the prototype. Our evaluation methodology was informed by a feasibility framework [32], technology acceptance model [33], and usability scale—Usability Metric for User Experience—Lite (UMUX-Lite) [34]. We conducted scenario-based usability testing via a focus group interview with community health workers (who are also family advocates as part of the community) and via a web-based survey with social workers to examine the usability and feasibility of DAPHNE (semifunctional prototype) for families and communities. During these sessions, participants interacted with the chatbot to simulate the process of accessing and evaluating social resources (refer to [Multimedia Appendix 1](#) for the scenario and questions). They used the chatbot to enter responses, navigate resource information, and provide feedback on its functionality qualitatively and quantitatively (via UMUX-Lite). Community health workers (n=4) and social workers (n=9) were recruited within the hospital network via email or phone (January to February 2023). Participation was voluntary for all participants.

Ethical Considerations

This study received ethics board approval (NCH institutional review board #00003766). All participants provided informed consent to participate to the study. Participants did not opt out

of the study. Collected data and transcripts were deidentified. Participants received compensation for their participation, if permissible. This paper reports an aggregate summary of the data generated during the study, without any identifiable information. Due to privacy and confidentiality reasons, we are not able to share individual data points or transcripts.

Data Collection

In study 1, after participants provided consent, they completed a survey about their experiences. The survey captured their experiences and perceptions regarding the accessibility of social need resources. Questions included items on the awareness of and ability to access community support programs, methods used to obtain resources, and openness to using technological tools such as chatbots for resource assistance. Responses were collected anonymously, and the entire data collection process was structured such that the security and confidentiality of the participants were ensured. In study 2, iterative design sessions consisted of interactive interviews with open discussion guided by the research questions and moderated by a researcher. Wire frames were used to communicate initial design and revised designs of the chatbot ([Figure 1](#)). In total, three 1-hour sessions of stakeholder interviews were held between September to December 2022. The research team continuously communicated

with the stakeholder group via email to share iterative improvements in the prototype. Throughout the sessions and conversations, stakeholder feedback was captured as conversation notes and observational notes. In study 3, social workers completed a 20-minute web-based scenario-based study to use the chatbot prototype and provide feedback (refer to [Multimedia Appendix 1](#) for scenario and survey details). They responded via a web-based survey tool (REDCap [Research Electronic Data Capture]; Vanderbilt University). Community health workers were invited to a single-session focus group interview at the hospital (approximately 1 hour). The study team introduced the chatbot and its functionalities, shared examples, and provided a scenario-based demonstration. Usability questions and questions about dialogue and conversational design, voice interaction, perceived opportunities, and barriers were verbally discussed, which followed a similar approach to the web-based survey protocol. Data were collected via field notes.

Data Analysis

Study-1 analysis included descriptive statistics to summarize demographic information and responses to survey questions. We compared observed distributions of income, age, and employment status with responses to the questions on the ability to meet social needs, knowledge about community resources, and perception of chatbot use. Then, we conducted chi-square analysis to assess the association and independence of categories. In study 2, we conducted content analysis to inform the chatbot development process [35]. Stakeholder feedback was systematically analyzed by a single researcher to identify emerging themes, patterns, and insights, which were instrumental in understanding stakeholders' needs and expectations. Given the nature of semistructured interviews and scenario-based surveys, study-3 data were analyzed using thematic analysis to synthesize the qualitative data and to understand the meanings and experiences reported in response to open-ended questions and captured during the interviews [36]. The process began with 2 researchers independently conducting initial coding of the data. This coding was primarily inductive, allowing themes to emerge from the data, although a preliminary framework based on existing literature was also considered to guide the analysis. Regular discussions were held to review codes and themes, ensuring consistency and comprehensiveness. Data saturation was assessed to determine when no new themes were emerging, indicating sufficient depth of inquiry. Discrepancies between researchers were resolved

through consensus; if consensus could not be reached, a third researcher was consulted to make a final decision, ensuring objectivity and reliability. In addition, we reported the total score of UMUX-Lite, with an expected usability score of ≥ 60 [34,37]. The thematic analysis and usability results were triangulated to provide a robust understanding of both user satisfaction and deeper user experiences.

Results

Study 1: Family Needs and Perceptions

We surveyed 201 low-income households, each with at least 1 unmet social need, to understand their willingness to use a chatbot for resource assistance. As shown in [Table 1](#), demographic data showed an equal sex split (male: 100/201, 49.8%; female: 100/201, 49.8%; unreported: 1/201, 0.5%). Age distribution skewed toward the 21-40 years range (122/201, 60.7%), and the most reported income level was from US \$20,000 to US \$29,999 (84/201, 41.8%), followed by <US \$10,000 (47/201, 23.4%). Employment status varied, as 24.4% (49/201) of the participants were full-time employees, and 21.9% (44/201) of them were not in paid work. Regarding unmet social needs, 33.3% (67/201) of the participants found it moderately hard to meet. The majority of participants (106/201, 52.7%) were aware of and had used community resources. A substantial portion of participants primarily used the internet for discovering community resources (133/201, 66.2%), and 60.2% (121/201) of the participants were open to using a chatbot for resource finding.

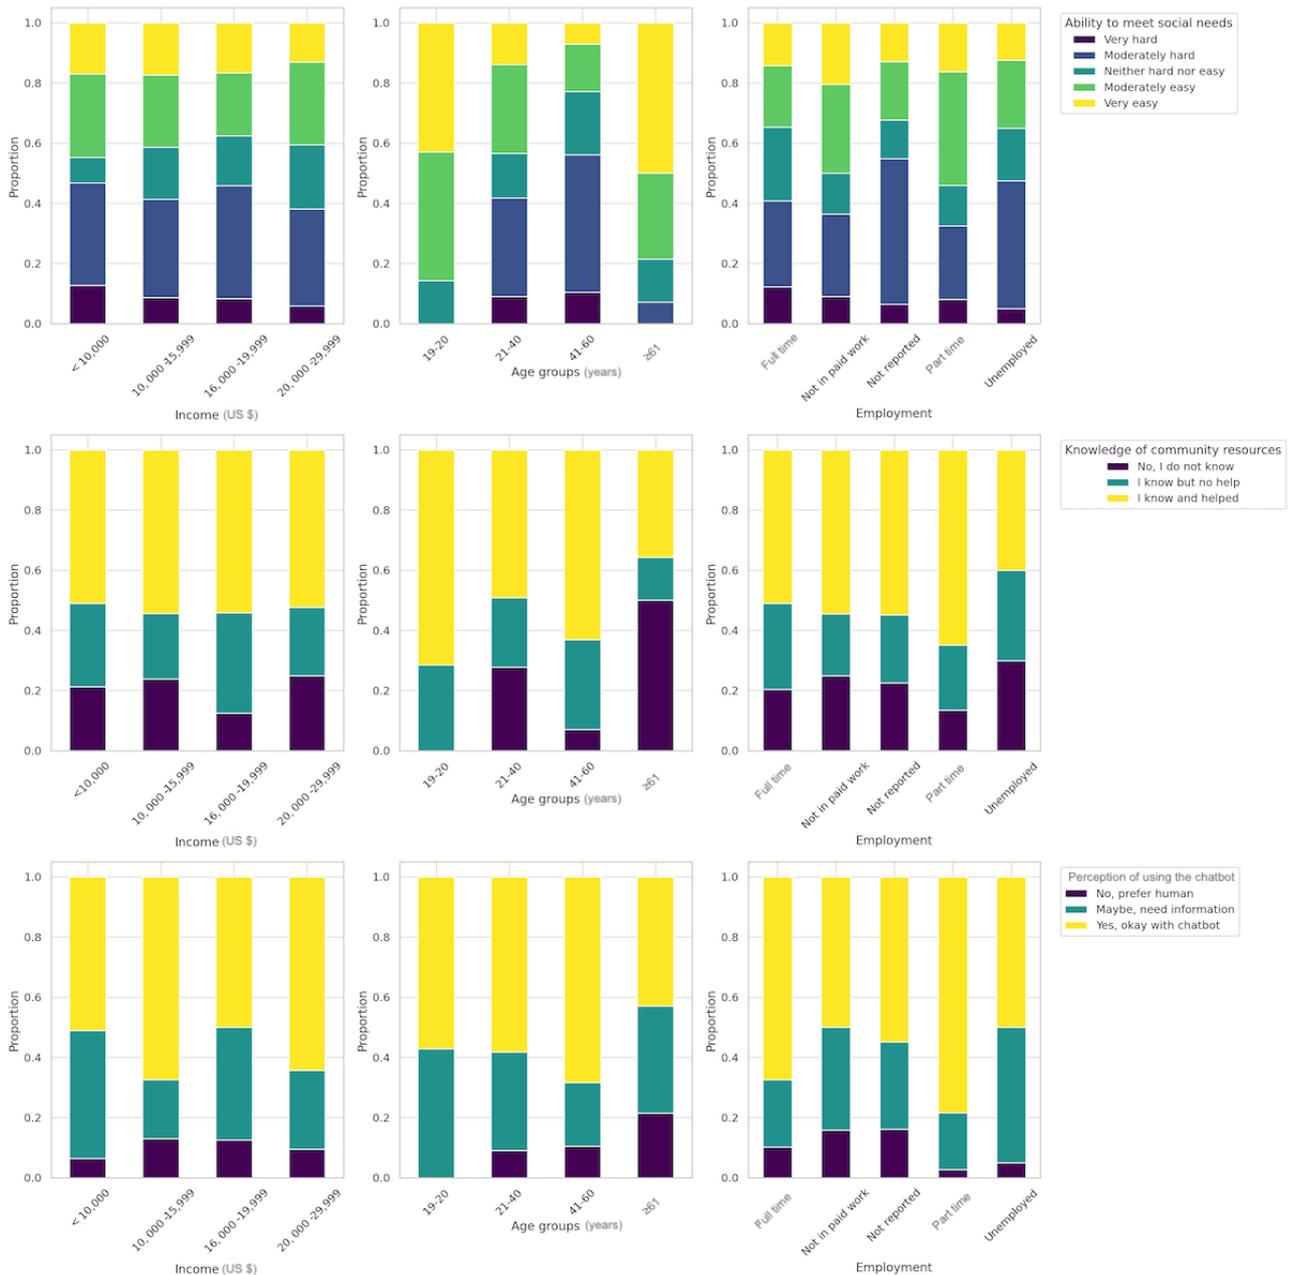

[Figure 4](#) outlines the proportional distribution of the responses. Lower-income groups reported a lower ability to meet social needs, with similar trends observed among middle-aged groups and those who were unemployed. There was an increase in meeting social needs among slightly higher-income earners, younger age groups, and individuals who were fully employed. Knowledge of community resources was lower among individuals who were unemployed, and the oldest age group, those aged ≥ 61 years, exhibited a lower level of community resource awareness and use of community programs. In terms of chatbot use, while there was a general receptiveness across all income levels, employed and younger individuals, particularly those aged between 21 and 40 years, demonstrated a higher tendency to use chatbot technology. In contrast, the oldest age group demonstrated a greater preference for human interaction over using chatbots.

Table 1. Demographics of web-based survey participants (n=201).

Characteristics	Participants, n (%)
Income range (US \$)	
<10,000	47 (23.4)
10,000-15,999	46 (22.9)
16,000-19,999	24 (11.9)
20,000-29,999	84 (41.8)
Sex	
Female	100 (49.8)
Male	100 (49.8)
Not reported	1 (0.5)
Race	
Asian	14 (7)
Black	24 (11.9)
White	146 (72.6)
Other	9 (4.5)
>1	8 (4)
Age group (y)	
19-20	7 (3.5)
21-40	122 (60.7)
41-60	57 (28.4)
≥61	14 (6.9)
Not reported	1 (0.5)
Employment status	
Full time	49 (24.4)
Part time	37 (18.4)
Unemployed (and job seeking)	40 (19.9)
Not in paid work (eg, homemaker, retired, or disabled)	44 (21.9)
Not reported	31 (15.4)
Ability to meet social needs	
Very hard	17 (8.5)
Moderately hard	67 (33.3)
Neither hard nor easy	34 (16.9)
Moderately easy	52 (25.9)
Very easy	31 (15.4)
Knowledge about community resources	
No, I do not know about these programs	45 (22.4)
Yes, but I could not get help	50 (24.9)
Yes, and they helped	106 (52.7)
Methods of finding community resources	
Internet (websites and email)	133 (66.2)
In person (such as at community centers and food banks)	93 (46.3)
Phone calls	61 (30.3)
Mobile apps	27 (13.4)

Characteristics	Participants, n (%)
Other	20 (10)
Perception about using chatbot	
No, I would rather talk to a person	20 (10)
Maybe, I need to know more about how it works	60 (29.9)
Yes, I would be okay with using a chatbot	121 (60.2)

Figure 4. Stacked bar graphs showing the proportional distribution of the survey responses for social needs and perception toward chatbot by income, age group, and employment status.

The chi-square analysis did not yield strong evidence of association of income ($\chi^2_6=7.9; P=.24$), age ($\chi^2_6=6.5; P=.37$), and ability to meet social needs ($\chi^2_8=6.2; P=.63$) with the perception of using a chatbot. However, there is a statistically significant association between knowledge about community resources and chatbot perception ($\chi^2_4=12.9; P=.01$). In addition,

the relationship between employment and chatbot perception is marginally close to being significant ($\chi^2_8=15.5; P=.051$).

Study 2: Iterative Design

The themes were grouped under 3 research questions. [Textbox 2](#) outlines the questions and themes for each question. Themes

included common pain points: technology opportunities and challenges and technology considerations, including inclusivity, personalization, and information about accessing resources. On the basis of stakeholder feedback, we improved our chatbot design (Figure 5). We updated the prototype to include chatbot

language options, modified language (eg, “What makes it hard to get food?”), and resource education options (ie, eligibility criteria, documentation requirements, and referral guidance). These components were initiated and are under development.

Textbox 2. Questions and themes from stakeholder group sessions.**“What are the pain points in current practices of social need screening and resource sharing?”**

- Inadequate or inconsistent screening tools: the tools used for social need screening may not be comprehensive enough for addressing all social needs associated with social determinants of health, resulting in incomplete assessments. In addition, there might be inconsistency in the use of these tools across different settings, leading to variations in the identification and understanding of social needs.
- Limited provider training and awareness: health care providers and other professionals involved in social need screening may lack sufficient training and awareness about how to implement screening, screen for unidentified needs, and address the unmet social needs. This can lead to lower quality of service as well as adversely affect the quality of life.
- Fragmented systems and lack of integration: social need screening and resource-sharing efforts are often fragmented across different divisions, departments, and organizations. This can lead to poor communication and collaboration, creating barriers to the effective identification and provision of resources.
- Insufficient resources and capacity: there may be a lack of adequate resources and capacity to address identified social needs based on the location and resources of institutions (rural vs urban health institution), resulting in unmet needs or long waiting periods for support. This can exacerbate existing disparities and negatively impact health outcomes.
- Stigma and privacy concerns: patients and families may be reluctant to disclose their sensitive information as well as their social needs due to concerns about stigma or privacy. This can prevent the accurate identification of needs and hinder access to appropriate resources.
- Cultural and linguistic barriers: cultural and linguistic differences may negatively impact communication among providers and patients or families, leading to misunderstandings and underestimation of social needs. This can result in the inadequate provision of resources and support.

“Why should we use or not use technology to facilitate this process?”

- Opportunities:
 - Improved efficiency: technology can streamline the screening and resource-sharing process, reducing the time and effort required by both providers and patients or families. Automated systems and digital platforms can facilitate data collection, storage, and retrieval, making it easier to identify and address social needs at scale, especially within low-resource settings.
 - Standardization and consistency: digital tools can help ensure that social need screening is conducted in a standardized and consistent manner across different settings, reducing variations in the identification and understanding of social needs.
 - Personalization and customization: technology can enable more personalized and customized approaches to social need screening and resource sharing, tailoring interventions to the specific needs and preferences of patients and families (which can be beneficial considering cultural appropriateness and language options).
- Challenges:
 - Digital divide: the use of technology may exacerbate existing disparities in access to digital tools, particularly among vulnerable populations. This can result in the further marginalization of those who may be most in need of support yet do not have access to the necessary technology.
 - Privacy and security concerns: storing and sharing sensitive data and private information electronically can raise privacy and security concerns for individuals and institutions. It might be particularly concerning if technology providers have not enforced appropriate safeguards to protect the information.
 - Implementation challenges: introducing a new approach using technology into social need screening and resource-sharing processes may involve significant financial and human resource investments as well as create barriers or burdens related to staff training, infrastructure, and technological compatibility.

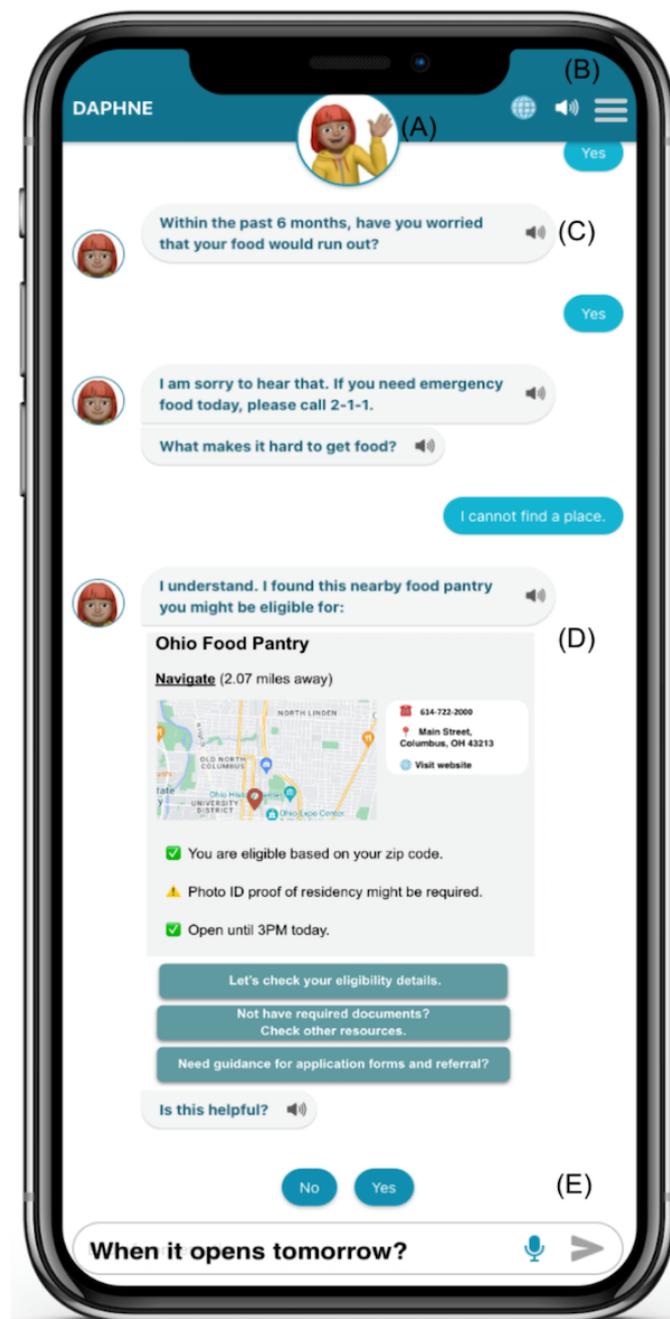

“How can we design and use a chatbot to connect with families in primary care settings in order to address social needs effectively?”

- Leveraging provider and technology collaboration: this means that chatbot and health care providers (eg, primary care team) and community centers can work together to serve families better and more effectively.
- Suggested use case 1: chatbot can be used as a triage follow-up tool for health care providers and community centers to follow-up on patients after their visit to ensure that patient and family needs are met and check whether resources are useful. Thus, the chatbot can timely inform providers to intervene in case of unmet needs as well as help identify invalid or noneligible resources and update their resource list and database accordingly.
- Suggested use case 2: chatbot can be used as a prescreening tool to inform providers and community centers about what needs to be communicated with families, getting them ready for detailed conversation about the resources and how to access them. The chatbot can ease the process of support and patient engagement so that providers can timely serve more families and spare more time to engage as well as for identifying and addressing urgent needs during their conversations.
- Conversational design could be guided to be more inclusive and personal.
- Current screening instruments are not individually relatable or personal, and chatbot can be guided toward more conversational personalized screening, which can eventually inform current screening tools. Reframing dialogues toward positive attitude and social norms are some of the methods discussed.
-

Cultural appropriateness and language barriers could be addressed by chatbot providing language options (eg, Ohio has a high rate of Nepali and Somali refugees with limited English proficiency and requires interpreter services) and culturally guided and appropriate conversations and dialogue flow, accounting in cultural norms and connotation (eg, In some cultures “free resource” still may mean you have to pay back due to cultural expectations or practices).

- Chatbots can help educate families about accessing resources (beyond sharing resources, guiding them on self-referral, how to check eligibility, and how to navigate web-based resources). This may eventually reduce dependency on low-risk or quickly accessible resources by families and patients, reserving time and resources of health institutions and community centers to be spent on patients and families having urgent or complex needs.

Figure 5. Revised semifunctional prototype (web application). (A) customizable avatar; (B) profile and setting menu, language selection, and enable or disable audio narration (text to speech); (C) repeating audio narration for preferred messages; (D) interactive resource screen with navigation and communication details and follow-up questions suggested by stakeholders; and (E) assistive buttons for quick response, text entry feature, and speech-to-text feature for voice interaction.

Study 3: Prototype Evaluation

We collected feedback from 13 participants, including community health workers (n=4, 31%) and social workers (n=9,

69%), within the NCH network (Table 2). Community health workers had <5 years of professional experience (3/4, 75%). They had limited experience with chatbots and conversational

agents. They are supporting families through the Connecting Families 4 Success program at NCH, which provides resource linkages to families with identified social needs.

The majority of social workers (6/9, 67%) had 1 to 10 years of experience in their current profession. Most (8/9, 89%) had prior exposure to chatbots. Social workers reported that they serve an average of 165 (SD 229) patients or families monthly. The social workers responded to the usability questions (UMUX-Lite) using a 7-point Likert scale, agreeing that the chatbot's capabilities met expectations toward addressing social needs (average score 5.4, SD 1.1) and that it is easy to use (average score 5.6, SD 1.8). Collectively, they agreed on the usability of chatbot, providing an average score of 72 on the System Usability Scale (calculated using the regression equation developed by Lewis et al [38]).

We analyzed responses from community health workers and social workers together and grouped them under the following 4 overarching themes: user experience (how users perceived the chatbot, its functionality, and its satisfaction and interacted with it), feature preferences (user preferences for additional features in the chatbot), resource concerns (the challenges related to the accuracy, relevance, and timeliness of the resources

provided by the chatbot), and perceived disadvantages and challenges (limitations and potential obstacles associated with using the chatbot; Table 3). The themes were informed by the interview and survey questions, focusing on user experience (meeting expectations and ease of use), chatbot dialogue, audio interaction, perceived advantages and disadvantages, and integration to clinical workflow. As outlined in Table 3, our thematic analysis suggests that the use of a chatbot is perceived to be useful for patients, caregivers, and providers and can help with addressing unmet social needs and resource sharing. More specifically, social workers and community health workers appreciated its clear interface but noted the need for detailed options on eligibility and documentation. Opinions on audio narration were mixed, with some valuing it for accessibility and others preferring text for privacy. The need for multilingual support and careful consideration of privacy with EHR integration was also emphasized. Users were concerned about the accuracy and currency of resource information and doubtful of the technology's current capability to update its content without human verification. Major drawbacks included the chatbot's inability to interpret nonverbal cues and complex situations, limited access to necessary technology for some users, and concerns about data privacy and trust.

Table 2. Study-3 participant demographics (n=13).

Demographics	Social worker (n=9), n (%)	Community health worker (n=4), n (%)
Have you ever used chatbots before for any purpose?		
Yes, multiple times	8 (89)	1 (25)
No, never	1 (11)	3 (75)
Age group (y)		
18-24	1 (11)	2 (50)
25-34	3 (33)	1 (25)
35-44	2 (22)	1 (25)
45-54	3 (33)	0 (0)
Experience (y)		
<1	1 (11)	2 (50)
1-5	3 (33)	1 (25)
5-10	3 (33)	1 (25)
10-20	1 (11)	0 (0)
>20	1 (11)	0 (0)

Table 3. Themes from interviews and web-based survey with social workers and community health workers.

Themes	Explanations	Quotes
User experience	<ul style="list-style-type: none"> Conversational interface was found to be simple and understandable. It was noted as “easy to use,” as it enabled turn-based conversation via natural language through SMS text messaging–like interface with the option of voice interaction. The simplicity of the dialogue was appreciated, although some suggested adding more options and details about resources, such as expanding options for eligibility, required documents, and forms. Although these components were included during the iterative design process, they were not functionally adapted in the prototype during the testing. 	<ul style="list-style-type: none"> “[Dialogues] were clear and easy to understand” (Participant #5). “Dialogue is overall acceptable. I’d be interested in hearing what ‘other’ options it may generate for people who have food instability due to other reasons” (Participant #8).
Feature preference	<ul style="list-style-type: none"> There was mixed feedback on whether audio narration would be preferable. Some participants thought it would be helpful, especially for those who face language barriers or have difficulty reading or writing or physical impairment. However, others believed that families may prefer text or typing in certain cases, such as when they are in public places. Several participants mentioned the importance of offering multiple language options to engage with a diverse population, including non-English speakers. Current service limitations and inability to follow-up due to language barriers necessitate such alternative support on communicating social needs. Opinions on integrating chatbot data with EHRs^a were mixed. Some participants supported integration for better decision-making and follow-up, while others were concerned about privacy, consent, and the potential for surveillance or stigmatization. 	<ul style="list-style-type: none"> “...voice to text can be sometimes challenging, as with Siri at times and this is more so common for individuals whose first language is not English” (Participant #4). “I think [chatbot] could [help if integrated to EHR] for basic medical records, but families might try to use this to ask medical questions thinking a doctor might respond” (Participant #3).
Resource concerns	<ul style="list-style-type: none"> Participants expressed concerns about the accuracy of resources and how to the resource information is up-to-date. The concerns were also about identifying relevant resources to specific age groups or situations, which may not be available in a single database or web resource. In the current practice, support teams (eg, community centers and social workers) need to reach out and check the availability of resources (eg, food pantry) and eligibility to ensure the resource provider is operational before referring to a patient and family. Participants emphasized their skepticism behind the need to use technology to ensure that resources are up to date (given the necessity of calling and communicating with the service providers to ensure the resource list is up to date). 	<ul style="list-style-type: none"> “[resources] might not always be accurate if all the places are not regularly updated in the system” (Participant #9) “It will also be useful to have more details about the pantry such as open hours of operation” (Participant #6).
Perceived disadvantages and challenges	<ul style="list-style-type: none"> Some participants expressed concerns about the chatbot’s major communication limitation, which is its inability to assess nonverbal cues and understand nuanced situations; therefore, it may not be able to articulate social need details to guide toward appropriate resources. Limited access to technology, broadband or Wi-Fi, or mobile devices could pose challenges for some families. It is noted that some families or patients might be uncomfortable sharing personal information with a chatbot or might not trust the information provided by a chatbot. 	<ul style="list-style-type: none"> “One disadvantage might be the chatbot not being able to assess nonverbal cues, or other concerns the family might have that can’t be typed into a box” (Participant #5). “[Chatbot] can’t share nuanced situations. Can it understand the intersection of different needs?... organizations that have food and housing resources if you are looking for orgs specifically with both” (Participant #4).

^aEHR: electronic health record.

Discussion

Principal Findings

We conducted a 3-stage study with a multistakeholder group, focusing on the development and evaluation of a social need screening chatbot for families. Engaging stakeholders, including low-income households, health care providers, and family advocates, throughout the need assessment and design and development process helped identify specific needs, preferences, perceptions toward using chatbots and potential barriers to

adoption. Our study highlights the importance of a multilayered and user-centered iterative design and the development of chatbots for social needs. Furthermore, it was a promising step forward to develop a chatbot collectively with partners and to serve families effectively via conversational systems [39,40]. It also contributes to the literature [19,21] by providing further evidence on diverse stakeholder perceptions of chatbot use in social need screening and resource sharing.

Our first study highlights that the awareness of community resources is traditionally less among lower-income and

unemployed groups, as well as among older households. However, the majority of participants, irrespective of demographics, use the internet to identify community resources. Although this is promising, further investigation is needed on how to leverage current communication technologies to close the gap in digital inclusion, improving the awareness of resources and access [41,42]. Furthermore, a broad acceptance of chatbot technology across all income levels is observed, as younger individuals, notably those aged 21 to 40 years, lead the charge in embracing this digital interaction. This suggests a generational pivot toward using chatbots similarly to prior observations with the acceptance of new technologies [43]. The knowledge and employment status of individuals with social needs are further associated with their perception about chatbots.

Our second study highlights potential implementation areas and improvements for the chatbot to be more engaging and effective. In the current health care ecosystem, chatbots may serve a dual function as follow-up tools and triage systems, as recommended by health care providers and community centers subsequent to family visits, ensuring the effective use of resources and helping meet social needs. In line with this, chatbot data can be used for timely feedback about health care systems about unmet needs as well as to facilitate the updating of resource repositories and databases (eg, user feedback on nonoperational food pantries). When deployed as prescreening instruments, chatbots can enable providers and community centers to be adequately prepared for comprehensive discussions about resource availability and access, thereby streamlining support procedures. Conversational design can be strategically geared toward providing more inclusive and personalized need assessment [44-46]. By enhancing the relational capacities of a chatbot [47] such as showcasing positive attitudes and adhering to social norms (eg, “Others have found assistance through this local agency.”) and implementing behavioral nudges (eg, “Completing this screening will require just a few minutes.”) within the conversational design, its engagement abilities can be bolstered. In addition, a chatbot can address cultural compatibility and linguistic barriers by providing multilingual options and culturally sensitive dialogues [48]. In the context of current practices to adequately address social needs [49], chatbots can act as supportive adjuncts, supplementing and enhancing these efforts. Furthermore, chatbots can play an educational role in assisting families in understanding and accessing resources, steering them through self-referral processes, eligibility assessments, and web-based resource navigation. As a next step, chatbots can be instrumental in augmenting health literacy [50], as they have been well received in addressing social needs among populations with low literacy levels [24].

