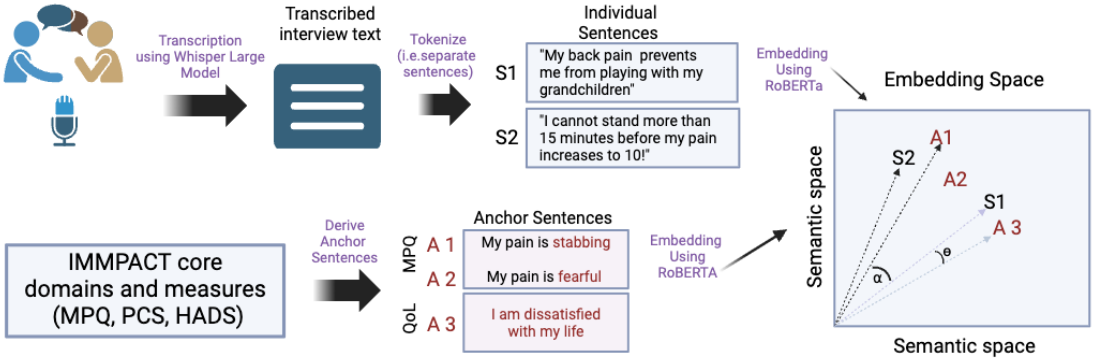
The patients completed the TICS and Montgomery-Asberg Depression Rating Scale over the phone as described earlier. All remaining pain ratings and questionnaires were completed after the interview to avoid any influence from these tools on the content of the interview. When in the laboratory, the patients rated their low back pain intensity on a visual analog scale (VAS) using a cursor on a line projected on the computer screen in front of them and completed the National Institutes of Health minimal dataset for CLBP [22]. They also completed questionnaires and measures recommended by IMMPACT [13], including the short form of the MPQ, the PainDETECT Questionnaire, the Pain Catastrophizing Scale, the Hospital Anxiety and Depression Scale, and the Roland-Morris Disability Questionnaire. The core domains recommended by IMMPACT overlap extensively with those identified in a more recent consensus report on core outcome sets [14]. In addition, the patients with CLBP completed the central sensitization inventory, as well as the neuroticism, extraversion, and openness personality inventory, and reported their list of prescribed medications.

Preprocessing of Interview Text

Voice data were recorded in 2 channels, one for the interviewer and one for the participant. Automatic audio transcription of the entire participants' interview was performed using the Whisper base model [38]. We used the transcriptions verbatim for further analysis and performed the analysis sentence by sentence. Sentences were obtained using the sentence tokenizer from the Natural Language Toolkit [39], which is an open-source Python library designed for working with human language data.

Data Analysis

Construction of Anchor Sentences



Our aim was to understand how the patients' personal accounts of their "pain stories" were situated in a multidimensional linguistic space relative to the core domains and validated measures recommended by experts' consensus [13,22]. These measures are often used in chronic pain research but are less commonly applied to monitor patients in everyday clinical settings. To achieve this, we constructed anchor sentences based on validated questionnaires that covered topics related to the sensory, affective, functional, and quality-of-life aspects of patients with CLBP. We present all the anchor sentences that we used in Table S3 in Multimedia Appendix 1, along with the source questionnaire from which they were derived. The questionnaires included the MPQ [16], the Pain Catastrophizing Scale [40,41], PROMIS [42,43], and the World Health Organization Quality of Life Questionnaire [44], which are measures tested for content validity and involved patients' population during their conception. Because LLMs can misunderstand negation [45,46], some of the anchor sentences were rephrased from the original questionnaires. Although the list of anchor sentences may not be exhaustive, we ensured that they addressed the biological, psychological, and social domains of patients' lives.

Feature Extraction

We used semantic embedding [47], a fundamental NLP and machine learning concept, for semantic feature extraction from the interview text. Figure 1 illustrates the overall approach. This method consists of projecting entire sentences into a semantic space and converting them to vectors with 1024 coordinates [48]. It enables computers to understand and process human language by mapping words, phrases, or entire documents to vectors of real numbers. These vectors can then be analyzed with a rich set of mathematical tools to extract valuable information from the text, facilitating tasks such as sentiment analysis, topic modeling, and semantic similarity measurement, which we used in this work [49-52]. We generated semantic embeddings using the RoBERTa (a robustly optimized bidirectional encoder representations from transformers pretraining approach) large model [48], which was trained on 160 GB of text.

XSL•FO
RenderX

Figure 1. Schematic representation of the data collection and analysis workflow. Transcribed interview text and anchor sentences were semantically embedded to calculate the semantic similarity between the anchor sentences and the interview text. The embedding space represented here is a projection to a 2D graph and is therefore a simplification of the actual space, which comprises 1024 dimensions. As depicted, sentence S1, uttered by the patient about daily life, is closer to anchor A3 than to anchor A1 (ie, θ<α). HADS: Hospital Anxiety and Depression Scale; IMMPACT: Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials; MPQ: McGill Pain Questionnaire; PCS: Pain Catastrophizing Scale; QoL: quality of life.

Analysis Using Anchor Sentences and Their Antithetical Pair

We wanted to evaluate whether the anchor set, derived as described in the previous section, adequately covered the interview topics by comparing the semantic distance between the interview sentences and both the anchor and its antithesis. More specifically, we calculated the semantic embeddings (Figure 1) of each sentence uttered by the patient—using the entire interview—the anchor sentence, and its antithetical pair. Next, semantic similarity was quantified by calculating the cosine similarity between the vectors of the anchor sentences and interview sentences, on the one hand, and the antithetical anchor sentences and the interview sentences on the other hand, providing a quantitative measure of their semantic resemblance. This calculation resulted in 2 distributions of semantic similarities for each anchor pair. We used the 95th percentile point (Figure S2 in Multimedia Appendix 1) of each distribution to represent the semantic distance of the interview sentences to the anchor and to its antithetical pair, respectively. This value, the 95th percentile of the similarity scores, represents a robust maximum after omitting outliers. The robust maximum is more resistant to outliers than the absolute maximum and is inherently invariant to the length of the interview. To further illustrate our approach, we plotted the distribution of semantic similarities from 2 participants representing the extreme ends of the number of sentences uttered during the interview to demonstrate the robustness of the 95th percentile, which falls within the 0.4 to 0.6 range of semantic similarity (Figure S1 in Multimedia Appendix 1).

Relating Semantic Similarities to Reported Back Pain Intensity

Ratings of chronic pain intensity are often used in clinical settings and are a mainstay of clinical pain research. Therefore, we tested the relationship of semantic similarities to the anchor sentences, showing significant differences in the previous analysis and the pain intensity reported on the NRS and the VAS. We calculated the correlation between semantic similarities to the anchor sentences, showing significant differences between the previous analysis and the reported pain back pain ratings. We also assessed whether the anchor sentences were sensitive enough to detect differences between interviews from the high- and low-pain subgroups.

Statistical Analysis

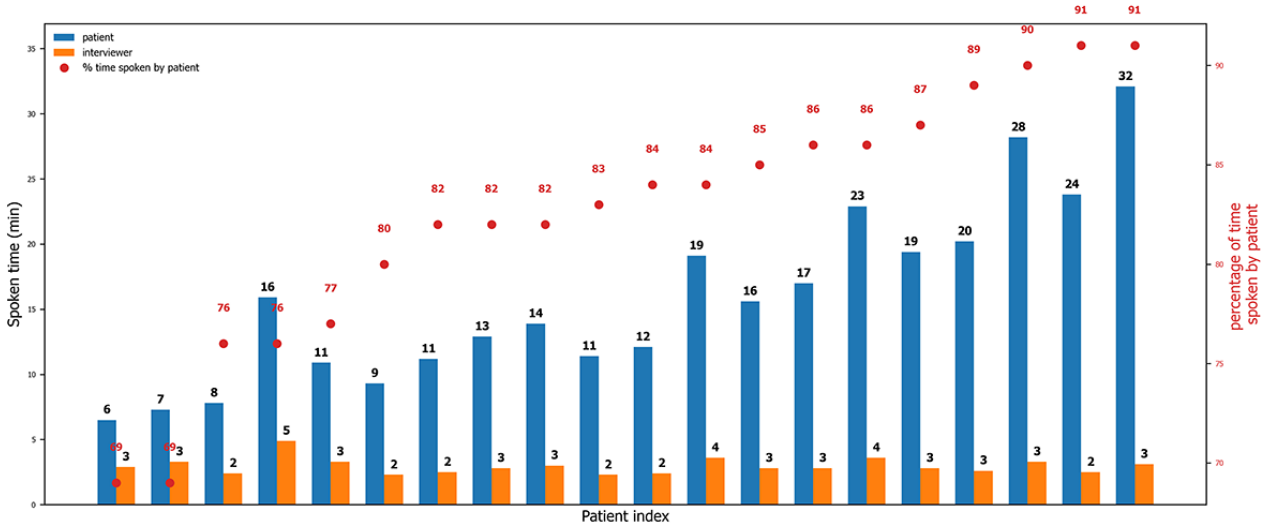
The Kolmogorov-Smirnov (KS) test was used to assess the differences between the distributions of semantic similarities. Specifically, we compared the distribution of the 95th percentile robust maximum for each anchor sentence with that of its corresponding antithetical sentence across patients. Because we analyzed 33 pairs of sentences, we corrected for multiple comparisons using the false discovery rate (FDR) method. Additionally, we compared the distributions of semantic similarities to the anchor sentences between the high-pain and low-pain groups using the KS test. Finally, we used Spearman's ρ correlation coefficient to examine the relationship between semantic similarities and reported pain intensity ratings.

Results

Demographic and Clinical Characteristics

Table 1 shows the demographic and clinical characteristics of the sample of 20 patients with CLBP. In total, 50% of the participants were female. By design, the patients did not have any evidence of cognitive impairment (*TICS*>33). Complete details of the patients' characteristics are reported in Table S1 in Multimedia Appendix 1.

Analysis of the Interviews



Interview Duration

The duration of the interviews ranged from less than 10 minutes to more than half an hour, with a total of 376.4 minutes of speech. The interviews across all participants included a total of 43,641 words of naturalistic language data with a unique vocabulary of 3158, making the total sample a substantial linguistic corpus. The vocabulary richness ratio was 0.072, and the natural speech rate was 115.9 words per minute, demonstrating genuine and varied linguistic expression rather than constrained responses [53,54]. The patients spoke between 69% and 91% of the interview time (Figure 2). There was no

XSL•FO
RenderX

statistically significant correlation between pain scores and interview duration (NRS and VAS: P=.94) or between pain scores and the percentage of time spoken by the participant (NRS: P=.42; VAS: P=.72). Because years of education may affect speech generation or the richness of the text generated, we examined the correlation between years of education and the interview features, such as duration, time spoken by the participants, and time spoken by the interviewers, as well as between years of education and the semantic embeddings of the anchor sentences (Table S4 in Multimedia Appendix 1). Years of education were negatively correlated with the time spoken by the interviewer, indicating that the latter prompted participants with fewer years of education more frequently than those with more years of education. Years of education were not correlated with the overall interview duration, the time spoken by the participant, the word content, or the pain scores. In addition, years of education were not significantly related to the semantic embeddings of the anchor sentences, except for "I rate my quality of life as poor" and "My physical environment is unhealthy."

Figure 2. Interview duration and percentage of time spoken by the interviewer and the patient. The left axis depicts the duration (in minutes) spoken by each patient (blue) and the interviewer (dark orange); the right axis depicts the percentage of interview time spoken by the patient (red dots). The x-axis depicts all patients (N=20), arranged by interview duration from shortest to longest.

Semantic Distance of Interview Texts to Anchor Sentences and Their Antithetical Sentences

Figure S2 in Multimedia Appendix 1 illustrates the distributions of semantic similarities for 1 anchor sentence—"I have no pain"—and its antithesis—"I am in pain." Table S5 in Multimedia Appendix 1 shows example semantic embeddings for 2 anchor sentences. The semantic embeddings of 7 pairs of anchor sentences and their antithesis showed statistically significant differences (P<.05; FDR corrected) in their similarities to interview sentences (Table 2). In total, 5 pairs of sentences were derived from the MPQ, 1 from the measure of pain variability, and 1 from the PROMIS-Pain Interference questionnaire. Table S6 in Multimedia Appendix 1 presents the results for all the anchor-antithesis sentence pairs tested.

XSL•FO
RenderX

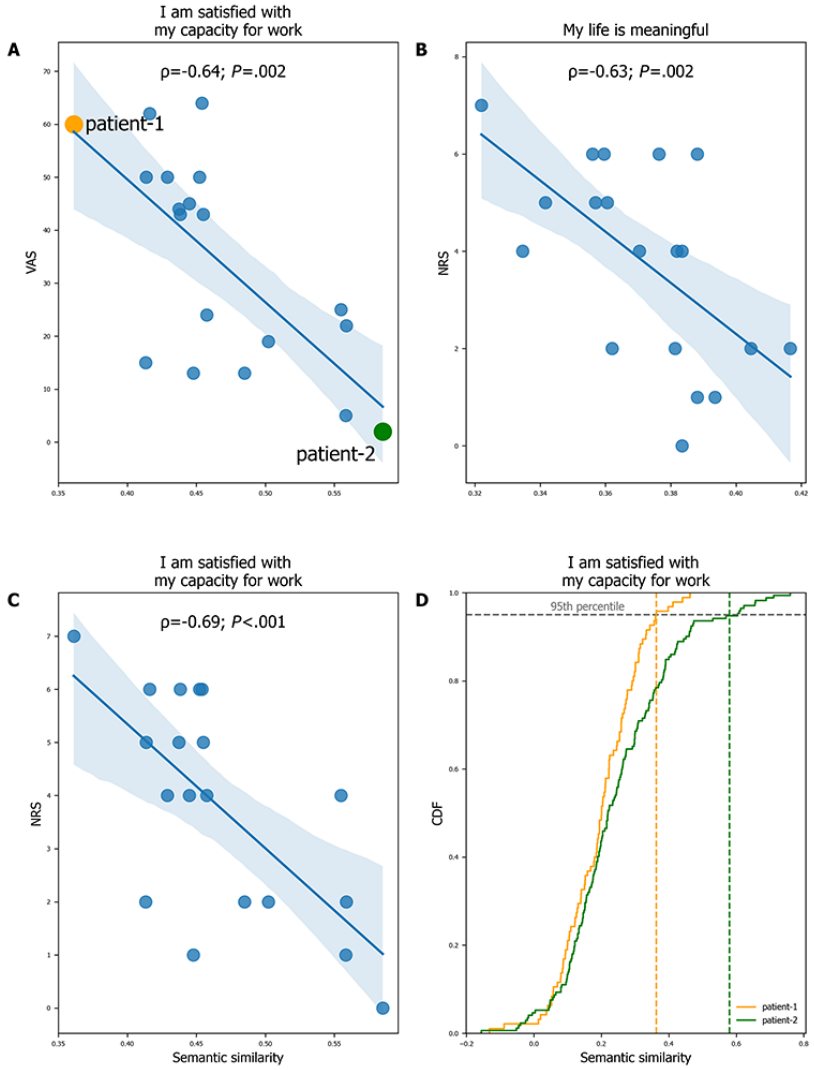
Table 2. Anchors and their antithetical sentences showing significant differences in their semantic similarities to the interview text.

Anchor	Antithesis	Questionnaire	KS[a] test	*P* value	q value[b]
My pain is cramping	My pain is relaxing	MPQ[c]	0.95	5.80×10^{1}	1.92×10
My pain is splitting	My pain is light and dull	MPQ	0.8	1.33×10	1.46×10
My pain is throbbing	My pain is steady	MPQ	0.65	2.70×10^{4}	2.23×10^{3}
My pain is stabbing	My pain is dull and aching	MPQ	0.65	2.70×10^{4}	2.23×10^{3}
My pain is tiring-exhausting	My pain is bearable	MPQ	0.55	3.97×10^{3}	2.18×10^{2}
I am in pain	I have no pain	Pain variability	0.85	1.43×10	2.37×10
I am unable to focus	I am able to focus	PROMIS[d]-pain interference	0.55	3.97×10^{3}	2.18×10^{2}

[a]KS: Kolmogorov-Smirnov.

[b]q value refers to the false discovery rate–adjusted *P* value. Each anchor sentence has its opposite (eg, I have no pain and I am in pain). We computed the semantic similarity between each sentence from the interview and the anchor. From that distribution of values (1 value per sentence), we retained the robust maximum (the 95th percentile, which is more resistant to outliers than the maximum value). We then repeated the same calculation for the antithesis of the anchor, also retaining the robust maximum semantic similarity. We repeated this for each participant, resulting in 1 distribution of values extracted from the anchors and 1 from their antitheses. We then compared these two distributions using the 2-sample Kolmogorov-Smirnov test to determine whether significant differences existed between the anchor and its antithesis used to query the data in this cohort. This nonparametric test is designed to determine if 2 samples originate from the same distribution.

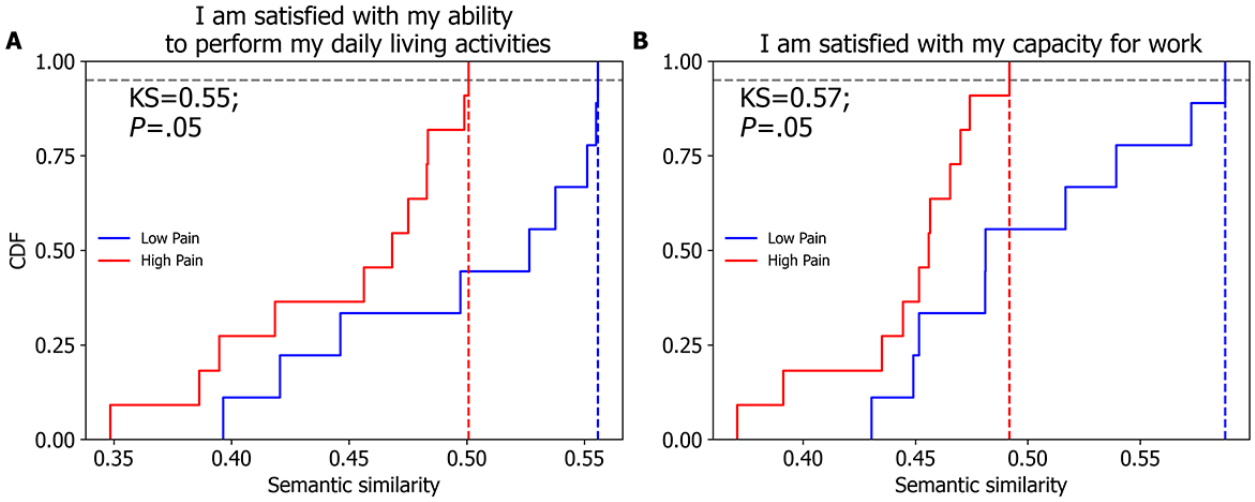
[c]MPQ: McGill Pain Questionnaire.



[d]PROMIS: Patient-Reported Outcomes Measurement Information System.

Relationship Between Semantic Distance of Interview Texts to Anchor Sentences and Back Pain Intensity

NRS and VAS are commonly used tools in clinical and research settings. Therefore, we tested whether the semantic distance of the patients' interviews to the anchor sentences scaled with the patients' reported pain intensity. Figure 3 shows 3 examples in which the correlations were statistically significant ($P<.05$; FDR corrected). The semantic similarity to the anchor sentence "I am satisfied with my capacity for work" was inversely related to both NRS and VAS scores. Similarly, the semantic similarity to "I am satisfied with my ability to perform my daily living activities" was inversely related to the NRS pain score. In the same figure, we illustrate the differences in the distributions of semantic similarity between the interview and the antithesis "I am satisfied with my capacity for work" for 2 participants: 1 with high pain (patient-1) and 1 with low pain (patient-2). Table S7 in Multimedia Appendix 1 presents all calculations performed between the anchor NRS and VAS, on the one hand, and the semantic embeddings of the anchor sentences, on the other hand. Notably, the NRS and VAS were most strongly correlated with the semantic embeddings of anchor sentences describing the quality of life. Another way of examining the relationship between the interview text and pain intensity was to compare the high- and low-pain subgroups. Patients who reported a VAS pain score ≤30 or an NRS score ≤3 were classified into the low-pain group; otherwise, they were classified into the high-pain group. Figure 4 shows the differences between the subgroups with high and low pain in the semantic similarity to "I am satisfied with my capacity for work" and to "I am satisfied with my ability to perform my daily activities." Not surprisingly, participants with high pain reported less satisfaction with their quality of life (Figure 4).



XSL•FO
RenderX

Figure 3. Relationship (Spearman ρ, *P*<.01) between the semantic similarity of patients' texts and anchor sentences and the rated back pain intensity. Significant correlations between back pain intensity and semantic similarity for "I am satisfied with my capacity for work" (A and C) and "I am satisfied with my ability to perform my daily living activities" (B). (D) Examples of 2 cumulative distributions of semantic similarity between the interview text and "I am satisfied with my capacity for work" obtained from 2 patients on both sides of the pain intensity spectrum, as shown in panel A. Patient 1 (dark orange) experienced relatively higher low back pain intensity and therefore showed smaller similarity to the anchor sentence, whereas patient 2 (green) showed the opposite pattern. Dashed lines represent the 95th percentile (the robust maximum used in our statistical analyses). The blue shading represents the CIs for the regression line. CDF: cumulative distribution function; NRS: numerical rating scale; VAS: visual analog scale.

XSL•FO
RenderX

Figure 4. Comparison of the distribution of semantic similarities to anchor sentences between high (visual analog scale [VAS]>30; red) and low pain (VAS≤30, blue) groups. The cumulative distributions of semantic similarity between the interview text and "I am satisfied with my ability to perform my daily living activities" (A), and "I am satisfied with my capacity for work" (B), differed significantly and were shifted to the left in the high-pain group compared with the low-pain group (Kolmogorov-Smirnov [KS] test, P<.01). CDF: cumulative distribution function.

Discussion

Principal Findings

In this study, we present evidence that subjective narratives of patients with CLBP, elicited through open-ended questions about their lives posed by an interviewer with no formal clinical training, can provide semantic features directly related to well-validated tools currently used to assess patients with pain [13]. Semantic embeddings, which assess the semantic similarity between anchor sentences—derived from validated pain and quality of life questionnaires—and sentences from the interviews, demonstrated statistically significant differences between negative and positive assertions about pain. In other words, the interview texts from patients showed asymmetric semantic similarities when queried with pain-related anchor sentences, providing evidence that NLP can detect clinically meaningful signals from the content of the interviews.

Additionally, the semantic embeddings differed significantly when their distributions were compared between subgroups with low and high pain levels. Notably, our analysis revealed a strong connection between the language used by patients with CLBP and their self-reported satisfaction with work capacity and other quality of life measures. Specifically, the semantic similarities of interview texts to anchors probing patient satisfaction with their life, such as "I am satisfied with my capacity for work" or "I am satisfied with my ability to perform my daily activities" were strongly inversely correlated with pain intensity, indicating that these aspects of patients' lives are deeply intertwined with their experience of pain. The statement "I am satisfied with my capacity for work," derived from the World Health Organization Quality of Life Questionnaire [44], reflects patients' perception of how pain impacts their ability to perform work-related tasks, maintain employment, and engage in productive activities. Satisfaction with work capacity may indicate a degree of pain management and coping strategies that enable individuals to continue participating in meaningful and fulfilling roles despite their condition [55]. Both anchors underscore the importance of addressing not only the physical symptoms of pain but also its broader psychological and existential impacts. This also suggests that patients' perception of their ability to work can serve as an indicator of their overall well-being and a potential target in chronic treatment. This finding aligns with the results of the INTEGRATE-pain Delphi process [14], which identified activities of daily living and quality of life as core outcome measures for chronic pain treatment. Furthermore, it highlights how applying NLP to patient interviews can extract patient-centered, quantitative measures that are not readily available from current state-of-the-art assessments in busy clinical settings, where the focus tends to be more on the sensory aspects of pain.