Building on stakeholder feedback, we implemented improvements in our chatbot prototype. In study 3, our descriptive analysis showed a diverse range of participants in terms of age, experience, and department affiliation, providing a rich perspective on the chatbot’s applicability with various contexts. Participants have generally rated the chatbot’s capabilities and ease of use as average to high. The results of our study indicate that the chatbot designed for addressing social needs is generally well received, with most users finding it easy to use and having a positive user experience overall. This

overlaps with the current trajectory of chatbot use in health care, as the capability as well as usefulness of chatbots increases [51,52].

Emerging Opportunities and Barriers

Audio narration emerged as a theme with mixed opinions. While some users believed it could benefit those facing language barriers or with difficulty reading, others felt that text-based communication would be more appropriate in publicly available spaces, which was also noted previously as a common concern about using voice interaction in health information exchange [53].

Resource accuracy and availability were identified as concerns by participants, emphasizing the importance of regularly updating resource information and ensuring that resources are relevant to specific age groups or profiles. To ensure the sustainability and maintenance of resources and accuracy of DAPHNE’s responses, automatic updates of the chatbot resource listings by syncing with APIs provided by established community resource platforms may ensure real-time accuracy. In addition, a user feedback mechanism is in place (regarding whether the resource is helpful) via the chatbot interface, allowing users to report any discrepancies or changes required in the resource information directly through the chatbot interface. Such a human-in-the-loop feedback mechanism is crucial for continuous improvement and helps maintain a high level of trust and reliability in the resources provided [54,55].

Integration with EHRs received mixed feedback, with some users supporting the idea for better decision-making and follow-up. Such implementation is principally viable to support decision-making with a feedback mechanism [56]. Others expressed concerns about privacy and potential stigmatization, which may lead to labeling and internalized negative stereotypes that may reduce disclosing social needs [57]. Therefore, EHR integration and adoption require detailed investigation to reduce barriers and inequality in medical documentation [57,58]. For privacy, data should be transmitted to EHRs via Health Insurance Portability and Accountability Act-compliant services and encrypted, and a governance body should be established for regular oversight [59,60]. In addition, where possible, data anonymization could be implemented to protect patient identity. To address stigma, training health care providers on handling sensitive information respectfully and confidentially is needed, which is crucial for integrating social determinants of health into patient care without bias [61].

Participants raised several disadvantages and challenges related to the chatbot’s ability to assess nonverbal cues and accurately screen needs, limited access to technology, and trust issues when sharing personal information with a nonhuman source. In this regard, using a single modality communication medium (no visual exchange) might limit the chatbot’s ability to process nonverbal cues. Multimodal approaches with chatbots may overcome this limitation in the future [62]. The chatbot’s dependency on technology platforms (computer, Wi-Fi, or smart mobile devices) and data plans may limit access. Although there are existing programs to support broadband access to low-income families (eg, Affordable Connectivity Program by Federal Communications Commission) [63] in the long term,

this underscores the importance of strategic consideration of the digital divide and accessibility challenges when designing and implementing chatbots for social needs. In earlier studies, interactive voice response systems and chatbots based on SMS text messaging have been viable alternatives, which might be adapted for social need screening and resource sharing, especially in rural areas [64]. The lack of trust between the chatbot and families might negatively influence its use. Some participants expressed concerns about sharing personal information with a nonhuman actor or not trusting the information provided by the chatbot. Literature has mixed evidence toward trust between humans and chatbot [65], and further research can inform the trust built between families and chatbot.

Expanding With Broader Social Needs

The potential scalability of the DAPHNE chatbot extends beyond its current application in food insecurity. At its current state, its design accommodates the integration of additional social needs by incorporating a flexible, rule-based conversational architecture that can be customized with minimal technical adjustments. For example, the chatbot could be adapted to screen for housing instability or transportation difficulties by updating the dialogue scripts and linking to different resource databases. Moreover, the backend infrastructure, built on cloud services, supports scalability to handle increased user traffic and data volume as the system expands.

Improving Technical Capabilities

Although the current chatbot conversational flow was designed to be rule based, transformer-based large language models and artificial intelligence (AI)-enabled conversational agents are alternative approaches to delegate a variety of tasks [66,67]. These intelligent chatbots include a large range of functionalities that set them apart from their predecessors, such as (1) engaging in discussions across multiple topics; (2) managing multiturn conversations; (3) retaining information from previous conversations; (4) operating in both task-based and non-task-based modes; and, most importantly, (5) collaborating effectively with users. In particular, being able to work together with users, listening to their instructions, and understanding their preferences through naturally occurring conversations open up a wealth of opportunities for both health care providers and families with social needs. Although there are major concerns related to privacy, reliability, and accuracy [68], we can expect the development of hybrid solutions that have the increased conversational competence of chatbots while being constrained by the strict specifications of a rule-based system. In addition, current guidelines and practices for developing skills to engage in a sensitive conversation, such as food insecurity, can be informative for AI-enabled chatbot development [69,70]. For instance, American Hospital Association's guidelines suggesting cultural competency, motivational interviewing, active listening, and empathic inquiry would be valuable input for conversational design and development [71].

Future Research

It is essential to evaluate the long-term effectiveness, scale-up capability, and impact of chatbots for addressing social needs

through rigorous and comprehensive evaluation methodologies [72,73]. Our study provides preliminary evidence on the iterative design and evaluation of the chatbot for addressing social needs (focusing on food insecurity screening and resource sharing with text and voice interaction). However, future research should investigate the impact of chatbot interventions on users' health outcomes, quality of life, and access to resources, as well as the cost-effectiveness and scalability of such interventions. While chatbots can play a valuable role in addressing social needs, they are unlikely to replace human service providers entirely. Instead, chatbots can be considered complementary tools that support and enhance existing services by providing timely, personalized, and accessible information and resources. Future research should explore the potential synergies and integration opportunities between chatbots and other digital health interventions, such as telemedicine, mobile health apps, and online support groups, to maximize the overall impact on users' health and well-being.

Limitations

There are several limitations that should be acknowledged while interpreting the study results. First, our participants in studies 2 and 3 consist of stakeholders representing providers more than patients and caregivers, which may potentially skew the feedback toward professional perspectives. Providers may have perspectives or biased interests that differ from those of patients and caregivers, potentially leading to an overemphasis on the functionality and clinical utility of the chatbot. This skew could limit the generalizability of our findings to broader end-user experiences and might overlook key usability challenges faced by less technologically proficient users. Moreover, the diversity and size of our participant sample may not fully represent the broader population, which could limit the generalizability of our findings. Second, our research was conducted in a controlled setting with a single scenario and did not involve any real-world testing and observations. As such, the practical implications of our study remain limited to self-reported and perceived usability, feasibility, and implementation with a limited user experience. Further research in real-world scenarios is required to evaluate the effectiveness and feasibility of the chatbot in addressing social needs. Third, our research focused primarily on qualitative data, thus lacking quantitative information to assess the chatbot's performance with a longitudinal observation. Although we collected preliminary data from households regarding their social needs and perception toward using the chatbot, the effort was limited in terms of demographic diversity and feedback (without chatbot engagement), and it may be subject to self-report bias. Future studies will aim to collect quantitative measures with real-world chatbot use, such as user logs, response accuracy, and user satisfaction rates, to provide a more comprehensive evaluation of the chatbot's performance in addressing social needs.

Conclusions

The study reported the iterative design and evaluation of a chatbot for social need screening and resource identification designed to scale screening and resource sharing for low-resource communities and disadvantaged neighborhoods. Furthermore, it may augment health center services, with

low-risk tasks (such as resource finding and sharing) being delegated to the chatbot to scale the services provided. The DAPHNE chatbot has garnered largely favorable responses, providing initial evidence for its practicality and viability. Crucial factors in designing chatbots for social needs involve fostering user confidence, ensuring the precision of resources,

and tackling accessibility obstacles. Future studies should investigate the efficacy, cost-efficiency, and expandability of chatbot initiatives, the opportunities provided by conversational AI technologies, and possible collaborations with other established digital health interventions.

Acknowledgments

The authors are thankful to the project advisory board for their valuable feedback and input: Amrik Khalsa, Nicholas Jones, Jeannette Foster, Lori McCullough, Huan Sun, LaToya Matthews, and Samantha Boch. The authors would like to acknowledge the support of the data science and design and technology teams to the design, development, and testing of the chatbot: Tyler Lieser, Brannon Oiler, Brandon Abbott, Silvio Fernandes, and Amad Hussain. This project was a recipient of phase 1 and 2 prizes of the Health Resources and Services Administration's (HRSA) "Building Bridges to Better Health: A Primary Health Care" Challenge in 2022-2023. Research reported in this publication was partially funded by the HRSA challenge prize.

Abstract

Background: Helsinki University Hospital has developed a digital care pathway (DCP) for people with multiple sclerosis (MS) to improve the care quality. DCP was designed for especially newly diagnosed patients to support adaptation to a chronic disease.

Objective: This study investigated the MS DCP user behavior and its impact on patient education-mediated changes in health care use, patient-perceived impact of MS on psychological and physical functional health, and patient satisfaction.

Methods: We collected data from the service launch in March 2020 until the end of 2022 (observation period). The number of users, user logins, and their timing and messages sent were collected. The association of the DCP on health care use was studied in a case-control setting in which patients were allowed to freely select whether they wanted to use the service (DCP group n=63) or not (control group n=112). The number of physical and remote appointments either to a doctor, nurse, or other services were considered in addition to emergency department visits and inpatient days. The follow-up time was 1 year (study period). Furthermore, a subgroup of 36 patients was recruited to fill out surveys on net promoter score (NPS) at 3, 6, and 12 months, and their physical and psychological functional health (Multiple Sclerosis Impact Scale) at 0, 3, 6, and 12 months.

Results: During the observation period, a total of 225 patients had the option to use the service, out of whom 79.1% (178/225) logged into the service. On average, a user of the DCP sent 6.8 messages and logged on 7.4 times, with 72.29% (1182/1635) of logins taking place within 1 year of initiating the service. In case-control cohorts, no statistically significant differences between the groups were found for physical doctors' appointments, remote doctors' contacts, physical nurse appointments, remote nurse contacts, emergency department visits, or inpatient days. However, the MS DCP was associated with a 2.05 (SD 0.48) visit increase in other services, within 1 year from diagnosis. In the prospective DCP-cohort, no clinically significant change was observed in the physical functional health between the 0 and 12-month marks, but psychological functional health was improved between 3 and 6 months. Patient satisfaction improved from the NPS index of 21 (favorable) at the 3-month mark to the NPS index of 63 (excellent) at the 12-month mark.

Conclusions: The MS DCP has been used by a majority of the people with MS as a complementary service to regular operations, and we find high satisfaction with the service. Psychological health was enhanced during the use of MS DCP. Our results indicate that DCPs hold great promise for managing chronic conditions such as MS. Future studies should explore the potential of DCPs in different health care settings and patient subgroups.

Introduction

Multiple sclerosis (MS) is a chronic inflammatory disease of the central nervous system with a continuously rising prevalence [1]. According to the Finnish National MS registry, there are currently more than 12,000 patients with MS in Finland. The mean age of diagnosis is around 30 years for relapsing-remitting multiple sclerosis (RRMS), a subtype of disease that accounts for 90% of patients at diagnosis. MS is the third most common cause for disability pension in Finland [2] and the yearly cost of MS to society was estimated to be roughly €50,000 (US \$54,400) per patient in a retrospective cross-sectional questionnaire study [3]. People with multiple sclerosis (pwMS) require long-lasting follow-up by a multidisciplinary team of neurologists, trained nurses, and rehabilitation specialists, to prevent disability accumulation.

Receiving a MS diagnosis is a major event often raising thoughts about a threat to career, social and family life, and independence. Social media is full of information on MS intertwining facts, assumptions, and feelings [4]. After receiving an MS diagnosis, it is common to experience severe reactions of stress [5]. Pharmacological treatment options are various for MS and patients would prefer shared decision-making in choosing the right one for them. Successful shared decision-making is not possible without reliable information [6]. A recently published study investigated barriers and adoption strategies for the early use of high-efficacy therapies in MS [7]. Further, 1 identified adoption strategy is providing patients with sufficient and reliable information, enabling shared decision-making, and improving treatment adherence [7]. From a psychological function perspective, a MS diagnosis has also been shown to cause fatigue, which is an important MS symptom related to underperformance in studies and in work [8].

Digital and telehealth services as an add-on to conventional treatment have shown to be useful in chronic illnesses. A Swedish study found that 63.9% of patients with chronic obstructive pulmonary disease and chronic heart failure found a digital platform and structured telephone support useful [9]. Glycemic control, kidney function, and lipid parameters in diabetics [10] were significantly lower for patients in a telemedicine intervention group compared to the control group, although it should be noted that the intervention and control groups were not completely balanced for socioeconomic factors in this study. An intervention of telehealth with a digital platform showed a significant lowering of systolic blood pressure in a patient group that had poorly controlled hypertension at recruitment [11]. Digital services as an option for a face-to-face model of treatment in osteoarthritis have been shown to have only 25% of the cost of the face-to-face model [12].

eHealth interventions for pwMS have shown varying results. Recent meta-analyses have shown telehealth-based rehabilitation to be an efficient intervention for pwMS [13,14]. Outside of rehabilitation, there are fewer studies on the effects of digital health care programs on pwMS. Further, 1 study found that medication adherence increased slightly from 0.85 to 0.87 in pwMS by a pharmacy and chronic disease treatment program [15]. However, the program did not affect health care use or hospital visits during follow-ups. A web-based self-management platform did not affect the use of health care services of pwMS, and at the end of this study, the control group had a better quality of life [16].

Early support for coping with MS and the change in life is mainly provided by national patient organizations. Online services are easy to use anonymously, and in some countries, these services are of high quality such as in the United Kingdom [17]. A few digital patient portals for pwMS have been created [18,19], but the patient satisfaction and patient-reported outcome measures (PROMs) of these have not been studied. A digital well-being app has been shown to improve well-being in patients with chronic conditions [20], among them pwMS. More established are data on the impact of web-based education programs and services, as shown in MS community members using the Understanding Multiple Sclerosis course [21]. Education on pathogenesis, treatment options, and self-care induced a change in lifestyle and self-management in 44.1% (247/560) of users, and the maintenance of the changed health behavior was measurable in two-thirds of them after 6 months. Similarly, in a randomized controlled trial, a significant reduction in fatigue was observed in pwMS after using a web-based self-management program supported by an email contact [22]. To our knowledge, there is only 1 previous digital health service as an add-on to standard care, aimed to give information about MS, give psychological support, and support lifestyle changes after an MS diagnosis [23]. This was found useful by pwMS.

We hypothesized that a digital health care intervention during the first years after diagnosis of RRMS could show an impact on the care of MS both from the perspective of the patient and the organization. We report on the user behavior on the MS digital care pathway (DCP) and adopt a case-control design to evaluate the health care use 1-year post diagnosis of the MS DCP group (n=63) and control group (n=114). In addition, we report on the PROMs on physical and psychological functional health using the Multiple Sclerosis Impact Scale (MSIS-29) questionnaire and patient satisfaction using net promoter score (NPS) of a separately recruited subgroup of users (n=36).

Methods

Patient Process for MS in the Neurology Outpatient Clinic

In Finland, MS is diagnosed solely in the public sector. The neurological outpatient clinic at the Meilahti Hospital covers the publicly organized health care of neurological diseases in Helsinki (0.66 million inhabitants, situation December 31, 2022 [24]). The diagnosis is confirmed with neurological examination, magnetic resonance imaging, and cerebrospinal fluid testing [25].

Follow-up of pwMS is organized as preplanned visits and phone appointments with a neurologist and a nurse. After diagnosis, most patients start immunomodulatory therapy requiring laboratory testing before and during treatment. Usually, a magnetic resonance imaging scan is performed after 6 months of medication initiation followed by a doctor's appointment. In addition, most patients have an appointment with a nurse to discuss in more detail the practicalities of medications and follow-up investigations. Newly diagnosed patients are invited to a group meeting with professionals giving information on the disease where patients have the chance to answer questions and meet peers. These events are held twice a year. During the disease course, patients will have preplanned visits to their neurologist at 6- to 12-month intervals, with additional visits if needed. In addition, patients will contact a nurse if they have new symptoms or questions between the visits. In 2022, Meilahti outpatient clinic had a care relationship with 1115 pwMS.

Contents of the DCP

The MS DCP was developed jointly by the staff and patients of the Helsinki University Hospital (HUS) neurology outpatient clinic in 2018-2020. The idea for the DCP started from the common feedback from pwMS that more support is needed after receiving a diagnosis and that there is health care practitioner-dependent variation in the information given about support services. In addition, pwMS found it difficult to get in touch with the outpatient clinic. The DCP aimed to (1) act as a patient education platform for pwMS, providing up-to-date and reliable information on MS, (2) standardize the information and support for all patients, (3) support the adaptation to a chronic illness of patients newly diagnosed with MS, (4) provide easier contact with the outpatient clinic, and (5) enable the timely use of resources for the patients in most need of health care appointments.

Thus, it was developed mainly with the newly diagnosed pwMS in mind. The DCP operates on the MyPath platform in the Digital Health Village, a digital service provided by all 5 University Hospitals in Finland. The Digital Health Village supports the traditional care paths with digital services and consists currently of 33 hubs, 400 DCPs, and 9 online knowledge centers [26]. The use of DCP is voluntary, does not rule out face-to-face contact at the outpatient clinic, and is free of charge for the patients. The service may be used by a mobile device or computer with an internet connection. The DCP is available 24/7 during the whole care relationship at the outpatient clinic.

The DCP contains information about MS, its treatment, and relapses, and provides support for the adaptation to living with a chronic disease, cessation of smoking, starting physical exercise, and coping at work. The adaptation training course of the DCP provides support to the patient after receiving the diagnosis. The DCP also contains questionnaires on symptoms and functional abilities which are encouraged to be filled in before a doctor's appointment. In addition, the patient has the possibility of sending a message to the health care professional (HCP) at the neurological outpatient clinic, and a video appointment can be launched as well. Patients can store their individual history of MS including time of diagnosis, used medications, social reimbursements, and rehabilitations received on the DCP for their own purposes, for example, used in other contacts with health care. The information content of the DCP is given on videos by professionals and patients sharing their expertise and experiences, on written text and self-assessment questionnaires, and by linking to other reliable websites. The specific contents sections of the DCP are as follows:

1. Welcome to the DCP: information on the DCP and its contents. Both written text and a video (1:06 minutes) with a neurologist introducing the DCP's different sections and how the DCP works.
2. My MS: a questionnaire about the relevant background information on the DCP user. Questions related to health conditions, ability to work, social benefits such as unemployment benefits, relevant health habits, possible rehabilitation, and how long the special reimbursement for MS medications is valid. This is meant to make the doctor's appointment smoother. The questionnaire is not standardized. It was developed for the DCP by the staff and patients of Meilahti Hospital.
3. Symptom questionnaire: a questionnaire about neurological symptoms often associated with MS. For all listed symptoms patients report whether they are asymptomatic, if the symptom is an old one, if an old symptom has become stronger, or if it is a completely new symptom. Patients are also asked to estimate how long they can walk, if they have problems with their medication, and what they would like to talk about with their doctor. The purpose of the questionnaire is for patients to fill it out before doctors' appointments to make the appointments smoother, personalized, and more purposeful. The questionnaire is not standardized. It was developed for the DCP by the staff and patients of Meilahti Hospital.
4. Information on MS: general information on MS. Links to reliable sources of information. A video (3:23 minutes) with two pwMS talking about finding information on the internet about MS, urging to be critical of the found information, what are reliable sources of information, and finding peers on online platforms.
5. Medication: information on medical treatment of MS. Links to reliable sources of information. Information on treatment of relapses with corticosteroid pulse therapy.
6. Adaptation training course: an adaptation training course to support the patient after receiving the diagnosis. The adaptation training course was modified to fill the needs of patients with MS from a template created by a psychologist

for all DCPs at HUS and contains information on the psychological process using the following steps:

- Step 1: shock. The first phase of shock and the different ways individuals will react. There are tools for how to cope at this stage and information on where to seek help from an HCP. A video (1:53 minutes) with two pwMS talking about how to accept the diagnosis.
 - Step 2: what has happened? The stage where the individual will start to confront the thought of MS. There are rehearsals to support this stage.
 - Step 3: how can I cope with MS? The stage where the individual will start to accept the situation. Encouragement is given to start seeking information on MS.
 - Step 4: a part of life: the stage where MS becomes a part of life, and the individual's thoughts are turning to the future. How to take care of one's resources. A video (1:40 minutes) with two pwMS talking about peer support and different forms of peer support.
7. Support for working life: information on the ability to work, and on how to maintain one's ability to work. Links to reliable sources of information are provided.
 8. Physical exercise and MS: what the importance of physical exercise is in MS. A video (3:13 minutes) of two pwMS talking about physical exercise and how to find the right sport. A link to another DCP which is developed to help people start exercising is provided.
 9. Quit smoking: the negative impact of smoking on MS and information on how to obtain support with quitting.
 10. Give feedback: questionnaires on patient satisfaction and response to the DCP. Links to technical and content feedback are provided.
 11. Send a message: the patient has the possibility of sending a message to the HCP at the neurological outpatient clinic.

Population and Study Design

All patients under the follow-up for MS in the neurology outpatient clinic at Meilahti Hospital were offered access to the DCP. Data on DCP user behavior were collected on all users of the DCP up to the end of 2022. Data was collected retrospectively and is descriptive in nature.

To evaluate the differences in health care use, a retrospective case-control study was adopted. A case group (n=63) was constructed of the patients who had logged into the DCP at least once and fulfilled the inclusion and exclusion criteria below. A control group (n=112) was constructed of those who had not logged into the DCP but fulfilled the criteria. Data are analyzed with statistical methods.

The inclusion criteria for the health care use part of this study were (1) diagnosed between January 1, 2020, and December 31, 2022, (2) aged ≥ 18 years, (3) a diagnosis of RRMS, and (4) a recorded Expanded Disability Status Scale (EDSS) score.

The exclusion criteria for this part of this study were (1) a diagnosis of primary-progressive multiple sclerosis (PPMS) and (2) a diagnosis of secondary-progressive MS.

Recently diagnosed pwMS were recruited to a prospective substudy on PROMs from February 1, 2021, to August 30, 2022.

The functional impact of MS and patient satisfaction with DCP was assessed, which required filling out surveys. Altogether 118 patients were given access to the MS DCP during the recruitment period, of whom 72 gave initial consent for this study. Of these, 35 were excluded due to a longer time from diagnosis or disease subtype of PPMS, and 1 patient decided to discontinue this study before the end of 12 months. Thus, the final study cohort of PROM consisted of 36 patients. The changes in PROMs are analyzed descriptively.

The inclusion criteria for this part of this study were (1) informed consent, (2) age ≥ 18 years, (3) ≤ 3 years from the diagnosis of RRMS at the time of consent, (4) fluent in Finnish language, and (5) experience in using and access to a computer or a smart device.

The exclusion criteria for this part of this study were (1) a diagnosis of PPMS, (2) a diagnosis of secondary-progressive MS, and (3) a severe psychiatric disease (eg, severe depression or a psychotic disease).

It should be noted that while the 3 samples (user behavior, health care use, and PROMs) used in this study are largely overlapping, they are not completely the same. Newly diagnosed patients were emphasized because the principal intended impact of the DCP is focused on newly diagnosed patients.

Measures

User behavior on the DCP was evaluated by descriptive statistics on the number of users, the number of logins, the timing of logins, and messages sent. These outcomes were chosen as simple metrics of how well the DCP is adopted by pwMS and at what point in their patient journey they use the service.

The health care use between the intervention group and the control group was evaluated using 7 simple quantitative measures: number of physical nurse contacts, number of physical doctors' contacts, number of remote nurse contacts, number of remote doctors' contacts, number of other service contacts (including occupational therapy, neuropsychological services, physiotherapy services, rehabilitation services, speech therapy, social worker services, and nutritionist services), number of emergency department (ED) visits, and number of inpatient days. For the first 5, only contacts to the neurological unit were considered as these were assumed to be related to MS. For ED and inpatient days no such filter was included. These measures were selected as the authors believed these can be used to accurately evaluate resource use overall. It should be noted that nonscheduled calls and messages to the MS nurses were not registered in the electronic health record (EHR) as separate contacts and were thus left out of the analysis.

Several factors were considered potential confounders in statistical analyses related to health care use. Previous research has found gender disparities in health care use for pwMS [27]. Age at diagnosis was considered, although previous research has not found a clear association between age at diagnosis and health care use [28]. The EDSS score was considered as a proxy for disabilities, which are known to be associated with higher health care use [29]. Whether or not the pwMS experienced at least one relapse during this study period was considered as a

binary variable for disease activity, which is known to be a predictor of health care use [30].

The MSIS-29 [31] was used for measuring the physical and psychological impact of MS during a 1-year follow-up in a prospective substudy cohort. The MSIS-29 self-report questionnaire allows for a detailed evaluation of a patient's functional health and well-being, encompassing physical limitations, emotional well-being, and overall quality of life. The Finnish version of the MSIS-29 has also been found valid and reliable in previous research [32]. The MSIS-29 score was collected from the patients of DCP at the 0-month, 3-month, 6-month, and 12-month marks. The scores were converted into a scale from 0 to 100 for ease of interpretation. A change of 7-8 points for the physical score [33-36] and a change of 4-6 points for the psychological score [35,36] is considered clinically significant. A higher score indicates higher perceived disability.

The NPS was used to assess the satisfaction of the DCP users at 3 key intervals: 3, 6, and 12 months. NPS is based on a simple question of whether the patient or user would recommend the service to others (rated from 0 to 10), and it has been widely adopted from business to health care [37]. NPS enables the comparison of patient satisfaction between different kinds of services and during service development. NPS is calculated as the percentage of promoters (rated 9 or 10) minus the percentage of detractors (rated 0 to 6). For reference, a previous study on a digital solution for MS care considered an NPS of over 0 "good," over 20 "favorable," and over 50 "excellent" [38].

Data Extraction

The quantitative data on user behavior (number and timing of logins, and number of messages) describing the use of the DCP were extracted from Power BI (Microsoft Corp) reports, and the patient information was gathered from EHRs Uranus (Consultants to Government and Industry Incorporated) and Apotti (Epic Systems Corporation) reporting tools. Patient-reported outcomes (MSIS-29 and NPS) were filled electronically in the DCP platform.

Statistical Analysis

Statistical analyses were performed with RStudio software (version 2022.12.0+353; Posit Software, PBC). Demographic data were presented in means and SDs as well as medians with minimum-maximum range and IQR. The Mann-Whitney *U* test was used in comparing the means of continuous variables, not requiring an assumption of normality [39]. Similarly, the

medians of continuous variables were compared using the nonparametric Mood median test. A *P* value of <.05 was considered statistically significant.

Multivariable linear regression models [40] were used to estimate the effect of the MS DCP on health care use in the presence of confounders. Further, 3 models with different confounder combinations were used to estimate the effect of the MS DCP on support service use. In addition, models with ED visits, inpatient days, and total elective visits were considered.

Ethical Considerations

This study has been approved by the HUS review board (HUS/2059/2020). The data processing practices followed the European Union Data Protection Directive Rules. This paper conforms with the applicable STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) statement.

Results

User Behavior on the MS DCP During 2020-2022

The DCP for MS was launched in March 2020 and has since had a steady flow of new users (Figure 1). Overall, as of the end of 2022, a total of 225 patients have had the option to use the service, of which 79.1% (178/225) have logged in to the service. This equals to 16% (178/1115) of all pwMS under follow-up in the Meilahti outpatient clinic. On average, a user of the MS DCP has logged in to the portal 7.4 times. As is evident from Figure 2, most sessions on the DCP take place shortly after the initiation of the access. Over the 2-year observation period starting from the initiation of the service, 18.1% (296/1635) of logins take place during the first month, 72.29% (1182/1635) of logins happen during the first year, and 27.7% (453/1635) during the second year. A minor peak in logins is seen 6 months after the launch of the service, coinciding with a common follow-up visit time. The data on which contents the patients have engaged with in the DCP is not available.

During the observation period, patients using the DCP have sent 1213 messages (average of 6.8 messages/patient) to HCP, usually MS nurses, who have answered the messages roughly in 1 working day. On the other hand, questionnaires on symptoms and functional abilities have been used on average once per patient, even though they were advised to fill it in before every appointment with the doctor.

Figure 1. Cumulative number of patients (circle) and number of new patients (triangle) in the Neurology Outpatient Clinic using the DCP shown from March 2020 until December 2022. DCP: digital care pathway.

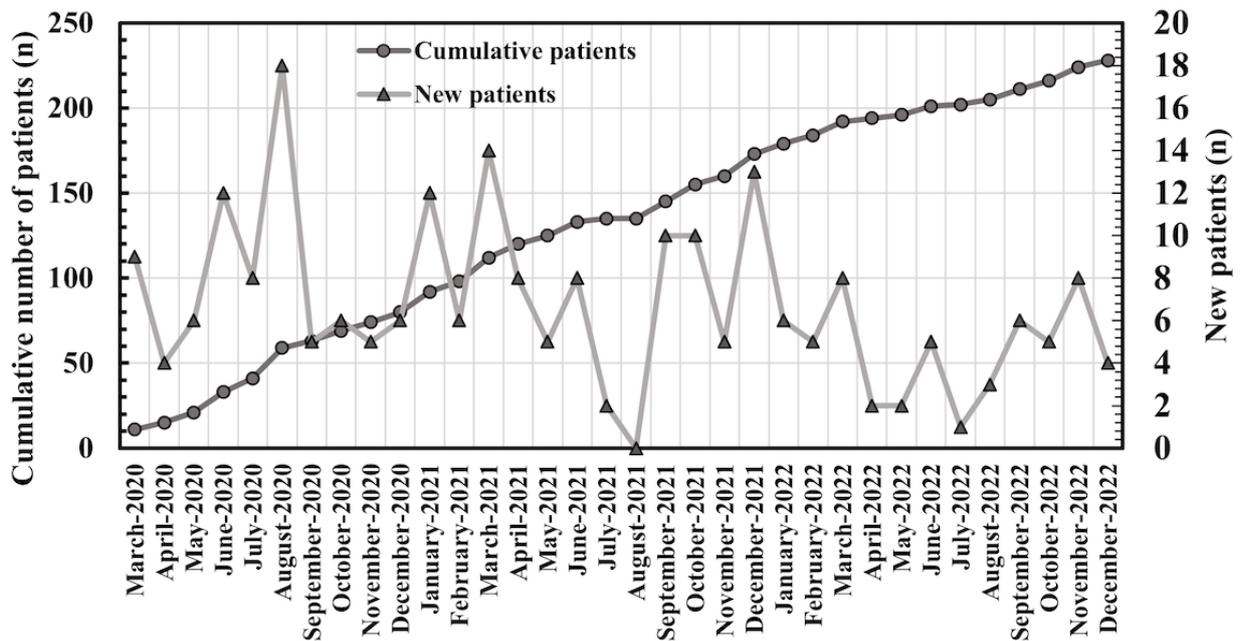

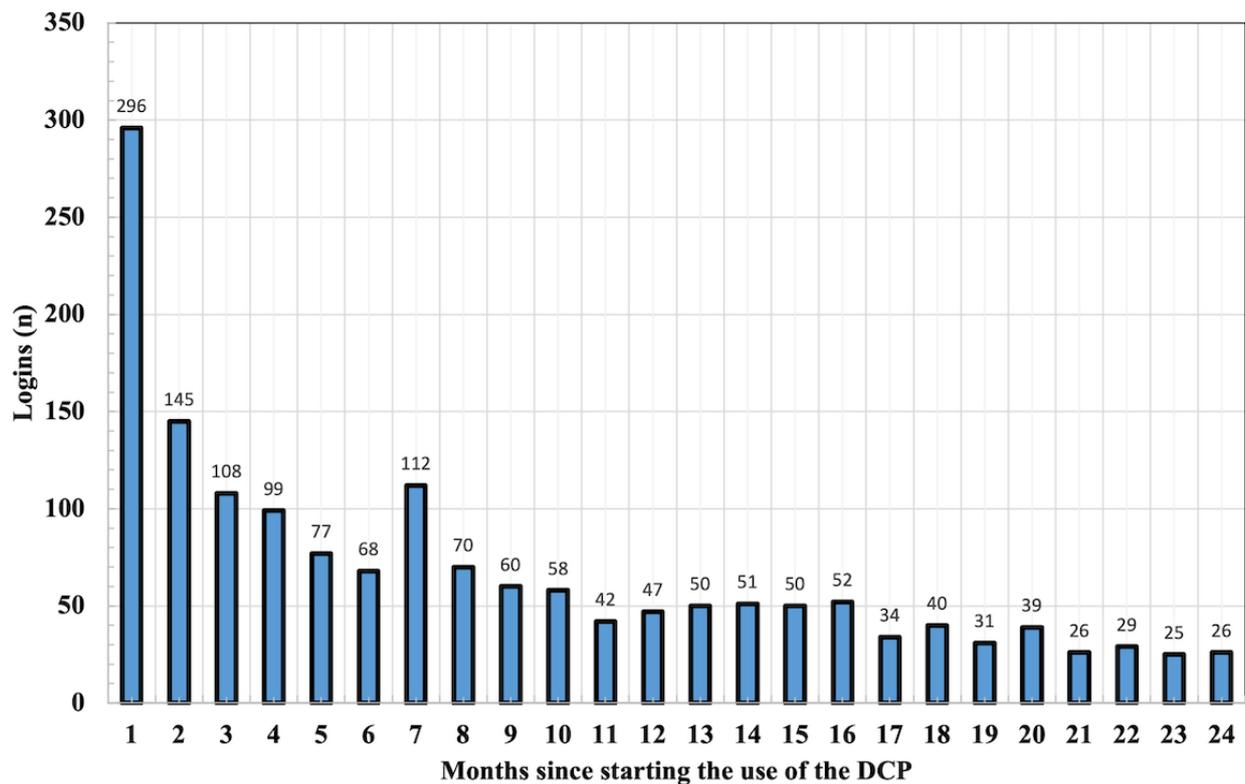

Figure 2. Summative number of logins to the DCP for all pwMS under follow-up in the Neurology Outpatient Clinic. The data are calculated from the time each individual first entered the DCP until 24 months. DCP: digital care pathway; pwMS: people with multiple sclerosis.

Health Care Use

Data on health care use was retrieved from EHRs for a total of 175 patients who fulfilled the inclusion criteria during the observation period. They were separated into an MS DCP user group (n=63) and a control group (n=112). The MS DCP group was made up of the patients who had logged into the DCP at

least once. The rest of the patients made up the control group. The groups had similar gender distributions of 73% (46/63) and 70% (79/112) of women, respectively, which well represents the overall female-to-male ratio in the prevalence of MS of roughly 2.35:1 [41]. The mean age was 34.7 (SD 9.83) years in the DCP group and 35.5 (9.76) years in the control group with no significant difference between the two. Similarly, the

mean EDSS scores were 1.56 (SD 1.26) and 1.63 (SD 1.19), respectively, with no significant differences. The control group had a higher proportion of pwMS who had relapsed at least once with a total of 13 (N=112, 11.6%) patients, in comparison to only 4 (N=63, 6.4%) in the MS DCP group. This difference, however, was not statistically significant. The characteristics of the MS DCP group and the control group are presented in Table 1.

There were no differences between the MS DCP group and the control group in physical doctor appointments (median 2 visits for both groups), remote doctor appointments (median 8 and 7 contacts, respectively), physical nurse contacts (median 1 visit for both groups), and remote nurse contacts (median 0 visits for both groups; Table 2). Similarly, there was no difference between the groups in emergency care visits (median 0 for both groups) nor inpatient days (median 0 for both groups). A statistically significant difference between the groups was found

in other service contacts with the MS DHP group having a median of 1 (minimum-maximum: 0-27) and a mean of 2.57 (SD 4.10) in other service contacts, in contrast to the control group with a median of 0 (minimum-maximum: 0-25) and mean of 0.58 (SD 2.47).

To test for the effects of possible confounders, linear regression models were used (Table 3). The first 3 models tested the association of the DCP and support service use in the presence of confounders. Model 1 considered only the MS DCP, model 2 considered the DCP, gender, and age, and model 3 considered the DCP, gender, age, EDSS score, and relapses. The MS DCP was found to be associated with higher other service use (1.99, 1.95, and 2.05 visits) in all models tested. In addition, linear models were used to confirm no association of the MS DCP with ED visits, inpatient days, and the total number of elective visits (physical or remote, nurses or doctors). No association was found between them.

Patient-Reported Outcomes

PROMs were assessed in a cohort of 36 patients (Table 1), with an initial response rate of 97% (35/36). The MSIS-29 looks for clinically important changes in functional health. A change of 7-8 points for the physical score [33-36] and a change of 4-6 points for the psychological score [35,36] is considered clinically significant. There was a large variability between the MSIS-29 scores reported (Tables 4 and 5). Over the course of this study period, there was no clinically significant change in the median physical MSIS-29 scores, but a clinically significant change was observed for the psychological MSIS-29 scores between the 3-month and 6-month points (an improvement from 22.2 to

16.7). The score, however, rose at the 12-month mark. Of the patients who reported MSIS-29 scores for the 0- and 12-month marks, the change in the median physical score was +3.3, and in the psychological score -3.7. The response rate declined during the year-long study period from 97.2% (35/36) to 47.2% (17/36).

An NPS index was calculated at 3 time points: 3, 6, and 12 months after first login to the DCP (Tables 4 and 5). The NPS at the 3-month mark was 21 indicating a "favorable" reception. At the 6-month mark increased to 30 and at the 12-month mark up to 63 passing the "excellent" limit. The response rate dropped from 80.5% (29/36) down to 44.4% (16/36) at 12 months.

Table 4. Patient-reported outcome measures in this study subcohort (N=36).

Measure	Score, median (minimum-maximum; IQR)	Response rate, n (%)
MSIS-29^a physical score		
0 months	11.7 (0-78.3; 17.5)	35 (97)
3 months	11.7 (0-73.3; 19.2)	31 (86)
6 months	10.8 (0-68.3; 20.8)	26 (72)
12 months	15.0 (0-86.7; 31.7)	17 (47)
MSIS-29 psychological score		
0 months	22.2 (7.4-85.2; 31.5)	35 (97)
3 months	22.2 (0-63.0; 18.95)	31 (86)
6 months	16.7 (3.7-44.4; 17.6)	26 (72)
12 months	18.5 (0-59.3; 22.2)	17 (47)

Discussion

Here, we described the contents of MS DCP developed in HUS, user behavior on the DCP, differences in health care use between pwMS using the DCP and those who do not, presented results on changes in perceived impact of MS on both physical and psychological functional health of the MS DCP users, and showed patient satisfaction with the service. We show that the DCP has seen a high adoption rate of 79% (178/225), with most logins taking place within the first year after diagnosis (1182/1635, 72.29%). We find a significant increase in other services use and no other differences in the use of services. There was no clinically significant change in the physical MSIS-29 score and while the psychological score oscillated, a clinically significant change was observed between months 3 and 6. Patient satisfaction as measured with NPS was high and improved during this study period (from 21 “favorable” to 63 “excellent”).

The pwMS in this study were young (Table 1), and age is known to be associated with activity in telemedicine services [42]. Thus, patients with RRMS appear to be an exceptionally well-suited patient group to address through digital health care, as the disease is usually diagnosed at an early age [43] and the intensity of the care required is often highest in the beginning when patients need the most support [44]. The impact of a web-based educative and cognitive training program has been demonstrated in a group of patients with MS in the United States and Germany having depression. Both quality of life and psychological health improved, more so with a therapist supporting the training [45]. In this context, the DCP we describe in this study has most content targeted exactly at the early stages of follow-up.

The results also indicate that those using the DCP find their way into available other (supportive and rehabilitative) services significantly more often than those who do not, with on average 2.05 (SD 0.48) more visits during the year after diagnosis than in the control group. This association stayed strong even when accounting for possible confounders: gender, age, EDSS score, and relapses (Table 3). Assuming the cost-effectiveness of rehabilitative and preventative services, in lieu of overtreatment, this could be assumed to be resource-efficient and a positive development both from the perspective of the health care organization and the patient. However, to demonstrate this, a longer follow-up study would be required to show that pwMS using support services either use less health care or have better health outcomes in the future. We found no change in other measures, which aligns well with the fact that the DCP was intended to be a complementary service rather than replacing some part of the regular patient with the MS pathway of the

neurological clinic. Finally, no difference in ED or inpatient days was found. All these findings remained when accounting for confounders (Table 3).

Our findings of the DCP being resource-efficient are in line with previous literature on other chronic diseases from Finland [46,47] and elsewhere [48]. In addition, we assume that our analysis underestimates the resource effects of the DCP because, although the health care use data lacked data on most unscheduled remote nurse contacts, unpublished results of analysis in HUS suggest that the nurse time needed for answering 1 patient phone call is 8 times longer than that needed for answering a message. The MS DCP supports messaging as the means of interaction.

A significant improvement in the psychological score was observed between the third and sixth months. Although this later increased, this is an initial indication that there may have been less psychological burden on the patients, which could be attributed to the DCPs educative role or possible time passing and the patient’s coming to terms with the disease. The response rate reduced a lot from 97% (35/36) at 3 months to 47% (17/36) at 6 months. Although this gives uncertainty to interpretation, there is also a possibility that those pwMS who had the biggest improvement dropped out of this study and stopped logging onto the DCP as it had already done its job and supported them with the start of their MS patient journey. Over the 0-month, 3-month, 6-month, and 12-month marks, there were no significant changes [33,34] in the median MSIS-29 physical scores of the patients with MS DCP indicating that there is at least no adverse effect of using the DCP, which was expected.

Patient satisfaction with care is central to the success of any health care delivery model. We used the NPS as a measure of satisfaction with the DCP. Overall feedback was generally positive, indicating a successful adoption of the DCP, with the final NPS index being 63 “excellent.” Again, however, the response rate dropped during this study period from 81% (29/36) down to 44% (16/36), which together with the increasing trend could be an indication that those who were most satisfied with the service kept coming back to it. The MS DCP has several attributes that can be thought of as contributing to patient satisfaction such as patients having access according to their own needs and returning to the information content whenever there is a need for revision. Previous literature has come to similar conclusions [46].

Our study’s primary strength was the comprehensive examination of the DCP’s impact on multiple dimensions—user behavior measures on the DCP, health care use with a case-control design, and PROMs on the impact of MS on functional health, and patient satisfaction. Specifically, we

present data on all users of the DCP and pwMS diagnosed within a defined period as our sample and follow all these pwMS over a period of 1 year. In addition, the PROMs were collected longitudinally at several time points which further strengthens our study. Considering these aspects, this study provided a well-rounded view of the MS DCP. However, there are some significant limitations. First, the cohorts studied in the different parts of this study do not completely overlap and have somewhat different inclusion and exclusion criteria limiting the possibilities of what can be said by combining insights from the groups. Second, it should be noted that although we found a very strong connection between the MS DCP and the use of other services, it is possible that some mediating variable outside of our analysis (ie, the probability of an individual seeking support) could be affecting the results. This fact also introduces some selection bias into our cohort. Third, the section of this study dealing with PROMs had a large reduction in response rates over this study period. While this can be partially explained by a natural attrition

rate in longitudinal studies, the sharp decrease in responses may have introduced bias into the results, with those reporting the highest satisfaction levels being more likely to continue engagement with the DCP.

Future studies should investigate whether there are specific patient subgroups, for example, younger patients or more digitally fluent patients that are more likely to engage with and benefit from the MS DCP. Another area for future research is to explore how the cost-effectiveness of the DCP compares to traditional care models in different health care settings, such as other DCP studies from the Finnish context [46].

In conclusion, digital service is a resource-wise way of importing information about MS and support in the early adaptation phase of the disease to pwMS. Our results warrant further research into the long-term effects of DCPs as complementary solutions to existing pathways in MS, and other chronic conditions as well.

Abstract

Background: Mobile health (mHealth) solutions can improve the quality, accessibility, and equity of health services, fostering early rehabilitation. For individuals with hearing loss, mHealth apps might be designed to support the decision-making processes in auditory diagnostics and provide treatment recommendations to the user (eg, hearing aid need). For some individuals, such an mHealth app might be the first contact with a hearing diagnostic service and should motivate users with hearing loss to seek professional help in a targeted manner. However, personalizing treatment recommendations is only possible by knowing the individual's profile regarding the outcome of interest.

Objective: This study aims to characterize individuals who are more or less prone to seeking professional help after the repeated use of an app-based hearing test. The goal was to derive relevant hearing-related traits and personality characteristics for personalized treatment recommendations for users of mHealth hearing solutions.

Methods: In total, 185 (n=106, 57.3% female) nonaided older individuals (mean age 63.8, SD 6.6 y) with subjective hearing loss participated in a mobile study. We collected cross-sectional and longitudinal data on a comprehensive set of 83 hearing-related and psychological measures among those previously found to predict hearing help seeking. Readiness to seek help was assessed as the outcome variable at study end and after 2 months. Participants were classified into help seekers and nonseekers using several supervised machine learning algorithms (random forest, naïve Bayes, and support vector machine). The most relevant features for prediction were identified using feature importance analysis.

Results: The algorithms correctly predicted action to seek help at study end in 65.9% (122/185) to 70.3% (130/185) of cases, reaching 74.8% (98/131) classification accuracy at follow-up. Among the most important features for classification beyond hearing performance were the perceived consequences of hearing loss in daily life, attitude toward hearing aids, motivation to seek help, physical health, sensory sensitivity personality trait, neuroticism, and income.

Conclusions: This study contributes to the identification of individual characteristics that predict help seeking in older individuals with self-reported hearing loss. Suggestions are made for their implementation in an individual-profiling algorithm and for deriving targeted recommendations in mHealth hearing apps.

Introduction

Mobile Health Solutions for Hearing Care

Hearing enables individuals to experience their surroundings and communicate with others. Thus, hearing difficulties can have a strong impact on individuals' quality of life. Hearing loss (HL) is one of the most common chronic diseases worldwide and affects 20.3% of the world's population. More than 60% of individuals with HL are aged >50 years, with the principal cause being age-related HL [1]. Untreated hearing difficulties have been associated with lower self-rated health, depression, and anxiety in addition to physical and cognitive decline, dementia, and hospitalization in the older population [2-4]. The primary rehabilitative strategy for individuals with moderate to severe HL is the use of hearing aids (HAs), which increase activity levels, general health, and quality of life [5] and decrease social isolation and depressive symptoms [6] by supporting hearing ability and communication efficacy. Despite the positive effects of hearing rehabilitation, the prevalence of HA use is still limited to approximately 25% of the population with hearing impairment [2,4,7,8]. Moreover, there is an average delay of 9 years between the time a person first acknowledges hearing difficulties and the first contact with a hearing health professional [9].

Developing easily accessible and affordable mobile health (mHealth) solutions in audiology would promote broader and faster access to diagnosis and health services, fostering an early rehabilitation and reducing the impact of HL on the individual. It is estimated that 55% of the global population and 87% of the European population will use internet services on a mobile device by 2030 [10]. Thus, it is evident that mHealth solutions have the potential to significantly impact behaviors in the population. Current studies indicate that the use of tablets and smartphones, including mHealth apps, is steadily increasing among adults aged ≥ 65 years [11-13], who are even reported to be the fastest-growing population of smartphone users [11]. In the last decades, various mHealth apps have been developed for ear and hearing assessment [14-18] and for HA rehabilitation [19,20], in addition to tele-audiology services [21] and hybrid clinics [22]. The ease of use and accessibility of mHealth solutions can have an impact on self-awareness and recognition of HL and foster knowledge and use of in-person services [19,23,24]. Moreover, mHealth solutions show the potential to promote more equitable health care in low- and middle-income countries where access to health care facilities and professionals is limited [16,25]. Finally, mHealth apps that are quick and easy to use in everyday life have the potential to provide clinicians with important information at both the diagnostic and intervention phases and can help explore and understand daily experiences of the user with HL and facilitate more timely responses [19].

An mHealth hearing app might become the first contact with a hearing diagnostic service and, therefore, should motivate

individuals in need to seek professional help in a personalized manner to maximize the impact of early health services on the population. However, even though professional support might be recommended given the hearing test result, many users might still be hesitant to seek help. This is particularly true among the older adult population, in which HL can be slow and gradual and is often considered a natural aspect of aging. In addition, individuals may not be aware of the rehabilitation options and hearing health care services available to them or how to access them [4]. Some users may even choose to ignore indications to seek help for various reasons, such as low awareness of HL or stigma associated with HA use. In addition, individuals high on neuroticism and low on agreeableness might generally distrust external advice. Acquiring more information about users' personal characteristics and generating their individual profiles can inform the creation of targeted recommendations, particularly for those users who need more convincing incentives to take action. These recommendations can aid skeptical individuals in their decision-making process. For example, repeated feedback on daily hearing tests could increase self-awareness of HL, and HA simulators could promote positive expectations regarding HAs. Moreover, information about users' personal characteristics collected via an mHealth hearing app could later assist clinicians in providing personalized counseling. It follows that the assessment of a person with hearing difficulties needs to go beyond the simple quantification of HL and should also take into account individual characteristics that have been shown to influence the readiness of individuals to seek professional help [4,26].

Predictors of Hearing Help Seeking and HA Uptake

Hearing help seeking can be seen as a first crucial step toward the decision to take up an HA [26]. Help seeking takes place after a contemplation stage [3] where a listener in need is initially ambivalent about making changes. Help seekers would then prepare (seek information and plan) and take action [3] toward a change in behavior and attitude, namely, consulting a health care professional about their hearing difficulties [4,27]. Acknowledgment and acceptance of hearing difficulties and their impact on everyday life have been discussed as the most important predictive features of hearing help seeking as well as later HA uptake [5,6,26,28,29]. In the older adult population, HL is frequently perceived as part of the natural aging process, and other health issues are prioritized for treatment [4,30]. Even when HL is identified, individuals might reject the use of an HA due to expected costs, stigma, and negative stereotypes [5,7,28]. However, a positive attitude toward HAs [26,27], high expectations to benefit from them [26,29], and perceived self-efficacy in their daily management [17,18] were shown to promote help seeking and HA uptake. Other relevant covariates that have been identified in the literature are personal attitudes, beliefs, and personality traits. Individuals who are more prone to seeking help and successfully uptake an HA show higher internal locus of control [2,17], self-efficacy [31,32], and agreeableness as well as lower neuroticism and openness [2].

Altogether, such individual characteristics refer to a general self-confidence in the ability to cope with critical situations, good acceptance of others' suggestions and recommendations, and less susceptibility to shame and embarrassment.

Given the wide range of traits and behaviors that have been reported in the literature to be associated with hearing help seeking and HA uptake, predictive models can be developed that take into account the multifaceted nature and association patterns of these traits and behaviors. Machine learning models are built on a large number of predictors simultaneously, usually leading to more accurate predictions than univariate or smaller models that take into account only a limited number of predictors. These models can capture complex and nonlinear relationships between the outcome and its predictors. In addition, when combined with cross-validation (CV) approaches, they draw more robust conclusions and generalize to new data. Currently, the use of machine learning to support health care applications is rapidly growing, particularly in the areas of predictive analytics, diagnosis and treatment, personalized medicine, clinical decision support, and population health management [33]. Machine learning algorithms and feature importance analysis can be used to identify the most relevant predictors of hearing help seeking from the many features hitherto reported in the literature. In an mHealth context, it is crucial to limit the number of features to a small set of key predictors to create a concise and efficient assessment battery.

Rationale and Objectives

This study aimed to identify the most important predictive features for hearing help seeking, planning to design an individual-profiling module for an mHealth hearing app. Such a module will categorize help seekers versus nonseekers and, ultimately, inform the design of targeted or even personalized treatment recommendations. For this purpose, data from a large number of questionnaires and tests covering different hearing-related and psychological characteristics, together with multiple assessments of a hearing screening test, were collected in a longitudinal study that simulated an mHealth hearing app. To target potential users of future apps of this kind, this study was geared toward individuals with subjectively perceived hearing difficulties who had not yet been compensated with HAs. We selected 25 assessment tools based on an extensive literature review of covariates of hearing help seeking and HA uptake. From these, a comprehensive set of 83 features was derived. We used supervised machine learning algorithms to predict the readiness to seek professional help as assessed at the end of the study and after 2 months as self-reports on intention to seek help. Feature importance analysis was used to narrow down the large number of features and identify a small

set of key traits to predict hearing help-seeking behavior. On the basis of these results, we aimed to derive suggestions for the implementation of a profiling module as a short and concise assessment battery that can be administered after an audiological test. This could be included in existing or future mHealth apps in a modular manner. Knowledge of a user's propensity to seek help can be used to provide specific recommendations to encourage the use of hearing health care services. Ultimately, our aim was to provide clinicians and mHealth app developers with relevant knowledge about personal characteristics that are helpful in promoting hearing health by encouraging the uptake of hearing health care services and HAs when needed.

The following research questions (RQs) guided our study design and analyses:

1. Which machine learning model can best predict help seeking and categorize individuals into help seekers versus nonseekers? (RQ 1)
2. Which hearing-related and psychological features are most relevant to classify individuals into help seekers versus nonseekers? (RQ 2)
3. How can feature importance measures inform the design of targeted recommendations for users of a future mHealth hearing app? (RQ 3)

Methods

Participants

Adults aged >50 years were recruited between August 2021 and August 2022 through the Ebay minijob announcement web platform and the university intranet and via mailing list services of several German universities' guest audience and senior programs. The inclusion criteria were subjective reports of hearing difficulties in daily life, ownership of and ability to use a smartphone, and good command of the German language. The exclusion criterion was the use of HAs. A total of 192 individuals were enrolled in the study. In total, 3.6% (7/192) of the participants dropped out during the study, resulting in a completion rate of 96.4% (185/192). The final data set included 185 participants—106 (57.3%) female and 79 (42.7%) male (0 diverse)—aged between 47 and 82 years, with a mean age of 63.1 (SD 6.5) years. One participant was aged <50 years (47 years) but was nevertheless included in the final sample given that this value only slightly deviated from the planned age threshold. Of the 185 participants who completed the study, 131 (70.8%) answered the follow-up questionnaire. A descriptive summary of participants' sociodemographic characteristics is provided in [Table 1](#).

Table 1. Main sociodemographic characteristics of the participants (n=185)^a.

Procedure

Study Overview

Interested participants contacted the study administrator via email and received extensive written information about the purpose of the project; study design; length of participation and remuneration; possibility to withdraw participation at any time; and data protection, management, and storage. The study design and implementation and data collection, analysis, and storage were conducted in accordance with current literature on ethical considerations in the context of mobile and mHealth apps [34,35]. Security and privacy recommendations were also adhered to. It was clearly stated that a medical diagnostic was

not provided in the study. Communication with the participants took place exclusively via email and SMS text message. A pilot study was conducted with a young (aged 23 years), healthy female participant in August 2021 to evaluate the usability and technical functionality of the mobile study.

The web-based study was conducted on the personal mobile phones of the participants to approximate the experience of using an app. Only 3.8% (7/185) of the participants used their computers due to technical difficulties with their smartphones. Data collection was carried out using formr, an open-source web-based application programming interface (API) for the R language that creates automated studies [36]. In formr, different questionnaires and tests (refer to Tables 2 and 3) were linearly

chained together as modules of a so-called *run*. A run reproduces the desired design and can be accessed by users through a specific link. The formr software first provides a unique study link to the run, which was shared via email with enrolled participants. Upon accessing this link, participants were assigned a unique visitor session in formr and provided with a second individualized link based on web cookies. The unique visitor session prevented users from providing multiple entries for the same survey. This unique session code enabled the anonymization of the data within formr and, for the duration of the study, was stored in a written coding list, where the participants' names and session codes were recorded. The customer communication platform Twilio (Twilio Inc) [37] was used to send the individualized study link to the participants through daily SMS text message reminders. Automated SMS

text message delivery was initiated via the *external link* module in formr, which uses Representational State Transfer API to connect to Twilio. Representational State Transfer API allows a software program (in this case, formr) to expose functionality and data to other programs (Twilio) in a consistent and secure format, ensuring privacy and data protection. With the individualized link received via SMS text message, participants could perform the study on their own smartphone's browser. For the 3.8% (7/185) of participants who completed the study on their computer, the daily SMS text messages were sent to their personal mobile phones as reminders. The individualized link was additionally sent via email at the beginning of the study to allow these participants to access the study via their computer browser.

ⁱSF-12: 12-item Short-Form Health Survey.

A detailed list of all assessment tools and their references, as well as the derived features for analysis, is provided in [Tables 2 and 3](#). Each assessment tool was implemented as a *survey* in formr. Most of the surveys included in the study were implemented following the paper-and-pencil version that was retrieved from the literature. The surveys that were developed or adapted specifically for this study can be shared upon request. The items assessed can be inferred from the features provided in [Tables 2 and 3](#). Submission of each survey was possible only after all mandatory questions had been answered. After submission of one survey, the study advanced automatically to the following questionnaire or test planned in the formr run. Users were not allowed to go back and modify their answers after submission.

The total assessment time of 8 hours was distributed across the working days of 3 consecutive weeks, with an overall daily active participation of approximately 30 minutes. The study design is detailed in [Multimedia Appendix 1](#). Participants could select the start date of the study to ensure that the assessment could be easily integrated into their personal schedule. The first week (baseline assessment) included 1 measurement time point per day (requiring approximately 20-30 minutes to complete), which could be performed at any time. On the first day, participants received an email with the study link and their unique participant code. After opening the study link on their browser, each participant was given the possibility to read a summary of the data protection conditions in the first page of the study again. Second, they were asked to provide a telephone number and email address, which were then stored in formr and used for the automatic SMS text message reminders. They would then receive an automatic SMS text message with the individualized link to the study, through which they could begin the assessment. From days 2 to 5, participants received an SMS text message with the link to the study at 7 AM, but they had been previously informed that they could perform the tasks at

any time during the day. An email reminder was sent at 7 PM in case participants had not accessed the study link by that time.

The second and third week included 2 measurement time points per day of approximately 15 minutes each. The longitudinal assessments were prompted via SMS text message at 7 AM and 7 PM. Participants were instructed to access the study at their earliest convenience after waking up and before going to bed, thus allowing them to accommodate the study to their daily schedules. In the morning, after clicking on the link they received via SMS text message at 7 AM, each participant was first presented with some questions on baseline mood and sleep quality. They were then required to click on a second link embedded in the following survey page that redirected them to the hearing assessment. Finally, participants were asked again to report on their mood after receiving feedback on their hearing performance. In case the participant forgot to access the link and perform the study, an email reminder was sent at 1 PM. If, after the reminder, the participant still did not take part in the study, the session was established as incomplete. The study administrator had to manually allow the participant to move to the next measurement time point (in this case, the evening assessment) within formr. This same assessment scheme was repeated in the evening. In this case, the SMS text message with the link to the study was sent at 7 PM, and the email reminder was sent at 11 PM.

At the end of the study, participants were asked to provide consent to be contacted after 2 months for a voluntary (and nonremunerated) follow-up questionnaire. Those who provided their consent received an email with a link to a single formr survey that required <5 minutes to complete. The short survey consisted of 2 multiple-choice questions and was completed by 70.8% (131/185) of the participants. Individuals were asked to report again on their action to seek professional help following the feedback received during the study and were asked to

indicate whether study participation improved their awareness of hearing difficulties.

Baseline Assessment

Overview

During the baseline assessment, cross-sectional data from a comprehensive set of 25 questionnaires and tests were collected. The questionnaires and tests were distributed on 5 consecutive days to maximize study compliance and avoid priming effects on different questionnaires. The following sections provide a concise summary of the measured predictors (features). We refer to [Tables 2](#) and [3](#) for a complete list of the assessment tools used in the study. We selected questionnaires and tests that have been previously used in studies investigating their association with hearing help seeking and HA uptake (as cited in the Introduction section and in the [Tables 2](#) and [3](#)). If the tools included in the study had not been previously used in similar literature, we explained our rationale for their selection in the following sections.