Not all anchor-antithesis pairs derived from validated questionnaires showed a statistically significant difference in their semantic distance to patients' narratives. In total, 21 of the 33 anchor pairs yielded a KS value ≥0.3, indicating a moderate-to-large separation between the distributions of semantic distances [56]. We predict that all these pairs will reach statistical significance with larger samples. The remaining 12 pairs had a KS value <0.30, indicating only a small separation. Several factors may account for these findings. These pairs may not adequately capture the nuances of the interview texts, or the way we constructed the pairs may have been limited. Another possibility is that the RoBERTa large model [48] used for semantic embeddings has intrinsic limitations. As these models continue to evolve, their embeddings are refined, potentially enhancing their ability to capture the relationships between questionnaire-based anchors and patients' narratives.

To date, there are no validated and widely accepted automated tools that can reliably assess patients with chronic pain; therefore, these patients must rely on verbal and nonverbal communication to convey their distress to others, including clinicians. Having such tools is critical for guiding clinical decision-making and for conducting valid, quantitative research on the mechanisms and therapeutics of chronic pain. Until recently, research on pain language has remained qualitative

XSL•FO
RenderX

[57] or was mostly limited to single-word descriptors embedded in questionnaires such as the well-known MPQ [16]. Nevertheless, studies using quantitative linguistic analysis of narratives from patients with chronic pain to measure pain or response to interventions have begun to emerge rapidly [20,21,58]. We have previously shown, for example, that by using LLMs to extract linguistic features from patients' interviews, we could distinguish between those with fibromyalgia and those with neuropathic pain, with an area under the receiver operating characteristic curve of 0.83 despite limited sample sizes [59]. Furthermore, we have demonstrated that NLP applied to patients' narratives can retrospectively [21] and prospectively predict response to treatment [20,58]. Nunes et al [60] analyzed short interviews recorded in response to 7 questions about patients' pain from 65 participants with various chronic pain conditions who reported mild, moderate, or severe pain. An NLP-based support vector machine model with early fusion of linguistic features was able to distinguish among the 3 groups of patients, thereby demonstrating, in a proof of concept, that NLP can be used to estimate chronic pain intensity. This emerging field, combined with the ease of obtaining voice recordings through the widespread use of smart devices, has the potential to provide novel, automated, and quantitative measures of patients' experiences of pain. These measures can be assessed frequently and can complement existing tools to enhance both patient care and research.

A review of the recent literature [61] studying pain language analysis using computational methods found that most studies relied on electronic health records and social media posts, with only a minority relying on patients' interviews. The most common objective was to classify patients with chronic pain. Our aim in this study was to demonstrate that a relatively brief interview (<30 min), inspired by the biopsychosocial assessment of pain and designed to elicit a subjective narrative of the patient's daily life and pain experience, can be analyzed using NLP tools to capture quantitative and clinically significant measures of the pain experience. These measures can then be used in future studies using the same approach to differentiate among patient groups, monitor progress, or evaluate treatment response. In addition to being patient-centered, substantial advantages of this approach include the ability to obtain data remotely and the absence of the need for a medical professional during data collection, both of which significantly reduce the cost of data collection.

Study Limitations

This study included a small sample of patients aged ≥40 years, which may limit the generalizability and linguistic representativeness of the findings. In addition, the small sample may have included subgroups of patients with CLBP—such as those with or without a neuropathic component—which could introduce heterogeneity into both the pain experience and the language used by the patients. Furthermore, the semantic distance calculations do not fully capture the complete meaning, with all its nuances, expressed by the patients. Thus, NLP cannot replace expert judgment but should rather be used alongside expert clinician assessments. Additionally, the process of constructing anchor sentences—particularly given the inability of LLMs to handle negations—may have affected the content validity of the anchors used, despite their derivation from content-valid questionnaires. Nevertheless, the language features related to validated pain questionnaires were strongly correlated with reported pain intensity and significantly distinguished between the high- and low-pain groups. Future research should explore larger and more diverse cohorts of patients with CLBP, including more representative age groups and groups with varying levels of common CLBP comorbidities such as depression, anxiety, or cognitive changes, to confirm these findings and investigate other aspects of the condition, such as its progression or response to treatment.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to participants' confidentiality.

Funding

This study was funded by the National Institutes of Health (grant NIAMS-R01AR080627).

Authors' Contributions

This study was designed by RN, JG, ZZ, CGA, JM, ZD, GC, and PG. AT collected the data. RN, GC, and PG analyzed the data, and all the authors critically reviewed the results. RN had the primary role in preparing the manuscript, which was edited by GC and PG. All the authors approved the final version of the manuscript and agreed to be accountable for all aspects of the work.

Conflicts of Interest

None declared.

Abstract

Background: Adolescents need comprehensive education and resources to promote their sexual and reproductive health (SRH) and make informed decisions about their SRH. However, many adolescents fail to secure an opportunity to learn accurate and reliable SRH information, as they face sociocultural barriers, fear of prejudice, and societal stigma. Information available on digital platforms may not always be evidence-based and can further spread misinformation. Digital knowledge translation interventions that provide evidence-based SRH information in North America are limited.

Objective: This study aimed to co-design a digital knowledge translation intervention, reflective of adolescents' voices, to provide evidence-based, accessible, and accurate SRH resources.

Methods: We conducted a large multisite project across 3 cities in Canada. Using a community-based participatory approach and principles of human-centered design, we established adolescent advisory groups (AAGs) to actively engage them in the design, development, and implementation of the intervention.

Results: A total of 26 participants were recruited from Edmonton, Vancouver, and Toronto to be part of the advisory groups. AAG members participated in design-thinking sessions to brainstorm ideas for website design, identify informational needs for content development, provide iterative feedback on the design of the intervention, and suggest strategies to improve engagement and interaction. With their input, 6 priority areas were identified to develop SRH resources (ie, puberty, menstruation, sexually transmitted infections, healthy relationships, sexual assault, and contraception). Their feedback informed the design's language, visual appeal, and engagement factors. To promote meaningful engagement of AAGs at each step, we used strategies such as gamification activities, group discussions, and flexible scheduling, resulting in high retention and ownership of the process among AAG members.

Conclusions: Co-designing with adolescents strengthened the intervention's cultural relevance, youth-friendliness, and credibility. Our process emphasizes the significance of involving adolescents in co-designing SRH interventions, which results in more meaningful, long-term, and youth-friendly solutions.

Introduction

Adolescence is an essential stage of growth and development that sets the foundation for all the consecutive stages of life [1]. For adolescents to grow healthy and develop successfully, they require access to information about their health and well-being, including comprehensive sexual and reproductive health (SRH) education [2]. As adolescents begin to explore their identities and experience significant changes (eg, puberty), SRH education becomes fundamental to protect them from negative SRH consequences, such as unintended pregnancy and sexually transmitted infections (STIs), and equip them to improve their sexual health and well-being (eg, healthy relationships) [3,4]. However, adolescents do not always have the opportunity to access reliable and accurate SRH information and often face barriers, such as stigmatization, discrimination, provider prejudice, and embarrassment while seeking help or accessing SRH resources [5,6]. These barriers are deeply rooted in sociocultural norms that stigmatize healthy sexuality and SRH, particularly among females; lesbian, gay, bisexual, transgender, queer or questioning, and plus (others; LGBTQ+) youth; and those from immigrant communities [7,8].

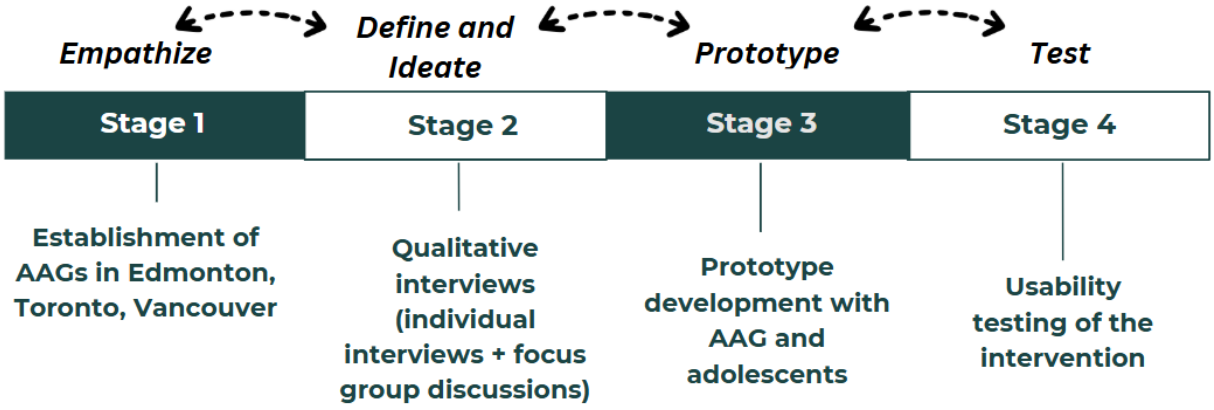
A significant challenge that these adolescents encounter is the lack of reliable and trustworthy sexual health information and services, which can be attributed to restrictive policies, caregiver's or provider's unwillingness to openly discuss sexual health issues, parental control, and lack of confidentiality [5,6,9]. Such challenges are intensified for adolescents from migrant backgrounds as they struggle with balancing cultural, religious, and familial expectations pertaining to their SRH, systemic issues (eg, language barriers and lack of culturally safe resources), and navigating access to SRH services dedicated to immigrant and marginalized populations [7,10]. Previous research with immigrant adolescents in Canada has documented how they often encounter structural barriers within health and education systems, which limit their access to SRH services and lead them to rely on informal digital sources (eg, Google and YouTube [Google]), which may not be evidence-based and can promote misinformation [4,8].

Digital knowledge translation (KT) interventions have the potential to offer promising and equitable venues for influencing various health practices while addressing barriers, including stigma, confidentiality concerns, and difficulties in receiving support [5,9,11,12]. KT interventions facilitate the dissemination of research-based information to health care consumers in a user-friendly format to meet information needs, including but not limited to mobile apps, websites, multimedia content (videos, infographics, etc), and social media platforms [13]. Particularly, in the realm of SRH, digital KT interventions have the potential to reach vulnerable and marginalized populations while providing anonymity and privacy on sensitive SRH matters [5,6,14]. A systematic review on the effectiveness of digital sexual health interventions reported that a higher proportion of website-based interventions were found to improve sexual health outcomes in adolescents, which was demonstrated by an increase in knowledge and access to sexual health services, improvement in STI prevention practices, and reduction in unhealthy sexual behaviors [15]. We conducted an environmental scan to understand the range of mobile health apps dedicated to adolescent SRH in Canada and found that very few apps offered comprehensive, reliable, and evidence-based information [16]. Furthermore, the findings combined with other literature in the field also highlighted gaps in cultural adaptations within such interventions and the need for youth-centered design in SRH digital intervention development [7,16,17].

Co-design is a participatory action research approach that brings together community members, stakeholders, and researchers to collaboratively develop, design, and implement interventions to address issues within the community [17,18]. This approach aims to actively and meaningfully engage individuals in the research process to understand their needs and integrate their experiences to design innovative solutions and improve outcomes [19,20]. This is particularly significant when working with adolescents, as it allows researchers to gain insights into their unique and creative perspectives and determine what would work best for them. Engaging adolescents as equal partners in the design process empowers them to take ownership and responsibility for the process, promoting the success of an intervention. The World Health Organization's framework for planning, developing, and implementing youth-centered digital solutions recommends that for digital interventions to succeed and be sustainable, adolescents should be meaningfully engaged at each step of the planning, design, and implementation process [2]. This ensures that the intervention is adolescent-friendly and accessible, acceptable, equitable, appropriate, and effective among youth [2]. The co-design approach is uniquely positioned to bridge gaps for immigrant adolescents by incorporating cultural perspectives and SRH information needs, addressing issues of trust and accessibility, and ensuring that the style and content of information delivery resonate with their lived realities [17].

Co-designed health initiatives are gaining traction for influencing health behaviors and improving health outcomes [12,17,21]. Several studies have documented the benefits of digital KT interventions in promoting health and well-being among adolescents, particularly with SRH outcomes [5,7,22,23]. Regardless, digital interventions that provide comprehensive, evidence-based, and reliable SRH education for adolescents, especially from migrant backgrounds, are somewhat limited in North America [16]. Also, a few studies have explored co-design in the context of immigrant adolescents' SRH, especially within Canada. Therefore, our aim was to co-design adolescent-friendly digital SRH KT interventions with and for immigrant adolescents in Canada to provide easy access to resources and services at their convenience with anonymity. In this study, we outline the process of engaging immigrant adolescents in the co-design of an evidence-based website as a KT intervention aimed at promoting SRH information.

Methods



Study Design

We conducted a larger multisite project (2023-2024), intending to co-design digital SRH interventions for immigrant adolescents in Canada. Conducting a multisite project helped to ensure that the intervention would reach immigrant adolescents across

XSL•FO
RenderX

Canada. We integrated the principles of community-based participatory action research and human-centered design (HCD) to maximize end user engagement at each step of the co-design process, which guaranteed that the outcome would be effective and sustainable [17,24]. HCD, which is also referred to as design thinking, is a creative and systematic problem-solving approach that prioritizes the needs, desires, and experiences of individuals at the core [24]. It not only focuses on the functionality of a certain solution but also considers the user's motivation, behavior, and challenges, ensuring that it is culturally relevant [24]. Building on these principles, we divided our project into 4 stages (Figure 1). This process helped us to keep adolescents' perspectives and needs at the center of the co-design process and maximize collaboration, participation, and engagement [18].

Figure 1. Stages of the project. AAG: adolescent advisory group.

Stage 1: Establishment of Adolescent Advisory Groups

We first developed and convened adolescent advisory groups (AAGs) in Edmonton, Toronto, and Vancouver regions. These cities have one of the highest percentages of immigrant populations in Canada [25]. Our purpose was to develop a mutual partnership with immigrant adolescents to actively involve them in various research activities, such as data collection, data analysis, resource development, concurrent feedback, and knowledge mobilization.

Research Team Composition

The research team, associated with recruitment and training of AAGs and coordinating co-designing activities, included the principal investigator (PI; SM), the project coordinator (MA), and a research assistant (AIR). The PI who conceived this project has extensive experience with community-based research methodologies and adolescent SRH initiatives with a desire to promote equitable access to SRH resources and services, especially among marginalized populations. We partnered with the Department of Computing Science at the University of Alberta to seek professional support and expertise in co-designing digital resources. The Vice Dean, along with graduate research assistants, dedicated their skills and knowledge to develop the website prototype, incorporate user feedback and preferences, and provide technical guidance at each step of the project. The research assistant (AIR) and project coordinator (MA) were responsible for developing content, connecting with SRH experts for content validation, organizing AAG meetings and activities, coordinating with the team in the Department of Computing Science to track progress, and completing research coordination tasks. With this mutual collaboration, we were able to design our digital intervention effectively and consult on technological-related issues.

Setting and Participants

Through multifaceted strategies, we recruited adolescents aged 12-19 years from various cultural and ethnic backgrounds, ages, and genders, and invited them to participate in our AAG meetings. We included adolescents who were either born outside of Canada and immigrated to Canada (first-generation immigrants) or who were born in Canada but had at least 1 foreign-born parent (second-generation immigrants). Our inclusion criteria required that participants reside in Canada at the time of the study, be able to communicate in English, and have access to a device with internet access to connect with the research team online. Research assistants, in collaboration with various youth organizations, community networks, and adolescent-friendly clinics, recruited adolescents to be part of the AAGs. We also promoted recruitment posters through social media advertising (eg, Facebook [Meta] and Instagram [Meta]) to target our population. We made efforts to develop recruitment materials and strategies to be inclusive of LGBTQ+ youth and those living with disabilities. After screening and recruitment of potential participants, the included AAG members were given a comprehensive explanation of the study objectives, its intended outcomes, risks and benefits, and implications. They were provided with a detailed information sheet, highlighting the particulars about the study and their participation expectations.

The AAGs were established based on practical considerations (eg, the number of adolescents interested in participating) and as per the recommendations of research team members, who had extensive experience working with AAGs. We decided that each advisory group at each site should consist of a reasonable target size of 8-12 adolescents to result in meaningful engagement (expected total AAG participants: 24-30). This sample size enabled us to exercise deeper relationship-building, promoted active participation, and gave opportunity to each member to express their voice. Literature on participatory

XSL•FO
RenderX

research design encourages smaller group sizes to maximize closer collaboration, equitable participation, and maintain a balance between diverse perspectives and group dynamics [17,24]. AAG members in each city were expected to meet online on Zoom (Zoom Communications) throughout the project and share their insights through design-think sessions on the development of the website and SRH resources through a systematic process.

Procedures (Co-Design Process)

To foster meaningful engagement, AAG members were provided with initial training on SRH concepts, qualitative and quantitative research methods (types of research methods, data collection, and interview methods), social determinants of health, and the process of adolescent engagement. An important component of the training sessions was to evaluate the effectiveness of the training, which we assessed through various strategies. For example, we asked AAG members to develop some sample open-ended interview questions to demonstrate their understanding of ethical research practices and their comprehension of research concepts. Each site AAG meeting or session was held separately and was scheduled based on members' availabilities. The sessions started in February 2023. After their training and familiarization with the project, the AAG members met regularly once every month, starting in July 2023 until January 2024 for approximately 60-90 minutes to discuss project updates, recruitment activities, and planning of further activities. As we developed the prototype and started an iterative cycle of feedback and integrating changes, the meetings were organized every other month until August 2024. All the meetings were conducted online over Zoom and were audio-recorded and transcribed verbatim after identifying information was removed. Furthermore, the research assistant and project coordinator maintained detailed notes and meeting summaries to document the co-design process and AAG feedback to capture their input in real time and ensure that their feedback was accurately reflected at each step.

The meetings were moderated by the PI (SM), project coordinator (MA), and research assistant (AIR). The moderators prompted active participation from all members through various techniques (eg, blackboard activities, quizzes, and feedback forms), to ensure that each participant was able to share their thoughts, feelings, and experiences in a safe space. Given the sensitive nature of SRH topics, we ensured to apply a trauma-informed and youth-centered facilitation approach. All team members were trained to identify any signs of discomfort and distress, and a distress protocol was developed to guide facilitators in responding to signs, including pausing the discussion and offering follow-up support. Participants were encouraged to join from private spaces and were reminded of their right to skip any questions, take breaks, or keep their cameras off. Recognizing the potential for power imbalances between researchers and AAG members, we implemented measures to enhance equitable participation, such as using youth-friendly language, giving options for providing feedback, ensuring all feedback was equally valued, and regularly consulting members on meeting structure, preference, and decision-making.

All members tried to attend all meetings, considering their academic commitments and other scheduling conflicts, but all members remained part of the advisory group throughout the project. Despite the occasional absences, the members were proactive in following up with the research team and identified ways to contribute their insights either during sessions or through asynchronous feedback. Throughout the AAG meetings, we facilitated healthy discussions about the learning and informational needs of adolescents, the cultural or social influences on SRH education, and the quality of the SRH education curriculum offered in schools.

Data Analysis

We used a descriptive qualitative approach to synthesize feedback and identify recurrent ideas related to SRH information needs, engagement strategies, and co-design experiences. Meeting transcripts, facilitator logs, and session summaries were reviewed by our research team to identify recurring topics, key insights, and decisions made collaboratively with youth. Two researchers (AIR, MA) independently reviewed the session notes to ensure consistency in interpretation and enhance analytic trustworthiness through iterative discussion and consensus. We kept a detailed log of all AAG interactions and systematically organized the information into categories to support the decision-making process. After evaluating the findings from these sessions, as well as the qualitative interviews conducted in stage 2 (findings are published elsewhere), we finalized priority areas to develop SRH educational content.

Ethical Considerations

We received ethics approval for this project from the University of Alberta Research Ethics Board (August 26, 2021; Pro00113664), the Toronto Metropolitan University Research Ethics Board (April 27, 2022; REB 2022-069), and the University of British Columbia (May 31, 2022; #H22-00395). We followed the Tri-Council Policy Ethical Conduct for Research Involving Humans [26] principles for seeking consent, which does not specify an age of consent for children. Following these guidelines, we determined whether adolescents had the capacity to understand the objectives, significance, implications, risks, and benefits of the study by explaining these topics and asking them to reiterate based on their understanding. The ethics committee from all 3 boards approved and stipulated that if participants were capable enough to understand the procedures and study details, they could provide consent for themselves. After addressing any questions, participants were asked to sign a consent form to confirm their voluntary participation as AAG members, along with a confidentiality agreement to protect the identities of fellow members and the experiences shared within sessions. All participants were deemed capable of providing informed consent for themselves. Participants were given an honorarium of CAD $20 (approximately US $14) per hour for participating in various activities.

Results

Participant Characteristics

We recruited a total of 26 participants for this stage of the study, with 88.4% (n=23) of participants identifying as female and

XSL•FO
RenderX

11.5% (n=3) as male. Out of the 26 participants, 53.8% (n=14) of participants were first-generation immigrants and 46.1% (n=12) were second-generation immigrants. Almost half of the participants were 19 years of age, whereas only 1 participant was 15 years old. None of the participants formally withdrew or disengaged from the project. The demographic information of participants is presented in Table 1.

Design Process

To initiate the development of SRH digital resources offered through our website, we consulted AAG members, stakeholders, and the interdisciplinary research team iteratively to co-develop the best course of action for planning, designing, and implementation. We started with brainstorming potential names for our resource website and its initial layout and design. After discussing many acronyms, we collectively decided to name our website PEER, which stands for Partnership to Empower adolescent Engagement in Research. This not only emphasizes the role that adolescents play in promoting research initiatives but also signifies our work to empower adolescents to drive changes by forming partnerships. We also reflected on various themes for our website and which color would be the most appealing to adolescents. Although some participants shared that bright colors (eg, dark blue and yellow) would be captivating, others commented that these colors might only complement some text and graphics. Therefore, we collectively decided on a neutral color tone (ie, light purple) with a white background. Our development team designed some sample logos and design patterns for the website, which were shared with AAG members.

Development and Delivery of Content

We finalized 6 priority areas to focus our SRH content on: puberty, menstruation, STIs, sexual assault, contraception, and healthy relationships. Our team developed evidence-based resources for every topic. We ensured all topics were covered at length and that common misconceptions regarding these topics were addressed. We identified the information to be delivered within each topic with the help of AAG members. We wanted the content to be informative and engaging at the same time. Hence, we did not rely solely on text-based information but also developed infographics, animations, and videos along with textual information to keep users engaged. We collaborated with 6 stakeholders and experts in the field (SRH researchers, clinicians, sexual health consultants, and SRH or public health nurses) to validate the content and ensure that it is factual, evidence-based, and unbiased. With their feedback, we were able to improve the language and delivery of the content as well as rectify any errors. For instance, validators suggested using language that does not blame an individual and is inclusive and gender-neutral (eg, menstruating people instead of menstruating girls).

Following content validation, we shared the SRH resources with our AAG members (sample content in Figure 2). They appreciated the simple language used to explain complex issues and the different formats that we used to deliver information. They also provided valuable feedback to improve our resources. We initially developed our content videos with audio voice-over using computer software, but members found the voice to be unnatural and robotic. They suggested that the research team record the voice-over instead to give it a more human touch. We welcomed their feedback, and a member of our team did the voiceover. In addition, members re-emphasized that the text under each category should be concise, in bullet form, and have graphics throughout. We considered their suggestions and tried to keep the information concise and bite-sized. Regarding the display of content on the website, we initially organized the subtopics (headings) through horizontal widgets. However, many AAG members did not find this format appealing and suggested that the widgets be organized vertically instead.

XSL•FO
RenderX

Figure 2. Examples of youth-centered sexual and reproductive health content developed for the Partnership to Empower Adolescent Engagement in Research platform.

(A) Content on contraception

(B) Content on puberty

(C) Content on healthy relationships

Integrating all the feedback from the AAG and stakeholders, we finalized the first prototype of our website. We agreed to display a video instead of a still image on the landing page as it seemed more attractive and engaging to the users (Figure 3). Also, we made the edits suggested by the AAG members within the SRH resources and rearranged some tabs on the website. As per their suggestions, we finalized the display and organization of the content. A sample of these resources is presented in Figure 2.

XSL•FO
RenderX

Figure 3. Landing page of the Partnership to Empower Adolescent Engagement in Research digital platform.