Assessment of Hearing-Related Features

First, the assessment included self-reports of participation and perceived handicap, focusing on self-reported hearing difficulties, consequences of HL, and social life participation. In addition, attitudes toward HAs were evaluated using questionnaires on HA expectations and stigma. Hearing-related personality traits were also taken into account. Noise sensitivity was measured as a personality trait, which was shown to be related to affect and neurosensory processing [\[61\]](#). We further assessed hearing habits aiming to gather more information about sound sensitivity and individuals' sound preference profiles [\[43\]](#). Finally, hearing health literacy was assessed as well as the ability to search, find, and understand information related to hearing health has been shown to be associated with better self-management of HL [\[31\]](#).

Assessment of Psychological, General Health, and Sociodemographic Features

Personality traits (the Big 5 [\[62\]](#)) were shown to be associated with help seeking and HA use and, therefore, were included in the baseline assessment. Anxiety and depression were also measured given their frequently demonstrated associations with HL [\[4,6\]](#), together with loneliness, which is seen as consequence of untreated HL [\[3\]](#). We further assessed optimism and sensory processing sensitivity, which refers to an individual's disposition to perceive and process stimuli (including auditory ones) more intensely than the average population [\[63\]](#). Attitudes and beliefs such as locus of control and self-efficacy were included as well for their association with help seeking and HA use. The belief that HAs are associated with old age and infirmity is often a barrier to HA uptake and use [\[4\]](#); therefore, attitude toward aging was assessed as well. Perceived stress was measured, too, as high levels of stress that are related to daily life, work, or social situations may boost help-seeking behaviors [\[3\]](#). General health was assessed given its predictive role for different steps of the HA uptake path [\[4,6\]](#). For completeness, we also measured cognitive abilities (crystallized and fluid intelligence) despite discordant findings on associations between cognition

and HA uptake [\[4,6,16\]](#). Finally, participants were requested to complete a comprehensive questionnaire on sociodemographics.

Longitudinal Assessment of Hearing and Affect

This microlongitudinal assessment accounts for potential daily fluctuations in hearing performance and affect, which might depend on particular daily events and states. The affect questionnaire included 14 items in line with the circumplex model of affect (Posner et al [\[64\]](#)). A total of 8 items were related to negative affect, and 6 items were related to positive affect [\[65\]](#). The items are listed in [Multimedia Appendix 1](#). The affect questionnaire was presented before and after the hearing test to assess mood at baseline and after receiving feedback on the hearing test, respectively.

Hearing performance was assessed using the digit triplet test (DTT) [\[45,66\]](#) by Hörzentrum Oldenburg gGmbH. This widely used screening instrument [\[67\]](#) measures speech intelligibility in noise by means of the speech recognition threshold (SRT), which indicates the signal-to-noise ratio (SNR; difference between speech and noise level) at which the participant reaches 50% speech intelligibility. SRT measures obtained using the DTT showed high correlations ($r>0.70$) with pure tone average measures while being relatively robust against changes in presentation level [\[68\]](#). Moreover, the DTT has shown to be robust to ambient noise levels outside of audiometric booth environments [\[68\]](#). Together with its low linguistic and cognitive demands [\[68\]](#), the DTT appears to be suitable for mobile, remote self-test-based screening of hearing abilities in the older population. Smartphone-based DTT has also shown the potential to provide widespread access to hearing screening in low- and middle-income countries and across different socioeconomic strata [\[69\]](#). After completing the hearing test, participants received feedback on their performance in the form of a traffic light color, where green indicated good performance ($SRT<-7.1$ dB SNR), yellow indicated intermediate performance ($-7.1\geq SRT<-5.1$ dB SNR), and red reflected poor performance ($SRT\geq-5.1$ dB SNR) [\[45,70\]](#). The [Multimedia Appendix 1](#) provides detailed information on the hearing test and [Multimedia Appendix 2](#) provides information on its feedback. Participants performed the hearing test with their personal smartphone and headphones. A total of 1.6% (3/185) of the participants used loudspeakers as headphones were not available to them. Calibration of the hardware equipment was not possible due to the remote assessment. However, SRT estimation is relatively robust against changes in presentation level, and no exact calibration is needed [\[71\]](#). Moreover, the use of different types or qualities of headphones has shown no impact on test reliability [\[67,69\]](#). Each hearing test began with a signal adjustment trial meant to set the stimulus at approximately 65 dB sound pressure level. The participant was presented with a digit triplet in noise and asked to "adjust the volume to hear both the digits and the noise clearly."

Outcome Measures

Overview

Classification of participants into help seekers and nonseekers was based on self-reports of planned actions to seek professional help for their perceived hearing difficulties and their motivation

to seek help. These variables, as retrieved at the end of the study and at follow-up, were chosen as outcome measures for the supervised machine learning (refer to the following sections). This information was also assessed at the beginning of the study. In total, 3 different classifications were considered as outcome

measures: action to seek help at study end, action and motivation to seek help at study end, and action to seek help at follow-up. The distribution of participants along the outcome classes considered is summarized in Table 4.

Table 4. Absolute classwise frequencies of observations at the 2-month follow-up across the 3 outcomes considered at the end of the study^a.

	Action at follow-up (n=52, 28.1%), n (%)	No action at follow-up (n=79, 42.7%), n (%)	No follow-up data (n=54, 29.2%), n (%)
Action (n=64, 34.6%)	33 (17.8)	12 (6.5)	19 (10.3)
No action and high motivation (n=47, 25.4%)	12 (6.5)	22 (11.9)	13 (7)
No action and low motivation (n=74, 40%)	7 (3.8)	45 (24.3)	22 (11.9)

^aThe 3 outcomes considered were action to seek help (n=185), action and motivation to seek help (n=185), and action to seek help at follow-up (n=131). In addition, the table provides an overview of those participants who did not complete the follow-up questionnaire.

Action to Seek Help

Help seeking (preparation and action [3]) was assessed at study end using the following question: “Given the feedbacks of this study regarding your hearing performance, have you made an appointment with one of the following physicians or a hearing care professional, or are you planning to do so?” (followed by a list of hearing professionals). This variable was used to create two outcome classes: (1) *action* class (64/185, 34.6%)—participants who were planning to seek professional help in the near future or had already made an appointment—and (2) *no action* class (121/185, 65.4%)—participants not ready to take action who did not plan to consult a hearing health professional in the future.

Action and Motivation to Seek Help

A second outcome measure was taken into account to further differentiate the *no action* class to provide further insights for the design of targeted recommendations in an mHealth hearing app. Information on readiness to take action was combined with the reported motivation to seek help at the end of the study. Motivation was assessed through the following question: “How motivated are you at the moment to seek help regarding your hearing problems?” (1=not motivated at all; 7=very strongly motivated). The answer spectrum was binarized by means of median split to create the following outcome classes: (1) *no action and high motivation* class (47/185, 25.4%)—participants not ready to take action with high motivation who might particularly benefit from personalized and tailored recommendations, (2) *no action and low motivation* class (74/185, 40%)—participants not ready to take action who reported low motivation to seek help, and (3) *action* class (64/185, 34.6%)—participants ready to take action regardless of their motivation level (this class was not further divided with respect to motivation as this would not result in different recommendations. Moreover, data exploration revealed that only 11% (7/64) of the individuals in this category reported low motivation).

Action to Seek Help at Follow-Up

The voluntary follow-up questionnaire (completed by 131/185, 70.8% of the participants) included a question on the intention or action to seek help following the feedback received during

the study. The answer range (4 multiple-choices) was binarized to achieve a class allocation comparable to that of the first outcome measure: (1) *action at follow-up* class (52/131, 39.7%)—participants who reported having completed an appointment with a hearing professional, who had an appointment scheduled but not completed, or who were planning to seek help in the near future; and (2) *no action at follow-up* class (79/131, 60.3%)—participants who did not plan to consult a hearing health professional.

Statistical Analysis

Data Preprocessing

Data analysis was performed using the R software (R Foundation for Statistical Computing) [72]. Raw data from all questionnaires were imported from the web-platform formr to the R environment using the dedicated *formr* package [73]. For each questionnaire or test presented at baseline, global scores were computed and considered as features. If both global scores and scale scores were available for a given assessment tool, only the scale scores were retained if considered differentially relevant for the outcome. Hearing test results were sent via email to the investigator from the researchers of Hörzentrum Oldenburg and imported into R as .eml files. The performance feedback category (green, yellow, and red) was additionally extracted and stored for each raw SRT result. Due to the particular implementation of the study in formr, participants could perform the hearing test more than once at each measurement time point. Whenever this happened, only the last SRT result at a given time point was kept for analysis. This led to a removal of 3.9% of the raw SRT results. The longitudinal data on daily mood and hearing performance were summarized into individual means and SDs. The summarized longitudinal data were merged with the cross-sectional data, resulting in a wide-format data frame including 83 features. Tables 2 and 3 provide a complete list of the features considered for analysis.

Completion rate for the baseline questionnaire was 100% (185/185), whereas there were missing data for the longitudinal measures of hearing performance and affect. A complete set of 20 SRT results was collected for 43.8% (81/185) of the participants, whereas at least 15 SRT results were obtained in 95.1% (176/185) of cases. Missing hearing data at a specific

time point were considered not available (NA). Where an SRT result was missing, the respective feedback and measures of affect at the posttest time point were established as missing as well (NA). Through visual inspection of the individual SRT distributions, some specific outlier patterns were identified. A total of 7.6% (14/185) of the participants showed a much larger SRT result at the first measurement, which qualified as an outlier following the IQR rule. These large SRT values (indicating poor performance) were considered to be caused by misunderstanding of the hearing test instructions and, therefore, were established as NA. However, the respective feedback category and measures of affect were not established as NA. This is because, despite the unreliable SRT value, participants' mood could still have been affected by the feedback received. With respect to daily affect measures, 1.1% (2/185) of the participants provided no data at measures of posttest affect such that summary measures could not be computed. In these cases, the mean imputation technique was applied—the sample mean and sample variance for negative and positive affect at the posttest time point were imputed to replace missing values.

Machine Learning

Overview

The data were fed into 3 machine learning algorithms for supervised classification. We chose naïve Bayes (NB), random forest (RF), and support vector machine (SVM) among other classifiers to cover a wide range of model complexity (from simple models such as NB to more complex and nonlinear ones such as SVM). The algorithms were implemented in R using the *mlr* package [74] following the approaches described in the work by Rhys [75] and Bischl et al [76]. Given the presence of 3 different outcome measures, the same analysis steps were carried out in parallel for each outcome with a slight difference in the input features included in the analysis. For the first outcome (*action to seek help*), data on motivation at the prestudy time point were kept in the feature space, whereas motivation to seek help at the end of the study was removed. The same applied to the third outcome (*action to seek help at follow-up*). Differently, for the second outcome (*action and motivation to seek help*), all data on motivation at the pre- and poststudy time points were removed from the feature space. Due to the relatively small data set and imbalanced classes, we chose not to split the data into training and test sets but to use CV instead. CV divides the training set into k equally sized parts and considers the k th part as a test set and the $k - 1$ part as a training

set at each iteration. Model results are then averaged across all iterations. The implementation details of the 3 algorithms are summarized next.

NB Classifier

This algorithm uses the Bayes rule to predict the probability of an observation belonging to one of the outcome classes given its discriminant function values. Given the prior probability, the likelihood, and the evidence for each observation, the relative posterior probability for each class is computed. The single observation is then assigned to the class with the highest relative posterior probability [75]. The 2 strong assumptions made by NB algorithms are the normal distribution of continuous features (or predictors) and the independence of these features. Model performance will suffer in case of violation of these assumptions [75]. In this implementation, after training the algorithm, repeated 10-fold CV was used to evaluate the model's performance. A stepwise approach was used to select the appropriate number of CV repetitions necessary to achieve accurate and stable performance estimates (50, 100, 150, and 300 CV repetitions).

RF Classifier

Tree-based methods use recursive binary splitting to stratify the features' space in smaller, nonoverlapping regions used for classification. At each iteration of the tree-building process, the algorithm selects among all features the one that best splits the data into 2 branches according to a specific question or rule (node) [75]. The process iterates until a stopping criterion is met and final regions (leaves) are identified. In a classification problem, the mode of the training data within a region is used for prediction—each observation is classified to the majority class within the leaf to which it belongs [77]. Trees are easy to interpret, but they lack predictive power as they tend to overfit the training data. Approaches such as RF can be used to improve prediction accuracy. RF is a nonlinear method that involves the generation of multiple uncorrelated trees from different bootstrapped training sets obtained through sampling with replacement from the original data. The final predicted outcome is retrieved from aggregating the prediction of all built trees and selecting the most frequent or modal prediction [75,77]. This algorithm requires the tuning of a set of hyperparameters that control the learning process and are selected (or tuned) by the algorithm to obtain the best performance. The hyperparameters shown in [Textbox 1](#) were considered.

Textbox 1. Hyperparameters for RF classifier.

Ntree

The number of trees to include. This value is usually fixed at a computationally reasonable value rather than tuned [75]. Ntree was set to 800.

Mtry

The number of features to randomly sample at each time. A popular value is given by \sqrt{p} (where p =the number of predictors) [78]. Different search spaces were explored, with Mtry ranging between 1 and 15.

Nodesize

The minimum number of cases to be included in a leaf. Different search spaces were explored, with Nodesize ranging between 1 and 20.

Tuning the algorithm and finding the best hyperparameter combination requires the definition of an optimization algorithm,

or search strategy, and evaluation method. We used grid search with 10-fold CV resampling. To evaluate model performance,

nested CV was applied. In this approach, an inner loop tunes the hyperparameters, and an outer loop evaluates a wrapped learner, which comprises the classification task, the learner type (RF), and the hyperparameter tuning process. In this case, a 5-fold CV was applied as an outer resampling strategy.

SVM Classifier

The SVM algorithm iteratively identifies a hyperplane that separates labeled classes also in case of nonlinear data distributions. It does so by adding an extra dimension to the data, which is found through the kernel function, a mathematical transformation of the data. The hyperplane is defined as a surface that has 1 dimension less than the number of variables in the data set. The position of the hyperplane depends on the

position of the support vectors, which are training set cases that define the class boundaries [75]. The optimal hyperplane is found by maximizing its margin, which is the region around the hyperplane that touches the fewest training observations. In fact, the distance from a training case to the margin can be viewed as a measure of the correctness of its classification [77]. In case the algorithm needs to separate >2 classes, several models are built and compared to find the one that best predicts new data. SVMs are computationally expensive but tend to perform very well on a variety of tasks conducted on nonlinearly separable classes. In addition, the algorithm has the advantage of making no assumptions on the features' distributional properties [75,77]. Similar to RF, SVM requires hyperparameter tuning. The hyperparameters in [Textbox 2](#) were considered.

Textbox 2. Hyperparameters for SVM classifier.

<p>Kernel</p> <p>The type of kernel function used to identify the hyperplane. Polynomial, radial, and sigmoid functions were included in the search space [75].</p> <p>Degree</p> <p>The shape of the decision boundary (in case of a polynomial kernel). The search space was limited to values from 1 to 5 to avoid the risk of overfitting [75].</p> <p>Cost</p> <p>The penalty for having cases fall inside the margin. It is recommended to tune both cost and gamma (refer to the next point) on the logarithmic scale [79], and a popular search space for cost is from 2^{-5} to 2^{15} [80].</p> <p>Gamma</p> <p>Influence of each case on the hyperplane. This hyperparameter search space was set to the popular range of 2^{-15} to 2^3 [80].</p>

Nested CV was used as previously described for RF. An inner resampling loop (with 10-fold CV) was applied for hyperparameter tuning, and an outer loop (with 5-fold CV) was applied for performance evaluation.

Classification Performance Metrics

The algorithms were evaluated in terms of prediction accuracy on the test set, which indicated the overall proportion of cases correctly classified by the model as compared to the observed outcome. However, class imbalance in the sample can negatively impact prediction accuracy, reducing its informativeness as a performance measure [81,82]. The Matthews correlation coefficient (MCC; *yardstick* package [83]) was additionally taken into account to evaluate model performance. This coefficient improves over accuracy measures in case of imbalanced data sets [82,84] and can take values from -1 to 1 , with 1 indicating perfect prediction, 0 indicating chance prediction, and -1 indicating inverse prediction. As an additional metric, we computed the confusion matrix (*calculateConfusionMatrix()*, *mlr* package). Its output provides the absolute number and the proportion of correct model predictions and misclassifications for each outcome class. For binary outcomes, the confusion matrix allows for the estimation of model sensitivity (ie, accurately identifying help seekers) and specificity (ie, accurately identifying nonseekers). In this study, obtaining high specificity was of particular interest in the context of an mHealth hearing app. Indeed, individuals with HL who are not prone to seeking help are the main target population for tailored treatment recommendations and counseling.

Feature Importance

After identifying the best-performing machine learning algorithm, feature importance was considered. Each feature receives a coefficient of importance that indicates its contribution to model performance regardless of the type of relationship (direction and linearity) between the feature and the outcome [85]. In RF, feature importance is model dependent and indicates how much the feature contributes in reducing node impurity. Importance values were retrieved using the function *getFeatureImportance()* (*mlr* package) applied on the RF model trained using the tuned hyperparameters. These importance results have the advantage of being inherent to the model and closely tied to its performance [86]. Conversely, there are no model-specific importance metrics available for NB and SVM. For these algorithms, the importance value assigned to each feature corresponds to the area under the receiver operating characteristic curve, which is computed from sensitivity and specificity measures [86]. The function *varImp()* from the *caret* package [87] was applied on the model trained using the function *train()* (*caret* package) after ensuring comparable performance with that of the same model previously trained on the *mlr* package.

Features with higher importance ranking were considered for inclusion in the profiling algorithm as they represented the most relevant predictors for telling apart help seekers and nonseekers. No statistical criterion exists to determine which importance value threshold should be used to retrieve relevant features. Hence, 3 threshold values were inspected (the first 10, 15, and

20 features in their importance ranking order) and evaluated in terms of predictive accuracy and interpretability. The classification accuracy of these 3 feature sets was assessed on the outcome data obtained at follow-up. For this analysis, the data set was reduced to 131 participants who completed the follow-up questionnaire. The important features were fed into the best-performing machine learning algorithm from the previous step.

Ethical Considerations

The study plan and data management have been approved by the Research Ethics Committee of the Carl von Ossietzky Universität Oldenburg (08.09.2021; EK/2020/020-01). The study supported the autonomy of participants through extensive informed consent, which was given both as a separate written document before enrollment and within the formr survey framework. Debriefing was included, and participants were invited to provide feedback at the end of the study. No direct risks associated with the study design were identified, and privacy risks were accounted for through appropriate data management and data protection concepts for all software and platforms used. Personal information collected during the study was pseudoanonymized using a written coding list stored in a closed locker accessible only to the study administrator. This coding list was destroyed at the end of data collection; therefore, the data have been completely anonymized since. Data collection

took place between September 2021 and September 2022. Participants were remunerated with €10 (US \$10.74) per hour. A further incentive for study participation was that participants received written feedback on their daily hearing test results.

Results

Machine Learning Classification Performance

Predicting Action to Seek Help

A summary of the model-specific classification accuracy for the first outcome (*action to seek help*) is provided in Table 5. The 3 algorithms showed similar overall performance accuracy estimates on the test set, correctly classifying approximately 65.9% (122/185) to 70.3% (130/185) of the cases in the full data set (n=185). RF was the best-performing algorithm with an accuracy of 70.3% (130/185) and an MCC of 0.28, indicating that the model's prediction improved to approximately 20% over chance. By inspecting the confusion matrix (Figure 1), we observed that RF shows high specificity, correctly classifying 90.9% (110/121) of the cases belonging to the *no action* class. The NB classifier (10-fold CV repeated 50 times) showed the best sensitivity compared with the competing algorithms, with 51% (33/64) of cases in the *action* class being correctly classified. RF and NB were selected for feature importance analyses given the good predictive performance and high specificity of RF as well as the high sensitivity of NB.

Predicting Action and Motivation to Seek Help

Table 6 summarizes the classification performance with respect to the second outcome (*action and motivation to seek help*), which includes 3 classes (refer to the previous section). RF provided the highest accuracy with 55.1% (102/185) and an MCC of 0.30 as compared to NB (10-fold CV repeated 100 times) and SVM. However, the confusion matrix revealed that none of the 3 models was able to adequately tell apart

individuals within the no action class who differed with respect to high versus low motivation. All algorithms could only correctly classify 2% (1/47) to 25% (12/47) of cases in the no action and high motivation class. Potentially, an improvement in classification accuracy could be achieved using a larger data set in which the classes are better balanced and with a more reliable and elaborate measure of the participants' motivation to seek help. In view of these limitations, the second outcome was not considered for feature importance analysis.

Feature Importance

Predicting Action and Motivation to Seek Help at Follow-Up

Feature importance was analyzed based on the RF and NB algorithms predicting the first outcome, *action to seek help* at study end on the full data set (n=185). Each importance value signifies the feature's contribution to the model's performance. However, as detailed in the Methods section, RF and NB models calculate these coefficients differently. Consequently, ranking values were used. In both models, the 83 features were initially ranked in descending order based on their importance values. Features with higher importance rankings were mostly relevant in predicting help-seeking behavior. Three sets of features among the most important ones were taken into account for subsequent analysis: (1) the top 10 features indicated by the 2 models, resulting in a total of 12 best features; (2) the top 15 features indicated by the 2 models, resulting in a total of 19 best features; and (3) the top 20 features indicated by the 2 models, resulting in a total of 28 best features.

Figure 2 shows all 28 features with their importance ranking values originating from the RF and NB models. The specific

importance values for each feature are provided in [Multimedia Appendix 3](#). Next, the 3 sets of features (top 10, 15, and 20 features) were evaluated for their predictive performance and classification accuracy on the reduced data set of 131 participants who completed the follow-up questionnaire. NB and RF were trained on the 3 different feature sets for predicting the *action to seek help at follow-up*. The results are summarized in [Table 7](#). They show that all feature sets provided good predictive performance and that the NB algorithm outperformed RF, with an overall accuracy ranging between 73.3% (96/131) and 74.8% (98/131) and an MCC between 0.43 and 0.47. Class-specific classification accuracy was comparable between NB and RF, with the action class correctly classified in 52% (27/52) to 63% (33/52) of the cases and the *no action* class correctly classified in 82% (65/79) to 86% (68/79) of cases. As can be seen from the confusion matrix in [Figure 1](#), sensitivity and specificity measures were comparable for both algorithms predicting action to seek help at follow-up using the set of top 10 most important features. Sensitivity ranged from 55% (NB) to 58% (RF), and specificity ranged from 84% (RF) to 65% (NB).

Figure 2. Ranking of the most important features to predict action to seek help at study end. Importance rankings are shown for the 20 most important features for the 2 models (naïve Bayes [NB] and random forest [RF]) trained on the full data set (n=185), as summarized in Table 5. A total of 28 features are arranged on the y-axis with respect to their average ranking between the 2 models. HA: hearing aid; HL: hearing loss; M: mean.

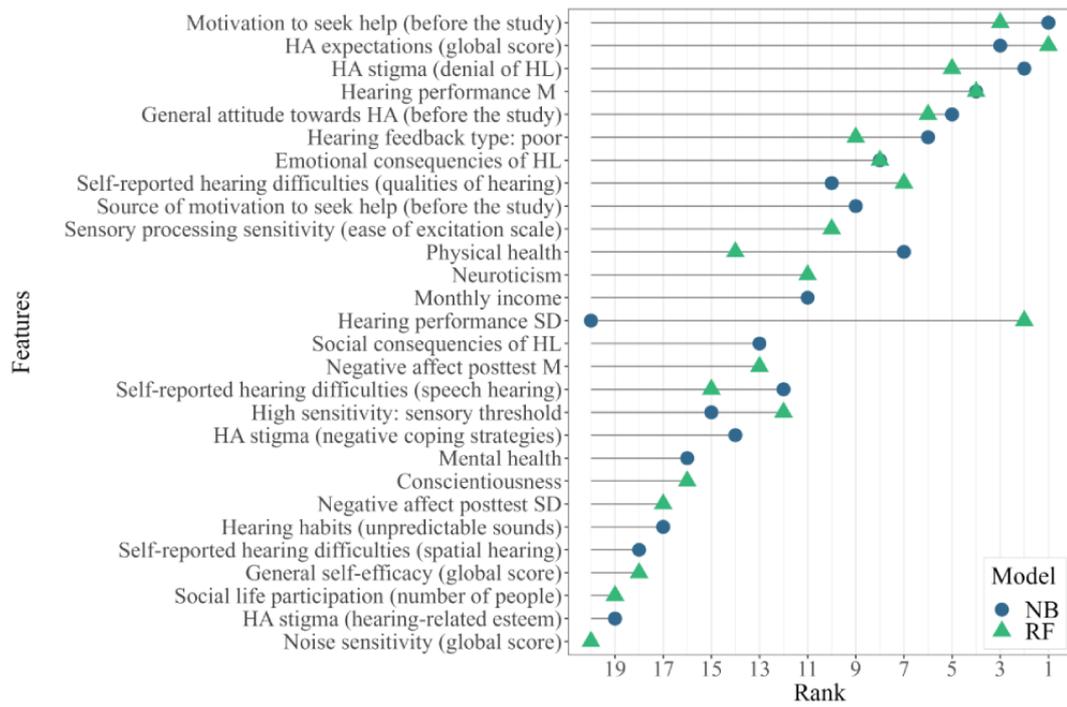

Table 7. Model-specific overall performance and class-specific classification accuracy rates for the outcome *action to seek help at follow-up*^a.

Important Features

Textbox 3 provides a brief description of 12 features ranked among the most important (previously named as the top 10

features for the 2 models) in the prediction of *action to seek help at follow-up*.

Textbox 3. 12 Features ranked among the most important in the prediction of action to seek help at follow-up.

- *Motivation to seek help* and *source* of this motivation at the beginning of the study
- Individuals' attitude toward and expectations regarding HAs, including *general attitude toward HAs*; *expectations regarding HAs*, as measured using the global score of the Expected Consequences of Hearing Aid Ownership questionnaire [38], which assesses positive and negative expectations regarding HAs, expected services and costs, and assumptions about change in the personal image in case of HA use; and *stigma toward HAs*, as measured using the Denial of Hearing Loss scale of the Attitudes Toward Loss of Hearing Questionnaire [41], which assesses acceptance of HAs and acknowledgment of HL
- *Hearing performance* (mean SRT and its variability as measured using the DTT [45,66]) and *percentage of negative feedback received* (indicating poor performance)
- Perceived consequences of HL, including *emotional consequences of HL*, as measured using the corresponding subscale of the Hearing Handicap Inventory questionnaire [39], and *self-reported hearing difficulties*, as measured using the qualities of hearing subscale of the Speech, Spatial, and Qualities of Hearing Scale [38], which addresses recognition, perceived clarity and naturalness of everyday sounds, and listening effort experienced in different hearing contexts
- *High sensory sensitivity personality*, as assessed through the ease of excitation subscale of the Highly Sensitive Person Scale questionnaire [51], which assesses emotional reactivity to physiological stimuli
- Reported *physical health*, measured using the corresponding items of the 12-item Short-Form Health Survey [60]

As outlined in the Methods section, ranking values up to 10 were arbitrarily chosen to identify the most important features. The following two features had slightly lower importance values (and received a ranking value of 11) but might provide further insights into targeted counseling in an mHealth hearing app: (1) *neuroticism*, which refers to a predisposition to experiencing negative emotions [2] and was assessed through the corresponding items of the Neuroticism-Extraversion-Openness Five-Factor Inventory questionnaire [46]; and (2) *monthly income*, which was categorized using 3 cutoff values (<€1500 [$<US\ \$1611.21$], €1500-€2500 [$US\ \1611.11 - $\$2685.35$], €2500-€4000 [$US\ \2685.35 - $\$4296.56$], and >€4000 [$>US\ \4296.56]).

Discussion

Principal Findings

Overview

This study contributes to the identification of individuals' hearing-related, psychological, and general health-related traits that predict the readiness to seek professional help for HL. Cross-sectional and longitudinal data were collected in a comprehensive mobile study. Potential users of a future mHealth hearing app, namely, individuals with subjective hearing difficulties, were classified into help seekers and nonseekers by means of supervised machine learning algorithms. The trait measures used in this study were collected from previous literature investigating health care seeking, particularly in the audiological domain. From these, we derived a comprehensive set of 83 features to be used for prediction and profiling. The 3 algorithms taken into account (NB, RF, and SVM) accurately predicted help-seeking behavior at the end of the study in 65.9% (122/185) to 70.3% (130/185) of cases. In particular, the RF algorithm achieved high specificity, meaning that it was most successful in identifying individuals who might not intend to seek professional help. By selecting a subset of important traits revealed by our empirical feature importance analyses to predict hearing help seeking, the prediction accuracy for action to seek help at the 2-month follow-up reached 74.8% (98/131). This study identified the following features to be most important in

the prediction of help-seeking behavior: perceived consequences of HL in daily life, motivation to seek help, attitudes toward HAs, sensory sensitivity, neuroticism, physical health, and income. We conclude that these individual characteristics should be assessed in a profiling module that could complement the main auditory assessment module for hearing screening of existing or future mHealth apps. The degree of HL but, importantly, also its day-to-day variability were among the most important predictors, suggesting the need to perform repeated hearing assessments, which could be prompted by the app at different times of the day. To streamline the implementation of the profiling module in a mobile app, the questionnaires and subscales used to measure these important features should undergo item selection analysis to derive simple and short yet reliable and valid scales. By incorporating a selected machine learning algorithm (RF), the app can profile users into help seekers or nonseekers based on the data collected through this short questionnaire battery. This information would complement the audiological data gathered through existing hearing screening or diagnostic tests, providing an informative user profile. The derived profile would guide the app in selecting the appropriate set of recommendations, optimizing an intervention on help-seeking behavior where needed. The results of this study will also provide suggestions for the design of such targeted treatment recommendations. Ultimately, our aim was to provide clinicians and mHealth app developers with relevant knowledge to promote hearing health by encouraging the uptake of hearing health care services and HAs when needed.

Best Machine Learning Model to Predict Help Seeking and Categorize Individuals Into Help Seekers Versus Nonseekers

In total, 3 machine learning classifiers correctly predicted *action to seek help* at study end in 65.9% (122/185) to 70.3% (130/185) of cases, clearly improving over chance prediction. This is a promising result considering the complexity of the prediction outcome. As discussed previously, several individual factors can influence the decision to seek hearing health care services, and there can be discrepancy among contemplating, planning, and taking concrete action [3]. RF showed the best prediction accuracy and high specificity, whereas NB showed the highest

sensitivity. When predicting *action to seek help at follow-up* using the selected important features, the performance of the RF and NB models improved up to 75% despite the smaller data set ($n=131$). NB showed higher predictive performance for this outcome. Overall, all models exhibited high specificity (ranging from 75% to 86%) and comparatively low sensitivity (31% to 58%). This could be attributed to the fact that the *action* class encompassed individuals who had sought professional help as well as those who were only considering taking action. RF showed high accuracy in identifying the *no action* class both at study end and at follow-up and, therefore, can be considered the best-performing algorithm in this framework. Accurate identification of nonseekers is the most relevant performance outcome in an mHealth app to design targeted recommendations. Indeed, the envisioned profiling algorithm should be a system with high specificity that motivates and promotes help seeking, especially in those cases in which users would not spontaneously take action.

Most Relevant Hearing-Related and Psychological Features to Classify Individuals Into Help Seekers Versus Nonseekers

Hearing performance appears to be one of the most important features to predict help seeking. The association between degree of HL and help seeking, as well as HA uptake, is well established in the literature [4,9,26,28,29]. These results also highlight—to our knowledge, for the first time in the literature—the predictive role of intraindividual fluctuations in hearing performance, emphasizing the need to move beyond the traditional view of hearing as a stable neurosensory process [88]. The implementation of repeated daily measurements of hearing performance provides further insights on the impact of HL on the individual's everyday life. In line with this, feature importance findings emphasize the relevance of self-reports on the consequences of HL. The assessment should consider self-reported listening effort in different contexts as well as perceived handicap and emotional consequences of HL. Indeed, individuals who report greater negative impact of HL in their lives are more prone to seek help and later uptake HAs [9,27]. Individuals' self-awareness of HL can be validated or improved by providing repeated feedback on hearing performance in an mHealth hearing app. As observed at the follow-up survey, 85.5% (112/131) of participants reported increased awareness of their hearing abilities after receiving repeated feedback during the study. Finally, according to these results and previous findings [26,27,29], investigating stigma, attitude, and expectations regarding HAs informs on individuals' readiness to seek help as well as later uptake of an HA. Stigma and negative stereotypes related to HAs may deter individuals from seeking help and can represent a barrier to HA use [7,28].

Audiological factors emerged as the most important features. Nevertheless, other general health and psychological factors were also relevant in the prediction of help seeking. In this study, physical health was an important predictor for help seeking, although the evidence on this relationship is discordant [26]. While people with better self-reported health were more likely to seek help [4,27], HA uptake was predicted by poor self-reported health [6]. Other important factors were related to

the personality traits of sensory sensitivity and neuroticism. Individuals characterized by high sensitivity to sensory stimuli [63] and emotionally unstable personality traits seem to perceive increased psychological discomfort following HL even in the presence of effective HA treatment [2]. Finally, income emerged as another important predictive feature. This is in line with evidence suggesting that higher socioeconomic status [9], higher income or pension earnings [3,27], and access to financial support [26] promote HA uptake.

Feature Importance Measures Can Inform the Design of Targeted Recommendations for Users of a Future mHealth Hearing App

By assessing and analyzing the aforementioned hearing-related and psychological traits, the algorithm developed in this study aims to profile the user as help seeker or nonseeker. Completing this profile with complementary audiological test results, an informative picture of the user can be derived. Using this profile, clinical experts and intervention app designers could propose different sets of recommendations to assist individuals in their decision-making process in a targeted manner. We propose to first differentiate between profiled help seekers and nonseekers, where the former should receive simple and straightforward recommendations only depending on their hearing status. For nonseekers, there is a need to design more specific and targeted recommendations based on information about the relevant characteristics to predict HA seeking. Users who were profiled as determined help seekers could receive clear and concise guidance on the hearing care they need. Those among them who should uptake a hearing device (given their audiological outcome) could benefit from additional information on available hearing care services and professionals to facilitate faster HA adoption rates. This would facilitate individuals' perceived competence and autonomy, which are important predictors of hearing health-seeking behavior [89]. On the other hand, users with HL who are profiled as nonseekers should receive more elaborate, targeted recommendations to motivate and promote access to hearing care services. Recommendations for nonseekers should be further differentiated and designed depending on their perceived consequences of HL; attitudes toward HAs; sensory sensitivity; neuroticism; and, potentially, income. These recommendations could act as an intervention on modifiable predictive features such as self-recognition of HL and attitude toward HAs. For example, users profiled as nonseekers with good awareness and self-recognition of HL but negative expectations regarding HAs and low income should receive a different set of recommendations than nonseekers with low self-awareness and high neuroticism.

Where HL is detected, the mHealth app could prompt repeated testing on different days and at different times of the day and provide individual feedback on the performance compared to normative data. More detailed feedback on daily hearing performance could improve awareness of the hearing deficit. The app could also inform the user of the risks of an untreated HL and the benefits of early intervention through HAs. Indeed, it has been shown that individuals are more likely to positively change their behavior when provided with actionable and meaningful information on their health status [90]. Where there

is a need to promote positive attitudes toward HAs, information could be provided on the wide range of devices available as well as examples of successful peer cases. Knowledge of accessible financial support for HAs by insurance companies could additionally promote HA uptake given the predictive role of income. Furthermore, an implemented HA simulator in an mHealth hearing app could offer possibilities to experience improved listening conditions and promote positive expectations regarding an HA. Elaborate information on HA technologies, such as the benefits of noise control and noise reduction algorithms, could promote help seeking by fostering the knowledge of individuals who are more sensitive to environmental noise (high sensory sensitivity trait). The effectiveness of such recommendations could be further increased through targeting or tailoring communication. Targeted messages are designed for a specific population, whereas tailored communication is individualized to the person and has been shown to be most effective in promoting health behavior change [91]. Indeed, messages that are congruent with the personality traits of the audience are more positively evaluated and persuasive and generate more interest [92]. The predictive role of neuroticism for help-seeking behavior can be considered for efficient communication both in the context of an mHealth hearing app and in clinical counseling. Individuals with a high neuroticism trait are more susceptible to perceived disease [93] and are drawn to action through motives of safety and security [92]. For example, recommendations that target profiled nonseekers with low expectations regarding HAs can be differentiated depending on personality traits. To promote positive HA expectations in individuals with high sensory sensitivity traits, recommendations could focus on the benefits of HAs related to noise control and noise suppression. However, such recommendations may not be effective for people who do not have this high sensitivity trait and who, for example, score high on neuroticism. Instead, they might be more convinced by recommendations that emphasize the risks of an untreated HL and the benefits of an early intervention through HAs.

Limitations and Future Directions

The predictive performance of the machine learning classifiers could be improved in future studies using a larger data set and more balanced classes. Classification accuracy could be further improved by including additional objective measures to complement participant self-reports. Continuous psychophysiological measurements (eg, heart rate variability) could be included as further predictive features. This information could complement the longitudinal assessment of affect and better characterize potential changes in arousal before and after the completion of the auditory measurements. Note that multicollinearity as a potential statistical limitation was ruled out (the correlation plots are available in [Multimedia Appendix 4](#)). Future studies might also benefit from a longer follow-up period to properly capture those individuals who took more time to take action to seek help. In this study, measuring help seeking 2 months after the end of the study provided a more valid measure of participants' behavior. For example, of the participants who were categorized as nonseekers at study end, 3.8% (7/185) reported having made an appointment with a hearing professional at follow-up and 6.5% (12/185) were

planning to do so in the near future. Another limitation that affects the generalizability of the findings is the specific sample included in this study—older individuals living in Germany, using a smartphone in their daily life, mainly coming from big cities (106/185, 57.3%), and having a monthly income above the national average net salary (€500 [US \$2685.35]) in 31.4% (58/185) of cases. The conclusions about relevant personal factors for predicting hearing help seeking may not be generalizable to people with HL in different socioeconomic situations. For example, socioeconomic factors were found to be the major limiting factor in seeking help for hearing difficulties in a South African periurban community [94]. To address this sociodemographic limitation, future studies may consider alternative recruitment strategies to achieve a more diverse sociodemographic sample. These findings may also not generalize to different age groups. For example, when considering young adults with HL, other personal characteristics may be more important in predicting help seeking.

Looking forward, this study sets milestones for the development and implementation of a short and concise profiling module in an existing or future mobile app for hearing screening linked to targeted recommendations, complementing the audiological assessment in a modular environment. In the context of this mobile study, individuals could provide any type of feedback in an open-question format at the end of the study. Of 185 individuals who completed the study, only 1 (0.005%) participant raised concerns related to usability and the user interface. This participant suggested enhancing the contrast between the fonts and the background and increasing the size of the click buttons. As this feedback was provided toward the end of our data collection period, we were unable to implement this suggestion in our design. Further studies that focus on user interface and usability are necessary for the future implementation of such a module in mHealth solutions that target an older population. Specific implementation strategies should be considered, such as simplicity of design; naturalness of navigation and task flow; clear interface elements; feedback [95,96]; large font sizes; contrasting colors; and clear, consistent, and simple instructions [11]. Perceived ease of use and perceived usefulness should be targeted to promote acceptance and use of mHealth solutions [11].

Conclusions

This research provides initial knowledge regarding a selection of tests and questionnaires that have been shown to predict hearing help seeking in persons with self-reported hearing difficulties. From these, we derived conclusions for the implementation of an individual-profiling algorithm in an mHealth hearing app. This study is innovative in that it considers a comprehensive range of personal characteristics and covariates previously cited in the literature, including 25 assessment tools and 83 features, and narrows them down to identify a short selection of the most important predictors for profiling. Complementing the audiological assessments with such a profiling algorithm will enable an mHealth app to deliver targeted and efficient treatment recommendations depending on relevant individual characteristics. The benefits of such a profiling module might also extend to other functions within an mHealth hearing app. Future studies might explore potential

relationships between psychological traits and, among others, HA fitting preferences and endurance in the fine-tuning process toward an optimal aiding solution; openness to try new, elaborate technical solutions; or preference for particular app usability features. We have seen how predictive models that use machine learning algorithms can be used to explore complex association patterns of individual characteristics and behaviors considering multiple predictors simultaneously and drawing robust conclusions through CV approaches. This provides further evidence of the advancement that the use of machine learning algorithms can bring to mHealth technology development [33]. mHealth solutions contribute to the evolution of hearing health care toward predictive, preventive, personalized, and participatory medicine (P4 medicine) [90].

We have seen how individual profiling in an mHealth hearing app can identify nonseekers, acting as a preventive action to reduce the risk of a late intervention for HL. It can also provide clinicians with data-driven insights on the individual health profile of the user for tailored and personalized treatments. Moreover, it can enhance the empowerment and participation of the individual in their own hearing health care, promoting informed decision-making. Indeed, personalization strategies (such as tailored treatment recommendations) increase the effectiveness of mHealth interventions [97]. To conclude, an mHealth hearing app that provides targeted treatment recommendations could facilitate faster access to hearing care services and subsequent earlier intervention where needed to pursue the long-term goal of achieving “hearing for all.”

Acknowledgments

This research was funded by the Deutsche Forschungsgemeinschaft (German Research Foundation) under Germany’s Excellence Strategy (EXC 2177/1; project ID 390895286). The authors thank all the participants who took part in this study and the universities that helped them with recruitment: Carl von Ossietzky University of Oldenburg, Guest study program; Goethe-University of Frankfurt am Main, University of the 3rd Age; Free University of Berlin, Guest-study-Card Program; University of Cologne, Guest and Senior Citizen Studies; University of Kassel, Guest Students Program; and University of Bielefeld, Studying from 50.

Data Availability

The data sets generated during and analyzed during this study are available from the corresponding authors on reasonable request. Analysis scripts are available in the Zenodo repository [98]. A preprint of the manuscript was published on medRxiv [99] in February 2023 and revised in August 2023. Preliminary results of this research have been presented at symposia and conferences of the Hearing4All Cluster of Excellence, at the Virtual Conference of Computational Audiology 2022, and at the German Society for Psychology Congress 2022. The data will be shared with interested researchers upon request as the data set will be used for further projects and cannot be fully shared at the current time point.

Authors' Contributions

GA, AH, and MB conceptualized the study and were involved in protocol development, study design, and data analysis. IK was involved in study design and data analysis. BK contributed to study conceptualization and obtained funding. GA was responsible for participant recruitment and data collection and wrote the first draft of the manuscript. All authors reviewed and edited the manuscript and approved the final version.

Abstract

Background: Surgical procedures on the lower extremities often require weight-bearing on crutches as part of the rehabilitation process. Orthopedic elective procedures enable patients to learn the correct use of crutches in a controlled preoperative setting. Digital assistance systems can safely circumvent a shortage of skilled staff and any contact restrictions that may be necessary.

Objective: The usability of a newly developed gait training assistant (GTA) for the use of crutches will be evaluated. An intervention group trained to use crutches by the digital trainer will be compared with a control group trained to use crutches conventionally by a physiotherapist.

Methods: As part of the development and implementation of a novel GTA, 14 patients learned to walk with crutches by completing specific exercises while receiving live feedback. Their movements were detected by a depth sensor and evaluated in real time. Specific parameters (step length, synchronous movement, crutch angle, and crutch distance to the feet) were compared with a control group (n=14) trained to use crutches by physiotherapists. The intervention group was also assessed by a physiotherapist. At the end of the study, the patients completed questionnaires to evaluate the usability of the system (Brooke's System Usability Scale score) and patient satisfaction.

Results: All patients trained by the novel GTA were able to use crutches correctly. The intervention group showed significantly better values for crutch angle (mean -6.3° , SD 3.5° vs mean -12.4° , SD 4.5° ; $P < .001$) and crutch position (mean 3.3 , SD 5.1 cm vs mean -8.5 , SD 4.9 cm; $P = .02$). Both groups reported that they felt confident in the use of crutches, were able to follow the instructions, and enjoyed the training. Even though the majority (12/14, 86%) preferred physical therapy over a purely digital approach, most participants enjoyed using the system (13/14, 93%) and were interested in trying out other digital assistants (11/14, 79%). The usability of the GTA was rated above average by the majority (9/14, 64%) of the patients.

Conclusions: The newly designed GTA is a safe method of teaching the use of crutches and is statistically superior to training by a physiotherapist. Even if patients prefer interaction with a physiotherapist over a purely digital approach, digital devices provide a safe and motivating opportunity to learn the essential locomotor skills for rehabilitation.

Introduction

Following accidents or surgical procedures, it is often crucial for the healing process to provide support to the affected body part. In the case of lower limb injuries or surgeries, this can be accomplished by crutches. In the case of elective surgery, patients can receive preoperative instruction in a controlled environment several days prior to the procedure. In Germany, this training is typically provided by specialized physiotherapists.

The use of digital assistive devices has already become ubiquitous in clinical settings and serves to mitigate the strain on hospital personnel, reduce costs, and enhance patient rehabilitation [1]. Despite these advantages, advanced technology applications are currently used in patient with orthopedic care only in the context of studies [2-4].

Walking on crutches is a clearly structured movement sequence. However, the teaching of this skill requires significant staff resources. The projected increase in the number of elective orthopedic surgeries in the future is exacerbating the already persistent shortage of specialized health care personnel [5], which has been further intensified by the COVID-19 pandemic and the associated restrictions on physical contact [6].

The current digital aids for learning to walk with crutches do not provide the comprehensive support that a physiotherapist can offer [7,8]. Some crutches equipped with sensors can monitor proper use, but there are currently no commercially available systems that provide simultaneous guidance and assessment, which puts a strain on the resources of physiotherapists.

This study aims to evaluate the efficacy of a custom-designed gait training assistant (GTA) in teaching the proper use of crutches. The primary objectives of this study are to determine (1) the capability of the digital assistant to impart proper crutch-walking skills using a 3-point gait, (2) patient receptiveness toward the digital walking assistant, and (3) the competence of the digital crutch-walking training assistant in comparison to a human physiotherapist.

Methods

Study Design

A total of 28 patients who underwent elective orthopedic surgery and needed postoperative weight-bearing (3-point gait) on the lower extremity were included. Patients who could not follow the instructions of the GTA, for instance, due to neurological diseases, were excluded.

The patients were randomly assigned to the intervention group (n=14) or control group (n=14). The intervention group learned the proper use of crutches with the GTA. The control group learned the use of crutches with the help of a physiotherapist. Baseline data (age and sex) were collected using a survey. In the intervention group, satisfaction was assessed by a questionnaire specially developed for the study. In addition, the usability of the GTA was evaluated using Brooke's System Usability Scale (SUS) [9]. The GTA and a physiotherapist evaluated the ability of both groups to use the crutches correctly.

Ethical Considerations

A prospective clinical trial was conducted in August 2022 after obtaining patient consent and institutional review board approval from the Saarland Medical Association (318/21). Data was anonymized and no compensation was provided to participants.

Implementation of the GTA

The GTA consists of a screen in portrait mode that gives visual guidance to the user and a 3D camera (Kinect v2 [Microsoft]) that tracks the position of the feet and crutches. While walking toward the screen, the gait pattern is automatically recognized and possible errors are brought to the attention of the user. The screen is also used to give instructions to the user (Figure 1). The user is guided through various exercises that aim to train a specific walking pattern (3-point gait). The software is designed so that each pattern can be described as a sequence of states, where each state specifies the crutch or the foot that needs to be moved. For 3-point gait, for instance, the user needs to move the injured leg, foot, or side and both crutches. Next, the noninjured leg, foot, or side is moved. This pattern is repeated. For simplicity, we focused on 3-point gait and forward movement only during this study, as other walking patterns and backward movement work similarly.

Figure 1. Training with the gait training assistant. The patient uses the crutches while the Kinect camera in front of him analyzes the crutches as well as the feet. The exercise to be completed is displayed with live feedback on the screen above the camera.

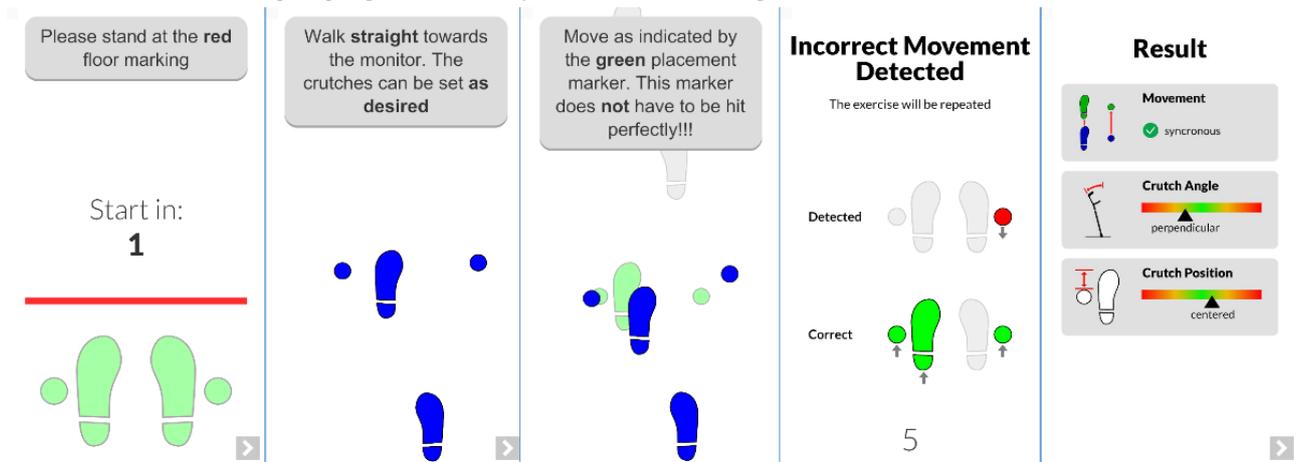

For simplicity, 2 infrared markers are attached to each crutch (handle and rubber foot) and each foot of the user to determine the movement of the crutches and feet. These reflective markers are extracted from the 2D infrared image and converted into 3D positions using the Kinect SDK. In this experiment, we focused on the 3-point gait. One step cycle was divided into smaller movements (eg, “Left foot and both crutches moving forward” and “Right foot moving forward”) that were derived

by the 3D positions of the tracked reflective markers. Besides the necessary compound movements (foot and crutches), individual movements of crutches and feet were also recognized.

As the aim of the system is also to give corrective feedback during the training, the system tries to fit the currently detected movement to the gait pattern. If the system detects a wrong state or a wrong order of movements, it alerts the users and asks them to repeat the exercise (Figure 2).

Figure 2. Excerpt from the instruction display with live feedback from gait training assistant. The first image (left) shows the start screen with the first instruction. The second image represents the instruction to use the crutches. The third image displays the live feedback. The fourth image signals an incorrect movement. The last image (right) provides the analysis of the exercise to the patient.

The 3D positions of the tracked markers are also used to compute a set of metrics while the user is walking. These metrics include crutch angle, crutch position, and the synchronicity of the movement and help to provide feedback to the user after each exercise. The crutch angle describes the tilting of the crutch along the walking path toward the camera when it is placed on the ground. It is computed using the upper and lower markers of the crutch with some additional offset to match the tilting of the crutch cane. For the crutch position, the depth offset between the crutch and the foot is measured after they have moved. As the optimal position is the center of the foot, an offset of 15 cm is subtracted from the tracked foot position. To measure the synchronicity of the movement, the time when the crutch and foot are moving together is divided by the overall moving time for the current state.

Statistical Analysis

The training performance of the GTA was assessed using an ANOVA. The number of correct runs during the analysis phase for each participant (independent variable) was compared

between the 2 groups (dependent variable). The 2 groups were compared using a multivariate ANOVA (MANOVA), wherein 2 independent variables (crutch angle and crutch position) were simultaneously used to investigate the differences between the 2 groups. A correlation matrix was used to explore whether there was a correlation between the participants' age and their perceived usability of the system.

Results

Baseline Data

In total, 28 participants were recruited for the primary study. The sample consisted of 13 female and 15 male participants with an age range of 18-73 (mean 41.1, SD 19.1) years. The participants' height ranged from 1.55 m to 1.96 m. Approximately half (15/28, 54%) of the participants had prior experience with crutches, in most cases several years prior to the study. A total of 3 participants had used crutches in the last 12 months, although not for learning a 3-point gait (Table 1).

Table 1. Presentation of the baseline data of the patients.

Characteristics	Intervention group (n=14)	Control group (n=14)	Total (n=28)
Sex, n (%)			
Female	6 (43)	7 (50)	13 (46)
Male	8 (57)	7 (50)	15 (54)
Age (years), mean (SD)	44.4 (20.7)	37.8 (17.6)	41.1 (19.1)
Body height (cm), mean (SD)	173.1 (11.6)	175.3 (11.9)	174.2 (11.6)
Used crutches before, n (%)			
Yes	6 (43)	9 (64)	15 (54)
No	8 (57)	5 (36)	13 (46)

A total of 2 participants (P3 and P5; intervention group) could only partially perform the training with the GTA, as after a few exercises, the tracking function of 1 of the crutches was no longer shown in the live position visualization. Subsequent analysis was, therefore, not possible. However, they both filled out all the questionnaires. One other participant (P10; control

group) had to be excluded from any analysis including the data recorded by the GTA, as no valid results were computed.

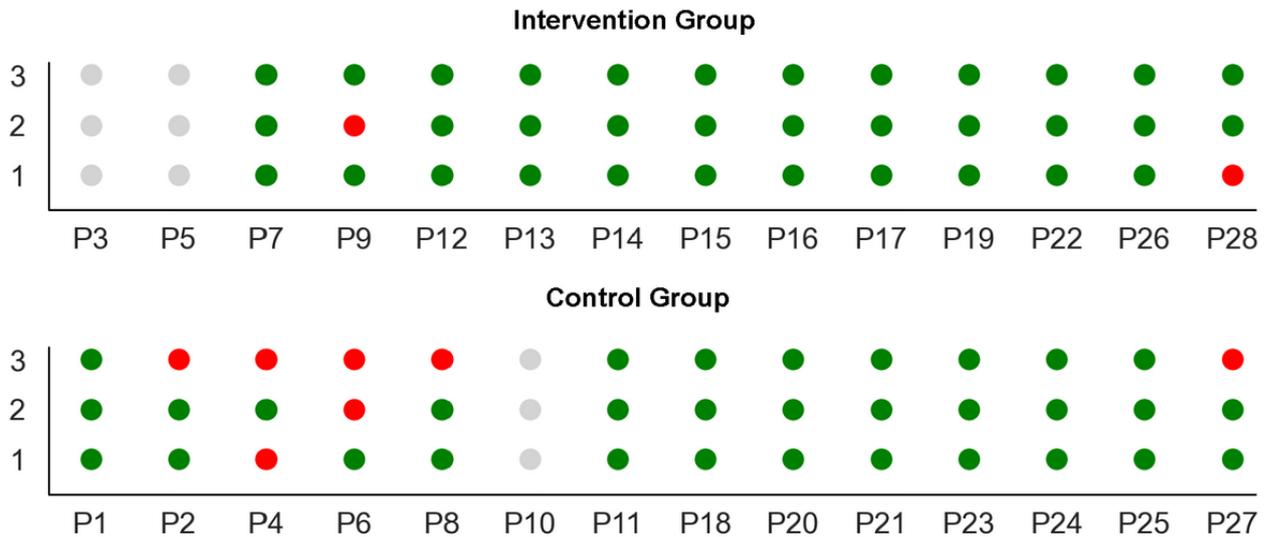

Evaluation of the Training Performance by the GTA

The GTA performance was determined by an analysis of the training sessions. Based on the number of incorrect exercises,

the performance was extrapolated. Due to incomplete data collection, P3, P5 (intervention group), and P10 (control group) were excluded from the analysis. In the intervention group, 2 patients were found to have performed 1 of the 3 exercises incorrectly. In the control group, 3 patients performed 1 of the

3 exercises incorrectly and 2 participants performed 2 exercises incorrectly (Figure 3). The differences in the number of correctly performed exercises between the 2 groups were not statistically significant ($P=.15$).

Figure 3. Status for each of the 3 exercises during the analysis: green: success; red: error (incorrect movement); and gray: excluded from the analysis. The upper image shows the results of the intervention group, and the lower image shows the results of the control group.

The parameters selected for comparison of the 2 groups were crutch position and crutch angle. The reason for this is that step length and step speed are individual, patient-specific movements, and the physiotherapists, therefore, had to train synchronous movement depending on the patients' physical condition.

The intervention group showed significantly better values for crutch angle (intervention group vs control group: mean -6.3° , SD 3.5° vs mean -12.4° , SD 4.5° ; $P<.001$) and crutch position

(intervention group vs control group: mean 3.3 , SD 5.1 cm vs mean -8.5 , SD 4.9 cm; $P=.02$). A MANOVA confirmed the superiority of the intervention group in the gait metrics (Table 2). Here, group assignment (intervention group and control group) was used as a factor, and crutch angle and crutch position were used as dependent variables. There was homogeneity of the error variances, as assessed by the Levene test ($P>.05$). The homogeneity of covariance was given by the Box test ($P=.86$). All tests revealed a statistical significance for $P<.05$.

Table 2. MANOVA^a analysis of gait metrics between the intervention group and control group^b.

Test	Value	F test (df)	P value
Pillai trace	0.433	8.39 (2, 22)	.002
Wilks Lambda	0.567	8.39 (2, 22)	.002
Hotelling trace	0.763	8.39 (2, 22)	.002
Roy largest root	0.763	8.39 (2, 22)	.002

^aMANOVA: multivariate ANOVA.

^bThe analysis showed that the training by the gait training assistant was significantly superior to the training by a physiotherapist.

Evaluation of the GTA Training Performance by a Physiotherapist

The physiotherapist evaluated the ability to walk on crutches based on clinical experience using the parameters of step length, step speed, crutch angle, crutch position, and synchronous movement. Only the intervention group was evaluated, as an

assessment of the control groups' training performance by the physiotherapist was estimated to be too biased.

The analysis showed that almost all patients (10/12, 83%) trained on the GTA achieved a perfect result. Only 2 patients in the intervention group (P12 and P13) presented a slight deviation from the ideal score (Table 3).

Table 3. Gait training assistant performance of the intervention group, as evaluated by a physiotherapist. Synchronous movement is rated from 1 (not synchronous) to 5 (synchronous). All other metrics are rated from 1 to 5, with 3 as optimal value (eg, rating for step speed: 1=too slow, 3=optimal, and 5=too fast).