We implemented various strategies to collect comprehensive feedback from AAGs on the prototype of the website and SRH resources. Some participants shared detailed feedback through Zoom sessions, whereas others also agreed to provide written feedback through Google Forms. We organized the feedback received from the members and collectively decided whether to implement the change or not. Some features were specifically difficult to implement at this stage as they required advanced technological adaptations (eg, helper chat). Table 2 illustrates some examples of feedback from our members and what steps were taken to address the suggestions.

Table 2. Feedback and response.

Prototype feedback	Team decision
"I would like for the bottom tab to be cleaner with the Land Acknowledgement and the Social links. YouTube is the only icon on a new level and the Land Acknowledgement left aligned text with the title on the left is a bit of putting. Maybe adding this acknowledgement on the About Us page makes more sense."	All the icons at the bottom of the page were aligned on the same line and adjusted to provide a better interface.
"I think the infographics should follow a color theme and be cohesive in one section. The headings could be bolded to make them stand out. All the infographics can be centered in the middle of the webpage."	Headings were bolded and graphics centered on the page. Fonts kept consistent across topics.
"Maybe a helper chat or who could answer any questions."	Feature cannot be added at this point.
"I think adding some basic information about some common reproductive issues/disorders such as PCOS or endometriosis would also help adolescents because some girls get irregular periods, which becomes scary."	Topic of menstruation expanded to include content on common menstrual disorders (eg, PCOS).
"To make the website better, I would maybe move the search bar upwards to somewhere easier for the viewer to see, instead of having to scroll down. That way in every section of the site you can search what you're looking for."	Search bar added to the top right corner as well.
"Change the color of the font. The font of the subtext on the website is very light gray and doesn't stand out as much. It is a little hard on the eyes to read."	All the text font change to black color.
"Include an option to quickly exit the website if learning SRH content and need to close the tab immediately (exist fast button)."	"Discretely exit website" button added to redirect user to a different web page.
"Make it more 'adolescent friendly' by adding brighter color schemes, more stimulating buttons, and more enticing for teens to want to be interested in."	More colors added with brighter graphics and fonts; each individual tab with a different brighter color.

Discussion

Principal Findings

Our project aimed to co-design adolescent-friendly digital SRH resources by actively engaging AAG. This process provided valuable insights into best practices for adolescent participation in digital health intervention development. The formation of our AAGs follows best practices for meaningful youth engagement, as recommended in the literature [17-20,27]. We ensured that meaningful youth engagement was not only fundamental but deeply ingrained in our methodology. By

XSL•FO
RenderX

empowering adolescents to actively participate in the design and execution of our intervention, we pushed beyond tokenism and manipulation, which can hinder genuine engagement [17,27]. Instead, adolescents were involved as co-creators, with their ideas, input, and leadership influencing every stage of creation.

We recruited a diverse group of adolescents aged 12-19 years from various cultural and ethnic backgrounds through schools, community organizations, and social media platforms. This approach represented different perspectives across age groups, cultures, and gender identities [28,29]. To prepare AAG members for effective contributions, we conducted workshops introducing key research concepts and SRH topics. This training addressed a gap in previous studies where adolescent advisory members often lack formal preparation [30,31]. Armed with this foundational knowledge, AAG members were then engaged in the co-design process using various participatory techniques. Throughout the AAG meetings, we used engagement methods tailored to different age groups, including gamified activities for younger adolescents and in-depth discussions for older teens. We also used structured feedback forms and open discussions. This diverse approach is supported by research showing that creative engagement methods can enhance youth involvement and input [24]. The iterative nature of our process, with regular meetings and opportunities for feedback, allowed for continuous refinement of the intervention based on adolescent input, a fundamental principle of co-design [32].

Our approach incorporated several effective strategies from previous studies in website development. We involved adolescents in naming the intervention, choosing color schemes, and determining content formats, aligning with recommendations for youth-centered design in digital health interventions [33]. Prototypes and iterative feedback cycles mirrored successful co-design processes described in other digital health projects targeting youth [12,20,21,34]. For example, the study by Wright et al [23] highlights how youth advisors in their study broadened the scope of their proposed digital intervention through an iterative co-design approach and helped to bring forward an innovative strategy to improve information-seeking behaviors. Our experience highlighted the importance of flexibility when working with adolescents. Offering online participation options and accommodating schedules enhanced engagement, consistent with findings from other youth advisory group studies [35]. In addition, providing compensation for AAG members' time and contributions promoted long-term engagement and valued their input.

AAG members played a crucial role in evaluating content readability and suggesting more adolescent-friendly language, addressing the need for accessible digital health resources. Their involvement in discussions about privacy features and discreet access options aligned with research emphasizing the importance of confidentiality in adolescent-oriented sexual health interventions [36]. For instance, AAG members suggested implementing a "quick exit" feature and disguising the website icon, which was incorporated into the final design to enhance user privacy. During pilot testing, users highly praised these features, with many expressing that these privacy measures made them feel more comfortable using these resources. The AAG members also expressed satisfaction with how their suggestions were implemented, reinforcing the value of their input in the design process.

In addition to the significance of the co-design process in our study, the content topics that were identified and co-developed offer unique insights into the SRH informational needs of immigrant adolescents in Canada. Participants emphasized that although puberty, menstruation, and bodily changes were basic SRH topics, they would appreciate culturally grounded discussions and insights into these topics (eg, tampons and myths). They also highlighted that immigrant adolescents do not always get the opportunity to learn about topics such as contraception or intimate relationships, and navigating access to confidential care, which is also supported by our previous studies and other literature [10,37]. Although platforms in Canada are increasingly adapting their approach to include culturally sensitive information, not many are designed specifically with immigrant adolescents in mind [13,16,17]. This further indicates the significance of this digital intervention.

While our process yielded valuable insights, it also presented challenges. Balancing adolescent preferences with evidence-based practices sometimes requires careful negotiation, which aligns with challenges noted in other co-design studies [20]. For example, when adolescents suggested including popular but scientifically unsupported remedies, we had to find ways to address these interests while maintaining medical accuracy. We navigated these situations by explaining the importance of scientific evidence, acknowledging the popularity of these remedies, and collaboratively finding ways to address the underlying concerns that made these remedies appealing. This approach ensured that adolescents felt heard and valued, even when their initial suggestions were not feasible. Unexpectedly, these negotiations led to innovative ways of communicating complex medical information in adolescent-friendly language, enhancing the overall accessibility of the content. Furthermore, to ensure the sustainability of adolescent involvement, we have established a rotating membership system for the AAG and are developing a mentorship program where experienced members can guide newcomers. This mentorship program will include training sessions for mentors, regular check-ins, and a 6-month mentorship cycle to balance continuity with fresh perspectives.

Future Implications

Preliminary feedback on the intervention has been positive, with pilot users reporting high levels of engagement and improved SRH knowledge. Specifically, users praised the website's discreet design, easy-to-understand language, and engaging features. However, long-term effectiveness studies are still ongoing, and findings from the usability testing are published elsewhere. These studies will track key metrics, including SRH knowledge retention, user satisfaction, frequency of website usage, and self-reported behavior change related to SRH practices. By monitoring these outcomes, we aim to comprehensively evaluate the intervention's impact and identify areas for future improvement.

XSL•FO
RenderX

Limitations

Through collaborative efforts in our co-design process, we actively and meaningfully engaged immigrant adolescents as active partners in developing the PEER digital SRH platform. However, our process also had its limitations. First, while our recruitment efforts aimed to include individuals from diverse gender identities and backgrounds, including LGBTQ+ youth and adolescents with disabilities, our advisory group lacked sufficient representation from these groups. Although this raises the question of the generalizability of our content to diverse groups, we ensured that our content was inclusive and included gender-neutral language. This was strongly emphasized by our AAG members and SRH experts working with adolescents. Second, our advisory group was predominantly female (n=23, 88%), and more than half of the participants were aged 18-19 years old. This demographic skew may limit the generalizability of our findings and could influence the content developed for the platform. The predominance of female voices may have emphasized certain gendered experiences and needs (eg, content on menstruation and pubertal changes), while perspectives of male and nonbinary youth may be underrepresented. To address this limitation, we intentionally explored the SRH information needs of male and gender-diverse adolescents by encouraging participants to discuss challenges faced by their peers across different gender identities. However, it can also be considered as a strength as participants were able to offer greater reflection based on their capacity to reflect on their previous experiences with SRH education. Our future research will aim to engage and seek a more gender-diverse group to evaluate the effectiveness of the intervention design and incorporate recommendations to reflect the full spectrum of adolescent SRH experiences and needs. Finally, maintaining consistent engagement over time and managing diverse opinions within the group required significant resources and facilitation skills from the research team. Future projects could benefit from establishing clear guidelines for resolving conflicts between adolescent preferences and evidence-based practices and developing long-term strategies for long-term engagement.

Conclusion

Adolescents need access to accurate and reliable SRH information for positive sexual health outcomes and to prevent unintended consequences, such as STIs, unintended pregnancies, and so on. However, they do not always have the necessary means to secure such information. Digital interventions have the potential to influence health behaviors and promote positive outcomes by reaching a wide range of audiences, especially those who are at risk of being distanced from mainstream services. We used the principles of community-based participatory action research and HCD to co-design digital SRH interventions with adolescents by keeping their needs at the center of the process. By giving them a voice in the process and the ability to influence decision-making, we were able to co-develop a resource that has the potential to be user-friendly, accessible, effective, and sustainable among immigrant adolescents. This process allows the cocreation of culturally relevant interventions that have the potential to reach vulnerable populations, particularly in conservative societies where stigma and misinformation are pertinent.

Acknowledgments

We would like to acknowledge Eleni Stroulia (Vice Dean of the Department of Computing Science, University of Alberta) and Nilanjan Ghatak (Graduate Research Assistant) for their contributions toward the digital intervention development. This work was supported by the Women and Children's Health Research Institute (WCHRI) and the Canadian Institute of Health Research (CIHR) (Grant # RES0053962).

Abstract

Background: Although research has found online peer support forums to be helpful for those with mental health conditions, no studies have explored the experiences of those who use forums for support with postpartum psychosis (PP) specifically.

Objective: This study aimed to understand the lived experiences of using online forums for PP, and how this form of support differs from professional and other informal support.

Methods: This study used a qualitative approach, including semistructured interviews with 8 participants. Recruitment took place via an online forum run by a charity called Action on Postpartum Psychosis. Transcripts were analyzed using interpretative phenomenological analysis.

Results: Four themes were developed in line with participants' experiences (1) from isolation to connection: validation, growth, and hope from shared experiences; (2) complementing not replacing: filling the gaps in support; (3) impacts of privacy, representation, and readiness to share on engagement; and (4) relational experiences within peer support: altruism, boundaries, and comparison. All participants believed forums were helpful to their well-being and recovery; however, some also reported difficulties with engagement, comparison, and regulating their own use. Findings suggest that forums may benefit from being designed in a way that protects users and their identities, for example, via trigger warnings and setting boundaries.

Conclusions: Peer online forums offer a unique and potentially effective addition to existing support provided by professionals and personal connections. Professionals should signpost people experiencing PP to forums, but should also understand the support that may be needed in terms of monitoring use and ensuring that appropriate boundaries are put into place.

KEYWORDS

postpartum psychosis; puerperal psychosis; postnatal psychosis; online peer support forums; online forums; peer-to-peer support; peer support

Introduction

Postpartum psychosis (PP) is a rare perinatal mental health condition, affecting between 1 and 2 in 1000 individuals [1,2]. It is a psychiatric emergency that can occur suddenly [3], usually between 0 to 185 days following childbirth [4]. Symptoms characterizing PP include mood changes, hallucinations, and delusions [5,6]. The risk of onset of psychosis is thought to be approximately 23 times higher in the 4 weeks following childbirth than at any other stage of life [7]. PP is less common and less understood than more common perinatal mental health conditions, such as postnatal depression, and may therefore be

XSL•FO
RenderX

less readily recognized [8]. Current understanding of what is helpful for PP is limited [9], and therefore it is important to consider support for people with lived experience of PP throughout and following this period.

Despite recent introductions of specialist perinatal support within the United Kingdom [10,11], and the time spans for which these services can support individuals being extended [12], gaps remain in both understanding and treating PP [4,13]. People with lived experience of PP have reported a lack of awareness from both the public and professionals [14], leading to delayed recognition and treatment [15]. PP is not formally recognized as a diagnosis by the National Institute for Health and Care Excellence [16] or the *DSM-5 (Diagnostic and Statistical Manual of Mental Disorders* [Fifth Edition]) [17]. The most common treatment options for PP include medication [18], psychological interventions [19], and, occasionally, electroconvulsive therapy [20]. Recovery from PP is thought to take between 6 and 12 months [21], with the most severe symptoms often resolving within 12 weeks when intervention is received [22]. However, there are many challenges that people with lived experience of PP encounter that these traditional interventions may not address. People with lived experience of PP report feeling isolated [14], overwhelmed [5], and stigmatized [19,23], indicating that psychosocial challenges for people with lived experience of PP are difficult to navigate throughout the recovery process.

An increasingly popular means of support for health-related challenges is through online mediums, and the use of this for mental health has become a fast-growing area [24]. It is thought that online support could be particularly helpful for mental health for reasons including the opportunity to remain anonymous when seeking support [25] to help decrease felt stigma [26], and the social isolation that is also commonly experienced [27].

Peer forums are a form of online support, characterized by the ability to anonymously provide and receive support among those in similar situations [28]. Previous research has found that peer support forums can reduce isolation [29,30], promote information sharing [30,31], and provide emotional support and hope [32]. In a recent realist synthesis to identify the impacts of online peer support forums for mental health [29], findings included improving self-efficacy and psychological safety, and connection. However, users of online support have also reported that they can sometimes feel triggered by others [30], receive misleading, defensive, or unempathetic responses [31], and struggle with their own boundaries [30], suggesting this may be a nuanced area.

When considering online support for those with PP, it is important to consider the unique experiences that could impact its use. Declines in mental well-being within the perinatal period can be distressing and overwhelming [33]. In addition, there is the challenge of navigating parenthood and the changes in identity that this and PP bring [19], alongside the impacts of symptoms on daily life, with those who experience relapse of PP being found to have more ongoing functional difficulties [34]. Online forums for support with parenting are commonly used for voicing feelings around parenting that might feel difficult to speak about openly in other contexts; however, research has found that forums tolerate these expressed emotions only to a certain level before it is implied the person may not be in the "norm" [35]. This limits the support available to people with lived experience of PP in these nonspecialist forums and suggests they might need to speak with others who understand to feel safe.

Despite there being no existing research that specifically examines the impact of peer online support for people with lived experience of PP, studies on wider topics have reported related findings. For instance, perceived social stigma is correlated with increased use of online support [36], and those experiencing perinatal mental health conditions tend to have higher levels of internal stigma [33]. Furthermore, findings have reported that increased use of forums could result in users being more likely to disclose their symptoms to professionals [33]. Research has demonstrated that those who conversed with others who have also experienced PP found this support helpful and normalizing [19]; however, with PP being rare, shared experiences may likely be more easily accessible through online mediums. Stawarz et al [37] suggested that technology and online support should not be a replacement for more formal support but instead should complement it and form part of a wider, holistic system. This may be particularly true for PP, which requires fast intervention and support [38], indicating the need for professional involvement alongside personal and social support.

NHS guidance directs people with lived experience of PP to peer support forums [2]; however, there have been no studies that have explored the impacts and safety of this type of support. Therefore, this study aims to explore the experiences of those who have used online peer forums for support with PP, to increase the evidence base and aid professionals in signposting decisions. For this research, support with PP was defined as when an individual had used the forum specifically in relation to any symptoms or difficulties related to their PP. The research questions posed were: (1) How do individuals with lived experience of PP use and make sense of online peer forums? and (2) In what way does online support differ from support from health care professionals and other informal support?

Methods

Study Design

In this study, Interpretative Phenomenological Analysis (IPA [39]) was used to explore the lived experiences of using online forums for PP, and how this form of support differs from that of professional and other informal support.

This included any support received within a forum environment that was related to symptoms or difficulties associated with PP. This broad definition of support meant that participants were able to speak about their own individual support needs related to their experiences of PP, which can vary between participants. In this study, "support" was operationalized as any form of emotional, informational, or experiential connection participants received through engagement with an online peer forum.

The method used for this study was IPA. This method most appropriately met the research aim to generate a rich and

XSL•FO
RenderX

detailed understanding of participants' experiences, rather than a broader and more varied focus, as is seen in other qualitative methodologies such as thematic analysis [40]. In addition, within IPA, there is a focus on lived experience, which helps to capture nuance between participants [41] and to explore the meaning behind experiences [42].

Patient and Public Involvement

Patient and public involvement (PPI) has been found to add insight from lived experience, achieve meaningful outcomes [43], make research more accessible, and ensure sensitivity to the topic [44]. The lead researcher held consultation meetings with a member of the public who had lived experience of using forums for support with PP. Consultations included input on the topic guide, completing a mock interview, and developing research materials. In addition, the researcher liaised with employees of Action on Postpartum Psychosis (APP) with lived experience of PP regarding research materials, the topic guide, and terminology used. In response to PPI feedback, wording in the research materials was changed, alongside edits to the research flyer to ensure language was accessible.

Inclusion and Exclusion Criteria

Inclusion and exclusion criteria were considered to ensure that the sample was relevant and focused on the research aims (Table 1).

Table 1. Inclusion and exclusion criteria.

Inclusion or exclusion	Criteria	Rationale
Inclusion	• Aged 18 or older • Having the capacity to consent • Having used peer support forums within the past 2 years • Symptoms of postpartum psychosis (PP) experienced at any time	• Able to give informed consent • Ensuring consent is ethically given • Forums are evolving quickly [45]; those who used forums longer ago may have had experiences less relevant to current experiences • Due to recognition that people with PP can need support for several years after onset, and recognizing that support has changed in recent years [11,12], and wanting to capture information from those who used the forums when support might not have been as available
Exclusion	• None beyond self-reported experiences of PP symptoms	• No formal mental health diagnosis required as PP is not recognized as a distinct diagnosis [17], and potentially issues of stigma [46] and lack of formal screening measures leading to PP going unrecognized [20]

Sampling

A purposive sampling approach was used between February and July 2024 to recruit people with lived experience of PP who had used forums for support. This method aligned with the aims of IPA, which prioritizes depth of experience over breadth of participants to gain a detailed understanding of the phenomenon of interest. A sample size of between 8 and 10 participants was sought, in line with recommendations for both qualitative research [47] and research conducted at a doctoral level [36]. It was anticipated that this would provide sufficient data to build an understanding of experiences of support, particularly due to the rarity of PP and therefore the likely small cohort of available potential participants who had both experienced PP and used forums for support with this. Furthermore, this sample size was considered sufficient to answer the research questions posed.

Recruitment

Participants were recruited through an international forum run by APP. This forum is hosted by HealthUnlocked, a worldwide community providing support for over 250 health conditions, with the APP forum accommodating 3793 users (figure correct on February 19, 2025). Participants could have accessed other forums for support with PP and still participated, as the research was not specific to the APP forum. Meetings were held with moderators of the APP forum, who posted a recruitment flyer on the forum to advertise the study. Forum users interested in taking part were invited to contact the lead researcher via email and then offered a screening call to check eligibility and to address any queries.

Study Procedure

Following the initial screening call, eligible participants were provided with an information sheet (Multimedia Appendix 1) and a consent form via email (Multimedia Appendix 2). Participants were then asked to return the consent form to the lead researcher if they wished to take part. Once the form was returned, an interview time and date were booked that were mutually convenient for both parties. Sociodemographic information (Table 2) was collected verbally at the start of each interview, and participants were given the choice to decline to answer any questions if they wished.

XSL•FO
RenderX

Table 2. Participant demographic information.

Participant	Pseudonym	Age (years)	Ethnicity	Country of residence	Time since onset
1	Jane	31	White Scottish	Scotland	2 years
2	Florence	39	White British	England	13 months
3	Emmeline	57	White American	United States	22 years
4	Frida	34	White British	England	2 years and 3 months
5	Ada	35	White, Mixed Asian	England	4 years
8	Rosalind	51	Black African	England	19 years
9	Marie	35	African American	United States	1 year and 7 months
10	Eleanor	43	White British	England	8 years

A topic guide (Multimedia Appendix 3) was used during the interviews to remain close to the research aims. The definition of support with PP was used to develop this topic guide, and the questions were reviewed and refined within research supervision and PPI meetings. A mock interview was conducted with a PPI representative, which led to some changes in the terminology and style of the questions within the topic guide, for example, reducing jargon in the questions.

Data Collection

Interviews took place at an agreed time over Microsoft Teams, Zoom (Zoom Communications), or a telephone call, depending on the participant's preference, and were recorded onto an encrypted audio device. Before commencing the interview, consent was checked. A topic guide was used as a prompt; however, in line with IPA [39] methodology, the interviews were guided by participants and their experiences [48]. This was done by allowing participants to speak about the phenomena they felt were pertinent to their experiences of using forums for support with PP. Participants were able to interpret questions in their own way, and further questions followed from responses given, meaning that a more thorough exploration of experiences could be undertaken. This helped to gain further context and understanding around the topics discussed by each participant, as well as a way to relate any responses given back to the research questions. Following the interview, participants were debriefed, and their safety was checked.

Data Analysis

To analyze the data, the first 3 interviews were transcribed by the lead researcher soon after completion to review the questioning style. The remaining 5 interviews were transcribed by a contracted transcriber, who had undergone screening and signed a confidentiality agreement. The reason for this was that the lead researcher was not feeling immersed in the data by transcribing, but instead by reading the transcript back while listening to the recording. As a transcriber was available, this was used to spend more time engaging with each interview. Reading the transcripts while listening to the interviews helped to understand context and emotive language and to become more familiar with the data, while also checking the accuracy of the transcripts. Analysis was performed in line with recommended processes from Murray and Wilde [48], which were developed for postgraduate IPA projects undertaken by those who are novices to IPA. This approach follows a stage process: first, initial coding, which involves notations for any elements directly relevant to the research aims. This process was completed by hand using Post-it notes. The second stage is grouping the codes into subthemes, with each subtheme given an interpretative summary and title. The following stage is producing interpretative summaries and titling themes for each participant. Following this, the stage of merging analyses across transcripts was completed, where the subthemes from each participant were merged into collective themes across participants, with narratives and titles created for each.

Reflexivity

IPA is a methodology underpinned by a critical realist epistemology [41]. This aligned with the lead researcher's critical realist view that, while the material world exists, our own perceptions and language shape the way in which we see and experience it [49]. This means that experiences of the world are all individual, such that although all participants had experience of using online forums, the meanings made from this would all differ.

The nature of IPA involves a process of double hermeneutics, with the participants interpreting their own experiences and the lead researcher further interpreting this themselves [49]. Therefore, the data output from this study is a secondhand account of the data collected, which may have been influenced by the demographics of the researchers (Multimedia Appendix 4). The lead researcher was a White, UK-based female trainee Clinical Psychologist with a professional background in social work. These personal and professional identities shaped the lens of focus when approaching the research, potentially influencing the analysis by orienting attention toward psychosocial, relational, and systemic elements of the data. In addition, the analysis was conducted from within a Western sociocultural context, with UK-specific mental health systems and norms likely influencing interpretation. While the researcher had no personal experience of PP, previous clinical work with individuals experiencing PP may have led to certain preconceptions or expectations.

To try to minimize the impact of these factors and enhance the trustworthiness of the analysis, several measures were taken. First, regular supervision was sought throughout the research process. Two supervisors supported the project; both were qualified clinical psychologists who were White, female, and living within the United Kingdom. One supervisor had expertise

XSL•FO
RenderX

in qualitative research methods, while the other had experience working within perinatal mental health services. Within supervision, they both reviewed developing codes and themes and offered critical feedback to help challenge assumptions and ensure that interpretations were grounded in participants' accounts rather than shaped by the researcher's preexisting frameworks.

The lead researcher also engaged in reflexivity through the use of a reflective diary, in which decision-making, emotional responses, and interpretations of the data were documented. This process helped identify where professional training or clinical experience might be influencing the interpretative process. Reflexivity was particularly prioritized after emotionally resonant interviews or when strong thematic impressions emerged.

In addition, moments of purposeful reflection were built into the analytic process—for example, pausing after the first interview and again after the first full transcript analysis, supported by supervision. This helped to preserve the integrity and transparency of the analysis and to ensure that findings remained grounded in participants' lived experiences.

Ethical Considerations

Ethical approval was granted by the Lancaster University Ethics Committee (FHM-2024-3722-RECR-3). An information sheet was provided to participants, and informed consent was obtained through a signed form. Participants were given the option to opt out at any point before data analysis was completed. Due to the potential for distress associated with the interview process, debrief materials were sent to all participants following the interview, with details of services they could contact for support if necessary. Contact details for a named professional involved in each participant's care were collected before the interview in case any risk issues were disclosed during the interview process. Data were deidentified and securely stored on the university's cloud storage. Participants were compensated with a £30 ($39.95) payment for giving their time to the research.

Results

Participant Characteristics

Initially, 15 people expressed interest in the study. Of these, 2 did not attend the initial screening call, and 3 were ineligible to participate due to not using forums for PP (n=2) or not using forums within the past 2 years (n=1). Two participants consented to be interviewed; however, they did not take part due to disengagement (n=1) and withdrawal (n=1). This resulted in a final number of 8 participants. Recruitment was a relatively easy process, with enough people showing interest through the APP without the research having to be advertised elsewhere. Participants were happy to discuss their experiences openly, with the average length of interview being 41 minutes. Participants were given pseudonyms, and demographic information was collected (refer to Table 2).

Analysis

Following the analysis, 6 interrelated themes were constructed to illustrate experiences of using a peer support forum. Multimedia Appendix 5 demonstrates which participants contributed to each theme.

Theme 1: From Isolation to Connection: Validation, Growth, and Hope From Shared Experiences

All participants are represented within this theme, which captured the evolving relationship participants had due to PP; beginning with feelings of isolation and stigma, progressing through validation and understanding when finding the forum, and resulting in a sense of growth, knowledge, and purpose. Validation of these experiences from peers who had shared similar challenges was identified as an important part of recovery.

> *"Reading the experiences of women who'd recovered gave me hope that I would too"* [Florence]

> *"I think it's given me a real validation that what I went through was real… and not just something they couldn't figure out"* [Emmeline]

This demonstrates the lasting impact of feeling misunderstood during the initial phases of PP, and how finding the forum, even many years after experiencing PP, helped to provide affirmation. For participants who experienced PP longer ago, the impact of having many years of no connection to other people with lived experience of PP was loneliness that was turned around by finding the forum.

The accessibility and anonymity of the forum made it particularly valuable. It allowed participants to engage when it felt emotionally safe and to return to the space whenever needed without pressure or stigma.

> *"I think the other thing is the accessibility day or night, in that if… maybe I couldn't sleep or I was up with the baby, you can access it at any time."* [Florence]

While many participants used the forum from the early days of diagnosis, Marie did not use the forum initially due to feeling in denial. She described how the forum helped her to accept her diagnosis, leading to her eventually being able to post herself.

> *"You're assisting people… whilst still receiving treatment for yourself, so yeah, I felt so strong again in the community"* [Marie]

The rarity of PP also impacted experiences, with participants feeling as if there was no one they could speak to before the forum who understood what they had been through.

> *"That's a long time to go without ever having talked to somebody about something that was so pivotal in your life, and so that was just amazing to me when I first got on and started talking to people. The feeling of validation, the feeling of connection, the feeling of wanting to help was overwhelming."* [Emmeline]

The use of the word "pivotal" here demonstrates the profound impact that forums can have for those who use them.

Two participants commented on how they had felt increased isolation due to others cutting them off following their experiences of PP:

XSL•FO
RenderX

> *"I've been shunned by people who I thought were friends"* [Rosalind]

> *"I felt isolated from everything, from the community, from my family"* [Marie]

Rosalind and Marie were also the only participants in the study with African heritage, which suggests it is worth considering the specific cultural impacts that PP can have and how PP might be viewed differently within different communities. For these participants, the isolation was felt on an additional level due to personal support feeling unavailable, highlighting how important the connection on the forum was.

Theme 2: Complementing, Not Replacing: Filling the Gaps in Support

All participants, except one, are represented in this theme, which recognizes the way in which forums supplement existing services and personal support. Peer support was experienced differently from any other support that had been offered, much of which had led to people with lived experience of PP feeling misunderstood and judged.

> *"[Peer support] is almost like a superpower because… you've got that empathy"* [Frida]

Even for participants who felt there had been a good support system around them throughout, it felt safer to speak to peers, with the benefit of feeling less like a burden:

> *"You don't want to burden your family either, so talking to your people on an online forum… is, I think, personally the better way."* [Eleanor]

There was a sense of safety felt within the PP community when speaking about these distressing thoughts, which may not be present elsewhere.

Personal support was felt to be lacking in the understanding that peer support can provide:

> *"I've always been so lucky to have friends and close family and support… but for this experience, it's not been good enough."* [Jane]

This demonstrates how there is a unique nature to PP that means personal support might not have the same impact when experiencing severe mental health difficulties. Jane describing how "*everyone close to me has had a different kind of experience of the same situation"* shows how PP adds a layer to the changes felt post partum.

When referring to professional support offered, most participants found this helpful and felt that such services should be complemented by the forums rather than replaced. There were concerns raised about people who might use the forums instead of speaking to professionals.

> *"Some of the women sounded like they just really needed to go and see their doctor, and that this forum wasn't necessarily quite the right place for them."* [Jane]

This highlights how PP is multifaceted and that one type of support may not be helpful in isolation. There is recognition of the limitations that the forum can have, particularly around medication and interventions. The acknowledgment of health care professionals being central to the start of recovery demonstrates how forums may become more useful at a later stage.

However, not all participants felt supported by professional services. Rosalind described how she felt let down by services, stating that she felt misunderstood. Rosalind believed that services are so overstretched that they cannot provide the support needed:

> *"It's ridiculous that we're having to use peer support in order to provide services that really the NHS should be providing. It's the walking wounded trying to help each other."* [Rosalind]

Rosalind's experiences may be different from those of other participants due to witnessing changes in services without having access to more specialist services that have recently been created (eg, being ineligible for MBU support or perinatal services support due to experiencing PP 19 years ago). As someone still experiencing the impacts of PP, Rosalind demonstrates a need for longer-term support than statutory services can provide. This was reinforced by Jane describing discharge from professional services as being a "*carpet from underneath you.*" It was felt that forums could help to fill this gap, as they can be accessed for as long as needed:

> *"Then once I get discharged from that, I'm like, 'right, I've still got my platform, I've still got the online stuff that I can still reach out to should I need it'… it's like you feel safe… you're not left to it."* [Ada]

This shows a potential disconnect between what specialist services provide (up to 24 months post partum) and what people with lived experience of PP believe would be helpful.

Theme 3: Impacts of Privacy, Representation, and Readiness to Share on Engagement

Two participants are not represented in this theme, which recognizes that although forums were valued by all participants, state of mind, age, and identity all played a role in how able people felt to share their experiences openly. Reflections were provided on the stages at which participants first started to use the forums, with Ada referring to how, initially, she felt paranoid and embarrassed and therefore did not want to use them. Eleanor echoed this point, stating that she did not feel able to speak about PP until 3 months following the onset. There were physical elements of PP that were thought to be involved in engagement, alongside being able to check in on emotional state.

> *"Then at the time when I was so acutely unwell, my brain was just firing off left and right, I could barely even use my phone at one point, and I couldn't organize my thoughts."* [Eleanor]

This adds weight to the importance of the type of support at different stages, acknowledging that symptoms of PP can make using forums more difficult and therefore other support may be imperative at this time. Privacy within forums was also a challenge, with the anonymity often provided not removing this concern:

XSL•FO
RenderX

> *"[Forum] is an international forum, and I do worry a little bit about privacy issues."* [Emmeline]

Florence referred to younger generations potentially finding forums easier to use, but in older generations, it is more common to keep one's feelings to oneself. As the interview progressed, Florence reflected on this and provided insights into how she can often still feel shame around PP, wondering if it could be helpful for her to open up more. This demonstrates the complexities of deciding what to share within forums and how this might continually shift as participants move through their recovery.

A nuance that came through within this theme was around ethnicity, with Rosalind feeling that there are impacts of being a Black woman on her use of forums. Rosalind described how Black women are more likely to experience birth trauma and be within the mental health system, and how this could translate to being more likely to use forums for support. However, this was not reflected in Rosalind's experience, with feelings of being underrepresented within the forums, which resulted in further isolation.

> *"If [forum] could have someone who is black, that would really help me as well, because I think in the black community, mental health isn't talked about or understood."* [Rosalind]

This demonstrates how identity can further lead to feelings of isolation and how this can replicate difficult experiences from other areas of life. In feeling unable to relate to others on the forum, there could be an impact on engagement and freedom to share, causing those from a global majority background to be at a disadvantage when engaging in peer support.

Theme 4: Relational Experiences Within Peer Support: Altruism, Boundaries, and Comparisons

One participant is not represented within this theme, which acknowledges the complexities that navigating a community can bring. On one hand, users could access information and support, and were given opportunities to use their experiences to help others. However, sometimes these opportunities brought pressure to respond and a sense of responsibility or comparison to others.

The forum was described by Marie as a "*happy place*" that allows participants to get their own support as well as give it:

> *"I just want to reach out… and tell them that they can get through it, there is an end, and I am proof there is an end."* [Emmeline]

This acknowledges the tie people with lived experience of PP tend to feel to the community, wanting to give back and *"do my bit for the community"* [Frida]. However, it also felt at times that this desire to give back became burdensome:

> *"The compulsion to post or to reply to people… that did cause me quite a bit of stress. Those feelings of like guilt."* [Frida]

The use of the words *"compulsion"* [Frida] and *"obsession"* [Florence] were used when speaking about using the forums when in a more vulnerable place. This shows how forums can have emotive impacts on those using them, who may already be experiencing their own distress and challenges. There was mention of moderation at these times being helpful:

> *"He'd [partner] realized what had been going on with me, going down a rabbit hole on the internet, obsessively looking for answers… so there was external moderation."* [Eleanor]

Boundaries were also described to help safeguard against feelings of responsibility. However, they were also acknowledged to be difficult to establish while mood is fluctuating, emphasizing the impact that symptoms of PP can have on engagement.

A further challenge of the forums arose from the tendency to compare. Upwards comparison was the most prominent in interviews, characterized by feelings of being patronized or not being good enough when speaking to those who had an *"easy"* [Jane] recovery.

> *"You think have I made a mistake? It's like am I doing it wrong? Like am I doing recovery wrong?* [Jane]

Ethnicity also played a role in upward comparison, demonstrating the impact that diversity within spaces such as forums can have.

> *"I just think in white women the care is generally a lot better, and I'm seeing women recover so much better, whereas with me now I'm disabled and it's ruined my full life."* [Rosalind]

This shows how forums can highlight discrepancies in care offered for PP and recognizes the impact that this could have on users.

Downwards comparison was also mentioned during interviews and seemed to be associated with feelings of being ungrateful for their experiences, feeling sad for others, and wondering "what if."

> *"I feel fortunate with the care that I got… but sometimes it makes me feel… ungrateful."* [Jane]

Questions arose about how representative forum posts are of the wider population of people with lived experience of PP. For example, Jane wondered if those who are struggling more tend to use forums more, interpreting this as feeling that those who recover well move on.

> *"It's just scary to see so much content and relapses and stuff, but that might be the people who might need support. I wonder if there's like a hoard of people who have not had like relapses or other diagnoses that don't need the support and are fine and not on the forum."* [Jane]

This poses an interesting point about the types of users that forums might attract, and whether this is reflective of different experiences of PP, or whether this tends to reflect certain narratives instead, such as people struggling to recover. However, a differing opinion was put forward by Rosalind, who felt as if there were not many people posting who were reporting difficulties, which left her feeling as if she was struggling more than others:

XSL•FO
RenderX

> *"At least online it feels like they have recovered more than I have… that's why I wish people would talk because I can't be the only one who's had an adverse reaction to their meds."* [Rosalind]

Discussion

Principal Findings

This research aimed to explore the lived experiences of using online forums for PP and how this form of support differs from that of professional and other informal support.

The findings demonstrate that this is a complex and nuanced area, and that people with lived experience of PP tend to use forums when reaching stability rather than in the initial acute phases of PP. It is also acknowledged that the use of forums can be helpful, supportive, and aid recovery. However, forums can also have challenges such as feeling responsible for other people with lived experience of PP, comparing to others, and needing to implement boundaries to maintain well-being. Individual experiences are impacted by many factors, including identity, other available support, and recovery. The research was novel in that it was the first investigation into the use of peer online forums for PP, adding to the limited research base on PP. The use of IPA allowed an in-depth, idiographic insight into the lived experiences, which did not just focus on forum use at a single point in time, but instead over the recovery trajectory of the participants. This created an understanding of how the use of forums changes, increasing knowledge of how these mediums can provide longer-term support for people with lived experience of PP.

An important element of this research was related to the rarity of PP [6], which was felt to increase the isolation that can be felt within perinatal mental health conditions [50]. Online forums give the opportunity for connection between people with lived experience of PP that otherwise may not occur, especially if situated in a more remote area. Connection found within forums was discussed by all participants, which demonstrates the extent to which online relationships can be felt as true connections despite potentially never meeting face-to-face. A recent systematic review has found PP to be a relational experience, both in recovery and management [51], and although this was regarding the couple relationship, considerations should be given to how the relational elements of PP might also be helped by connection on forums and with peers. The ability to engage on forums was found to be helped by accessibility and anonymity; this mirrors existing findings regarding forums that these factors remove barriers to support and reduce stigma [30]. This is particularly important within the PP community due to increased levels of stigma [52] and fears around social services involvement following disclosures [53].

Connection was felt to be an imperative part of forum use, linking to the CHIME recovery framework [54]. Forums played a clear role in promoting connectedness, instilling hope, shaping identity, and offering a platform for meaning-making and empowerment. However, it is important to note that this was related to personal recovery and that there are differences between this and clinical recovery [55], with both being important within psychosis presentations [56]. This contextualizes theme 2 and the importance of both professional supports to promote clinical recovery, while peer support can help achieve personal recovery.

However, connection can come with challenges, such as potentially feeling responsible for the well-being of other users. A key finding within this study was that participants felt they wanted to give back to the PP community, which was highlighted by several participants as being important for both their recovery and well-being. Although previous research has referenced helping others as potentially being related to reciprocity, and therefore expecting mutual benefit from this [57], within this study, participants suggested different reasons for this altruism. Particularly, this stemmed from an understanding of "dark" times and wanting to provide hope when approaching recovery. For participants who still felt in the midst of PP, helping others originated from a place of not wanting anyone else to feel the isolation and loneliness they experienced. Despite feeling that helping others was important to them, it is crucial to recognize the impact that this responsibility could have on forum users.

The results reflected how participants felt it was important to have boundaries when using online forums, and how this had to be learnt. This was found to be crucial during acute stages [30], which is particularly relevant as participants often engage on forums shortly after the onset of PP. Within the data collected, participants acknowledged how boundaries were more difficult to implement when experiencing more severe symptoms of PP. This poses a question of how forum users set boundaries during the time they potentially need them the most. Participants described feeling unable to step back, which resulted in obsessively scrolling for hours. This is similar to current understandings of social media addiction [58], with peer online forums being alike in characteristics; involving connection, community, and gaining information [29]. Understandably, this sensation akin to addiction could be felt more severely by people with lived experience of PP, who are potentially experiencing a lack of connection due to sleep deprivation [59] and symptoms of mania [7].

Conversations regarding professional support took place across countries and cultures, where participants explained how forums were helpful to them because they could access them for as long as was required; in turn, this helped ease the anxiety of being discharged from professional care. Research has found that levels of anxiety are often high at discharge from both hospital and community care [60,61], which could be particularly relevant within the United Kingdom, where specialist perinatal support is only provided for the first 2 years following birth [12], despite symptoms and impacts of PP sometimes continuing well past this point [62]. This links to Jane's feelings that the forum has an overrepresentation of people with lived experience of PP who have found recovery more challenging, as these users may have required more support and have therefore continued to use the forum. However, a related study recently reported that they did not find engagement with online peer support forums to be correlated with symptoms or disability [63], which makes it important to consider why people with lived experience of PP might continue to use forums.

XSL•FO
RenderX

The findings of the study showed that many of the participants felt they engaged in comparisons with other users on the forum. This can be understood within the context of social comparison theory [64], which has been found to have a strong presence in the use of online communities, such as social media [65]. While upwards comparison has been previously linked with promoting hope and downwards comparison has been thought to put things into perspective [66], this study found comparison to also have potentially detrimental effects. Upwards comparison resulted in the perception of insufficient recovery, while downwards comparison resulted in feelings of guilt about being ungrateful, as their situation could have been worse. It is important to understand the impact that both types of comparison may have on users, particularly if using the forum at a more vulnerable point.

Strengths and Limitations

The use of IPA as a methodology was found to be of value within this study, allowing the understanding of not only the commonalities between participants' lived experiences, but also divergences from these and an exploration of why these might occur. In addition, even with a small sample size, there was diversity in the ethnicity of participants, which contributed to understanding how culture may impact experiences. Using PPI within the research was also felt to be a strength, as this added the perspective and input of people with lived experience of PP, which allowed adjustments to the research when needed. The study added to the lack of existing research around PP to help increase awareness, understanding, and intervention options for people with lived experience of PP.

This research had some limitations in terms of its design. Participants in the study were recruited via one peer support forum for PP, which, although international, was based in the United Kingdom. Due to the recruitment methods, likely, the people who saw the flyer were still using forums, which indicates that they are more likely to have found the forum helpful or that they still needed support. Therefore, there may be a demographic of people who are not represented in this research. Although recruitment was only through one forum, participants were able to speak about experiences from any forums they had used for support with PP; however, this was not recorded. This meant that it is difficult to ascertain whether particular forums are more helpful than others or what characteristics of forums are more useful. In addition, all participants were aged between 31 and 53 years old, and an additional point made by Florence—that younger generations tend to find it easier to share online—poses questions around whether there are age differences related to how people use forums for support.

Despite recruitment taking place on an international forum, participants all resided in Western societies. Perinatal support within these countries can differ greatly from what is offered elsewhere [52]; therefore, it is important to acknowledge that these findings may not be generalizable beyond this population. In addition, it has been recognized and evidenced that those from the global majority can experience worse outcomes regarding mental health care [67], maternal support [68,69], and birthing experiences [70]. Within this research, there are views offered by 2 participants from a global majority background and one from a mixed ethnic background; however, this is a small proportion of the sample, and a more culturally balanced sample could have been beneficial to ensure a more comprehensive understanding of experiences.

Finally, the lead researcher of this study had not personally experienced PP. Within interviews, some participants described the value of shared experience, in that anyone who has not experienced PP cannot understand it. This highlights the impact of the researcher's understanding and interpretation of the interviews as someone who has not shared these experiences. Consequently, the findings of this study may have looked different had they been analyzed by someone with lived experience.

Clinical Implications

Following completion of the analysis, several recommendations were made related to the data.

For forums, trigger warnings and clear titles should be displayed on posts to ensure that readers are making an informed decision about what they are about to read. This links to theme 4, which acknowledged how safeguards against feelings of responsibility are important, as they help users to maintain appropriate boundaries and assess their own well-being before accessing content they might find upsetting.

A key consideration for forums is around representation and how this is managed within an online environment, as discussed within theme 4. Experiences related to diversity were central for the participants from the global majority in this research, with comments on how those within their families and communities did not understand, and how they felt shunned. There was also a reference to how, within the black community, mental health is not spoken about. This highlights a lack of spaces that people with lived experience of PP with black heritage can speak about their experiences. Given this, it might be helpful for forums to consider specific areas for the global majority to share their stories and experiences. This is supported by a recent study that found those from the global majority believed a space for peer support would help have open discussions and create a sense of belonging [71].

When considering implications for professionals, it would be helpful if professionals could signpost to forums where it would be beneficial for people with lived experience of PP. As noted in theme 2, forums have the potential to complement professional support; however, for people with lived experience of PP to use forums, they need to be aware of their existence. Signposting has the potential to reduce load on services, which was described by participants within theme 2 as an extra medium of support. However, it is also important that professionals recognize the potential for distress when using forums and help those they are working with to set boundaries and monitor usage. This is particularly important for people with lived experience of PP, who may be in the initial stages or who might be at risk of relapse.

Within future policies regarding perinatal mental health, it could be helpful to consider the expansion of peer support roles, helping people with lived experience of PP to guide while

XSL•FO
RenderX

having services involved that help to safeguard their own well-being. Theme 1 recognized how people with lived experience of PP could go many years without connection with anyone who had also experienced PP and the impact this had on their feelings of isolation. Although PP peer support roles do exist, involvement of people with lived experience of PP is limited; increasing this support could help increase accessibility and extend it to those who may be less likely to use forums. In addition, this research has highlighted existing knowledge around perinatal services often being western-centric in their approach [72]. It would be helpful for future policy to consider how to increase cultural competence, to tailor support, and improve access for communities that may otherwise be underrepresented within services.

Future Research

In the future, it would be helpful for research to more closely examine the longer-term impacts of PP. Participants within this study highlighted how specialist support was withdrawn at a time when help was still needed. Understanding the continued needs of people with lived experience of PP post recovery could help to improve service provision and increase appropriate signposting. In addition, future research related to the longer-term impacts of using peer online support forums could also be beneficial. As forums are a relatively new medium for support, the lasting impacts of their usage are unknown. As previously stated, the 2 participants within this study who had found the forum long after the onset of PP still found it beneficial. It could be helpful to understand why this might be, and how long people with lived experience of PP continues to engage with the forum, to understand what variables are involved in continued use.

Finally, with a limitation of this research being related to generalizability across cultures, future research should consider cultural differences when it comes to peer support for PP. It would be particularly useful to explore potential barriers to accessing peer support, representation issues, and how cultural perspectives of mental health play a role in disclosure and help-seeking.

Conclusion

This research study demonstrates the impact that online peer forums can have for people with lived experience of PP , recognizing that they help to increase connection, provide unique support, and play a role in recovery. There are challenges associated with the use of forums, such as issues with representation, comparison with others, and a sense of responsibility for other users. Helpful considerations include forums introducing spaces for global majority users and including trigger warnings to help users maintain boundaries. In addition, it was suggested that increasing professionals' awareness of forums as a channel of support and assisting people with lived experience of PP to access these would be beneficial to both services and service users.

Acknowledgments

Thank you to the participants of this study, who volunteered their time, shared their stories, and made this research possible, and to the patient and public involvement representative who used her lived experience to help shape the study. Thank you to Action on Postpartum Psychosis for providing consultation in designing the study and for allowing participants to be recruited from their forum.

Funding

This research was completed as part of the Doctorate in Clinical Psychology program at Lancaster University and was funded by the National Health Service. The funder had no role in the study design, data collection, analysis, interpretation, or writing of the manuscript.

Abstract

Background: Physiotherapists lack training opportunities for repeated practice of pelvic examinations for the identification of pelvic floor disorders (PFDs), leading to low confidence in the clinical setting. Pelvic simulators exist and are a valuable supplement to the medical curriculum, yet none demonstrate pelvic floor muscle (PFM) function or dysfunction. To design effective simulators, an assessment of end-user requirements is essential.

Objective: This study aimed to elicit physiotherapists' needs and requirements for a high-fidelity PFM simulator and the associated use cases.

Methods: This study followed a mixed methods design by collecting qualitative and quantitative data from a web-based survey. Quantitative data were analyzed using descriptive statistics and differences between demographic groups were calculated using 2-sample Kolmogorov-Smirnov 2-sided tests. Qualitative data were analyzed using thematic analysis.

Results: In total, 66 physiotherapists completed the survey. The most common suggested use cases of the simulator were for training and professional development (56/66, 84.9%), and patient education (48/66, 72.7%). Pelvic organ prolapse and muscle tone function and dysfunction were identified as the most useful PFDs for the simulator to demonstrate. Positional tracking and force sensing were considered important features and there was a preference for a generic over a pathology-specific or patient-specific simulator. A total of 3 themes emerged through the qualitative analysis: prioritizing patient care; representing the variability in anatomy and PFDs for simulator realism; and consideration of the implementation, cost, and accessibility of simulators.