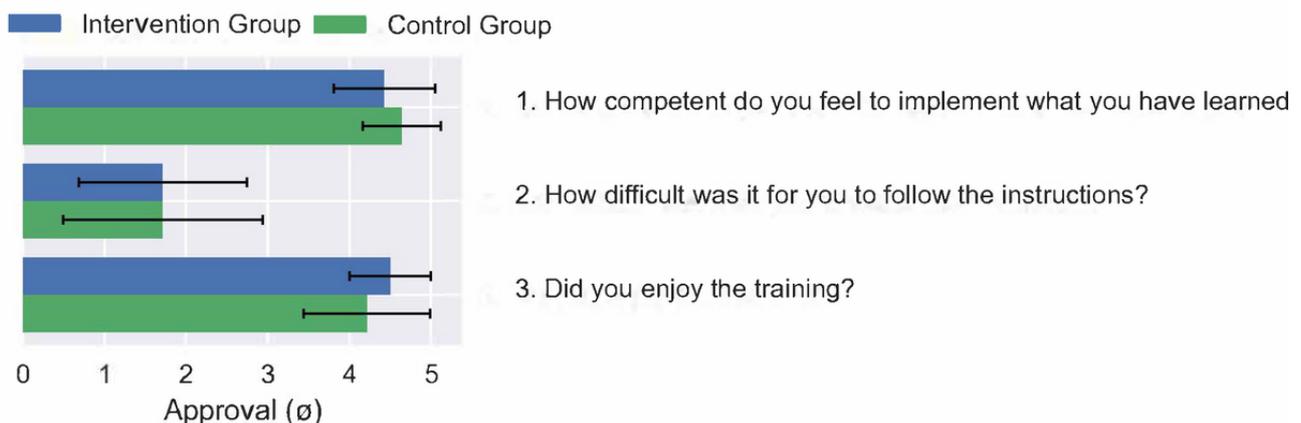

Parameters	Patient and rating											
	P7	P9	P12	P13	P14	P15	P16	P17	P19	P22	P26	P28
Step length	3	3	2	3	3	3	3	3	3	3	3	3
Step speed	3	3	2	3	3	3	3	3	3	3	3	3
Crutch angle	3	3	3	3	3	3	3	3	3	3	3	3
Crutch position	3	3	3	3	3	3	3	3	3	3	3	3
Synchronous movement	5	5	5	4	5	5	5	5	5	5	5	5

Training Evaluation

Both groups felt that they were competently trained (intervention group: mean 4.43, SD 0.62; control group: mean 4.64, SD 0.48; Figure 4). All patients reported that they were able to follow the instructions of the physiotherapists and the GTA (intervention group: mean 1.71, SD 1.03; control group: mean

1.71, SD 1.22). The participants in both groups indicated that they enjoyed the training, with the GTA performing slightly better (intervention group: mean 4.5, SD 0.5; control group: mean 4.21, SD 0.77). The differences between the groups were very small and were not statistically significant (MANOVA Wilks Lambda: $F_{3,42}=0.872$; $P=.47$).

Figure 4. Evaluation of the training and comparison of patients from the control group and Intervention group. Rating from 1 (not at all) to 5 (very). Competence—intervention group: 4.43 (SD 0.62) and control group: 4.64 (SD 0.48). Difficulty—intervention group: 1.71 (SD 1.03) and control group: 1.71 (SD 1.22). Enjoyment—intervention group: 4.5 (SD 0.5) and control group: 4.21 (SD 0.77).

Experience With the GTA

The participants in the intervention group were asked to complete a questionnaire with binary response options (yes or no). All participants indicated that they had learned to use the crutches safely and felt adequately prepared (14/14, 100% agreement), but 43% (6/14) of them indicated a desire for reevaluation by a physiotherapist. Nearly all participants (13/14, 93%) reported that they had understood the instructions provided by the GTA, 86% (12/14) reported that they were able to

properly follow the instructions of the GTA, and 79% (11/14) stated that they would like to use a trainer for additional exercises. On the other hand, only 14% (2/14) of the participants wished to have purely digital rehabilitation without the support of a physiotherapist, while 29% (4/14) preferred training with a physiotherapist. Although 93% (13/14) of the participants enjoyed the gamified aspect of the GTA, only 14% (2/14) reported that it was more motivating than working with a physiotherapist (Table 4).

Table 4. Results of the questionnaire given to the patients in the intervention group. The results present the percentage of subjects who agreed with the question (answer: yes).

Question	Approval (n=14), n (%)
1. Have you learned how to safely use forearm crutches?	14 (100)
2. Do you feel prepared using forearm crutches confidently?	14 (100)
3. Would you like to be rechecked by a physical therapist?	6 (43)
4. Did you understand all the instructions of the program?	13 (93)
5. Have you been able to follow all the instructions of the program?	12 (86)
6. Would you like to learn more exercise through an interactive training program?	11 (79)
7. Would you perform a purely digital rehabilitation (ie, without a human physical therapist)?	2 (14)
8. Would you have preferred to learn how to use forearm crutches from a physical therapist?	4 (29)
9. Do you think the interactive trainer is more motivating than a physical therapist?	2 (14)
10. Do you like the playful concept of the interactive trainer?	13 (93)

Assessment of GTA Usability

The usability of the GTA was evaluated using the established SUS [10]. A value of more than 68 can be considered above-average usability. A total of 9 (64%) of the 14 patients rated the usability of the GTA as above average. There was a tendency for younger patients to rate usability higher, but no significance was shown for this observation (Pearson $r=-0.381$; $P=.18$).

Discussion

Principal Findings

In the context of this study, a specifically designed GTA was used to teach patients how to use crutches. An RGB-D camera captured the position of the crutches, as well as the position of the study participant in the room. The training program guided the patients through a series of exercises and monitored their progress in real time, providing immediate feedback. This allowed simultaneous training and supervision. The results showed that compared with a control group that received conventional physiotherapy-led crutch training, the intervention group was not inferior and was able to effectively learn proper crutch use by the end of the exercise period. Although patients in the intervention group expressed positive feedback regarding the GTA and perceived it as useful, some remained skeptical about the potential for solely digital rehabilitation. The GTA was rated as having above-average user-friendliness.

Digital interventions are now increasingly integrated into everyday clinical practice for musculoskeletal rehabilitation. In particular, telerehabilitation [11] and mobile health (mHealth) applications [1] are available and prescribed by responsible therapists. At present, purely digital applications that work autonomously and can guide the patient while at the same time recognizing and preventing faulty exercises are not widely available. The programs available to date are mostly used only for the purpose of clinical studies [12]. Digital applications are rarely used in prerehabilitation.

The camera used in this study is the Microsoft Kinect camera released in 2010. Compared with other systems that only use

body-worn markers (eg, Vicon [Vicon Motion Systems Ltd] and OptiTrack [NaturalPoint Inc]) for tracking (and are considered the gold standard for accuracy), the Kinect system can achieve similar precision in motion detection [13,14]. The Kinect system has already been embedded in several studies and successfully applied in rehabilitation programs [15,16]. The camera makes it possible to analyze gait without great expense or complex analysis systems. However, the short detection range of the camera is a disadvantage that can only be improved by using other more cost-intensive systems.

The analysis of the correct use of crutches can also be achieved by using sensors in the crutches themselves in addition to external systems such as a camera. Here, acceleration can be measured in addition to pressure. However, the established crutches are used almost exclusively in the measurement of load limits at partial weight-bearing. Tsuda et al [8] tried to overcome the limited detection range of the Kinect system (approximately 4 m) by using crutches with sensors. The disadvantage here is that the freedom of movement gained requires a wired connection to a computer and thus again leads to a disproportionately higher constraint.

In addition to the correct use of the crutches in terms of the movement and positioning of the crutches in the room [17], weight-bearing is important in some cases. Another study investigated forearm crutches with a built-in weight sensor. By using such a system, additional data can be displayed for the patient in real time, and the rehabilitation process can be further improved [18].

According to the available studies, the use of digital training systems is becoming increasingly popular and seems to be effective and safe [7,19,20]. In our study, there were no significant differences between the control and intervention groups. Although this is not proof of equality considering the low number of incorrect exercises, it can be concluded that the assistant can successfully teach a 3-point gait.

The comparison of crutch angle and crutch position reveals that in both cases, the intervention group achieved lower values with statistical significance. In terms of stability, it can be argued that the crutch angle closer to a vertical orientation provides

greater contact between the rubber feet and the ground, thus reducing the probability of sliding. Regarding the crutch position, a smaller distance to the center of the foot can have the same effect. From this perspective, training with the digital assistant outperforms training with a physiotherapist. However, it is impractical to compare these metrics regarding a single optimal value. A slightly more tilted crutch can provide almost the same degree of stability, for example, due to the deformation of the rubber foot. Thus, a whole range of optimal values should be considered. This goes hand in hand with the evaluation of metrics by the physiotherapists, who rated all participants with a perfect score, that is, regardless of whether the angle was -14° or -4° . In this regard, both groups performed equally, and we can conclude that the digital assistant can compete with a human physiotherapist.

According to the completed questionnaires, both training approaches (GTA and analog) were similarly acceptable to the participants. Although the majority rejected a purely digital-based rehabilitation, most of them would have preferred

training with a physiotherapist and even liked the concept of the assistant. However, the disadvantage of the system mentioned most often was the absence of interpersonal communication. A possible approach in future projects would be the use of artificial intelligence for communication or the use of professionals to monitor performance. Even if this again requires the involvement of staff, in the long term, the use of human resources is significantly lower.

Conclusions

The use of the newly designed GTA is a safe method of learning to use the crutches and is statistically superior to training by a physiotherapist. Even if patients prefer interaction with a physiotherapist over a purely digital approach, digital devices provide a safe and motivating opportunity to learn essential locomotor skills for rehabilitation. Even though the range of the trainers is currently limited, in the future, the use of more advanced hardware can provide a comprehensive physiotherapeutic experience.

Abstract

Background: Our prototype smoking cessation chatbot, Quin, provides evidence-based, personalized support delivered via a smartphone app to help people quit smoking. We developed Quin using a multiphase program of co-design research, part of which included focus group evaluation of Quin among stakeholders prior to clinical testing.

Objective: This study aimed to gather and compare feedback on the user experience of the Quin prototype from end users and smoking cessation professionals (SCPs) via a beta testing process to inform ongoing chatbot iterations and refinements.

Methods: Following active and passive recruitment, we conducted web-based focus groups with SCPs and end users from Queensland, Australia. Participants tested the app for 1-2 weeks prior to focus group discussion and could also log conversation feedback within the app. Focus groups of SCPs were completed first to review the breadth and accuracy of information, and feedback was prioritized and implemented as major updates using Agile processes prior to end user focus groups. We categorized logged in-app feedback using content analysis and thematically analyzed focus group transcripts.

Results: In total, 6 focus groups were completed between August 2022 and June 2023; 3 for SCPs (n=9 participants) and 3 for end users (n=7 participants). Four SCPs had previously smoked, and most end users currently smoked cigarettes (n=5), and 2 had quit smoking. The mean duration of focus groups was 58 (SD 10.9; range 46-74) minutes. We identified four major themes from focus group feedback: (1) conversation design, (2) functionality, (3) relationality and anthropomorphism, and (4) role as a smoking cessation support tool. In response to SCPs' feedback, we made two major updates to Quin between cohorts: (1) improvements to conversation flow and (2) addition of the "Moments of Crisis" conversation tree. Participant feedback also informed 17 recommendations for future smoking cessation chatbot developments.

Conclusions: Feedback from end users and SCPs highlighted the importance of chatbot functionality, as this underpinned Quin's conversation design and relationality. The ready accessibility of accurate cessation information and impartial support that Quin provided was recognized as a key benefit for end users, the latter of which contributed to a feeling of accountability to the chatbot. Findings will inform the ongoing development of a mature prototype for clinical testing.

KEYWORDS

artificial intelligence; chatbot; smoking cessation; behavior change; smoking; mobile health; apps; digital interventions; smartphone; mobile phone

Introduction

In 2019, a total of 1.1 billion people worldwide smoked tobacco regularly, and 13.6% of all deaths were attributable to smoking tobacco [1]. Tobacco's burden on human health is compounded by the chronic relapsing-remitting nature of tobacco dependence [2]; 96%-97% of people are unsuccessful when trying to quit without assistance [3]. Smoking cessation behavioral support increases individual quit attempt success [4] and increases further when pharmacotherapy is used, supporting the physiological and behavioral needs of the individual [5]. However, the scalability and reach of professional interventions such as behavioral counseling are limited due to accessibility [6,7] and individual awareness [8,9]. Digital interventions, such as smartphone apps, have therefore been explored to improve the reach of smoking cessation information and behavioral support. However, there is currently limited evidence to support the routine use of smartphone apps in smoking cessation [10-12], and questions remain surrounding the impact of the level of engagement with an app on its effectiveness.

The use of conversational agents for smoking cessation is an emerging area of research that may, through personalization and tailoring, enhance engagement with digital smoking cessation interventions, thereby increasing their impact. Conversational artificial intelligence (AI), such as chatbots, allows for synchronous communication with users via text and/or audio using natural language processing and machine learning algorithms with a rule-based and/or probabilistic approach [13]. Over time with increasing use and data generation, these interactions may become more natural, responsive, and tailored to the user [13]. Mohr's model of "Supportive Accountability" states that engagement with digital health interventions is promoted with the addition of human support by cultivating a sense of personal accountability to a competent, trustworthy, and caring coach [14]. Chatbots capable of emulating this type of human support via a highly accessible platform such as a smartphone app may bridge the gap between scalable personalized interventions and effective behavioral counseling. Furthermore, the current evidence supporting the effectiveness of conversational AI interventions on smoking cessation outcomes is limited but promising [15-17], and previous studies have found that they are generally an acceptable tool among participants [13,18-20].

Quin is a prototype chatbot that aims to improve access to personalized, evidence-based smoking cessation information and support via an app. Quin has been developed as part of a multiphase program of co-design research by a multidisciplinary team. Quin was designed using a "bottom-up approach," in that we analyzed and applied findings from real-world evidence-based counseling interactions (ie, consumer- and stakeholder-driven research) rather than a top-down approach by applying behavior change theories or frameworks from the outset. A detailed description of the design and development of the Quin prototype has been published elsewhere [21] and a

screenshot of Quin's user interface is provided as [Figure 1](#). Our co-design approach is based on a 3-stage model developed by the Good Things Foundation (National Health Service, UK Government), which aims to promote digital inclusion [22]:

- Stage 1: Define user and stakeholder needs and experiences
- Stage 2: Ideas and prototype
- Stage 3: Iterative testing and delivery

The design foundations of Quin are embedded in stage 1 by understanding and translating user and stakeholder needs and experiences at 2 levels, the platform or user interface (ie, smartphone app) and the content (ie, smoking cessation counseling and education). To understand the user experience of existing mobile smoking cessation (mCessation) apps, we first analyzed unsolicited user reviews of apps to determine important design recommendations across domains of app personalization, relationality, functionality, and credibility [23]. To understand the counselor-patient relationship and interaction, we analyzed real-world Quitline counseling sessions to identify conversation themes and topics, including how topics map to conversation stages and specific statements, questions, and responses from counselors and clients [21, 24]. Quitline counselors are trained to deliver cognitive behavioral therapy strategies and/or motivational interviewing alongside evidence-based smoking cessation information during counseling conversations.

We applied these findings to Quin's conversation design and technical development (stage 2). The types of human-computer interactions with Quin include conversing (via text or speech-to-text), instructing (eg, user selecting options), and responding (eg, notifications or initiating the conversation upon opening) [25]. Quin's dialogue is structured into "initial" and "support" conversations. The initial conversation constructs a personalized "quit plan" from demographic, smoking, and quit histories ([Figure 1](#)) to guide a personalized discussion about pharmacotherapy options and behavioral considerations or support. Based on the agreed quit plan, follow-up conversations are scheduled to check in on users' progress and review and to answer questions and troubleshoot issues [21]. Quin was programmed using a collection of natural language processing algorithms within CSIBot, the Commonwealth Scientific and Industrial Research Organisation health chatbot framework. The primary response system is a case-based reasoner, which applies both syntactic matching and sentiment analysis algorithms [21]. Examples of these algorithms are presented in [Figure 1](#). The syntactic matching algorithm uses a radix tree data structure to store and search for a template response that can include wildcard substitutions and extra chatbot operations (eg, log data) [21]. As such, the conversation is guided and tailored by free-text and preset responses which Quin can store and recall to determine subsequent conversation paths.

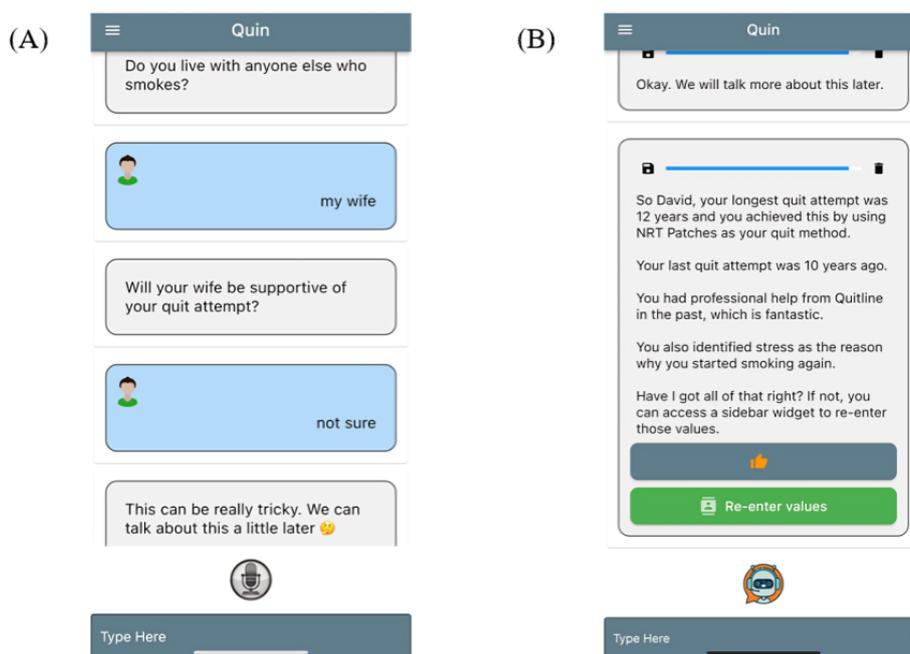

At all times, we aimed to keep the language and responses very positive and affirming. For example, if the user states that the cost of smoking is a motivator for quitting smoking, Quin

reinforces this by saying “Extra cash is a great reward for quitting smoking! Are you saving up for something?” Where applicable within the conversation, Quin also provides links to relevant external resources such as educational videos and Quitline services and generates a “to-do” list based on the user-defined quit plan. For example, if the user has indicated they are interested in using a prescription medication, the list will include “Speak to your doctor about using [medication].” Users also have the option to upload motivational images during the initial conversation, and Quin uses information collected within the conversation to inform a cost analysis to track savings and editable summary of user profile information.

Having developed the prototype Quin (stage 2), we now present the first phase of iterative testing (stage 3), which sought to understand how stakeholders perceive and interact with Quin,

a fundamental step for ongoing phases of iterative development and refinement prior to clinical efficacy trials. Our data collection included qualitative inquiry to provide a deeper understanding of the user experience, end user preferences, and priorities, as this is an important aspect of human-centered design. As such, this study aimed to gather feedback on the Quin prototype from end users and smoking cessation professionals (SCPs) via a beta testing process to (1) identify factors that positively and negatively influence the user experience, including general views on chatbot technology for smoking cessation and suggestions for improvement; and (2) compare and contrast subjective feedback from end users and SCPs. Acknowledging the importance of applied consumer-driven research, we will then seek to apply the findings to produce a mature prototype for clinical testing.

Figure 1. (A) Quin user interface; (B) Example of personalization in Quin dialogue.

Methods

This focus group study was completed in Queensland, Australia, and collected qualitative data from focus groups, and feedback logged within the chatbot app.

Ethical Considerations

Ethics approval was granted by The Prince Charles Hospital Human Research Ethics Committee (HREC Project ID: 69623). Written informed consent was obtained from all participants before taking part in the study, and they were free to withdraw at any time. End user participants who completed a focus group were given an Aus \$40 (US \$26.65) gift card. Focus group transcripts were deidentified prior to analysis, and logged in-app feedback was anonymous.

Recruitment and Participants

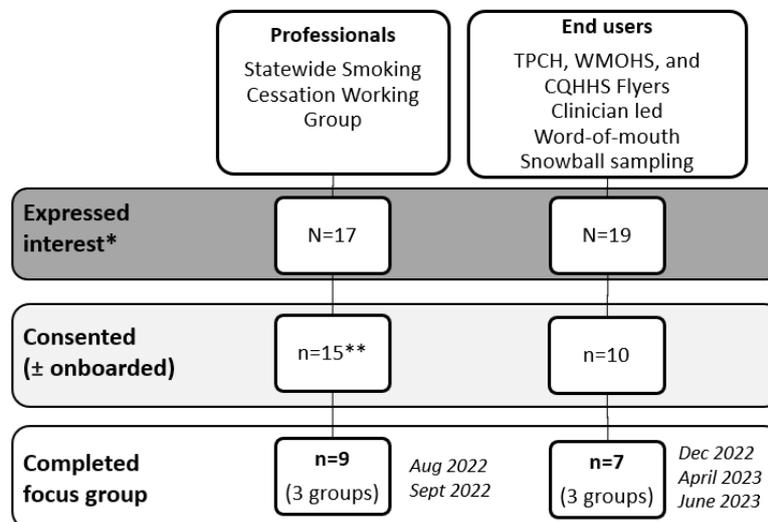

Multiple methods of active and passive recruitment were used. SCPs from the Queensland State Health Department (Statewide Smoking Cessation Working Group and Quitline) were invited

to participate via email distribution lists. End user recruitment was broad and included priority populations for smoking cessation assistance, such as people from regional or rural areas, older people with respiratory conditions or diseases, and people from low-income areas. Targeted recruitment included electronic flyer distribution via a regional public health unit to associated community organizations and physical flyer distribution via clinicians and visual display within respiratory clinics and mental health units at The Prince Charles Hospital and dental clinics at West Moreton Hospital and Health Service. We also recruited end users via word of mouth and snowballing methods. Inclusion criteria for end user participants were people aged 18 years and older who self-identify as currently smoking, either not ready or attempting to quit smoking, or have recently quit smoking (within the previous 12 months); were English-speaking; and owned a smartphone (Apple or Android) and could download apps. Participants who expressed interest were sent an electronic participant information and consent form via the survey platform REDCap (Research Electronic Data Capture; Vanderbilt University) hosted at The University of

Queensland. Following informed consent, participants were sent an electronic survey to collect demographic and smoking

and quit history information. The recruitment process is outlined in [Figure 2](#).

Beta Testing Procedures and Focus Groups

Consenting participants were onboarded to the Quin app 1 to 2 weeks prior to their scheduled focus group. Onboarding meetings with the lead researcher (HB) or a research assistant were completed via videoconferencing with a summary email of written instructions or only via a summary email if a participant was not available to videoconference. These meetings allowed the research team to assist with downloading the beta version and to provide general testing instructions to maximize the collection of user feedback. Users were encouraged to create multiple demographic profiles to test chatbot responses to different combinations of information and were instructed how to log feedback within the app if anomalies were found (eg, spelling errors and incorrect responses). Logged feedback was stored on a Google Firebase server. Study team members were available to assist with any issues during the testing period.

SCP focus groups were completed first to ensure the accuracy and breadth of smoking cessation information provided within Quin. Following prioritization and incorporation of feedback from SCPs as major updates, end user focus groups were completed. All focus groups were held via videoconferencing. To improve anonymity, participants had the option to leave their camera off and use their first name only (eg, username and in discussion). The focus groups were moderated by the lead investigator (HB), an early career researcher who has formal training and experience in qualitative research as well as expertise in health promotion and public health. Senior researchers SL and/or HMM were present during focus groups to take notes and assist with probing or follow-up questions where applicable. SL is an experienced qualitative researcher with expertise in health psychology, health promotion, and public health. HMM is a thoracic medicine specialist with a bachelor of psychology (honors) and research interests in smoking cessation interventions. At the end of the focus group, upon departure of participants, the investigators remained in

the meeting to reflect on the session, feedback, and notes taken. The focus group sessions followed a Human Research Ethics Committee–approved interview guide ([Multimedia Appendix 1](#)) based on the categories of feedback within the end user version of the Mobile App Rating Scale [26] but allowed for probing and follow-up questions to expand on discussion. End users were asked exploratory questions regarding smoking and quitting histories and barriers and enablers to smoking cessation as well as experiences, if any, using mCessation apps; SCPs were asked similar questions reframed as their experience of what clients commonly tell them. The moderator ensured all participants were given an opportunity to speak and expand on others' ideas. Focus groups were recorded, transcribed verbatim, and deidentified prior to analysis. All participants had the option to continue testing the app and provide additional feedback after their focus group.

Analysis

Quantitative data from demographic surveys were analyzed descriptively. In-app feedback was downloaded from Google Firebase after completion of all SCP focus groups and after each end-user focus group. This feedback was categorized using content analysis, reviewed, and prioritized for incorporation into Quin by all investigators.

Focus group transcripts were imported into NVivo software (version 12; Lumivero), and analysis was completed in 2 ways. First, after completion of all SCP focus groups, transcripts and notes were reviewed by HB to identify key improvements to be made prior to end user focus groups. These findings were presented, discussed, and agreed upon by our multidisciplinary research team before updates to Quin were made. This approach is reflective of Agile development methods, and we present major changes to Quin using theme, epic, stories, and tasks [27]. Second, following the completion of all focus groups, transcripts were analyzed inductively by HB and SL using thematic analysis [28]. To address the aim of the study, 1 researcher (HB) broadly

coded data into categories of positive and negative feedback and suggestions for improvement. Both study team members then generated an initial set of codes within each category, which were reviewed and combined to define and refine themes and subthemes. Disagreements in data interpretation and theme development were able to be resolved via discussion between HB and SL, but a third researcher (HMM) was available to discuss differences in interpretation during thematic analysis. We present the themes and subthemes, including direct quotes, by aforementioned categories and compare and contrast feedback between professionals and end users.

Results

Overview

Three focus groups of 9 SCPs were completed in August (n=4) and September (n=3; n=2) 2022 testing Quin (beta version 21).

Three focus groups of 7 end users were completed in December 2022 (n=3) and April (n=2) and June (n=2) 2023, testing Quin beta versions 28, 30, and 31, respectively. The mean duration of focus groups was 58 (SD 10.9; range 46-74) minutes. Participant demographic characteristics are summarized in [Table 1](#). Occupations of SCPs included clinical nurses, occupational therapists, pharmacists, Quitline telephone counselors, and health promotion officers across metropolitan, rural, and Indigenous health services, of which the majority (n=8) delivered smoking cessation counseling and advice regarding nicotine replacement therapy. Most end users currently smoked cigarettes on a daily (n=3) or less than daily basis (n=2), and 2 had quit smoking. Nicotine dependence scores were calculated using the Fagerström Test for Nicotine Dependence [29], but results may be unreliable, as most end users anecdotally indicated they had fully or partially (ie, dual use) transitioned to e-cigarettes (either as a tobacco product or cessation aid) and answered the questions in the context of cigarette smoking.

Logged Feedback

In total, 46 instances of feedback were logged within Quin by 6 SCPs. Feedback related to pattern matching errors (ie, user inputs were misinterpreted or unable to be detected by the chatbot; n=13, 28%); missing conversation trees (ie, topics that require more than 1 response; n=6, 13%), smoking cessation information (n=9, 20%), and responses (ie, information to be programmed; n=8, 17%); logic issues (ie, the decision to enter a conversation tree; n=4, 9%); dialogue content (n=2, 4%); spelling or grammatical errors (n=2, 4%); notifications (n=1, 2%); and user interface (n=1, 2%). In contrast, 4 end users logged 9 instances of feedback related to logic issues (n=2, 22%), pattern matching errors (n=2, 22%), missing responses (n=2, 22%), dialogue content (n=1, 11%), notifications (n=1, 11%), and user interface (n=1, 11%).

Major and Minor Updates to Quin Between Cohorts

Two major updates were made to the Quin prototype between versions 21 and 28 following a review of the focus group and logged feedback from the SCPs, a process illustrated in [Figures 3](#) and [4](#). First, we reviewed and implemented changes to the

conversation flow to improve the visual delivery of information within the app. This included consolidating information into smaller dialogue bubbles, including links to relevant resources, and slowing the delivery of information by including a timer based on the length of text and animated ellipses to indicate the chatbot “typing.” Second, we designed and implemented a conversation tree to better handle instances when a user may be craving a cigarette (ie, a “Moment of Crisis”). Quin was programmed to identify more statements that suggest an acute craving and to work sequentially through pharmacotherapy options and behavioral strategies depending on the context of the craving (ie, trigger), of which questions or responses were tailored if the user had created a quit plan. Quin was also programmed to check in with the user to see if the craving had passed and offer positive reinforcement or more options for strategies.

Other minor updates were made between versions to correct errors and improve functionality based on logged feedback, which included spelling errors, connecting programmed but inactive conversation trees, coding missing pattern matching or sentiment analysis, and updates to the chatbot dialogue and smoking cessation information.

Figure 3. Changes to conversation flow using Agile methods.

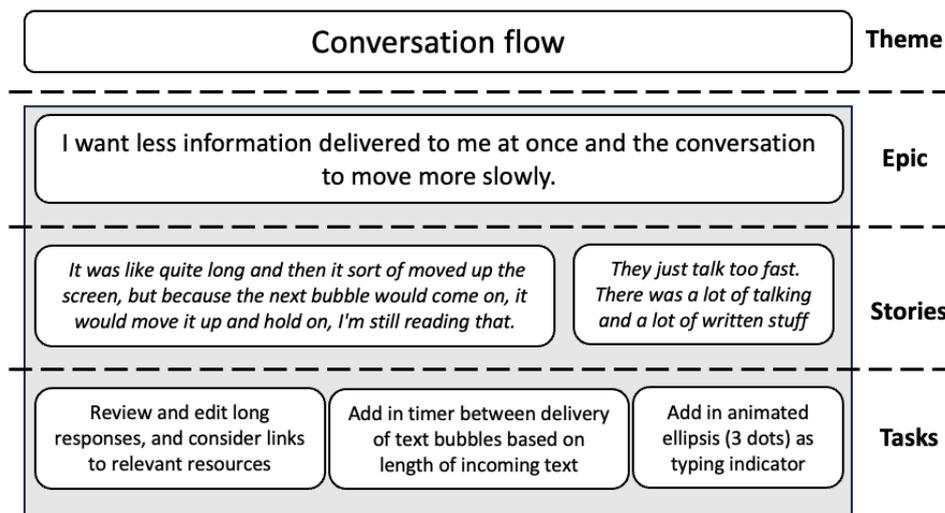

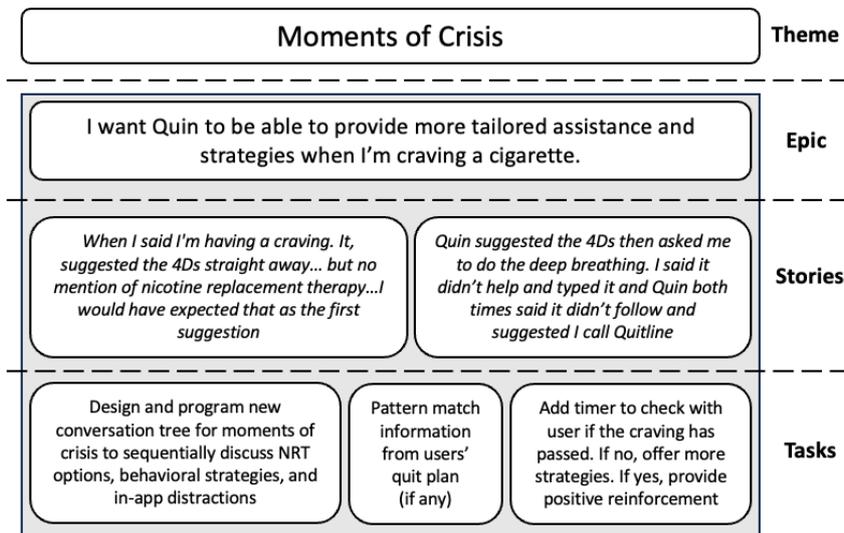

Figure 4. Changes to the conversation in response to acute cigarette cravings using Agile methods. NRT: nicotine replacement therapy.

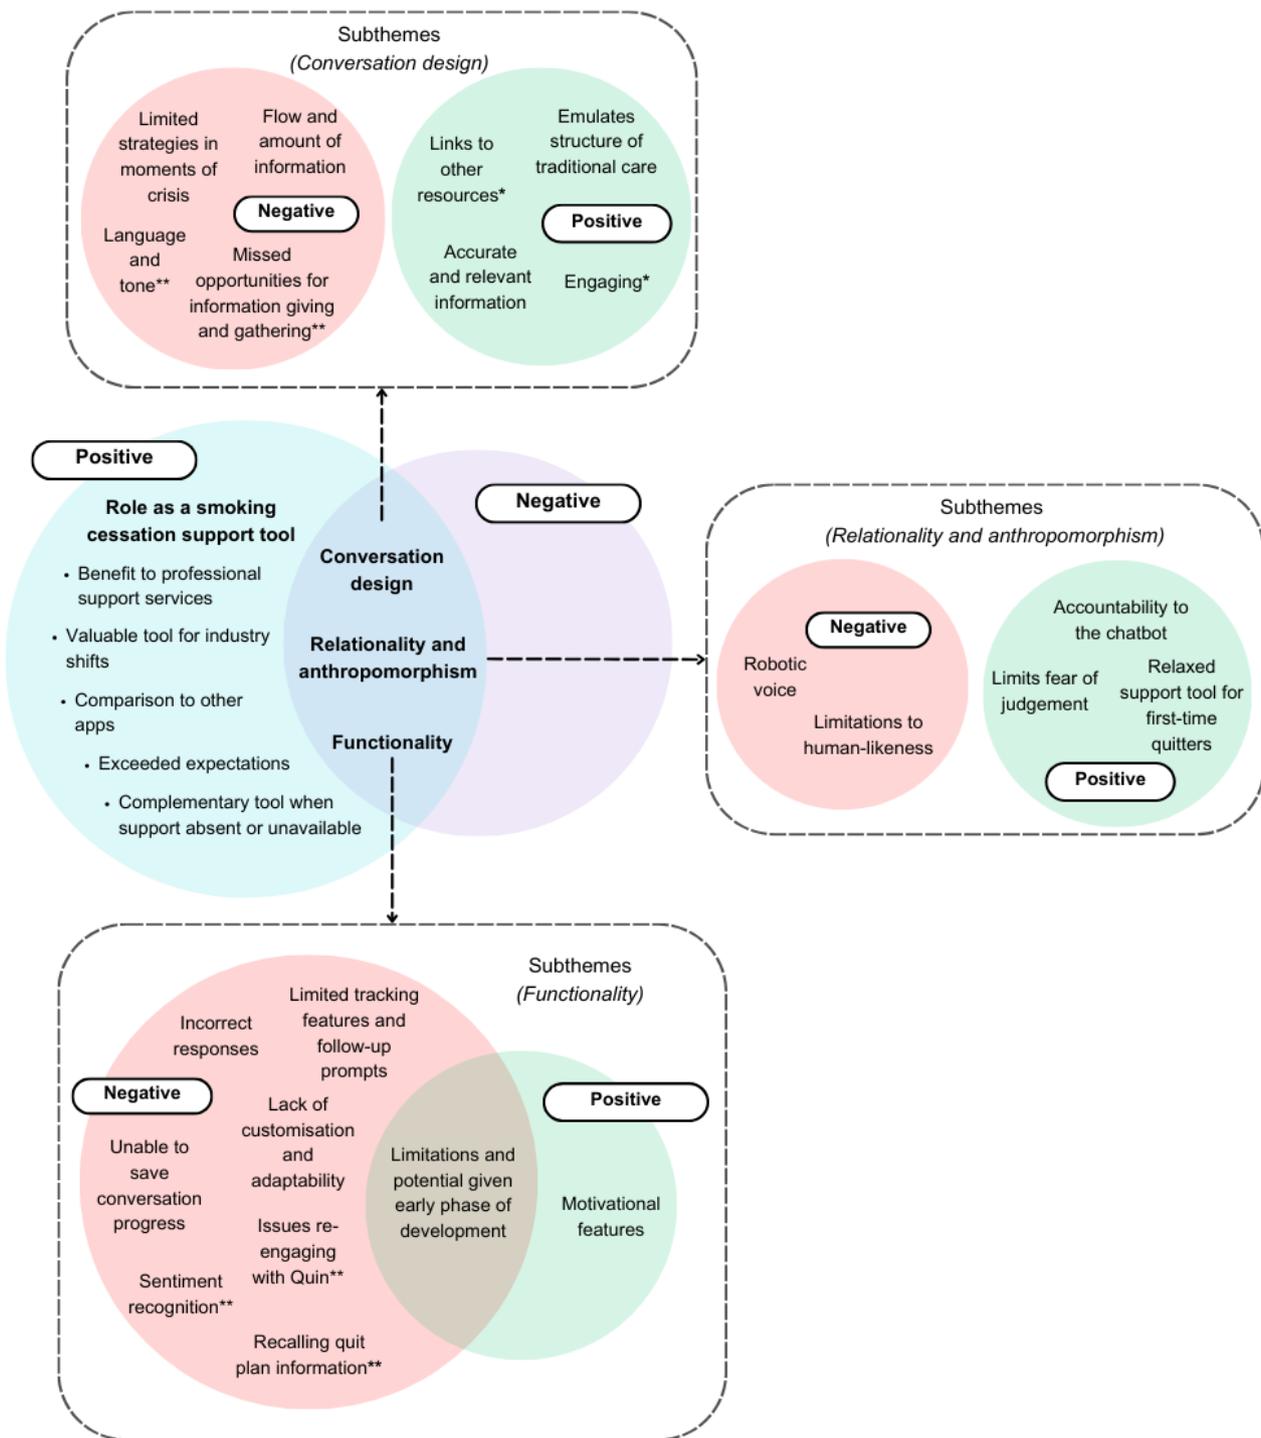

Feedback Themes

Overview

Four high-level themes encompassing positive and negative user feedback were identified (Figure 5). While these themes

are reported separately, there was a crossover between them within individuals' feedback, given the technical connection between the features. We also provide a summary of chatbot design recommendations based on this feedback (Textbox 1).

Figure 5. Positive and negative feedback themes and subthemes. SCP: smoking cessation professional. *End users' feedback only, **SCPs' feedback only.

Textbox 1. Summary of recommendations for smoking cessation chatbot design based on focus group feedback.

Smoking cessation support features

- Provide tailored assistance in moments of acute cravings
- Ability to develop a quit plan based on previous experiences and personal preferences
- Follow-up conversations for user self-reflection on quit plan
- Proactive check-in times and notifications to enhance the sense of accountability
- Accurate educational content and cessation information
- Ability to integrate into or complement existing services (eg, preparation tool and after-hours support)
- Offer distraction and motivational tools within the conversation (eg, photo upload and tracking tools)

Conversation design

- Maximize opportunities for personalization and information gathering or giving
- Speed (delivery) of chatbot responses should emulate human conversation (eg, typing)
- Outsource large amounts of information by linking to other resources
- Include positive reinforcement in responses
- Limit the cyclical nature of conversation trees

Functionality

- Avoid errors in responses and sentiment analysis
- Include safeguards and referral pathways when the chatbot is unable to respond
- Automatically save progress within conversations
- Automatically save, store, and recall user-defined quit plan
- Ability to respond to changing preferences and information

Conversation Design

A key omission from the conversation reported by SCPs was Quin's ability to provide assistance when the user is experiencing a cigarette craving by suggesting rapid-acting nicotine replacement therapy and behavioral strategies. As such, this feedback informed the inclusion of the "Moments of Crisis" conversation tree (Figure 4). The first iteration of this conversation tree was then tested by end users; however, limitations to Quin's ability to respond correctly or appropriately in these instances were also reported.

At times, SCPs found the amount of information being delivered was too much and too fast, which disrupted the visual flow of information as they needed to scroll back through the conversation to read Quin's responses. This feedback informed the previously described updates to the conversation flow (Figure 3). Progression through the conversation, such as when to type a response or use a radio button, was also unclear to some SCPs. After updates were made between cohorts, this issue regarding conversation flow was not raised by end users during open discussion, even when prompted.

Participants across both cohorts found the information provided within Quin to be accurate, relevant, and educational. Some end users reported a humanlike feel to the dialogue content and visual conversation flow and appreciated outsourcing large amounts of information by linking to relevant resources as a more efficient way to learn.

It did link to those videos. And one thing that I appreciated was, it was clearly YouTube content that I'd been pushed towards rather than Quin ... I've noticed that Quin, quite cleverly, never has more than a really easily digestible amount of prose that that comes back. And I thought that was a really cool feature. [End user 1, Focus group 5]

Even the little dot dot dots to make you think that it's typing, I think that's really cute. Obviously it needs a moment to process, and that makes you think that you're talking to a human, it really does feel like you're having a chat with someone it's not like for the most part generic robot answers ... for the most part the conversation style with the bot was really good. [End user 3, Focus group 4]

End users and SCPs also thought the conversation structure emulated that of traditional care, in that users had the ability to form a quit plan alongside receiving smoking cessation information. Furthermore, reminders about aspects of their quit plan within future conversations with Quin were found to be motivating by one end user.

I really like this app because there's the information as well as the planning side of things. [SCP 3, Focus group 2]

One end user noted the chatbot conversation to be quite cyclical and scripted but also acknowledged the resources needed to expand the scope of the technology to improve this. Missed

opportunities for giving and gathering information were identified by SCPs including limited prompts to see a general practitioner and asking users about motivations or reasons for previous quit attempts and caffeine and alcohol use. Finally, one SCP perceived the tone of a specific response related to quitting unassisted (ie, cold turkey) to be slightly patronizing and provided suggestions to better promote positive reinforcement. In contrast, no end users commented on the tone of the chatbot dialogue.

I found the tone of it was probably a little bit condescending. It was like, "Oh, well, you must have great willpower to do that," and it didn't kind of go on any more to say, "Hey, Great! That's great. Have a try. But remember, we've got lots, lots of options." [SCP 1, Focus group 2]

Functionality

Issues with chatbot functionality recounted across cohorts were largely related to its inability to respond correctly to some user inputs, which occasionally resulted in the conversation to end abruptly. There were also instances where negative sentiment in users' language was not recognized.

Frustration was expressed by both cohorts when progress was lost during the initial "appointment," as the conversation did not save when they left the app and suggested to include an indication of time required to complete the first conversation. Issues re-engaging with Quin to restart the quit plan discussion and recall quit plan information were also raised.

I sort of got halfway through ... when I went back in it didn't sort of pick up where we left off. I found myself having to start again. That was a yeah, a peeve moment for me. [End user 1, Focus group 5]

End users and SCPs reported a lack of customization for user responses to some questions as well as limited adaptability of chatbot responses to changing quit preferences and information.

I've gone in a couple of times since then, typed in questions ... "I'm not having any luck with cold turkey. Can I follow up with something else." And I think I got an exploding robot, so no response. [SCP 1, Focus group 2] *Represents Quin not being able to provide a response*

Despite the issues highlighted, many participants (largely end users) acknowledged the functionality and potential of Quin relative to its early phase of development and limited resources. Participants from both cohorts reported being able to complete an initial conversation and set up a quit plan. Motivational features prompted by the chatbot, such as the ability to upload images and the cost analysis of money saved per year, were valued by end users.

The app is really good in that I can pick up the app, which I have been using a lot, I look at my motivations, so what a picture of myself and my husband ... They're really really motivating as well. [End user 2, Focus group 5]

Relationality and Anthropomorphism

Both cohorts described limitations to Quin's ability to emulate humanlike characteristics and how this impacted their user experience. Most participants expressed they felt like they were talking to a robot, and this feedback was often linked to functionality issues. Some end users did report they initially felt like they were talking to a human, but errors in chatbot responses impaired this effect, causing frustration, which discouraged them from continuing to use it.

End user 2: You think you're talking to someone. And then, when that happened, you're like, "Oh, this is just a bot," and it actually annoys you and makes you go well exit... I'm not talking to this thing. Yeah I had that feeling a couple of times with it.

End user 1: Yeah, the same thing. You're talking to it ... You think you're talking to a person, and then ... it answers to something totally irrelevant. Well, I think. "Oh it's a machine I'm talking to." [Focus group 4]

End users highlighted the benefit of Quin being an impartial proactive support for a quit attempt. Some participants expressed a sense of accountability to the chatbot and appreciated the nonconfrontational nature of the interaction, which in turn limited the fear of judgment. As such, it was a relaxed support tool for first-time quit attempts and a source of positive reinforcement.

I think it would be useful for me ... It would keep me honest. Asking me you know "How many of you smokes have you had today? When did you have your last smoke?" Things like that. Yeah, it would keep me honest. [End user 1, Focus group 4]

I totally agree with ... End user 1 who said about the chatbot feature being non confronting instead of having to talk to someone. I definitely think that would help. You know, countless people who don't really want to talk about it face-to-face with someone. [End user 2, Focus group 4]

Role as a Smoking Cessation Support Tool

End users from all focus groups believed the chatbot app was an appropriate and acceptable support tool for smoking cessation. For some, their experience exceeded their expectations, in that they simply enjoyed using the chatbot or they got more cessation support or educational benefit from the technology than anticipated.

It was a good tool to bounce back at myself. Which I honestly can say I didn't expect from a bot. It was, it was much more helpful than I thought it would be, even though I'm not actually in the process of quitting smoking. I still found it quite like a quite positive experience to use. [End user 1, Focus group 6]

Encouragingly, an end user found it provided them the extra support they needed during their current quit attempt. Others felt that Quin was more helpful in comparison to other smoking cessation apps due to the educational content and interactivity with the chatbot. More importantly, one end user also

highlighted the benefit of the potential for rapid adaptability of this technology in response to new health challenges and cessation support as a result of industry shifts (eg, vaping prevalence and cessation support).

Ease of access to smoking cessation information and support was seen as a key benefit by both cohorts. From the perspective of SCPs, the chatbot had the potential to integrate into and complement their services as both a client preparation tool and proactive complementary tool alongside professional support including when this support is unavailable (ie, after hours).

I think that that is an awesome concept for anything after hours, you know, if you're really really struggling at like three o'clock on a Sunday morning. You can still feel like interacting and getting immediate responses rather than just, you know, reading something that's already there printed. I think you know it's just a good to know that you can have an answer 24/7 essentially, I think that that's really great. [SCP 2, Focus group 3]

The idea of being able to share information from the app with Quitline could be a very beneficial thing ... they've got the background on the client, and it's a really straightforward-based way to start a conversation ... So I think it's a great way to, yeah, it kind of builds rapport. It's strength based ... and possibly cuts down on a bit of time as well, which would be valuable for the individual client as well as the service. [SCP 3, Focus group 2]

Discussion

Principal Findings

This focus group study, with an embedded beta testing process, aimed to explore SCP and end user feedback on the user experience of a prototype smoking cessation chatbot. We found the qualitative feedback to be similar between cohorts; yet, some feedback subthemes were also exclusive to cohorts, with end users reporting more positive feedback and SCPs reporting more critical feedback. This is likely due to major updates made to Quin between cohorts but may also reflect differing priorities and expectations placed on the chatbot by SCPs and end users, which is a trend we have observed in our previous study of smoking cessation apps [23]. Overall, initial testing feedback on the user experience from both participant cohorts shows promise for Quin as an acceptable smoking cessation support tool; however, aspects of usability require improvement. Our findings build upon and reinforce previous qualitative research on user experiences with conversational agents for smoking cessation [13,18,19,30], and results will be incorporated into future iterations of Quin to produce a mature prototype for clinical testing.

Comparison to Prior Work

Key benefits of Quin highlighted across cohorts included the smoking cessation information being relevant and acceptable and the accessibility of the chatbot as an impartial support tool. Smoking cessation often requires a multifaceted individualized approach [31], delivered over a medium- to long-term period

of months to years; expanding the avenues of behavioral support is a step toward overcoming barriers to care. Consulting with SCPs allowed us not only to ensure the accuracy of the information but also to explore the potential interoperability and integration of Quin within their professional services, with many acknowledging it as a preparation tool for both the client and counselor prior to a course of care and support tool outside of service hours. Previous research has found people disclose information to and interact with chatbots similarly to how they would a human [32], and in the context of smoking cessation, that chatbot support was superior to that of family and friends [19]. Participants in our study identified Quin as supportive, nonconfrontational, and nonjudgmental. This finding reflects previous qualitative inquiries, which found that groups of sexual and gender minority young adults [30] and veterans [18] found embodied conversational agents provided nonjudgmental and/or humanlike smoking cessation support. Future first-time clients may therefore feel more comfortable providing smoking and quit histories to Quin, from which a counselor could use this information to build rapport with the client or clients may wish to only engage with Quin due to feelings of judgment or shame commonly experienced by people who smoke.

Our findings are consistent with those reported in a similar qualitative study [19], in that the sense of accountability to the chatbot reported by end users partially supports Mohr's model of "Supportive Accountability" [14]. The model states that engagement with digital health interventions is promoted with the addition of human support by fostering a sense of personal accountability to a legitimate, trustworthy, and caring coach [14]. This qualitative study of 14 people found that engagement with, and feelings of accountability to, a smoking cessation chatbot was attributed to the humanlike features and interaction style of the chatbot alongside users' perceived need for support [19]. However, the legitimacy and trustworthiness [14] of Quin beta versions may have been compromised by functionality issues, which impeded the relationality of the chatbot as a coach. Therefore, improved functionality must be consistent to sustain its legitimacy as a coach.

All participants across cohorts expressed negative feedback regarding the usability and user experience of Quin among aspects of conversation design, functionality, and relationality. Given the technical connection between these features, the functionality of the AI system is at the core of these identified issues. When we consider the usability goals described by Rogers et al [25], the reported inefficiencies in Quin primarily affected the utility (eg, limited tracking features and follow-up prompts) and efficiency (eg, unable to respond correctly). A key design feature of Quin is that the conversation is largely driven by free-text responses via a rule-based system to enhance user engagement and better emulate traditional human support. Previous qualitative research has also found that this approach to smoking cessation chatbot design is preferred by end users, in that responses and questions are tailored and relative to their momentary needs and situations [19]. While Quin's current response system allows for adaptability and greater control over the accuracy of health information being provided, it is limited, in that it requires a defined structure with comprehensive coding of all potential utterances, which may increase the chance of

errors, and health information needs to be reviewed and updated on a regular basis. Yet, to rely solely on a predictive model may increase the risk of incorrect information being delivered, which in the context of health behavior change could be problematic or even counterproductive, and limit the degree of personalization in responses [33]. Moreover, rule-based systems require relatively small computational and memory resources and can operate on a mobile device greatly increasing the privacy of user data with minimal operating costs. Most predictive models of suitable performance operate as a server accessible via the internet and require human utterances to be transmitted to the server potentially exposing sensitive data that may be intercepted by a hostile actor. Furthermore, there are known ethical issues and biases associated with the collation and marking of large amounts of training data required for predictive models [34], which can further compound existing inequalities (eg, sex, race, ethnicity, and socioeconomic status). However, the high flexibility of such systems is persuasive, and we believe future technological advances may resolve some of these issues. Therefore, we suggest that a carefully balanced combination of a rule-based system with a more flexible predictive model may improve the adaptability and relationality of a conversational agent intervention as a digital coach.

Contrasting feedback between cohorts following major updates lends support to the Agile development process. Significant changes made to the delivery of information within Quin were validated through end user focus group feedback, with most finding the dialogue and visual conversation flow emulated that of a human and observing specific updates (eg, animated typing ellipses and outsourcing information to links). A similar iterative development process between participant cohorts has also been used in the training of an automated motivational interviewing-based chatbot for unmotivated people who smoke [13]. The traditional path to market for medical devices and pharmaceutical products consists of 4 sequential clinical evaluation phases to determine safety, efficacy, dosing, and effectiveness [35]. In contrast, digital health product development is dynamic and nonlinear due to the rate at which technology evolves and can be modified. Agile development processes allow for greater flexibility and ability to adapt to continuous iterative feedback. Like co-design, Agile methods also prioritize collaboration between developers and end users for effective solutions [36].

Future Directions

Finally, there are potential opportunities for Quin's development and future role in smoking cessation services. Quin's dialogue is continually modifiable, and the benefit of this technology is that it can be easily updated to reflect changing evidence or advice in response to industry shifts and new health challenges and tailored to target specific population groups. The Quin prototype in its current state is the foundation, upon which we plan to iteratively build using our co-design methodology to analyze Quitline cessation support for priority groups (eg, people who are pregnant) and e-cigarette use and to ultimately work backward toward a theory-informed intervention. The accessibility of Quin will allow it to complement and support

existing counseling services and primary care. For example, Quin may act as a liaison to initiate cessation support on an on-demand basis after-hours or for the time between referral and initial contact, ideally with interoperability with relevant patient management or health systems to promote continuity of care. Conversely, as previously mentioned, Quin alone as the anonymous coach may be the preferred form of cessation support for people reluctant to access services.

Strengths and Limitations

A strength of this study was the early involvement of key stakeholders in the app development process through an open and informed dialogue. This is an important stage of co-design for digital inclusion [22] and is considered a principle of digital development [37]. Furthermore, the capacity to review and incorporate key feedback between cohort groups allowed for the validation of some updates, evidenced by changes in feedback following major updates to the conversation flow. We also included a variety of end user participants across most age groups, including older age participants who are a key demographic for smoking cessation and mobile health interventions as well as participants from regional and remote locations. However, there are several limitations to this study. First, our participation rate in focus groups was low due to attrition. While we made many efforts to engage with potential participants, some did not respond after contacting the study team to express interest in participating or after consenting or were unable to attend the focus group after being onboarded to the app. As such, our recommendations for smoking cessation chatbot design are limited in their generalizability. Second, current objective nicotine dependence scores among end users were mostly low, which may limit the generalizability of our findings, as people with higher nicotine dependence may have different experiences and needs. This should also be interpreted with caution, as most end users reported in the focus groups that they had transitioned to disposable e-cigarettes, which are known to contain high levels of nicotine, and their use is not captured in the assessment. As such, the true level of nicotine dependence was likely higher among end users. Nevertheless, all end user participants, and some SCPs, had recent previous experience with daily cigarette smoking from a young age and multiple quit attempts. Third, while we encouraged open and honest feedback, a degree of social desirability bias may have influenced subjective feedback.

Conclusions

Feedback from end users and SCPs on the user experience of the Quin prototype highlighted the importance of functionality and its impact on the conversation flow and relationality of chatbot technology. Despite this, participants recognized the benefit of Quin to provide easily accessible information, nonjudgmental support, and positive reinforcement, including how this can complement existing cessation support services. Ongoing development will incorporate these findings to produce a mature prototype for clinical testing, and the design recommendations provided may assist future smoking cessation chatbot developments.

Acknowledgments

The authors would like to thank David Oates for his assistance with onboarding smoking cessation professionals. The authors would also like to thank Jenny Peek, Kalie Green, and Dr Kelly McGowan for their assistance and support with end user recruitment at The Prince Charles Hospital, Central Queensland Hospital and Health Service, and West Moreton Hospital and Health Service, respectively. This work was supported by a New Investigator Grant (NI2021-31) awarded to HB from The Prince Charles Hospital Foundation and by an Investigator Grant (GNT1178331) from the National Health and Medical Research Council awarded to HMM. HB receives a top-up scholarship from the Commonwealth Scientific and Industrial Research Organisation. CG is supported by an Australian Research Council Future Fellowship (FT220100186) and holds funding from National Health and Medical Research Council grants (GNT1198301 and GNT2019252).

Data Availability

The data sets generated and analyzed during this study are not publicly available due to ethical considerations, as the qualitative data are of personal nature and are only available to the study team on approved servers.

Conflicts of Interest

None declared.

Abstract

Background: Secondary prevention is an important strategy to reduce the burden of cardiovascular disease (CVD), a leading cause of death worldwide. Despite the growing evidence for the effectiveness of digital health interventions (DHIs) for the secondary prevention of CVD, the majority are designed with minimal input from target end users, resulting in poor uptake and usage.

Objective: This study aimed to optimize the acceptance and effectiveness of a DHI for the secondary prevention of CVD through co-design, integrating end users' perspectives throughout.

Methods: A theory-driven, person-based approach using co-design was adopted for the development of the DHI, known as INTERCEPT. This involved a 4-phase iterative process using online workshops. In phase 1, a stakeholder team of health care professionals, software developers, and public and patient involvement members was established. Phase 2 involved identification of the guiding principles, content, and design features of the DHI. In phase 3, DHI prototypes were reviewed for clarity of language, ease of navigation, and functionality. To anticipate and interpret DHI usage, phase 4 involved usability testing with participants who had a recent cardiac event (<2 years). To assess the potential impact of usability testing, the System Usability Scale was administered before and after testing. The GUIDED (Guidance for Reporting Intervention Development Studies in Health Research) checklist was used to report the development process.

Results: Five key design principles were identified: simplicity and ease of use, behavioral change through goal setting and self-monitoring, personalization, system credibility, and social support. Usability testing resulted in 64 recommendations for the

app, of which 51 were implemented. Improvements in System Usability Scale scores were observed when comparing the results before and after implementing the recommendations (61 vs 83; $P=.02$).

Conclusions: Combining behavior change theory with a person-based, co-design approach facilitated the development of a DHI for the secondary prevention of CVD that optimized responsiveness to end users' needs and preferences, thereby potentially improving future engagement.

Introduction

Patients with coronary heart disease (CHD) are at high risk of recurrent cardiovascular events [1], with 1 in 5 experiencing a recurrent event in the first year after hospital discharge [2]. To minimize this risk, guidelines recommend early initiation of evidence-based, secondary prevention lifestyle and pharmacological treatments, together with access to a cardiac rehabilitation (CR) program [1,3]. However, in reality, only a minority of patients with CHD achieve optimal risk factor control and less than a half attend CR, usually several weeks or even months after hospital discharge [4]. The promising role of digital health interventions (DHIs), including mobile health (mHealth) apps, in addressing this implementation gap is increasingly recognized [5]. Indeed, the widespread availability of smartphones and mobile devices means that mHealth apps are one of the most common types of DHIs being developed to improve the secondary prevention of CHD [6,7].

mHealth apps have the potential to enhance patient empowerment and self-management [8], with growing evidence to support their use for secondary prevention of cardiovascular disease (CVD) [5]. Recent meta-analysis data show that mHealth apps can improve exercise capacity, physical activity, adherence to medication, and quality of life, as well as reduce hospital readmissions in patients with CHD [9]. However, beyond the research setting, the uptake and usage of health apps is low [6,10,11]. In addition, there is limited understanding of how these apps are developed and what their "active ingredients" include [12,13].

Involving end users in the design and development of DHIs is recognized as essential to maximizing their acceptance, uptake, and effectiveness [5,14]. Despite this, the majority of mHealth apps are designed with minimal input from target end users [13]. For example, in a recent scoping review, the use of co-design methodologies in the development of CVD secondary prevention interventions was reported in only 4 out of 22 studies related to mHealth apps [15]. Furthermore, none of these studies reported using a theoretical framework to guide the development of the intervention, including the use of theory-based behavioral strategies. Although this absence of reporting is not uncommon [16], it impacts on our ability to understand which parts of digital behavior interventions contribute to outcomes [17].