Conclusions: There is value in PFM simulators for physiotherapists for multiple use cases. Design recommendations include using realistic materials, demonstrating PFM dynamics, modularity to vary the complexity for different end-users, offering a range of feedback modalities for position and pressure sensing, and ensuring affordability and curriculum integration.

KEYWORDS

pelvic examination; high-fidelity simulation; simulation-based learning; medical education; medical devices; physiotherapy

Introduction

Background

Over 60% of people with female-at-birth anatomy experience symptoms of pelvic floor disorders (PFDs) [1] such as incontinence, pelvic organ prolapse (POP) and pelvic pain. In the first course of treatment for PFD symptoms, it is recommended to contact a physiotherapist who will perform a pelvic examination to assess the pelvic floor musculature [2]. Most physiotherapists learn examination skills through peer practice which provides a way to teach ethical consent and allows students to practice their skills on each other's bodies before a patient [3]. However, peers may not present with any PFDs and the idea of being examined by a peer can be uncomfortable for some who if they choose to opt out, miss this opportunity to develop their clinical skills. As a result, it is difficult to gain experience diagnosing and assessing the numerous PFDs.

Physical simulators play a valuable role in supporting obstetrics and gynecology education and training, from offering visualization of anatomy to refining examination skills through repeated practice [4]. While a range of pelvic simulators are on the market, none represent the dynamics of the pelvic floor muscles (PFMs) to the degree of fidelity required to transfer knowledge and skills from the classroom to the clinic.

In a systematic review of simulation training for pelvic examination, simulation-enhanced education was found to improve students' technical skills, comfort and communication

XSL•FO
RenderX

with the patient. However, where offered, the most effective training method is by Gynecological Teaching Associates (GTAs) or standardized patients, volunteers with whom students can practice hands-on examination techniques [5]. As supplements to the medical curriculum, simulation-based teaching has proven effective in improving technical and communication skills for physiotherapists specifically [6]. Simulators can uniquely offer the opportunity for repeated practice and incorporate necessary proprioceptive, visual and tactile feedback to enhance the practitioner's motor control without risk of harm to patients, GTAs or standardized patients [7].

In simulation, (engineering) fidelity is defined as the extent to which the appearance and behavior of a simulator resembles reality, whereas realism, or psychological fidelity, refers to the authenticity of the scenario in which the simulator is used [7,8]. More recently, fidelity in simulation-based education has been subdivided into the following four elements [8]: (1) environmental element - the training facility and equipment used. (2) Patient element - the virtual reality, full body or part-task trainer used to represent the patient. (3) Semantical element - the scenario in which the simulator is used and the associated intention for the user. And (4) phenomenal element - the engagement of the user through their emotional and cognitive experiences while involved in the simulation activity.

It is commonly agreed that the levels of fidelity and realism of a simulator are dependent on the skills it is being used to teach, and for whom it is intended [4,7-9]. Accordingly, the first stage to developing simulators is identifying the skill or procedure that must be learned or demonstrated [7,9,10]. Engaging with end-users is the only reliable way to ascertain these skills and subsequently, the relevant design requirements needed to teach them [9,11].

Most commercial pelvic simulators focus on childbirth, pelvic examination and surgical skills [12]. To the authors' knowledge and at the time of writing, no commercial simulator demonstrates any PFD or even the difference between increased, normal and reduced muscle tone. Decreased or reduced tone and incorrect functioning of the PFMs are some of the main causes of PFDs [13].

Previous Work

Although simulators for certain PFDs have been explored in the research literature, their fidelity and validity vary. In addition, it is rare to describe the design requirements or user needs which would support the future of simulation-based education in pelvic health care. In one of the few simulators designed to mimic the PFM activity for practicing digital examination, Saleme et al [14] modelled the levator ani by 5 springs attached at the relevant points on a resin bony pelvis model. The modified Oxford scale was simulated by varying the spring tension and a physiotherapist identified most differences between the scale points by digitally palpating a specified site between the springs [14]. While this simulator was shown to be a complementary tool to the curriculum, its fidelity was limited by the use of nonrealistic materials. These examples show that both high- and low-fidelity simulation can be effective in medical education, especially for visualizing the 3-dimensionality and dynamics of PFM function and for building confidence before examining patients.

A dynamic and high-fidelity POP simulator was shown to significantly improve the understanding and confidence in performing the pelvic organ prolapse quantification (POP-Q) examination [15]. This simulator was designed such that a user can manually invert a silicone vaginal canal to different extents and angles to simulate anterior, posterior, and apical prolapse. Although medical students and residents at all levels of training were included in this study, responses from all participants' pre- and post-tests were averaged. In another study it was shown that medical students preferred a low-fidelity sock and tube model in their first and second years of residency compared to third and fourth-year residents who had neutral attitudes toward the utility of the model and preferred conventional learning modalities [16]. In an attempt to make what can often be an awkward part of medical training more lighthearted, a Santa Claus hat was used in another study to visualize and simulate POP-Q but the model itself was not evaluated with any meaningful metrics [17]. Through a robust Delphi study, Meyer et al [18] developed a list of criteria for a 3D pelvic model for anatomy and physiology education. While a range of experts from different disciplines were consulted and the methodology was validated rigorously, no physiotherapists were included in the study, the model in question was computer-based and was neither intended for clinical examination nor to have dynamic features. Physical 3D pelvic models and simulators described in the literature tend to be co-designed by medical professionals working in pelvic health [19-22] which may indicate why no user requirements have been published previously. In the evaluation of the 3D-printed model by Kiesel et al [23], medical students reported that the option to remove parts of the anatomy and parts being printed in different colors was helpful for their understanding of the anatomy. Students also found it useful to be able to angle the model in upright and tilted positions and would approve of models that simulate certain medical conditions and operations.

Although the aforementioned examples show positive efforts toward the use of simulation for teaching pelvic examination skills, they highlight the need for more advanced methods, incorporating higher levels of fidelity for more effective training as seen in numerous soft robotic organ models in the literature [24]. This need is even more pronounced considering that veterinary students practice palpation and even the assessment of pain symptoms in the pelvic region of cows and horses using simulators enhanced with haptic feedback [25,26] whereas pelvic physiotherapy training for humans with female-at-birth anatomy continues to rely on peer examination.

The research in this area shows an appetite for high-fidelity simulation training in the gynecological curriculum with a lack of investigation into the specific needs of physiotherapists who are one of the main treatment providers for people with PFDs.

Aims of This Study

In this study, we aimed to explore physiotherapists' perceptions of the value, requirements and potential use cases of a high-fidelity PFM simulator for female-at-birth anatomy. Through a mixed methods survey, we sought to elicit the design

XSL•FO
RenderX

recommendations for such a simulator and gain a deeper understanding of the motives behind these preferences.

Methods

Survey Development

We took a mixed methods approach by collecting qualitative and quantitative data through an internet-based survey. The quantitative component, which comprised the majority of the survey, informed the preferences of certain features and functionalities of the simulator. The qualitative component was intended to gather a deeper understanding of how a simulator can be integrated into pelvic health education and research, along with the associated challenges.

The survey consisted of 10 closed-ended (quantitative) and 3 open-ended (qualitative) questions. The complete questionnaire is shown in Multimedia Appendix 1. Up to 3 additional open-ended questions were asked to respondents who selected certain choices from three of the closed ended questions to better understand their choices. Respondents had the opportunity to add any further comments at the end of the questionnaire and provide a contact email if they wished to be contacted for an informal follow-up interview. Questions on professional experience and demographics were asked at the beginning and end of the survey, respectively.

Closed-ended questions formed the quantitative component of the survey and concerned the features of the simulator. These questions were formulated after exploring state-of-the-art commercial (Clinical Female Pelvic Trainer; Limbs and Things, Bristol, and United Kingdom) and research-based [15,20,27] simulators. We compiled potential use cases, target anatomy, and any additional features into multichoice, ranking and rating scale questions.

The rating scale questions varied from 3- to 5-point scales to reduce the chance of respondents becoming fatigued which can discourage survey completion and result in satisfyingbehavior [28]. The number of scale points was chosen depending on the most appropriate level of granularity for each item that would provide a meaningful understanding of the respondents' opinions [28]. Where relevant, closed-ended questions included optional free text if respondents felt that their attitude or opinion was not offered in the choice options.

Open-ended questions were designed to understand the reasons behind some selected choices of closed-ended questions and to prompt respondents to reflect on their training and development as well as the challenges they face in diagnosing and treating patients' conditions.

As this study aimed to understand the values and preferences of potential users of a pelvic simulator rather than their views of a specific simulator, no proposed solution was provided to avoid influencing respondents' answers. Respondents were only informed that the simulator could be used for medical training, patient education and medical device testing.

The survey was pretested before dissemination by 1 urogynecologist, 1 pelvic medical device engineer, 1 junior doctor, and 2 researcher engineers. The pretesters were asked to provide feedback on the usability of the survey and its presentation, the clarity of the questions, and how long it took to complete. No suggestions were made on the content of the questions. The resulting feedback regarding the usability and readability of the survey was implemented accordingly. The responses from the pretest were not included in the study results.

Ethical Considerations

Ethics approval was granted by the University of Bristol's Faculty of Engineering Research Ethics Committee (reference number 13989). Respondents were required to complete the inbuilt consent form to take part in the survey. Respondents could withdraw their data from the study within 4 weeks of taking part, but none chose to do so. There was no financial compensation offered for taking part in the survey. Any identifyable data were stored separately from the analyzed data on an encrypted hard drive which only the main researcher had access to.

Recruitment and Data Collection

The survey was originally designed for and advertised to professionals working in different areas of pelvic health. As a result, recruitment emails were sent to 2 professional networks of pelvic health practitioners for distribution among their members: the British Society of Urogynaecology [29] and Pelvic Obstetric and Gynaecological Physiotherapy [30]. Individual recruitment emails were sent to pelvic health practitioners with experience in medical education who were identified through their affiliated university profiles and organizations such as Lead Midwives for Education [31]. Pelvic floor medical device engineers and designers were recruited through their companies. Although the recruitment emails were targeted at United Kingdom—based professionals, those working abroad whether they had relocated or been forwarded the email by a colleague in the United Kingdom, were also encouraged to participate in the survey.

The recruitment email briefly explained the purpose of the study, signposted recipients to an attached 2-page document for further information and encouraged them to ask any questions relating to the study. Recipients were invited to complete the internet-based survey by following a URL link and were encouraged to forward the email to colleagues working in pelvic health.

The survey was hosted on Qualtrics (Qualtrics International Inc) and was available for completion for 3 months between May and August 2023 and for an additional month between March and April 2024. Respondents were advised that the survey should take roughly 10 minutes to complete and were notified that once the survey was begun, they would be able to return to it to complete at a later time if convenient.

Data Analysis

Identifiable information such as email addresses, if provided, was removed before analyzing the data. Data from respondents who did not fully complete the survey were not included in the analysis and responses were excluded where there were fewer than 10 respondents from a given profession to ensure statistically meaningful results. Quantitative data were analyzed

XSL•FO
RenderX

in Python (Python Software Foundation) using descriptive statistics such as the mean and SD. For rating scale data, the scales were mapped to a numerical scale: for example, not important=1, moderately important=2, and very important=3 to calculate the variables. Differences in results based on demographic groups were identified using 2 sample Kolmogorov-Smirnov 2-sided tests. Qualitative analysis was conducted in NVivo software (Lumivero) using thematic analysis [32]. Using this method, the principal researcher (YZ) identified themes after familiarization and initial coding of the responses to the open-ended questions. The themes were then refined by 2 researchers (YZ and AT) and codes were grouped into concepts relating to the themes.

Results

Demographic Data

In total, 146 people initiated the survey, and 85 surveys were fully completed, 66 of which were by physiotherapists. There were less than 10 respondents from other pelvic health professions which were excluded to focus on one core group's needs and requirements. At the time of survey dissemination, there were 1219 active members of the Pelvic Obstetric and Gynaecological Physiotherapy who would have received the recruitment email which indicates a 5% response rate. With a 90% CI and 10% margin of error, an ideal sample size for a population of 1219 is 65 people [33].

Table 1 presents the demographic composition of the respondents included in the analysis. Most respondents were female (61/66, 92%), between 45 and 54 years of age (21/66, 32%), with more than 10 years of professional experience (44/66, 67%) working in the United Kingdom (62/66, 94%). Although an additional open ended demographic question on ethnicity was asked, we have not included the responses as the types of answers were too varied (eg, some answered based on ethnicity and others on ethnic category).

Table . Respondent demographics (n=66).

Demographics	Values, n (%)
Professional experience (years)	
Less than 5	8 (12.1)
5 - 10	14 (21.2)
More than 10	44 (66.7)
Country of practice	
United Kingdom	62 (93.9)
Hong Kong	1 (1.5)
Australia	1 (1.5)
Prefer not to say	1 (1.5)
Sex	
Female	61 (92.4)
Male	1 (1.5)
Prefer not to say	4 (6.1)
Age range (years)	
25 - 34	5 (7.6)
35 - 44	20 (30.3)
45 - 54	21 (31.8)
55 - 64	17 (25.8)
65 - 74	2 (3)

Quantitative Results

Use Cases

Respondents were asked how they see themselves using a pelvic floor simulator in their practice. The most common use case is for training and professional development (n=56), followed by educating patients (n=48) and practicing examinations (n=44). Less common use cases of the simulator include as a research tool (n=16) and for medical device testing (n=11). Although 1 respondent said that they would not use a simulator, due to not seeing it as useful at the current stage of their career (specialist pelvic health physiotherapist), they added that it could be helpful for patient education. There was no significant difference between the respondents' choices of use case and their professional experience (P>.49).

Simulator Features

Respondents considered the PFMs, bony pelvis, pelvic organs (excluding the ovaries and fallopian tubes), nerves, and ligaments to be the most important anatomical structures to

XSL•FO
RenderX

include in a simulator. Figure 1 illustrates the mean Likert rating of each structure alongside the raw data.

Out of the 6 presented options for functions and dysfunctions for the simulator to demonstrate, all were considered to be very or moderately useful. Table 2 presents the overall mean and SD between all respondents. Prolapse and muscle tone had the highest mean scores of 3 and 2.95, respectively. There was no significant difference between the respondents' considered utility of the functions and their professional experience (P>.34).

Respondents were asked whether it would be useful for a simulator to be compatible with imaging modalities such as ultrasound. This feature could enable users to practice probe positioning and diagnostic skills. Table 3 shows that compatibility of the simulator with medical imaging is not of strong importance. On average, all modalities scored between 1: not at all useful and 2: moderately useful.

Figure 2 illustrates the preference for a generic over a case-specific (pathology) or patient-specific simulator: a generic simulator was the most preferred (39/66, 59%) and a patient-specific simulator was the least preferred (35/66, 53%). Where respondents ranked the options equally, their preferences were counted for each option.

The preference between auditory, tactile or visual feedback modalities varied, as seen in Figure 3. Overall, visual feedback was most preferred (mean score 4.2, SD 3.8) and acoustic feedback was the least preferred (mean score 2.95, SD 2.8). There was no significant difference between respondents' feedback preferences and their years of professional experience (P>.27) nor their age (P>.35).

Table 4 summarizes respondents' preferences toward the modularity and sensing capabilities in a pelvic floor simulator as well as the term used to describe it. 54 respondents (54/66, 82%) agreed that there was some value in the simulator being modular, that is, for parts to be removable. In total, 82% (55/66) of respondents considered both the position and the pressure of a user's interaction to be useful feedback through sensors embedded in a simulator. Overall, respondents preferred the term 'simulator' (43/66, 64.2%) over model, phantom or manikin.

Figure 1. Rated level of importance of anatomical structures to be included in the simulator. PFM: pelvic floor muscle.

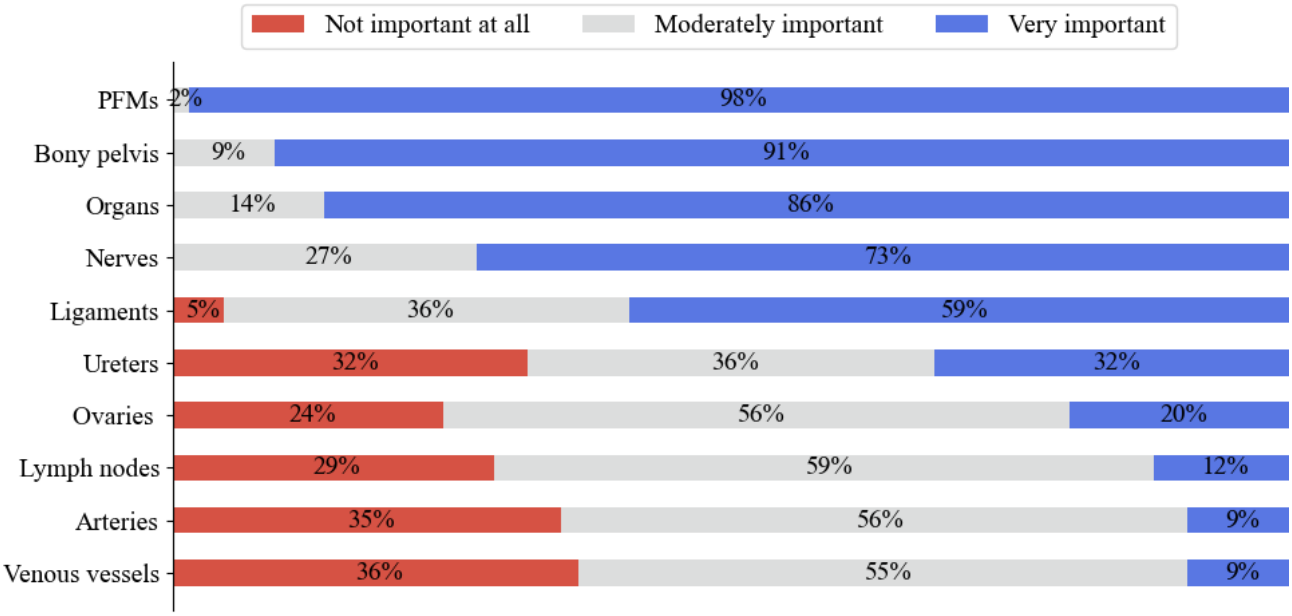

Table . Utility of functions and dysfunctions to be demonstrated.[a]

Function or Dysfunction	Values, mean (SD)
Prolapse	3 (0)
Muscle tonicity	2.95 (0.21)
Intraabdominal pressure	2.94 (0.24)
Breath	2.9 (0.48)
Stiffness	2.82 (0.39)
Posture or gait	2.75 (0.43)

[a]Responses were on a 3-point Likert scale (1=not useful at all; 2=moderately useful; and 3=very useful).

Figure 3. Preference for feedback modalities of the simulator's sensors.

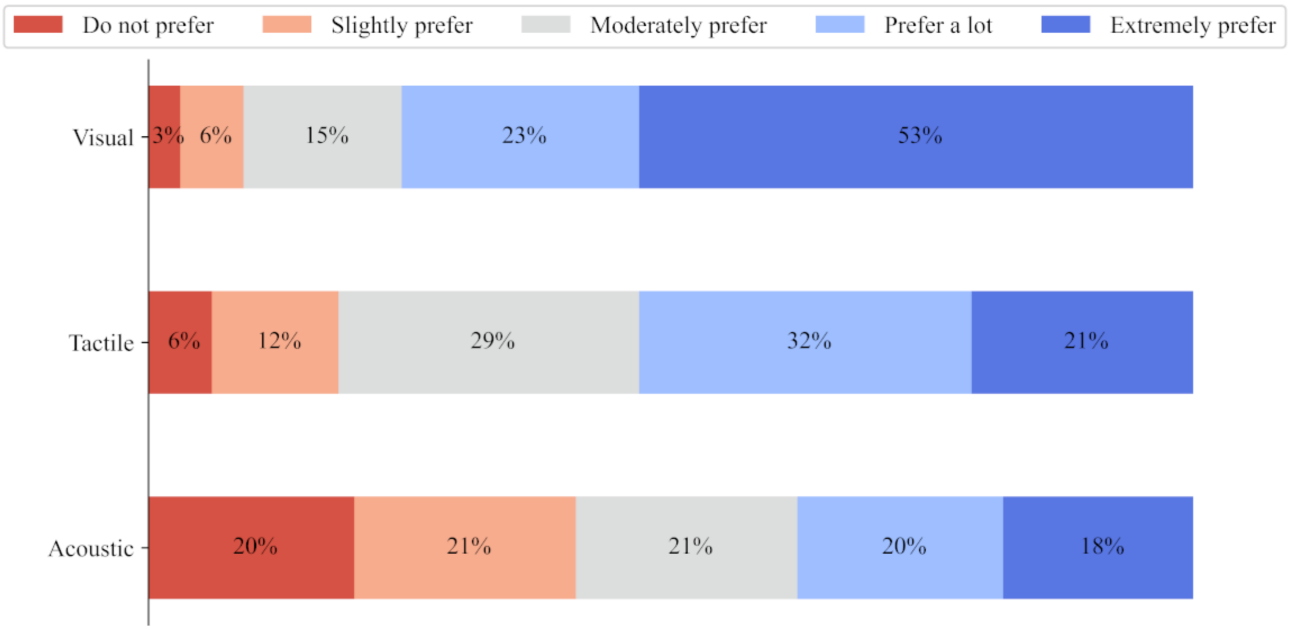

Table . Respondents' attitudes toward modularity, sensing, and terminology preferences for PFM simulators.

Questions and answers	Values, n (%)
How important is it for the pelvic floor simulator to be modular?	
Not at all important	12 (18.2)
Moderately important	29 (43.9)
Very important	25 (37.9)
What information from sensors would be useful to provide?	
Unsure	1 (1.5)
Positional tracking	2 (3)
Pressure applied	8 (11.9)
Position and Pressure	55 (82.1)
Which term do you prefer to describe a pelvic floor simulator?	
Simulator	43 (64.2)
Model	22 (32.8)
Phantom	0 (0)

Qualitative Results

Overview

The most common areas where better training needs were identified were the assessment of muscle tone (normal contractions, hypertonicity, and tone variation) (n=27) and POP (n=22). The need for better vaginal (n=11) and rectal (n=10) examination training was also identified, as was the need for anatomical mapping skills (n=4), that is, feedback on which muscle is palpated internally. Other areas include levator ani avulsion (n=6), vulvodynia (n=4), dyssynergy (n=3), pessary fitting (n=3), vaginismus (n=3), and nerve dysfunction (n=3). In total, 7 respondents felt that there were no areas where better training was needed.

Table 5 presents the most common training needs with respect to the respondents' years of professional experience. For example, 62.5% (5/8) of physiotherapists with less than 5 years of experience reported a need for better training in identifying and assessing POP. This was almost triple that of physiotherapists with over 10 years of experience (10/44, 22.7%). Although only 8 respondents had less than 5 years of experience, better training for pelvic examination (rectal and vaginal) and anatomy mapping skills were not mentioned by them.

Three main themes emerged from the thematic analysis of the open-ended questions, summarized in the following sections. The themes, subthemes and a subset of the respondents' quotes are shown in Table 6. In the optional further comments, 9 respondents expressed positive sentiments and excitement regarding a dynamic pelvic floor simulator as a potential

XSL•FO
RenderX

outcome of this research. A total of 13 respondents expressed concern over a potential simulator, however these were mainly to do with the cost and implementation and are included in the analysis in Section 3.3.4.

Table . The most common areas where needs for better training were identified per physiotherapists'' years of professional experience.

Training needs	<5 years, n (%)	5 - 10 years, n (%)	>10 years, n (%)
None	1 (13)	—[a]	6 (14)
Tone variation	3 (38)	9 (64)	15 (34)
Prolapse	5 (63)	7 (50)	10 (23)
Vaginal examination	—	2 (14)	9 (21)
Rectal examination	—	2 (14)	8 (18)
Levator Ani avulsion	1 (13)	1 (13)	4 (9)

Table . Emergent themes with a subset of the respondents' quotes from thematic analysis of the open-ended questions.

Themes and subthemes	Quotes
Prioritizing patient care	
Simulators can reduce the burden on patients of learning 'on-the-job'	• "There could be better ways [than peer practice], as colleagues might not have dysfunctions, so one ultimately needs to learn often about those 'on the job'" • "[We need better training for] More simulated examples of what might be a cause for concern. I found it difficult in the beginning to identify prolapse." • "[We need better training for] Correct pelvic floor contraction (have to feel a lot before you work out what is normal)."
Simulators have value in medical training and for patient education	• "I think this is a wonderful development for pelvic health training and development" • "I am excited at the prospect of having access to a pelvic floor simulator"
Patient communication is as important as practical examination skills	• "I learn as much from listening to my patients as the physical examination but I don't think this aspect [of] treating someone is very well explored in many pelvic health education courses." • "[We need better training for treating] Neurodiverse people with potential differing requirements regarding treatment. This could be related to communication style, or environmental or anatomical sensitivities, which can (should) impact how treatment is performed." • "[We need better training for] Supporting people with learning difficulties or physical disabilities in fulfilling the potential for safe physical relationships." • "[We need better training for] Transgender people and how physiotherapists and other health care professionals can support their journey better."
Simulators as supplements, not replacements to human models	• "Pelvic floor muscle function assessment techniques need human volunteers for learning and practice" • "Other online courses are available but in my experience are not as beneficial as practicing on a live model."
Representing the variability in anatomy and PFDs[a] characterizes simulator realism	
Need for simulators that are representative of anatomical variation and properties	• "[We need better training for] Variations on 'normal'" • "[We need] More examples of anatomical differences" • "[We need] More lifelike pelvic floor models. That show that tension in pelvic floor" • "[We need] A dynamic pelvic floor muscle assessment model for both Vaginal and Anorectal assessment of the pelvic floor muscle function - ideally includes superficial and deep muscle activity"
Requirements of the simulator depend on the use case and user	• "I don't really need to know about the vasculature for my examinations" • "A simple model would be better for teaching professionals new to the area of pelvic health. A more detailed model for more advanced practice or teaching." • "Patients wouldn't be likely to need to see arteries/ venous vessels or lymph nodes"
Importance of implementation, cost and accessibility in the design of simulators	
Doubt in technological capability	• "[I'm] unsure if any model could do this, for example, exam for prolapses" • "There are no simulators or models that can mimic the dynamic parameters that are tested by physiotherapist via vaginal or anorectal examination."
Practical importance of integration with health services	• "cleaning accessibility [should be considered]." • "As I work in the NHS[b] I am just mindful of getting the simulator to work alongside current IT systems"

XSL•FO
RenderX

Themes and subthemes	Quotes
Simulator features depend on affordability	• "It sounds ideal for teaching! However cost will be a big factor for NHS staff or departments" • "Important it is not too complex and expensive so that it isn't out of reach for physios to purchase. Yet sounds amazing if it can fulfill the previous suggestions" • "It's likely to be far too expensive for an NHS physiotherapy department to buy''

[a]PFDs: pelvic floor disorders.

[b]NHS: National Health Service.

Prioritizing Patient Care

Value was found in high-fidelity PFM simulators both for medical students' practice and for communicating with patients. Respondents reported that peer practice was the most common modality for practical training. However, as fellow colleagues may not present any of the variety of PFDs, respondents reported that diagnosing PFDs is learned "on-the-job" at the start of their careers. Although several respondents considered peer practice or using human volunteers as the best way to learn, respondents also indicated that an alternative option such as a simulator would be favorable.

The importance of communication skills was highlighted as much as the examination skills in treating a patient. Respondents mentioned difficulty communicating with patients or adapting to potentially differing needs of neurodivergent patients. While a simulator may not always be the answer in the context of improving patient communication, it may be useful as a tangible tool for some of the areas where respondents reported difficulties in their practice. For example, challenges in supporting differently abled patients in fulfilling safe physical relationships and considering sensitivities in examining survivors of sexual abuse or trauma. A simulator may assist a practitioner as a demonstrative tool in communicating with such patients.

Representing the Variability in Anatomy and PFDs for Simulator Realism

The use of simulators was the second most common practical training modality reported. However, respondents recognized that existing simulators lack realism. Specifically, pelvic models with no tension in the pelvic floor.

The anatomical structures to be included in a simulator were reported to vary depending on user and use case. This agrees with the aforementioned commonly shared opinion that the appropriate level fidelity is contingent on the type of task it is used for and the expertise of the user [4,7,8]. For example, if used to demonstrate the symptoms of a condition to patients, it would not need the lymph nodes, whereas these are important anatomical structures for oncologists. However, the same requirements were not shared by all respondents. Some considered vasculature to be important for patients, and others did not consider it to be relevant. Overall, respondents suggested that there should be less detail if the simulator is used to educate patients than if it is used for health care professionals. Some respondents thought no changes would be needed, while some considered this to be on a case-by-case basis.

Consideration of Implementation, Cost, and Accessibility of Simulators

The affordability of a simulator that could offer some of the features included in the survey was a shared concern amongst respondents, specifically for the United Kingdom's National Health Service (NHS) departments. The challenge of logistical integration within the NHS computer systems was also noted. For example, if the simulator needed to be plugged in to a computer to provide visual feedback on a screen. Although no specific simulator was proposed in his study, 2 respondents had low faith that any simulator or model could offer some of the features mentioned.

Design Requirements

In total, 6 recommendations for the design of future pelvic floor simulators have been formulated as a result of the survey findings and are displayed in Table 7.

XSL•FO
RenderX

Table . Design recommendations elicited from survey responses.

Design recommendation	Explanation
Realistic materials	Materials with similar properties to human muscle and skin, such as silicone should be used to provide a high level of fidelity.
Demonstrates prolapse and muscle tone	A simulator should at least demonstrate increased, normal and reduced PFM[a] tone for example, with a material that has stiffness-changing properties which users can apply resistance as if assessing actual muscle tone. This would also allow medical devices such as PFM trainers to be evaluated for their ability to differentiate between increased, normal or reduced tone.
Modular in design	A simulator should comprise adaptable anatomical complexity for patients and professionals with different experience levels
Position and pressure sensing	The palpation location should be tracked, and forces applied should be measured, both to be displayed and fed back to the user
Range of feedback modalities	Feedback modalities should be customizable according to preference. Feedback would be useful for supervisors or teachers and observers to better understand (ie, see and hear) the interactions between the simulator and the user, who would be the only one receiving tactile feedback.
Affordable and accessible	A simulator should be affordable and be designed in line with the relevant curriculum to maximize the number of people able to access it.

[a]PFM: pelvic floor muscle.

Discussion

Principal Findings

The results from our survey agreed with and built on previous research on the design and use of 3D pelvic simulators and models. All but one of the respondents reported that they would use a pelvic floor simulator for at least one use case. In addition, respondents held strong value in the simulator as a tool for demonstrating pelvic floor function and dysfunction which supports the existing literature [15,21,23].

The anatomical structures rated of high importance, illustrated in Figure 1, confirm those found by Meyer et al [18], namely, the bones, muscles, organs, and nerves. However, the experts consulted in their Delphi study considered some ligaments to be unimportant to include, and ovaries and veins as important, with the opposite being the case in our results. This discrepancy may be explained by the difference in health care professionals consulted in their study (basic scientist, obstetrics and gynecology clinician, and urologist). For example, ovaries are not always easy to palpate in a pelvic examination if a patient is overweight or unless there is a cyst or dysfunction [34]. As a result, the inclusion of ovaries may be of less importance to physiotherapists in the context of skill-based training than would be the case for gynecologists who would need to refer to these structures in surgical training [35]. Commercial pelvic simulators demonstrate this distinction, for example, the surgical [36] simulator from limbs and things includes the ovaries whereas the clinical simulator [37] does not.

As aforementioned, the level of fidelity depends on the skills being taught and the intended users [4,7,8]. High-fidelity simulation is often associated with high cognitive load and may be better suited for more experienced trainees or continuing professional development. This was echoed in our results whereby respondents suggested the simulator would need different levels of complexity depending on the user and considered modularity as a useful feature, which lead to including modularity as a design recommendation. Removing certain anatomical structures through a modular function has also been suggested in the evaluation of a virtual PFM anatomy simulator [38].

Learning from GTAs or through peer practice is considered the best form of training for learning and practicing the pelvic examination [39,40]. Training with GTAs has been shown to improve confidence and decrease anxiety for performing examinations in clinical settings [41], as has training with simulators [42]. Respondents mirrored this whereby it was reported that although peer-practice provides the most realism, an alternative would be beneficial. Pelvic simulators can be integrated into the curriculum alongside GTAs or peer practice, providing a supplementary tool that can offer repeated practice while reducing both the risk of causing harm to a peer or GTA and medical students' fear of causing it [43,44]. This evidence supports the design recommendation of using realistic materials and materials with smart properties to provide higher fidelity.

Feedback in medical simulators has been identified as one of their most valuable features [45,46]. Similar to the feedback that would be received through GTA or peer practice, feedback from sensors embedded in simulators can provide the information required to conduct the examination effectively. Figure 3 shows that the preferred modes of feedback from sensors were foremost through a visual display and second, by a tactile vibration or applied pressure which have been previously reported as the 2 commonly preferred modalities of urologists [47]. In physical examinations, physiotherapists rely on a combination of tactile, visual, and acoustic information. For internal examinations, tactile feedback would be the most realistic to integrate into a simulator as visual and acoustic cues would be more indicative of a patient's facial and uttered expressions to signal discomfort [48]. While the use of feedback

XSL•FO
RenderX

is included as a design recommendation, it would be important to consult with end-users during the design process to optimize how this feature is integrated. Without mentioning the price of a potential simulator in the survey itself, several respondents expressed concern over the cost and resulting lack of accessibility or included functionalities. Given that most respondents were working in the United Kingdom at the time of participating in the survey, there was specific mention of NHS departments being unable to afford a simulator that offered such features. It may be that some of the questions were answered with this consideration in mind. However, a study of over 400 final year medical students in the United Kingdom found that simulator-based teaching is less expensive per student for pelvic examination training than GTA-led teaching [49].

Certain features, such as sensors which were of interest to users, may increase the cost of a simulator beyond budget constraints despite being included as a design recommendation. Through careful design and consultation with end-users, a balance can be struck between cost and fidelity, ensuring the simulator provides high-quality, curriculum-relevant training while remaining affordable and accessible.

As a tool for patient education, the use of 3D models has proven efficacy in enhancing communication with patients [50], ensuring young patients' parents understand their conditions [51,52], and improving the attitudes toward pelvic examination by teaching nonmedical professionals how to perform the examination [53]. The survey results indicated that patient education was the second most popular use case of a pelvic floor simulator, with respondents highlighting several ways in which it could be used to assist in specific conditions. At later design stages, it would be beneficial to include patients in the design process as potential end-users themselves.

Limitations and Further Work

Further work should explore other pelvic health experts' opinions in equal detail and widen the participation to other countries as well as to patients with PFDs, who could also be users of such a simulator. For simplicity, anatomical structures were grouped to reduce the length of the survey. In the design stages of a given simulator, the importance of including some individual anatomical structures should be considered. For example, the pudendal and sciatic nerves are important structures that can cause pelvic pain when damaged whereas smaller, less significant nerves may be less relevant for a given use-case.

Conclusions

Our study highlighted the value of dynamic and high-fidelity pelvic floor simulators for pelvic health physiotherapists in their own education and as a tool to aid communication with their patients. The primary outcome was 6 recommendations for the design of future dynamic pelvic floor simulators, specifically for physiotherapists needs. Our findings revealed that while there is a strong need for educational tools to supplement the pelvic health curriculum, the cost of such innovations is an important factor that needs to be considered to ensure they are accessible to those who can benefit from them.

This contribution provides pelvic simulator designers with the knowledge of the needs and concerns of a crucial target user group which can better inform their product development. The importance of end-user involvement at each stage of the design process is paramount to ensuring such tools will serve the community of pelvic physiotherapists and their patients.

Acknowledgments

The authors would like to thank the respondents for their time and contributions to the study. This research was funded by the EPSRC Centre for Doctoral Training in Future Autonomous and Robotic Systems - FARSCOPE (grant number EP/L015293/1).

Abstract

Background: Performance-related musculoskeletal disorders are common among musicians, requiring precise diagnostic and therapeutic approaches. Physiotherapists face unique challenges due to the complex relationship between musculoskeletal health and the demands of musical performance. Traditional methods often lack the necessary precision for this specialized field. Integrating clinical movement analysis (CMA) with clinical decision support (CDS) could improve diagnostic accuracy and therapeutic outcomes by offering detailed biomechanical insights and facilitating data-driven decision-making.

Objective: This study aimed to identify design requirements for an interactive dashboard that aids clinical decision-making by incorporating CMA to assist physiotherapists in managing musculoskeletal disorders in musicians.

Methods: A qualitative user research study was conducted, using human factors engineering methods from problem-driven research, user-centered design, and decision-centered design. Data collection included a domain-specific literature review, workflow observations, and focus group discussions with domain experts, including 4 physiotherapist experts and an expert for clinical reasoning and applied biomechanics. This qualitative data was triangulated to characterize the domain, identify the CMA workflow, user needs, key cognitive tasks, and decision requirements. These insights were translated into concrete design requirements.

Results: A workflow for integrating musician-specific CMA into physiotherapy was established. In total, 21 user requirements, 7 key cognitive tasks, and 5 key decision requirements were defined, along with 49 design seeds. Key features identified include (1) efficient integration of musician-specific biomechanical findings into therapy, (2) combining heterogeneous data types for holistic assessment, (3) providing an adaptive overview of patient-related information, (4) using adequate visual representations and interaction techniques, (5) facilitating efficient visual-interactive analysis of findings and treatment results, and (6) enabling preparation and export of therapy findings and analysis results. Additionally, 14 CDS recommendations and 11 technical prerequisites were identified. These requirements guide the design of an interactive tool featuring advanced visualization, interactive data exploration capabilities, and contextual integration of clinical and biomechanical data.

Conclusions: An interactive physiotherapy dashboard with CDS incorporating CMA data holds significant potential to enhance decision-making in physiotherapy for musicians with performance-related musculoskeletal disorders. By addressing cognitive demands and integrating advanced visualization techniques, the tool can support physiotherapists in making more accurate assessments, potentially improving patient outcomes, reducing injury recurrence, and supporting musicians' career longevity. Ongoing research is essential to refine such a tool and validate its usability, decision support, and clinical effectiveness. Future work should explore advanced analytics, adapt to various CMA systems, and expand applications across musicians and therapeutic domains to enhance its impact.

Introduction

Background

Musculoskeletal disorders are common among musicians due to repetitive movements, muscle strain, poor posture, and intensive practice, affecting their ability to perform and sustain careers [1-3]. At least 50% of musicians experience performance-related musculoskeletal disorders (PRMDs), which cause pain and other symptoms that hinder performance [4-6]. However, targeted therapy is underused, and specialized assessment and treatment strategies are needed [7,8].

Musician-specific physiotherapy is beneficial for identifying and treating these issues, focusing on aspects of posture, movement behavior, and musical expression that affect health [8-10]. Effective treatment requires a thorough understanding of musician-specific characteristics and identification of functional disorders in the musculoskeletal system through clinical neuro-orthopedic examinations and analyses of the musician's movement while performing [11].

In physiotherapy, clinical reasoning is essential for decision-making, often using a hypothetical-deductive method [12]. Accurate diagnostics are crucial to prevent misjudgments [13], and comprehensive information gathering is vital for effective therapy planning [14,15]. Technology-driven assessments can enhance diagnostic accuracy, moving beyond subjective methods and trial-and-error approaches [16].

Clinical movement analysis (CMA) provides objective, quantifiable data on functional disorders, supporting personalized medicine [11,17] and offering physiotherapy applications that conventional assessments cannot achieve [18,19]. As an apparatus-based biomechanical analysis for individualized functional diagnostics, CMA uses techniques such as motion capture and electromyography [20,21]. It helps evaluate complex movements during performance, allowing for the identification of aberrant postures and movements contributing to PRMDs in musicians [22-24]. Thus, CMA aids in diagnosing functional disorders, planning individualized therapy, and monitoring therapeutic measures [17,19,25], minimizing the risk of false results [26,27].

The *RefLabPerform* project [28] aims to develop a reference laboratory for PRMD assessment in musicians, integrating CMA with physiotherapeutic assessments, which will be implemented at the Institute for Applied Physiotherapy Osnabrück (INAPO). Advanced instruments will be used by specialists for musician-specific CMAs, with results provided to physiotherapists for further clinical evaluation.

However, interpreting CMA data requires expertise and time, presenting challenges for clinical practice, highlighting the need for efficient, intuitive presentation for analysis and decision-making [11,29,30]. Current tools for biomechanical analysis lack guidance for musicians' physiotherapy, leading to concerns about accuracy and usability [30,31].

A tailored health technology for musicians' physiotherapy is essential to efficiently record, process, provide, analyze, and interpret musician-specific CMA data for routine use. Hereby, an interactive dashboard with clinical decision support (CDS) can improve diagnostics by integrating CMA findings, facilitating comprehensive decision-making and effective therapies [32]. Adapting research approaches from health while considering physiotherapy-specific conditions will ensure the tool aligns with the clinical workflow, balancing perceived benefit, effort, and costs [16,33].

Human Factors and CDS Design

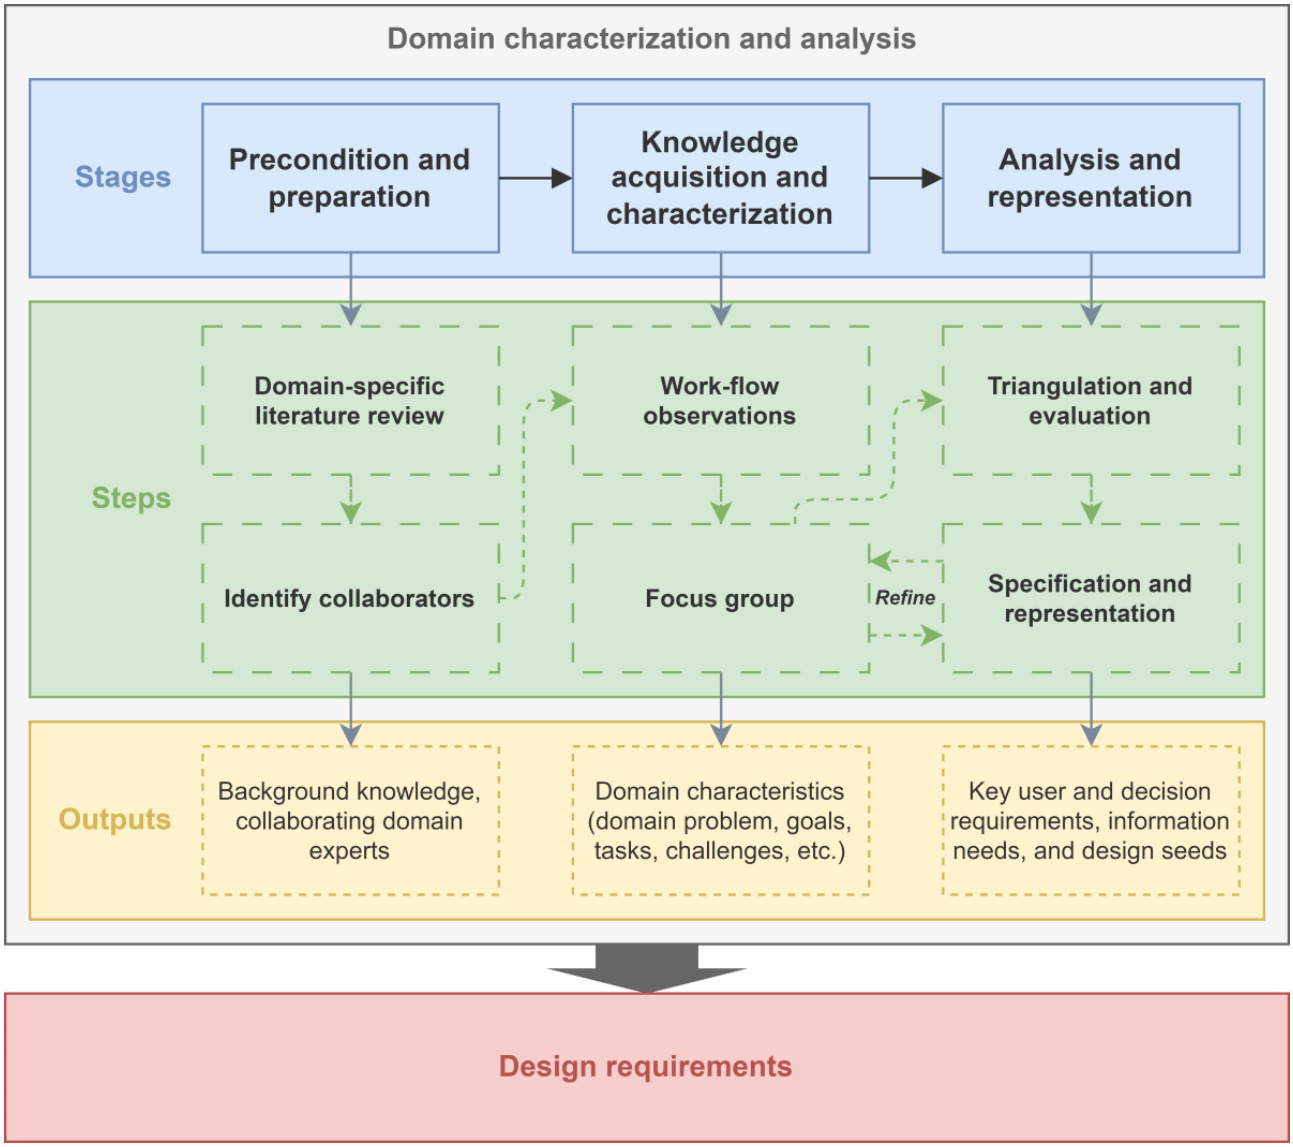
Human factors engineering (HFE) is crucial for designing interactive health technologies and CDS tools, focusing on usability and workflow integration for decision support [34-36]. Effective CDS requires speed, efficiency, meaningful alerts, consistency, and logical grouping with intuitive interface design [37-40]. Hence, designing such a technology must address user needs, working environments, cognitive demands, decision-making requirements, and advanced interactive visualizations for data analysis.

In total, 3 HFE approaches—design study methodology (DSM), user-centered design (UCD), and decision-centered design (DCD)—provide guidance for this. DSM is a problem-driven research paradigm focused on creating innovative visualization solutions through iterative collaboration with domain experts to address real-world problems [41]. UCD emphasizes understanding user tasks, goals, and needs by involving users from the beginning, which informs the specification of user requirements and guides the design process [42]. DCD aims to improve decision-making in critical scenarios, such as medical diagnosis, by enhancing human decision-making [43,44]. Cognitive task analysis identifies key cognitive demands and translates them into decision requirements, guiding the design process to improve clinical performance [45]. These approaches share a human-centered, iterative, and multistage methodology, leveraging in-depth analysis and expert contributions, while each addresses distinct aspects of the design process.

Objectives

The study aimed to identify design requirements for an interactive tool, specifically a physiotherapist dashboard, that aids clinical decision-making for musculoskeletal problems in musicians within the *RefLabPerform* project. This involved considering the working environment, clinical procedures, and user needs from the beginning and gathering detailed information on how decision-making in musicians' physiotherapy can be supported technically, especially with the integration of CMAs.

To achieve this, requirements elicitation methods from DSM, UCD, and DCD were followed to comprehensively describe the domain and the underlying problem, resulting in well-informed requirements and recommendations. This approach is expected to enhance usability and acceptance, improve user efficiency and accuracy, and reduce the cognitive workload of the future tool.



XSL•FO
RenderX

Methods

Research Approach

This qualitative user research study followed a problem-driven research paradigm and formed part of the initial *domain characterization and analysis* phase within a larger design study [46]. It systematically integrated elements from DSM, UCD, and DCD to elicit and structure design requirements for an interactive dashboard with CDS functionality in physiotherapy (see Figure 1). The requirements elicitation process drew on the first 4 steps of DSM (*learn*, *winnow*, *cast*, and *discover*) [41], the initial 2 phases of UCD (*understanding context of use* and *specifying user requirements*) [42], and the first 3 stages of DCD (*preparation*, *knowledge elicitation*, and *analysis and representation*) [44]. These approaches were merged and operationalized into three stages: (1) precondition and preparation, (2) knowledge acquisition and characterization, and (3) analysis and representation, with subsequent design and evaluation phases planned for future work. DSM ensured methodological rigor and problem characterization through iterative domain expert engagement; UCD emphasized contextual inquiry and stakeholder needs; and DCD supported the analysis of complex cognitive processes in physiotherapy decision-making. Together, they provided a robust foundation for deriving clinically relevant, user-informed, and cognitively aligned design requirements. A detailed mapping of their contributions is presented in Table 1.