For DHIs to reach their full potential, we need to better understand how they are developed and what the core elements

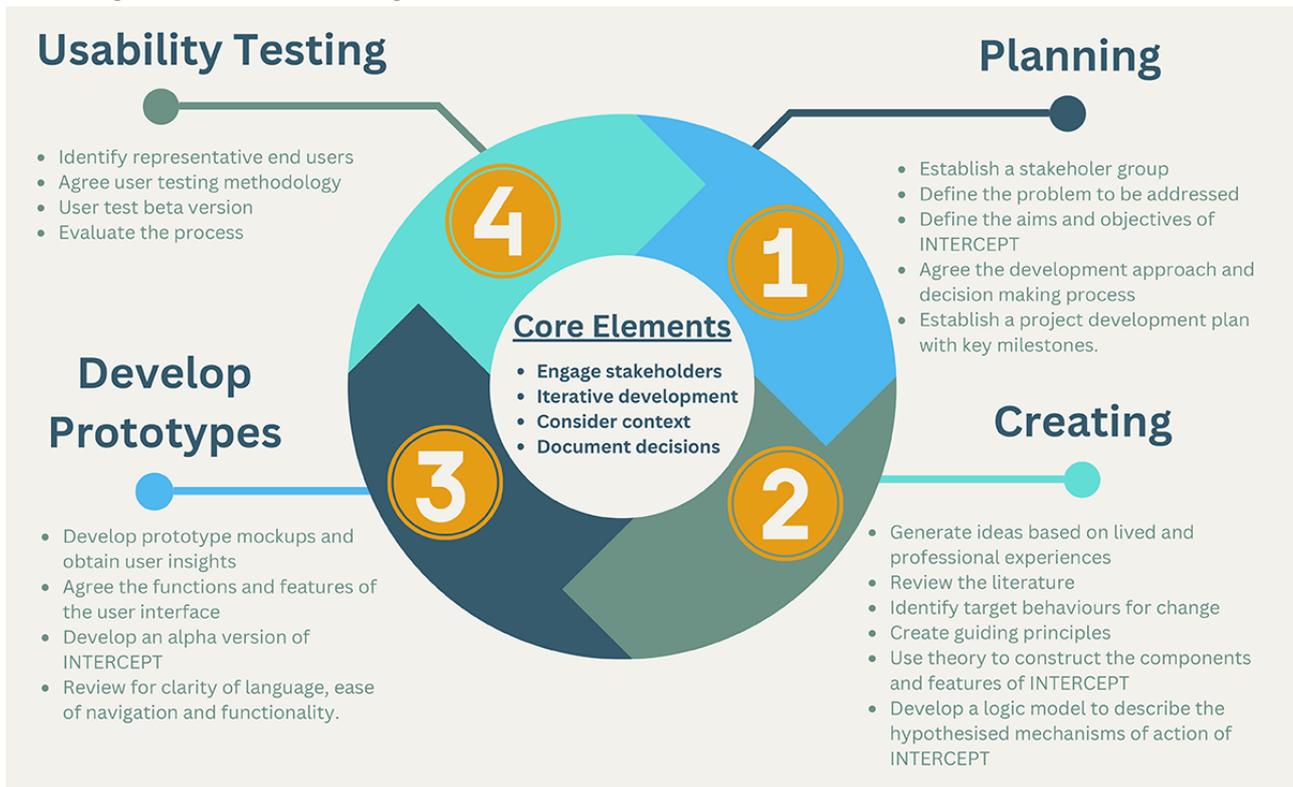

of effective interventions are [13]. This paper aims to describe the development of a multicomponent, complex DHI called "INTERCEPT" to improve secondary prevention in patients with CHD. Developed by the Irish National Institute for Prevention and Cardiovascular Health, INTERCEPT aims to promote self-management and support patients to achieve a healthy lifestyle, manage CVD risk factors, and improve adherence to cardioprotective medications. It includes an mHealth app, which integrates with a web-based health care professional (HCP) portal, a fitness wearable, and a blood pressure monitor. Responding to the need for early initiation of prevention after an index event [1], particularly given delays in patients accessing traditional (CR) programs [18,19], INTERCEPT is designed to be introduced to the patient at the time of their acute hospitalization and before discharge home. In this way, it provides a bridge to CR or an alternative for patients who choose not to join a CR program.

To maximize the potential effectiveness of INTERCEPT, the aim of this study was to adopt a theory- and evidence-based approach to development, integrating end users' (patients and HCPs) perspectives throughout. We use the term "development" to capture the whole process from initial planning to designing and usability testing.

Methods

Overview

We used a theory-driven, person-based approach to the development of INTERCEPT in an iterative co-design process. Our overall approach was guided by the UK Medical Research Council (MRC) framework for developing and evaluating complex interventions [20]. While co-design refers to meaningful end-user engagement across all aspects of intervention development [14], the person-based approach focuses on the psychosocial context of users and the behavioral elements of an intervention [21]. Through a series of qualitative workshops, conducted between May 2021 and December 2022, we adopted a 4-phase approach to development (Figure 1). As development commenced during the COVID-19 pandemic, all workshops were conducted online (Zoom, Zoom Video Communications). This paper is reported in accordance with the GUIDED (Guidance for Reporting Intervention Development Studies in Health Research) checklist (see Multimedia Appendix 1) [22].

Figure 1. Four phases of INTERCEPT development.

Phase 1: Planning

To ensure a diverse and inclusive approach to intervention development, an interdisciplinary stakeholder team was established. This comprised HCPs, software developers, and members from the public and patient involvement (PPI) panel of Croí (Gaelic for heart)—an Irish heart and stroke patient organization. Membership was determined by the individual's relevant expertise in the secondary prevention of CVD, including the design of complex DHIs; health behavior change; software development; and lived experience of CVD. To establish meaningful partnership relationships and enhance engagement, roles and responsibilities were agreed upon from the outset and a process for documenting and making decisions was established [15]. Furthermore, to enable stakeholders to participate to the best of their capabilities, a flexible and supportive approach to development was adopted. For example, workshops were centered around participant availability, and supports to address digital health literacy challenges were made available. Initial meetings focused on project conceptualization and identifying the key needs and challenges to be addressed. This led to the development of the intervention aim and objectives and identification of specific target behaviors for change. These behaviors were related to lifestyle (smoking cessation, making healthy food choices, and increasing physical activity), CVD risk factor management (blood pressure, lipids, and glucose), and adherence to cardioprotective medications. A project plan with key milestones for developing INTERCEPT was established.

Phase 2: Creating

This phase aimed to identify the guiding principles, including the design objectives, content, and features of INTERCEPT. In

keeping with the person-based approach, guiding principles help to keep development focused on what is appealing and useful to the intended user, thus helping to maximize its acceptability and effectiveness [21]. INTERCEPT guiding principles were developed by (1) synthesizing the literature [10,23-26], (2) drawing on the stakeholders' clinical and research experiences of developing and implementing DHIs [26-28], and (3) obtaining patient lived experience insights. Informed by these principles, we used social cognitive theory (SCT) [29] and select behavior change techniques (BCTs) from the behavior change taxonomy [30] to help construct the intervention components and features required to achieve the objectives of INTERCEPT. Incorporating behavior change theory in the development of health interventions is known to enhance their effectiveness [20], and SCT is one of the most commonly used theoretical frameworks in secondary prevention DHI studies [12]. This process was facilitated by a series of structured brainstorming workshops with the stakeholder team, where creative idea generation around strategies to address specific target behaviors was encouraged. Contextual insights into the clinical care pathway after a cardiac event were incorporated by involving HCPs and patients in the user journey mapping process. In line with UK MRC guidance, a logic model was developed to articulate the key components of INTERCEPT and its expected mechanisms of action [20].

Phase 3: Developing Prototypes

To help visualize the basic layout and functionality of the app, the software developers initially produced a series of prototype mock-ups of the INTERCEPT digital interface. Through a series of workshops, these mock-ups underwent several iterations, integrating feedback from the entire stakeholder team, until a more refined design solution was reached. This led to the

development of a usable first version of the app (alpha prototype), which was pilot-tested among the stakeholder team and reviewed multiple times for clarity of language, ease of navigation, and functionality. At this stage, decisions regarding the INTERCEPT logic (eg, to trigger push notifications), functional requirements (eg, registration process, user login, and safe data storage), integration of data with the HCP portal, and the use of analytics to capture usage patterns were made. Furthermore, to promote user trust and to ensure compliance with general data protection regulations (GDPR), a series of data privacy and security measures were considered in this phase. These included the introduction of encryption and access controls, adhering to data protection standards for data hosting and storage and ensuring data minimization, by developing the app to collect only the necessary personal information. In addition, a privacy policy detailing how personal data are collected, processed, and stored was developed.

INTERCEPT was developed for both iOS (Apple) and Android (Google) mobile phone platforms and was tested multiple times across a range of devices and operating systems to guarantee reliable performance and compatibility. Feedback from the workshops was collated and formulated into design specifications using a custom-designed data extraction spreadsheet. All new design features and content changes were prioritized based on their alignment to the guiding principles and their overall potential to enhance the acceptability and usability of INTERCEPT.

Phase 4: Usability Testing

To further develop INTERCEPT, the finished product (beta version) was subjected to usability testing by a separate group of patients, who were not part of the PPI panel. Usability testing is critical to determining if an intervention is meeting the end-user needs, and, ideally, it should be completed with end users in real-life contexts [31].

End-User Recruitment

Using purposive sampling, participants were recruited through 3 community groups, including Croí, the heart and stroke patient organization; a group representing Travellers (Indigenous ethnic minority individuals); and a farming organization. There was a specific focus on recruiting women, those living in rural isolation, and ethnic minority groups as these individuals are often underrepresented in digital health research [6,12]. Eligibility criteria included participants aged ≥ 40 years with a recent (≤ 2 years) diagnosis of CHD. Participants were required to have a smartphone, and family members were included as they play an important role in supporting engagement with technology in the home [32]. To minimize barriers to online engagement, participants were offered training in the use of Zoom technology. Furthermore, as trust in data security and privacy is a frequently reported barrier to DHI engagement [10], participants were informed of the measures taken to ensure that INTERCEPT was compliant with GDPR. We aimed to recruit a sample size of 10-12 participants to test usability, as this has been demonstrated to detect a minimum of 80% of usability problems, which is considered satisfactory for complex intervention testing [33].

Ethical Considerations

Ethical approval for phase 4 was granted by the clinical research ethics committee at Galway University Hospitals (Ref: C.A.2797) on May 11, 2022. Informed consent was obtained from all participants, who were informed of their right to withdraw from the study at any time. Data obtained from participants was handled according to GDPR and all data were anonymous to the study team.

Iterative Co-Design Workshops

Once consent was obtained, participants in phase 4 were provided with a link with instructions to download the app via email, a pedometer (Sportline 340; HRM USA Inc), a blood pressure monitor (UA 651 device; A&D), and a user support manual. The manual incorporated a diary, which participants were encouraged to use to document their experiences of using INTERCEPT [21]. Participants were invited to 5 online workshops over a 12-week period. This was considered sufficient time to allow participants to test the behavioral change elements of the app, such as goal setting and self-monitoring. Furthermore, this allowed for iterative amendments to be made to the app based on usability feedback. We were unable to find guidance for conducting co-design in an online environment; therefore, we adapted best practice principles for facilitation of in-person, co-design workshops, to help optimize engagement [34,35]. This involved presenting the value proposition “sharing your insights will benefit others,” having clear workshop objectives with defined roles and expectations, allowing time for participants to share their lived experiences, being supportive around the use of technology, keeping the duration of usability workshops to no longer than 1.5 hours, and offering options for out-of-hours workshops as well as individual sessions. The topic guide (see [Multimedia Appendix 2](#)) for the usability workshops was developed with input from the stakeholder team, and participants were encouraged to refer to their diary to aid recollection of their experiences.

The validated System Usability Scale (SUS) was selected to evaluate the impact of usability testing [36]. The SUS assesses components of usability, effectiveness, efficiency, and satisfaction and includes 10 questions with a Likert scale, with values ranging from 0 to 100. Participants in phase 4 were invited to complete the self-administered SUS after an initial 2-week trial of the app and after the last workshop when final modifications to the app were made. To measure eHealth literacy, the validated eHealth Literacy Scale, an 8-item scale, presented as a score out of 40, was utilized [37]. Although there is no fixed cutoff to distinguish between high and low literacy, a higher score reflects a high level of eHealth literacy. Data on baseline characteristics of participants, eHealth literacy, and the SUS were obtained by providing participants with an email link to an online survey that was created using Survey Monkey.

Data Analysis

All quantitative data were analyzed using Stata (version 18; StataCorp). To compare the SUS data between the 2 time points, the nonparametric Mann-Whitney *U* test was used. Patient characteristics, information technology usage, and digital literacy were summarized using descriptive statistics. Qualitative

data were analyzed by 2 study team members (IG and CJ) who used a deductive approach to map to 3 key aspects: usability (functionality and ease of navigation), comprehensibility (language), and content.

Results

Participant Characteristics

INTERCEPT followed an iterative cycle of development, involving 29 participants. These included 20 participants from the stakeholder team (4 nurse specialists, 1 physiotherapist, 1 physical activity specialist, 2 dietitians, 1 pharmacist, 2 health psychologists, 2 cardiologists, 2 software developers, and 5 PPI members), who were based in 6 different countries, and a separate group of 9 patients who were recruited for usability testing in phase 4.

INTERCEPT Guiding Principles

A review of the associated literature identified the following key app features: self-monitoring of health behaviors, behavior change motivation, education, personalized content, ease of use, and the ability to integrate with other apps and devices [10,23]. Feedback from the stakeholder team yielded further insights. INTERCEPT should (1) engage and motivate the user, (2) facilitate psychosocial support and contact with an HCP, (3) be credible and evidence based, (4) ensure data privacy, and (5) be introduced early in the recovery journey as patients often experience delays or have limited access to CR. By consolidating findings from the literature with stakeholder team insights, we identified 5 key guiding principles for the development of INTERCEPT. An outline of these principles, comprising of design objectives and intervention features to address these objectives, are presented in Table 1.

Table 1. INTERCEPT design-guiding principles.

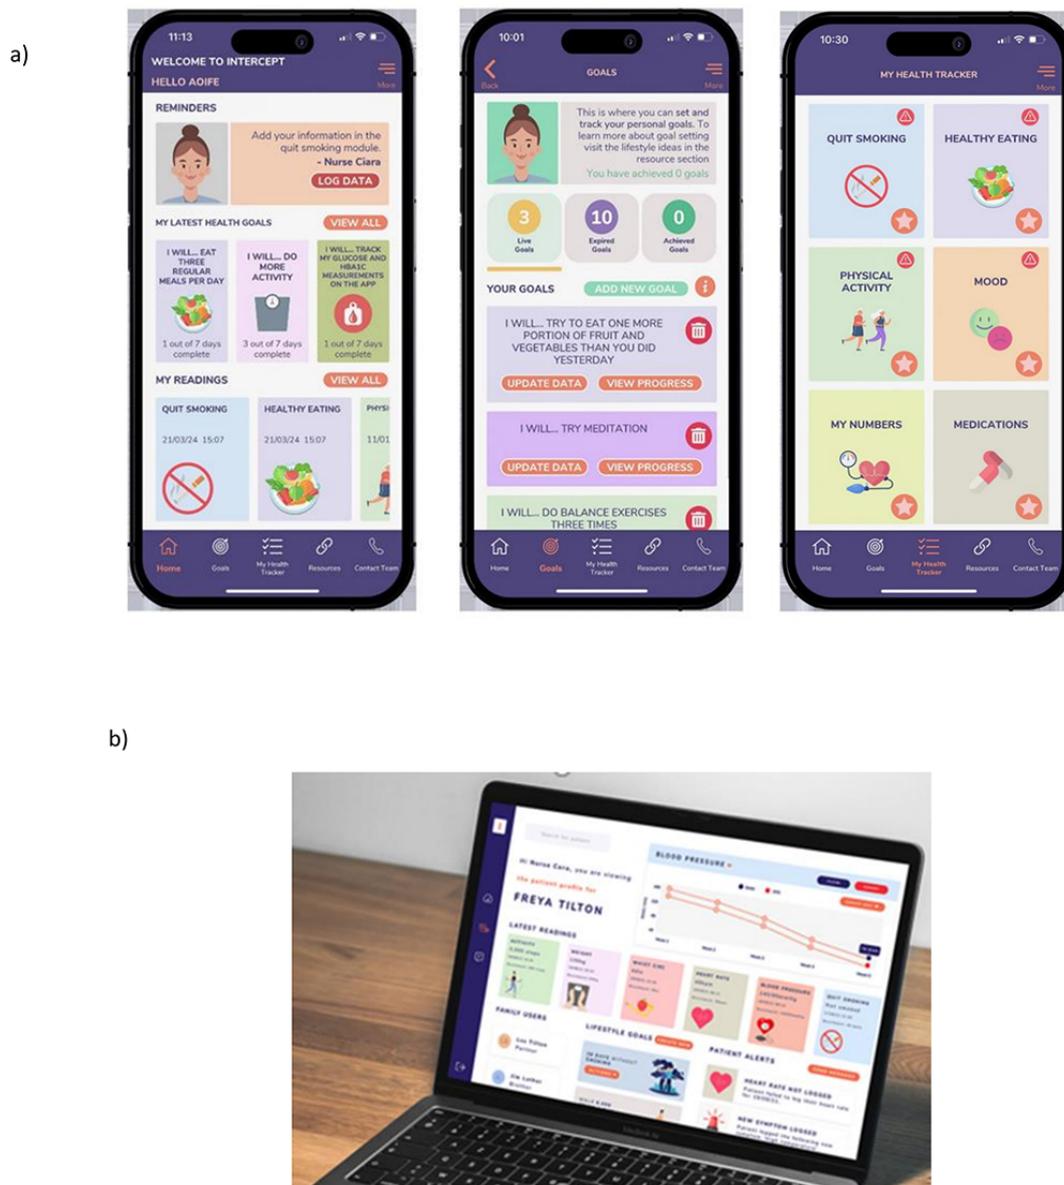

Design objectives	Intervention features
Promote user competence	<ul style="list-style-type: none"> • Ensure simplicity across layout, language, and navigation procedures • Provide clear guidance on how to use INTERCEPT
Incorporate strategies to motivate and engage users in healthy behaviors	<ul style="list-style-type: none"> • Support goal setting, self-monitoring, and tracking of behaviors • Acknowledge app usage, and provide tailored feedback on self-reported progress, using rewards where appropriate • Use positive language, promoting the benefits of engaging in health behaviors
Adopt a personalized approach	<ul style="list-style-type: none"> • Offer choice in relation to how users engage in the app (graded goal setting, turning notification on and off, timing of reminders, and personalized messages)
Promote system credibility	<ul style="list-style-type: none"> • Be explicit in stating the organizations or people involved in developing INTERCEPT • Use trusted and credible resources, with appropriate links to reputable, noncommercial organizations • Comply with data privacy obligations, ensuring that appropriate data security measures are in place
Social support	<ul style="list-style-type: none"> • Establish a communication link with health care professionals through integrating the app with a health care professional portal

Developing Prototypes

After a series of workshops (n=7) with the stakeholder team (2 workshops with HCPs and 5 with PPI collaborators), the core components and features of INTERCEPT were agreed upon. In brief, the components included goal setting to motivate and support healthy lifestyle change; a health tracker to support self-monitoring of physical activity, mood, healthy eating, medications, blood pressure, cholesterol, and glucose levels; educational resources to increase knowledge and awareness of healthy lifestyle changes, psychosocial health, and adherence to cardioprotective medications; notifications to motivate and prompt engagement; and a link to an HCP portal to enable remote monitoring and support. A description of these components is provided in the TIDieR (Template for Intervention Description and Replication) checklist (see Multimedia Appendix 3), and screenshots are presented in

Figure 2. To operationalize the intervention components and features, 14 BCTs from the taxonomy of BCTs were used. An overview of these BCTs, and how they align to the components and features of INTERCEPT, including the proposed mechanisms of actions and outcomes, is presented in the INTERCEPT logic model (see Multimedia Appendix 4). Examples of how this feedback influenced the end product features are as follows: (1) to promote user competence, additional guidance on goal setting was provided and a hard copy support manual was developed; (2) to motivate and engage users, the value proposition of the app describing its potential benefits was introduced on the home screen; (3) to ensure a personalized approach, a schedule of tailored notification messages mapped to individual usage patterns was developed; and (4) to emphasize psychological health, credible resources and messaging were included.

Figure 2. Screenshots of (A) the home screen, goal setting, and health tracker and (B) the health care professional portal.

Usability Testing

Usability testing was conducted between July and October 2022. In total, 11 individuals were recruited and 9 attended either the workshops (n=6) or semistructured interviews (n=3). Reasons for nonattendance were related to illness and family caring responsibilities. Baseline characteristics of participants, including demographics, CVD diagnosis, technology usage, and digital literacy, are reported in [Table 2](#).

The mean age of participants was 62 years; 67% (6/9) were female, 89% (8/9) had a diagnosis of CVD, and 1 (11%) was a

family member. Although the majority (7/9, 78%) of participants reported frequently using apps, the mean eHealth literacy score was 27.6 (SD 6.1). While acknowledging the small sample size, improvements were identified in overall mean SUS scores from 60.8 (SD 23.5) at commencement of usability testing to 82.8 (SD 7.1) after usability testing ($P=.02$; [Table 3](#)). Although improvements were observed across all 10 questions, they were significant for questions 2 (I found the app unnecessarily complex; $P=.04$), 3 (I thought the app was easy to use; $P=.02$), 5 (I found the various functions of the app well integrated; $P=.03$), and 9 (I felt confident using the app; $P=.03$).

^beHEALS: eHealth Literacy Scale.

Across the 3 key areas of usability, comprehensibility, and content, participants made 64 suggestions for INTERCEPT, and of these, 51 were implemented. Through stakeholder consensus, reasons for not implementing suggestions were related to practical considerations (budget and time) and misalignment with the guiding principles. A summary of suggestions, across the themes of usability, comprehensibility,

and content, were mapped to the intervention components ([Multimedia Appendix 5](#)). The following are selected insights. To enhance functionality and minimize the user burden associated with manual data entry, participants identified the importance of integrating data from the fitness wearable and blood pressure monitor with INTERCEPT. However, this change was not feasible to implement immediately, as it required

consideration of multiple technical and user experience factors. These included ensuring reliable data transfer and compatibility between INTERCEPT and other devices; privacy and security; and the provision of adequate technical support, including user instructions and manuals to guide setup. Although addressing these factors required additional time and resources, data integration was achieved following usability testing. To motivate the user, participants recommended including rewards for setting and achieving goals and using language to promote more personal ownership, for example, changing “your data” to “my

data.” In recognizing the acute clinical context of implementation, participants emphasized the importance of including welcoming messages on the home screen to acknowledge the early stages of recovery. To enhance navigation, participants recommended greater integration between components. For example, if a user achieves a low mood score, they should receive prompts with links to the goal setting and resource sections, rather than having to access these components separately.

Table 3. Pre- and postusability testing System Usability Scale scores.

Question	Preusability testing (n=9), mean (SD)	Postusability testing (n=8), mean (SD)	P value
1. I think that I would like to use the app frequently	2.7 (1.4)	3.5 (1.1)	.12
2. I found the app unnecessarily complex	2.6 (1.1)	3.6 (0.5)	.04
3. I thought the app was easy to use	2.6 (1.2)	3.8 (0.5)	.02
4. I think that I would need assistance to be able to use this app	2.1 (1.3)	2.6 (0.9)	.39
5. I found the various functions in the app were well integrated	2.3 (1.0)	3.4 (0.7)	.03
6. I thought there was too much inconsistency in the app	2.3 (1.1)	3.1 (0.4)	.05
7. I would imagine that most people would learn to use this app very quickly	2.3 (1.2)	3.3 (1.0)	.08
8. I found the app very cumbersome or awkward to use	2.4 (1.2)	3.4 (0.5)	.06
9. I felt very confident using the app	2.8 (0.7)	3.5 (0.5)	.03
10. I needed to learn a lot of things before I could get going with the app	2.2 (1.6)	3.0 (0.5)	.37
Total score	60.8 (23.5)	82.8 (7.1)	.02

Discussion

Principal Findings

This paper describes the methods used to develop INTERCEPT, a multicomponent DHI, which integrates a smartphone app, HCP portal, fitness wearable, and blood pressure monitor to improve secondary prevention in patients with CHD. By providing a comprehensive and transparent description of methods used, we envision that our reporting will facilitate replication of the design process for future DHIs while also contributing to the growing science of intervention development. For creating effective DHIs, the use of the best combination of approaches to intervention development is required [38]. Accordingly, we used a combination of behavioral change theory, co-design, and the person-based approach to developing INTERCEPT. To our knowledge, this is one of the first studies to adopt this approach for the development of mHealth secondary prevention interventions. The broad range of actions undertaken across the development phases ensured the success of this approach. Many of these actions, for example, planning, designing, and creating, are consistent with guidance from the taxonomy of approaches to developing interventions by O’Cathain et al [39]. This highlights the relevance of using a taxonomy for future CVD DHI development research.

Developing DHIs is increasingly being recognized as a transdisciplinary endeavor, and meaningful stakeholder involvement is critical to successful co-design [15,38]. Despite

this, a recent scoping review revealed that establishing meaningful relationships was the least reported process used in co-design studies in CVD secondary prevention [15]. Moreover, PPI is often absent from approaches to intervention development [39]. We addressed this by engaging PPI early in the development process and by using specific strategies, such as agreeing roles and responsibilities to foster meaningful relationships. Given the high level of stakeholder diversity (HCPs, patients, and software developers), the role of facilitators (study team members IG and CJ) was critical to ensuring an authentic understanding of the stakeholders’ real-world experiences. Through their backgrounds as CVD nurse specialists, they were able to operate in an empathetic way, while also managing potential power imbalances between members of the stakeholder team. The interdisciplinary expertise of the stakeholder team helped to ensure that the users’ needs and preferences, the influence of behavioral theory, best practice CVD prevention guidelines, and technical and practical factors were considered throughout development. Through dynamic, iterative cycles of development, this resulted in the development of a complex intervention, targeting multiple behaviors for change through a personalized user interface, with bidirectional communication via an HCP portal and remote monitoring technology. Consistent with findings from other DHI co-design studies, having the same PPI and HCP group involved throughout enhanced this process, allowing for more in-depth and intensive iteration along the development continuum [35,40].

Although most secondary prevention DHIs focus on outpatient settings, INTERCEPT is designed to be introduced to patients as early as possible after the diagnosis of CHD [41]. Based on recent systematic review and realist synthesis evidence, focusing on early engagement, ensuring a personalized approach, and providing opportunities to connect with an HCP are all features associated with improved participation in telehealth CR and CVD health outcomes [42]. Although HCP support has been identified as one of the most important factors associated with engagement in mHealth DHIs [25], it is important to establish the extent to which it can add further value, without becoming resource intensive [43]. The INTERCEPT portal strives to achieve this balance through protocol-driven remote monitoring and support based on real-time data.

To our knowledge, INTERCEPT is one of the few secondary prevention mHealth DHIs that target multiple behaviors for change. This is particularly important as lifestyle- and medical-related CVD risk factors and their corresponding behaviors are strongly interlinked [1]. Although the guiding principles were key to identifying key components and features to help address these behaviors, using BCTs targeting determinants of SCT helped to operationalize them. Many of the BCTs included in INTERCEPT (eg, self-monitoring of behavior [2.3], information about health consequences [5.1], and goal setting [1.1]) align to recent systematic review evidence for effective BCTs in CR DHIs [12]. By presenting an overview of these BCTs as part of the INTERCEPT logic model, we respond to the increasing calls for explicit reporting of components and expected mechanisms of action of co-designed interventions [15,20].

Similar to findings by Tay et al [44], this paper highlights that it is feasible to develop DHIs in an online environment. Importantly, this enabled us to foster an inclusive approach to intervention development where geography was not a barrier. Indeed, the diverse group of representative end users in the stakeholder team and recruited for usability testing was a key strength of the INTERCEPT development process. For example, among those recruited for usability testing, one-third had never previously attended CR; almost 70% were women; 78% were enrolled in the General Medical Scheme (means tested provision of state health care); 1 individual identified as an Irish Traveller; and eHealth literacy levels were mixed, with scores ranging from 15 to 34 out of 40 (mean score 27.6). Given how cultural and socioeconomic factors including gender and digital literacy influence the acceptability of DHIs, involving diverse populations in their design is essential to optimizing their potential benefits [5]. Outcomes from the usability-testing phase resulted in a number of refinements being made to INTERCEPT. Data from the SUS evaluation suggest that these refinements potentially led to improvements in its usability. This highlights the important value of usability testing in optimizing the user experience and overall quality of the product [35].

Following UK MRC guidance for developing and evaluating complex interventions, our next step in the intervention development process is to evaluate the feasibility of INTERCEPT among a sample of patients with CHD in a real-world clinical setting. By conducting a nonrandomized, mixed methods, feasibility study, the acceptability and usability of INTERCEPT will be assessed. These insights will help to (1) inform further refinement of INTERCEPT and (2) determine the feasibility of a definitive randomized controlled trial. The protocol for this feasibility study is detailed elsewhere [45].

Limitations

The INTERCEPT development process had some limitations. First, the outcomes of our co-design process focus primarily on the development of INTERCEPT. However, there is also a need to report on stakeholder experiences and cost-effectiveness [14,46]. This would help address the paucity of data on the impact of co-design processes on stakeholders, while also informing strategies to optimize participatory approaches for intervention development [47]. Second, co-design is time-consuming, and the evolving nature of technology demands more fast-paced design processes to ensure that DHIs remain relevant and engaging [46]. Although our development timeframe was consistent with in person co-design studies [13], further research is required to ascertain if online approaches can improve efficiencies. Third, usability testing of INTERCEPT required participants to retrospectively report their experiences over a defined period of time, which may have resulted in insights been forgotten or distorted. Including the use of think aloud interviews, whereby participants are asked to give their immediate reactions to every element, may help to address this. However, further guidance on using this approach online is required. Fourth, social desirability bias may have influenced the SUS results; to address this, the survey was self-administered and the results were anonymous to the study team. Finally, because of the low sample size, the SUS results should be interpreted with caution; further research with a larger sample size is warranted to help evaluate the usability testing process.

Conclusions

The proliferation of DHIs including mHealth has enabled the development of new and innovative approaches for the secondary prevention of CVD. However, careful attention to the development of these DHIs is required to increase their effectiveness and uptake in clinical practice. This paper illustrates how combining behavior change theory with a person-based, co-design approach to DHI development is feasible and can result in the successful development of an intervention that responds to end users' needs and preferences, including desired content and features. Additionally, our comprehensive reporting offers guidance to other researchers for developing future DHIs, thus facilitating the translation of evidence into practice.

Acknowledgments

The authors wish to thank the participants who kindly participated in this study; members of the Croí public and patient involvement panel, who advised on all aspects of the development of INTERCEPT (Mary Harrahill, Eilish Kelly, Mary Lillis, Pat McDonald,

Terry Small, and Mary Verbruggen); the staff of Croí including Annie Costelloe and Maeve Frawley, who supported with recruitment; the staff of Citrus Suite who supported technical and software development; and Professors Julie Redfern and Robyn Gallagher from the University of Sydney, who provided expert project advice. This research study is supported by the Health Research Board Ireland Collaborative Doctoral Award 2019 (CDA-2019-001); the National Institute for Prevention and Cardiovascular Health, Ireland; the Preventive Cardiology Trust, United Kingdom; and a SOLVE CHD SYNERGY Grant, University of Sydney, Australia. The development of the INTERCEPT software was supported through an unrestricted educational grant by Novartis and NovoNordisk.

Conflicts of Interest

None declared.