Figure 1. The domain characterization and analysis process comprised 3 stages with multiple steps and outputs, ultimately defining design requirements for an interactive physiotherapy dashboard.

XSL•FO
RenderX

Table . Detailed mapping of each method's contributions to domain characterization and analysis.

Research stage	Design study methodology (DSM)	User-centered design (UCD)	Decision-centered design (DCD)
Precondition and preparation	• Domain understanding • Relevant terms and jargon • Identification of collaborators	• Understanding user group characteristics and context of use	• Identification of cognitively challenging activities from previous task descriptions
Knowledge acquisition and characterization	• Focus on real-world domain problem characterization • Domain expert engagement	• Participatory engagement through workflow observations and focus groups • Elicitation of user needs • Focus on user goals and task alignment	• Identification of cognitive demands, critical cues, and information needs
Analysis and representation	• Iterative synthesis of findings into design seeds • Structured representation of design implications	• Specifying user requirements • Integration of usability concerns • Clarity and traceability of user needs to system design	• Specifying decision requirements • Integration of cognitive support needs in clinical workflow • Translation of decision-making needs into design recommendations

The main author (EW) conducted the workflow observations and moderated the focus groups in German in March and April 2021. His researcher characteristics are the following: "gender: male," "experience: 6 years research experience in health informatics, main focus in physiotherapy and movement analysis projects," "degree: M.Sc. in Computer Science," and "occupation: Research assistant."

Ethical Considerations

The study was conducted in accordance with the Declaration of Helsinki and approved by the institutional review board (or Ethics Committee) of Osnabrueck University of Applied Sciences (protocol code HSOS/2021/1/1, date of approval March 17, 2021). Signed informed consent for publication was obtained from all participants after providing them with a written information sheet and verbal explanation of the study context, the intended procedure, and data usage. All participants were given a copy of the signed informed consent as well as confirmation of anonymization of study data. The study data were anonymized, so participants cannot be identified. Participants did not receive any financial compensation for their participation.

Precondition and Preparation

Domain-Specific Literature Review

Domain-specific literature from physiotherapy, clinical biomechanics, and movement analysis of musicians was reviewed to gather background information about the domain and user group characteristics and to become familiar with relevant terms and jargon [6,8-11,13-15,17,19,21,23,29,31,47-58]. Previously articulated task descriptions, such as clinical reasoning and functional diagnostics, were examined to gain domain understanding and to initially identify cognitively complex components.

Identify Collaborators

The INAPO, a specialized facility for treating neuromusculoskeletal disorders, served as a cooperation partner. INAPO has specialized in the treatment of musicians in close cooperation with the "Institute for Music" at Osnabrück University of Applied Sciences. Admitted patients receive tailored treatment and exercise programs. INAPO emphasizes staying updated with scientific progress in musicians' health and movement sciences, using modern therapy methods. As part of the *RefLabPerform* project, a CMA lab was established at INAPO, equipped with optoelectronic motion capture, surface electromyography sensors, and force plates. Requirements were gathered based on the CMA lab and INAPO's clinical practice needs.

In total, 4 physiotherapists (1 male, 3 female) from INAPO and an expert in clinical reasoning and applied biomechanics from the University of Applied Sciences Osnabruck were selected face-to-face as domain experts for systematic collaboration during requirements elicitation. Purposive sampling ensured the inclusion of a representative sample of practicing physiotherapists with extensive experience in managing musicians with musculoskeletal problems.

Knowledge Acquisition and Characterization

Workflow Observations

We used contextual inquiry to observe the workflow of physiotherapists managing musicians with musculoskeletal problems at INAPO prior to the focus group discussion. Contextual inquiry, a qualitative user research method, involves observing and interviewing potential users in their work environment as they perform actual tasks [59], ie, watching them perform tasks while asking questions about their actions and thought processes. This method uncovers tacit knowledge, reveals detailed work practices, and provides reliable, relevant information about user needs and behaviors. The goal was to identify and gather domain experts' needs and preferences for a physiotherapist dashboard and CDS concerning their (cognitively challenging) tasks and daily data encounters. Additionally, we asked the experts about their thoughts on the

XSL•FO
RenderX

integration of musician-specific CMAs into the diagnostic process and the application in clinical decision-making.

EW observed 3 physiotherapists experienced in managing musicians with musculoskeletal problems, previously selected for collaboration, during their daily work routines over 1 week. Each session lasted about 2 hours, allowing for detailed observation and discussion. Observations continued until thematic saturation was reached. Workflow diagrams were created from observation notes and presented at the focus group meeting to facilitate discussion on workflow processes.

Focus Group

We conducted a web-based focus group [60] lasting approximately 270 minutes (4.5 hours), comprising 7 participants: the 4 collaborating domain experts, 2 computer scientists, and 1 user experience designer. Video and audio recordings were made using Zoom (Zoom Video Communications, Inc). The focus group aimed to gain a deeper understanding of the domain, exploring the working environment, clinical procedures, user needs and decision-making processes in musicians' physiotherapy, providing essential information for the tool's design. The primary goal was to establish a common understanding of the domain and address the following key discussion topics for the specific setting: goals, skills, and barriers in musicians' physiotherapy; required collaborations, tools, and equipment; workflow structure and objectives of each step; information, tools, and activities per work step; and motion analysis lab workflow and physiotherapist interaction.

Given the lack of standardized procedures for focus group data collection and analysis, which depend on the research question and time frame, we opted to organize the results into a mind map during the discussion to facilitate consensus-building. Following the focus group session, the research team held a debriefing session to review the discussions and identify key points.

Analysis and Representation

Triangulation and Evaluation

The qualitative data was triangulated and evaluated to determine how the tool can address the domain problem and user needs, and support decision-making. First, the insights from workflow observations and the focus group were organized and contextualized with domain-specific literature to understand and describe the domain characteristics. Further evaluation of the findings revealed key user needs, as well as cognitively challenging tasks, strategies, difficulties, and critical aspects in musicians' physiotherapy.

Specification and Representation

Based on the prior findings, the solution's characteristics were specified. First, a workflow for integrating musician-specific CMA was established and visualized. Key user requirements, cognitive tasks, decision requirements, and associated information needs were then derived and formulated. Subsequently, design seeds to support decision-making were created. These findings were organized in tabular form.

In a second web-based focus group discussion, which lasted approximately 180 minutes (3 hours), the identified domain characteristics, specified user and decision requirements, and design ideas were revisited with the same group of experts and researchers. During this session, these elements were discussed in detail and refined based on their feedback.

Finally, incorporating knowledge and conditions from the theoretical background and domain, concrete design requirements were specified, including key features, technical prerequisites, and decision support recommendations.

Results

Characteristics of the Domain

To describe the domain, the characteristics were categorized under the following themes: domain problem; goals, skills, and competences, work equipment, and barriers; and tasks, routines, and challenges.

Domain Problem

The unresolved domain problem is integrating musician-specific CMA into musicians' physiotherapy and offering visual-interactive access to aggregated findings and treatment data for decision support.

Musicians' physiotherapy, an integral component of "musicians' medicine," specializes in the assessment and treatment of neuromusculoskeletal disorders prevalent among musicians. This specialty uses standard physiotherapeutic tools along with musician-specific questionnaires and CMAs to enhance diagnostic precision and facilitate data-driven therapeutic decisions. Post intervention, the collection of relevant patient questionnaires and repeated CMAs is crucial for effective therapy evaluation. However, an efficient technical solution for the comprehensive integration and analysis of clinical and biomechanical data tailored to musicians' physiotherapy remains absent. The primary beneficiaries of such a solution would be physiotherapists, with musicians gaining from improved, targeted therapies. Additionally, specialized physiotherapists or movement scientists trained in musician-specific CMAs would benefit from enhanced integration of CMA into the therapeutic process.

Documentation, typically on paper, should be electronic for comprehensive evaluation. Integrating CMAs adds complexity, requiring standardized data processing and effective communication between physiotherapists and movement labs. Current software for biomechanical analysis is not user-friendly for physiotherapists, lacking advanced visualization, interactive data exploration, and contextualization of clinical and biomechanical data. A new solution is needed to simplify data analysis and visualization for therapists, with requirements evolving during implementation.

Goals, Skills, Competences, Equipment, and Barriers

Textbox 1 summarizes the goals, skills, competences, work equipment, and (potential) barriers cited by domain experts. The primary goal of physiotherapists is to provide high-quality patient care to enhance or maintain sensorimotor self-determination. This requires addressing the patient's main

XSL•FO
RenderX

problems and goals efficiently to implement effective, targeted therapies. It is crucial to assess the effectiveness of therapeutic measures continuously, aligning interventions with the patient's condition and goals. Achieving these outcomes demands extensive skills and competencies, particularly in CR, which is central to effective therapy [58].

Textbox 1. Domain-specific goals, skills and competencies, work equipment, and barriers.

Goals:

- Enhancing or maintaining sensorimotor self-determination
- Improving the main problem
- Addressing patient goals

Skills and competencies:

Background knowledge:

- Patho-anatomy and physiology (clinical patterns, clinical picture, and musician-specific traits)
- Reference values (standard, individual, and musician-specific)
- Scientific evidence for assessments, tests, interventions

Clinical experience:

- Communication skills
- Manual skills
- Recognizing clinical patterns
- Techniques
- Test interpretation

Equipment:

- Patient questionnaires
- Diagnostic questionnaires
- Body tables
- Numerical rating scale
- Measuring instruments (eg, goniometer, algometer)

Barriers:

Physiotherapist:

- Lack of background knowledge
- Lack of clinical experience
- Shift in knowledge and beliefs, eg, through further education and training
- Premature judgments

Patient:

- Compliance
- Background (cognitive, social, and educational)
- Negative experiences
- Unreasonable expectations

General conditions:

- Legal: Limited time, lack of resources (eg, financial)
- Institutional: Limited time, lack of resources (eg, premises, measuring instruments), availability of qualified therapists

Domain experts highlight the importance of a solid background in (patho-)anatomy, physiology, normative and comparative values, and evidence-based assessments, tests, and interventions. Clinical experience is also vital for developing communication

XSL•FO
RenderX

and manual skills, refining techniques, interpreting tests, and recognizing clinical patterns. Further general requirements for physiotherapists are outlined in the literature [58]. Domain experts identified several tools used in therapy, including musician-specific patient questionnaires, body tables, numerical rating scales, goniometers, and algometers.

Physiotherapists face several barriers that can impede therapeutic objectives, including insufficient background knowledge, limited clinical experience, and shifts in knowledge due to ongoing education. Patient-related barriers include compliance issues and unrealistic expectations. Additionally, legal or institutional barriers, such as limited examination and treatment time, and insufficient financial, technical, or spatial resources, also pose significant challenges.

Tasks, Routines, and Challenges

The cyclical CR process consists of 8 main phases: looking, collecting, processing, deciding, planning, acting, evaluating, and reflecting [12]. These phases are interrelated and often overlap. The technical solution should explicitly assist the therapist in 5 of these steps (Textbox 2):

Textbox 2. Five steps that a technical solution should assist the therapist.

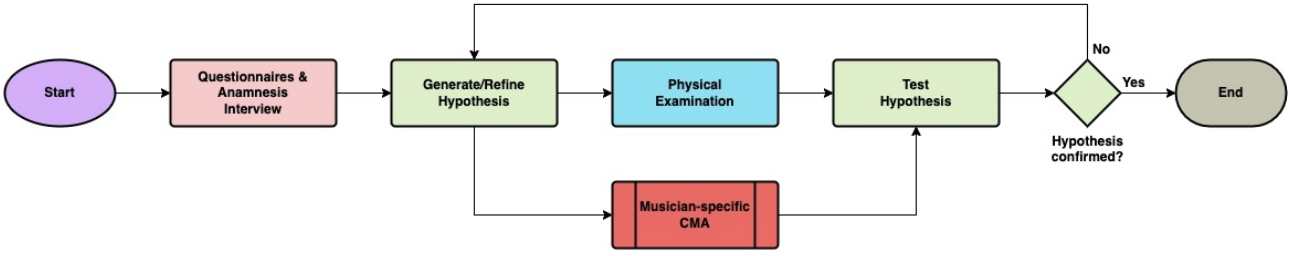
- **Collecting:** recording all subjective and objective findings
- **Processing:** analyzing and interpreting the findings
- **Deciding:** assessing the findings for diagnosis and planning
- **Evaluating:** assessing the interventions based on the repeat findings
- **Reflecting:** assessment of therapy effectiveness

The diagnostic process in physiotherapy involves examination, evaluation, and reassessment of findings and therapy measures under significant time pressure. Therapists must extract relevant information to make accurate treatment decisions, recognizing anomalies and changes in data [61].

Workflow observations and focus group discussions provided a deeper understanding of the therapeutic and diagnostic processes in musicians' physiotherapy. Before the first consultation, patients' complete musician- and problem-specific questionnaires, and the results guide the subjective examination, including background information and symptoms. This information helps generate diagnostic hypotheses tested during a physical examination, often using tools like goniometers. The results confirm or reject these hypotheses, leading to a physiotherapeutic diagnosis and a customized treatment plan. Treatment effectiveness is evaluated regularly, with reassessments before each follow-up to adjust or stop treatment as needed.

Specification and Representation

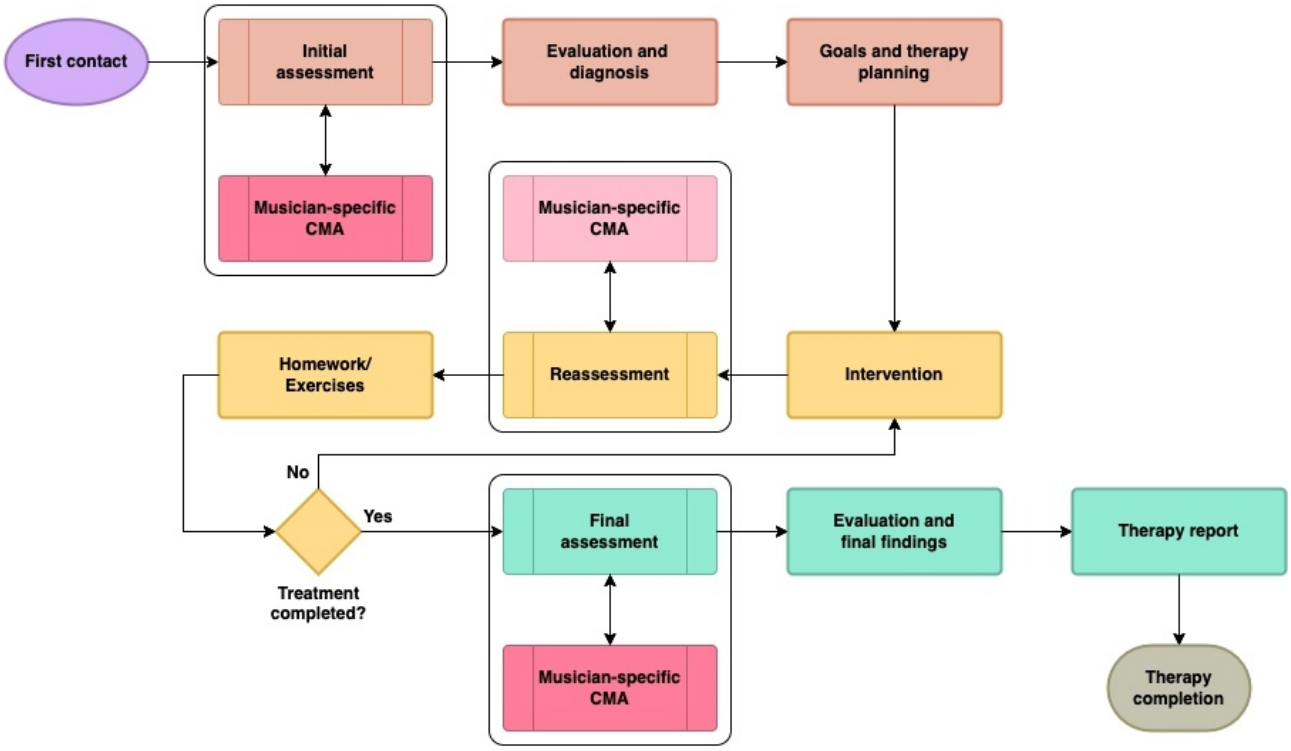
The findings from the prior domain characterization were further examined and discussed with the domain experts. This process aimed to address the integration of musician-specific CMA into physiotherapy, identify user requirements, and determine key cognitive tasks and decision requirements.



Integrating Musician-Specific CMA Into Physiotherapy

Based on the domain experts' input, the integration of musician-specific CMA into physiotherapy was designed. It is crucial to incorporate CMA efficiently, providing valuable information on a musician's dysfunction. The timing, execution, and result delivery are critical for high clinical benefit and rapid transfer from the movement analysis lab to the therapist. The CMA aims to test diagnostic hypotheses and evaluate therapeutic measures' effectiveness. Biomechanical data should be classified and interpreted within the clinical context, structured as additional findings, and made available to therapists.

Figure 2 proposes integrating CMA into the assessment process alongside the physical examination. Clinical reasoning underpins CMA use, starting with a clear question based on a working hypothesis, guiding the selection of muscles, starting positions, testing types, and biomechanical characteristics. This procedure is referred to as a movement analysis protocol based on Kontaxis et al [62].



In addition to using CMA for functional diagnostics during the initial assessment, a subsequent CMA is conducted post treatment, as depicted in Figure 3. This allows for a pre-post comparison to evaluate the effectiveness of the treatment interventions.

Figure 2. The revised diagnostic process integrates clinical movement analysis (CMA) as a complementary tool alongside physical examination (own illustration). It begins with musician and problem-specific questionnaires and anamnesis, followed by the generation of diagnostic hypotheses. A physical examination is then conducted to test these hypotheses. Simultaneously, a musician-specific CMA, guided by the hypotheses and a predefined movement analysis protocol, provides objective validation. If hypotheses require refinement or new ones emerge, additional physical exams and CMA assessments are performed until the final hypotheses are confirmed.

XSL•FO
RenderX

Figure 3. The modified clinical procedure integrates clinical movement analysis (CMA) for pre-, intra-, and posttreatment assessment (own illustration). Following the initial contact, an assessment is conducted, leading to findings evaluation, final diagnosis, goal setting, and therapy planning. After intervention, a reassessment is performed, and patient homework exercises are provided. If treatment continues, further interventions and reassessments follow; if completed, a final assessment, therapy evaluation, and report are conducted before concluding therapy.

User Requirements

Contextual analysis, informed by the domain-specific literature, workflow observations, and focus groups, revealed user needs concerning the solution's characteristics. In total, 21 user stories were defined based on these needs, reflecting the users' expectations of the physiotherapist dashboard's functionality [63]. These user stories pertain to clinical findings and treatment documentation, CMA, analysis and evaluation, and reporting. The full list of user requirements is available in Multimedia Appendix 1.

Cognitive Tasks and Decision Requirements

Cognitively challenging activities were identified, such as diagnostics, treatment planning, and therapy evaluation, informed by task descriptions from literature and the findings from knowledge acquisition and characterization. For each activity, we identified critical cues used by experts, potential errors, and procedures to meet cognitive demands. Physiotherapists generate and test hypotheses by interviewing patients and conducting or commissioning examinations, continuously integrating, and interpreting the information. Each activity is a cognitively challenging demand, requiring decisions on what information to gather and when to stop, as well as determining the next steps in treatment.

Finally, seven key cognitive tasks were identified: (1) querying specific patient questionnaires, (2) subjective examination of the patient, (3) testing diagnostic hypotheses, (4) consolidating and evaluating the information relevant to therapy, (5) planning the adapted therapy, (6) treating a patient's specific problem in an iterative approach, and (7) evaluating the therapy results. The final list of key cognitive tasks and the associated strategies, (potential) errors or difficulties, and critical hints of the domain experts can be found in Multimedia Appendix 2.

In coordination with the domain experts, key decision requirements were extracted from these activities, focusing on planning and assessing examinations and treatments while considering musician-specific CMA. Information needs for each decision were defined, specifying the clinical information needed. This approach led to design recommendations for decision support, offering early human-computer interaction concepts for organizing and visualizing information.

In total, five key decision requirements were identified incorporating musician-specific CMA in the context of physiotherapeutic diagnostics: (1) plan a functional diagnostic examination; (2) assess CMA findings; (3) prepare overall findings, and, if necessary, a report of findings; (4) compare results of reassessments and evaluate treatment effectiveness; and (5) evaluate therapy results and success. Based on the key decision requirements and associated information needs, a total of 49 design seeds were identified. The final list can be found in Multimedia Appendix 3.

Physiotherapists must decide if, when, and how to perform a CMA for a patient, considering basic patient information, contributing factors, symptoms, previous CMA parameters, and time and number of previous treatments. They must quickly evaluate findings to plan next steps, gaining an overview of the

XSL•FO
RenderX

patient's problem, identifying patterns, and confirming diagnostic hypotheses to formulate a physiotherapy diagnosis. They must determine which data are therapy-relevant to create an overall finding or report.

Throughout treatment, physiotherapists continuously assess findings and treatment effectiveness, deciding if measures positively impact the patient's problem or need adjustment. They review therapy-relevant information before and after treatments to identify trends and changes. They reflect on therapy outcomes and their actions, assessing whether therapy was successful and identifying key factors. They monitor achievement of therapy and patient goals using data from baseline and follow-up findings, treatment results, and relevant questionnaires, including post-intervention CMA results.

Design Requirements

The *domain characterization and analysis* informed concrete design requirements for a physiotherapist dashboard, specifying key features and CDS recommendations based on user needs for decision support. The use case defined technical prerequisites for implementation.

Key Features

Based on the insights gained, we identified 6 key features (KF) that form the basic pillars of the tool and must be fulfilled during design and implementation:

- **KF$_1$**. *Provision of biomechanical findings:* Musician-specific CMAs should be efficiently integrated into therapy to give physiotherapists valuable insights into a patient's dysfunction. Biomechanical data must be processed, modeled, and stored to produce a report with relevant characteristics for further analysis.
- **KF$_2$**. *Integration of heterogeneous data types and sources:* For a holistic inspection and assessment of all available information from the subjective and objective examinations of a patient's problem, it is necessary to combine different types of data from different data sources. This includes clinical findings and treatment data from physiotherapy documentation, results from web-based questionnaires, and biomechanical findings data from movement analysis.
- **KF$_3$**. *Adaptive overview:* A simplified aggregated overview is essential for quick and clear inspection and monitoring of patient-related information. This should include basic therapy data, recent findings, and treatments, as well as relevant individual patient details. Information should be adaptive and patient-specific, allowing physiotherapists to manually add or remove data. Detailed views should be accessible via a drill-down function.
- **KF$_4$**. *Adequate visual representations and interaction techniques:* Efficient visualizations, such as lists, tables, diagrams, and illustrations, should be chosen to aid physiotherapists in effective decision-making. Therapists should be able to manually arrange and configure these elements and use familiar interaction techniques like drag-and-drop, sorting, searching, and filtering.
- **KF$_5$**. *Efficient visual-interactive analysis of findings and treatment results:* Physiotherapists need an efficient solution for interactive visual analysis of findings and treatment results to identify abnormalities, trends, and patterns in clinical and biomechanical data. Established visual analytics methods will be used to explore and compare multivariate and time-oriented data.
- **KF$_6$**. *Preparation and export of findings and analysis results:* Physiotherapists should be able to summarize and export therapy findings as a report for discussion with colleagues and patients, or for continued treatment elsewhere. The report should be presented in a clear, customizable format.

CDS Design Recommendations

The user needs and design seeds addressing decision requirements formed the basis for specifying concrete CDS design recommendations (DR; see Textbox 3).

For planning musician-based diagnostics, it is helpful to have a note indicating if such an examination is possible for the patient (DR$_1$). CDS should remind the physiotherapist to conduct pre- and post-interventional exams if possible (DR$_2$). Additionally, suggested configuration parameters should be provided when creating an examination order to save time (DR$_3$).

To efficiently query and inspect findings and treatment results, essential data should be preselected for the overview (DR$_4$). Information should be summarized in aggregated elements and presented in suitable display formats (DR$_5$). Relevant therapy events should be shown on a timeline (DR$_6$). Additionally, visual cues should highlight significant data changes to reduce cognitive load and speed up decision-making (DR$_7$).

For interpreting findings, integrating normative and comparative values is desirable (DR$_8$). Therapists should be able to create interactive annotations (DR$_9$), marking specific data values or time intervals. To support diagnosis, findings and annotations should be linked to diagnostic hypotheses, showing which data support or refute them (DR$_{10}$). Additionally, marking applicable or inapplicable hypotheses interactively should be possible (DR$_{11}$).

For therapy evaluation, directly comparing baseline and final findings is essential (DR$_{12}$). An interactive review of patient and therapy goals helps determine therapy success, requiring target parameters for goal achievement (DR$_{13}$). Preselecting relevant entries and suitable presentation forms aids in report preparation (D$_{14}$).

XSL•FO
RenderX

Textbox 3. Overview of the clinical decision support design recommendations (DR).

Planning musician-specific examinations for functional diagnostics

DR_1: Indicate if musician-specific examinations are possible for the patient.

DR_2: Remind physiotherapists to conduct pre- and postinterventional examinations.

DR_3: Provide suggested configuration parameters for examination orders to save time.

Query and inspection of diagnostic findings and treatment results

DR_4: Preselect essential data for efficient querying and inspection.

DR_5: Summarize information in aggregated elements and suitable display formats.

DR_6: Map relevant events on a timeline.

DR_7: Use visual cues to highlight abnormal data or significant changes.

Analysis and interpretation of the findings data

DR_8: Integrate normative and comparative values for interpreting findings.

DR_9: Allow interactive annotations for specific data values or time intervals.

DR_{10}: Link findings and annotations to working hypotheses.

DR_{11}: Mark working hypotheses as applicable or not with appropriate presentation.

Therapy evaluation and reporting

DR_{12}: Enable direct comparison of baseline and final findings for therapy evaluation.

DR_{13}: Facilitate an interactive review of patient and therapy goals, with target parameters for goal achievement.

DR_{14}: Preselect relevant entries and use appropriate presentation formats for report preparation.

Technical Prerequisites

Technical prerequisites (TP) must be established to enable the physiotherapist dashboard (see Textbox 4). The tool should allow physiotherapists to access patient data and case history (TP_1), including anamnesis, physical exams, and treatment records (TP_2). Patients must complete validated musician- and problem-related questionnaires web-based, with results integrated into the findings overview (TP_3). Biomechanical data from musician-specific CMAs should be available as findings (TP_4).

Functional diagnostics occur in a CMA lab within a physiotherapy practice, staffed by specialists. Physiotherapists must submit *electronic exam orders* with relevant CMA details (eg, patient ID, instrument group, and symptoms; TP_5). The lab requires an *order management system* to track requests and update CMA status (TP_6) and a *data management system* for recorded measurements (TP_7). Standardized, musician-specific CMA protocols should be implemented (TP_8), integrating existing measurement tools and software (TP_9). Data processing and calculations should be largely automated (TP_{10}), with results provided as biomechanical findings (TP_{11}).

Technical prerequisites (TP)

Integration of therapy-related patient data

TP_1: Integration of patient and case data

TP_2: Integration of clinical findings and progress data

TP_3: Integration of the web-based questionnaire results

TP_4: Integration of the biomechanical findings data

Laboratory system

TP_5: Electronic order entry

TP_6: Laboratory order management

TP_7: Laboratory data management

TP_8: Standardized motion analysis protocols

TP_9: Integration of existing biomechanical measuring instruments or systems and analysis software

TP_{10}: (Largely) automated processing and calculation of relevant features

TP_{11}: Providing data from CMA as biomechanical findings

Discussion

Principal Findings

We proposed and applied a novel HFE process model to inform the design of a physiotherapist dashboard with CDS for CMA of musicians with musculoskeletal problems, using methods, and addressing aspects from DSM, UCD, and DCD. Following this model, we first identified and thoroughly described the characteristics of the domain and problem area. We explored user needs, cognitively challenging tasks, information needs, and decision-making challenges faced by physiotherapists managing musicians with musculoskeletal conditions. We then proposed design seeds for CDS, translating user and decision requirements into concrete design requirements, including key features, technical prerequisites, and recommendations for decision support.

Key features include efficient integration of biomechanical data, combining heterogeneous data types, and providing adaptive overviews for quick data inspection. The tool should present patient data in a suitable form and facilitate interactive visual analyses using familiar techniques like filtering, highlighting, and annotating. Summarizing and exporting findings for communication are also essential. User and decision requirements led to specific decision-support recommendations: CDS should indicate if musician-specific diagnostics are possible, remind physiotherapists of physical exams, suggest efficient configuration parameters, preselect essential data, highlight significant changes, integrate normative values, support interactive annotations, compare baseline and final findings, and provide tools for reviewing patient goals and preparing reports. To enable the tool, technical prerequisites must be met, including access to patient data (anamnesis, physical exams, treatments, and problem- or musician-related questionnaires), biomechanical data from musician-specific CMAs, support for electronic diagnostic orders, and management of these orders and CMA statuses. The tool should use standardized protocols, integrate with existing tools, and automate data processing to present biomechanical findings.

Additionally, our study contributes to the existing literature by detailing a methodology for requirements elicitation, comprehensively describing the domain of musicians' physiotherapy, and identifying requirements for the successful use of the tool. Our findings support previous research indicating that HFE is crucial for designing CDS technologies [34,35], emphasizing aspects such as speed, efficiency, user needs anticipation, workflow integration, meaningful alerts, consistency, logical grouping, interface design, and design simplicity [37-40].

Limitations

This study is in the early stages of design, focusing on establishing a structured foundation for the tool's design and domain-specific clinical workflows, relying primarily on qualitative methods like workflow observations and focus group discussions. While the findings provided in-depth qualitative insights from a small group of domain experts, generalizability is limited, and broader validation is needed. To address this, we plan to conduct a Delphi study involving a larger and more diverse panel of physiotherapists, movement scientists, and other relevant stakeholders [64]. This structured, iterative process will facilitate expert consensus on the tool's design requirements, ensuring their robustness and applicability across various physiotherapy contexts. The Delphi study will also help refine the identified requirements based on collective expert feedback, enhancing the tool's validity before further prototyping, usability testing, and implementation in clinical practice.

At this stage, no functional prototype exists, and technical features or implementation details, such as specific visualizations, interaction methods, and decision logic, were not addressed. These aspects will be defined and iteratively

XSL•FO
RenderX

refined during future stages of prototyping and evaluation. Furthermore, quantitative evaluation of metrics such as diagnostic accuracy, efficiency, or patient outcomes is not yet feasible. Future work will involve the development of a prototype, followed by iterative usability testing and structured evaluations. These evaluations will incorporate quantitative measures—such as time-to-decision, task completion rates, diagnostic decision support effectiveness, efficiency gains, and user satisfaction scores—to assess the tool's impact and clinical utility in real-world physiotherapy settings.

In addition, artificial intelligence (AI)–based CDS features were overlooked. Integrating machine learning and predictive analytics could significantly enhance precision and relevance [65]. In future development stages, machine learning algorithms can be incorporated to support early diagnosis, pattern recognition, as well as personalized treatment planning and outcome prediction considering individual patient characteristics. For example, supervised learning models could be trained on annotated CMA data to automatically identify movement anomalies or classify injury risks [65]. Predictive analytics could also be used to forecast recovery progression based on patient-specific parameters such as movement patterns, therapy progress, and contextual factors (eg, instrument type or workload) [66]. These enhancements would augment the therapist's decision-making with advanced data-driven insights while maintaining transparency and clinician control. Overall, this highlights the tool's extensibility and long-term innovation potential.

Moreover, while the proposed CDS approach focuses on integrating CMA with gold-standard methods, AI-driven approaches like computer vision-based pose estimation (eg, OpenPose [67]) should be explored. Sensorless systems could provide nonintrusive, real-time movement tracking, making assessments more accessible, especially in nonlaboratory settings. AI pattern recognition could automate impairment classification and suggest diagnostic hypotheses, aiding physiotherapists and improving decision-making. It could also enable remote physiotherapy, allowing musicians to exercise at home with real-time feedback. However, challenges in accuracy, occlusion, and clinical validation must be addressed before full integration into physiotherapy workflows.

Opportunities and Challenges

The integration of CMA into physiotherapy and incorporating clinical and biomechanical data with CDS within an interactive dashboard present both opportunities and challenges. Our study emphasizes the need to tailor CDS to real clinical environments and therapists' workflows. Ensuring these technologies are perceived as useful is crucial, as the balance between perceived benefits and implementation effort significantly affects adoption. Developing an interactive tool for supporting diagnosis and treatment of musculoskeletal disorders in musicians requires a multidisciplinary approach, combining health informatics, biomechanics, and clinical practice. Collaboration with domain experts ensures the tool meets practical needs. Requirements were elicited through problem-driven research, ensuring that real-world problems were addressed, as well as UCD and DCD approaches, considering user needs, cognitive demands, and decision requirements, aiming to enhance the usability and usefulness of the solution.

Most existing tools in physiotherapy focus on general clinical documentation [68] or basic measurement instruments like goniometers and numeric rating scales [18], with limited quantitative and objective significance. Advanced biomechanical analysis systems (eg, Qualisys [69]) remain primarily research tools—technically complex and disconnected from everyday clinical decision-making, lacking user-friendliness, tailored visualizations, and integration with clinical reasoning. CDS tools in physiotherapy are still emerging, with AI-based approaches showing promise for personalizing treatment and predicting patient-specific outcomes [70-72]. However, they lack integration of CMA into clinical workflows and provide limited support for context-specific decision-making, particularly for niche populations like musicians with PRMDs. Existing visualization tools support rehabilitation or monitoring but do not incorporate CMA data [73,74], and those that do focus on clinical gait analysis or specific disorders [75,76]. Currently, no tool integrates CMA data into the decision-making process for physiotherapists managing musicians with PRMDs.

An interactive tool based on the identified design requirements would fill this gap by directly integrating CMA into clinical workflows, aligning with physiotherapists' reasoning. It would enable interactive visualizations tailored to the needs of diagnosing and treating musicians with PRMDs, offering flexibility for different instruments and playing styles. Unlike existing tools, it bridges the gap between biomechanical analysis and clinical practice, providing musician-focused support and a platform for integrating advanced analytics to enhance diagnostic precision and longitudinal tracking. Such a system aims to integrate CMA into real-world physiotherapy workflows, providing context-aware support and decision facilitation across all therapy stages, particularly for underserved populations like performing artists.

The successful deployment of a future CDS tool will require addressing key technical and ethical challenges. Integration into existing health care IT systems involves overcoming data heterogeneity, ensuring interoperability, safeguarding data privacy, and achieving clinician adoption. Many institutions rely on proprietary electronic health records [77], complicating seamless data exchange. Standardized protocols such as HL7 (Health Level Seven) and FHIR (Fast Healthcare Interoperability Resources) can help address interoperability [78], while compliance with regulations like GDPR (General Data Protection Regulation) will require robust encryption, anonymization when applicable, and role-based access controls. Diverse IT environments further necessitate system compatibility; a modular, cloud-based architecture could offer the flexibility and scalability needed for broad adoption [79]. Clinician adoption will depend on smooth integration into existing workflows, user-friendly interfaces, and comprehensive training [80].

Future work must standardize and integrate diverse data sources—such as motion capture outputs, clinical notes, and patient records—into a unified platform compatible with physiotherapy workflows. Ethical considerations are equally

XSL•FO
RenderX

critical. The envisioned tool is designed to assist, not replace, physiotherapists by providing objective biomechanical data to enhance—not automate—clinical decision-making. The system will maintain clinician autonomy, ensure transparency and interpretability, and be developed in adherence to data protection regulations. Although risks related to automation or bias are minimal at this stage, they will remain important considerations in later development phases, particularly as data handling, user control, and AI components evolve. Finally, the evolving nature of clinical practices and data types presents ongoing challenges for maintaining a CDS tool's relevance. Continuous updates are needed to keep pace with advancements in clinical knowledge and technology, which can be resource-intensive. Addressing these challenges in future research will enhance such a tool's usability, adaptability, and impact on clinical decision-making.

In conclusion, successful implementation of the physiotherapist dashboard with CDS based on musician-specific CMA depends on alignment with clinical workflows, ease of use, successful integration in existing IT infrastructure, maintaining data protection and clinician autonomy, and demonstrable benefits in diagnostic accuracy and treatment efficiency. Insights from this study provide a solid foundation for designing an interactive tool for physiotherapists, incorporating CMA for musicians with musculoskeletal demands, aiming to improve patient outcomes and support clinical decision-making. Iterative feedback from domain experts during design and development should ensure the tool addresses real-world problems, is validated through practical application, and is continuously refined based on user insights. The involvement of physiotherapists and movement scientists from initial design to validation is pivotal.

While this study focuses on the niche context of musicians with PRMDs, the identified design requirements, domain-specific decision-making insights, and integration of CMA hold potential for broader application. The underlying framework and methodology can be adapted to other physiotherapy contexts that involve complex, movement-related diagnostic and therapeutic challenges—such as in athletes, dancers, or individuals with work-related repetitive strain or posture-related injuries. These populations similarly require tailored functional assessments and context-specific CDS [81-84]. Modular, task-oriented design supports adaptation across these groups by enabling customization of movement analysis protocols, clinical decision parameters, and visualization formats to meet domain-specific needs. This enhances both the generalizability and scalability of the proposed framework. Future work may explore how the proposed process model and design requirements can be transferred and tailored to other physiotherapy contexts, extending the broader relevance and impact of this research beyond musicians.

Conclusion and Future Work

This work contributes to HFE, physiotherapy, CMA, and CDS for musicians with PRMDs by combining rigorous research methods with expert insights. The proposed process model helps stakeholders identify user needs and decision-making requirements at the point of care, while the design requirements lay the groundwork for developing a specialized interactive physiotherapist dashboard integrating CMA with CDS. This tool can enhance diagnostic accuracy and therapy effectiveness through interactive, visual data presentation, streamline workflows, and maintain clinical relevance. Ultimately, it aims to improve patient outcomes, reduce injury recurrence, and support musicians' long-term careers.

In the next phase, we plan to translate the design requirements into a functional prototype as part of a physiotherapy-integrated diagnostic system [85]. To ensure practicality and effectiveness, we will conduct rigorous usability testing and evaluations with physiotherapists. This will involve iterative feedback loops through think-aloud protocols and task-based evaluations, ensuring that the tool aligns with clinical workflows and cognitive demands. Structured feedback will be used to refine interface features, data presentation, and interaction flows, providing empirical evidence of feasibility, usability, and alignment with the identified requirements.

Future research should validate usability, decision support, and clinical effectiveness; explore advanced analytics; adapt to various CMA systems (eg, sensorless tracking); and expand applications across diverse musicians, instruments, and therapeutic domains to enhance its impact.

Acknowledgments

The authors would like to thank Florian Avermann, Camilla Kapitza, Heike Schemmann, Sabrina Friehe, Dirk Möller, Johanne Weber, and Lars Dorenbusch for contributing their time and expertise. This work is part of the RefLabPerform project and was funded by the Federal Ministry of Education and Research (BMBF; research grant 13FH113PX8).

Authors' Contributions

EW conceptualized the study, recruited participants, collected, and analyzed data, and wrote the manuscript. KM contributed to the study's conceptualization and reviewed the final manuscript, while SM reviewed and finalized it.

Conflicts of Interest

None declared.

Abstract

Background: Increasing use of computational methods in health care provides opportunities to address previously unsolvable problems. Machine learning techniques applied to routinely collected data can enhance clinical tools and improve patient outcomes, but their effective deployment comes with significant challenges. While some tasks can be addressed by training machine learning models directly on the collected data, more complex problems require additional input in the form of data annotations. Data annotation is a complex and time-consuming problem that requires domain expertise and frequently, technical proficiency. With clinicians' time being an extremely limited resource, existing tools fail to provide an effective workflow for deployment in health care.

Objective: This paper investigates the approach of intensive care unit staff to the task of data annotation. Specifically, it aims to (1) understand how clinicians approach data annotation and (2) capture the requirements for a digital annotation tool for the health care setting.

Methods: We conducted an experimental activity involving annotation of the printed excerpts of real time-series admission data with 7 intensive care unit clinicians. Each participant annotated an identical set of admissions with the periods of weaning from mechanical ventilation during a single 45-minute workshop. Participants were observed during task completion and their actions were analyzed within Norman's Interaction Cycle model to identify the software requirements.

Results: Clinicians followed a cyclic process of investigation, annotation, data reevaluation, and label refinement. Variety of techniques were used to investigate data and create annotations. We identified 11 requirements for the digital tool across 4 domains: annotation of individual admissions (n=5), semiautomated annotation (n=3), operational constraints (n=2), and use of labels in machine learning (n=1).

Conclusions: Effective data annotation in a clinical setting relies on flexibility in analysis and label creation and workflow continuity across multiple admissions. There is a need to ensure a seamless transition between data investigation, annotation, and refinement of the labels.

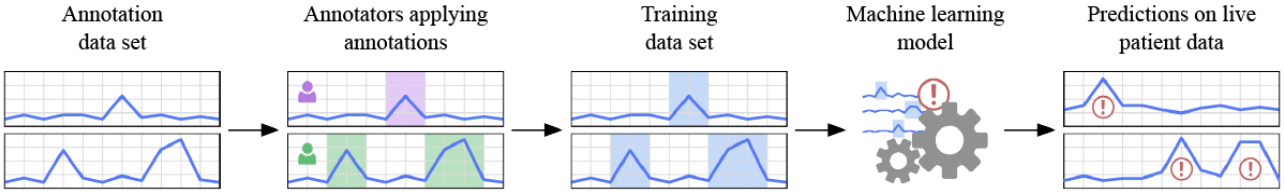
Introduction



Background

Artificial intelligence (AI) is a field concerned with leveraging computers to mimic human cognitive functions, such as problem-solving and decision-making [1,2]. Depending on the task, this process can use a variety of methods and take many forms ranging from relatively simple rule-based expert systems (following if-then pathways) through regression (modeling the relation between different variables to predict their values) and clustering (grouping objects with similar properties together) to more complex systems such as artificial neural networks (computing systems imitating the anatomy of human brains capable of modeling nonlinear processes) [1,3,4]. Particularly complex problems may require solutions that cannot be achieved by traditional approaches, such as preprograming the desired behavior. Instead, techniques such as machine learning (ML) form a subset of AI in which the algorithms are used to analyze large amounts of data to derive a method for computing a solution [5]. In ML, the practice of arriving at a solution is called "learning" (or training), and the produced output is known as the ML model. The heavy reliance on data in ML highlights the importance of ensuring the appropriate quantity and quality of data and signifies its impact on the effectiveness of the created model [6]. The continuously increasing popularity of ML and its rapid adoption rate in life sciences suggest that AI is at the forefront of bringing innovation to health care [7,8].

Intensive care units (ICUs) are busy and complex health care environments where critically ill patients frequently require continuous monitoring and multiple-organ support. To provide care for those patients, clinicians working in the ICUs use a broad range of medical devices, such as ventilators, monitoring devices, and intravenous pumps and lines among many others. The information captured by those devices, as well as that entered by the ICU staff, is collected and collated in a clinical information system, which enables health practitioners to access large quantities of data routinely required as part of their job. This data-rich nature and the direct influence of data on the provision of care provide a tremendous opportunity for the deployment of ML models in health care and in particular ICUs [9].

While the data gathered in the ICUs can often be used directly, for example, to present the correlation between different vital signs and the patient prognosis, complex tasks that rely heavily on clinical experience and expertise may require human involvement to provide further guidance [10]. This guidance, most frequently referred to as labels or annotations [11], can deliver additional information or context to the existing data. An example of such a label could be a "yes" or "no" indicator of whether a patient is ready for discharge, or the type and size of tumor present on a radiograph. With this further knowledge, ML models can take advantage of the human experience to tackle complex problems and deliver solutions that could not be inferred from raw data alone [12] (Figure 1).

Figure 1. Annotating data can provide additional information and context necessary to train machine learning models.

While the large volumes of data available in intensive care offer significant opportunities, working with these data also presents a unique set of challenges, as the effort required to annotate the dataset increases proportionally to its size [13]. Furthermore, the complex nature of the health care data and the fact that applying a single label can require clinicians to look at multiple parameters, patient history, and laboratory results make the annotation task highly labor-intensive. With the clinician's time being a remarkably valuable resource, ensuring the effectiveness of the data annotation workflow is paramount. The lack of an annotation system tailored to the unique nature of the health care data (eg, accessing a subset of relevant variables from a list of potentially hundreds of parameters [14]) further complicates this problem.

In addition to the difficulties associated with working within clinical settings, it is equally important to consider the inherent challenges of data annotation in their own right. These include the need to account for multiple different types of bias that could be introduced throughout the process [15]. For example, the annotators themselves may have their own preferences and preconceptions that will guide the approach they assume when annotating data. This could stem from the amount and diversity of their clinical experience in a context specific to the annotation task, such as the familiarity with the clinical problem, the specific population within which they have treated it, or even the specific tools and methods they have used in the past. Similarly, by annotating historical data that span the entire duration of the admissions, annotators may create labels with an inherent temporal or selection bias. Alternatively, annotators tasked with creating specific annotations may focus on a subset of the admission where they would expect to create the annotation, such as reliance on medication, which may decrease toward the end of the admission but could equally change throughout its overall course.

Current literature on the applications of computational methods within health care highlights data annotation as a primary bottleneck in the ML pipeline [16]. This effect is attributed to the need for domain-specific knowledge and therefore access the expert population, as well as the considerable investment of their time [16-18]. Because of this, existing methods aim to reduce the number of required annotations required for positive results by using a variety of techniques including active learning [17], machine-assisted annotation [19], or synthetic data generation [20]. Nevertheless, the majority of studies continue

XSL•FO
RenderX

to rely on human annotations in the cases where labels cannot be easily derived, or are inadequately documented in structured data [16]. Designing a tool for the annotation of large clinical datasets is therefore a problem that needs to be approached carefully. The expert nature of the annotators means that both their numbers and time are limited and are therefore resources that need to be used efficiently [16]. Furthermore, clinical datasets frequently aggregate data spanning several years, resulting in a volume of data that is infeasible for manual annotation, suggesting a need for a semiautomated approach that could scale up to an entire dataset with limited input from the domain experts.

Involving end users in the design process of new tools prior to their development is an important aspect of designing effective software [21]. It minimizes the risk of creating a system that is inefficient and helps ensure that the developed solution meets users' expectations and requirements [22,23]. In the context of the data annotation software used by experts in intensive care, this participatory design is especially critical, as each of the variety of roles (eg, junior doctors, doctors, nurses, and consultants) can generate a unique set of requirements. Furthermore, while the staff working in the ICUs are experts in the medical domain trained to treat patients, extracting their knowledge through data annotation is an entirely different process. For this reason, it is crucial to deploy a strategy that will ensure that the design of the tool follows a structured and systematic approach that can capture a wide variety of perspectives from its end users while also accounting for the needs and priorities of the data science experts who will use the created annotations.

Objectives

The primary objective of the research is to establish a set of criteria for the design of a data annotation tool that can be used effectively by clinicians to annotate time-series datasets from intensive care. To achieve this goal under the limitations of working within the health care setting, the system needs to account for limited access to the annotators and large volumes of data. Finally, to ensure the efficiency of the process, the subtleties of how clinicians approach the problem of data annotation need to be understood and accounted for in the design. The overarching goal is, therefore, to gather requirements for a data annotation platform that is purpose-built for the intensive care data and clinicians and, as such, one that facilitates an efficient annotation workflow in that domain.

Methods

Study Design

To understand how clinicians approach and reason about the data annotation process, we conducted an experimental study that involved members of the clinical staff from the ICU manually annotating excerpts of time-series data printed on paper. Observations taken during task completion served as a basis for analysis and were used to derive the requirements for the data annotation software. This choice of methodology was influenced by constraints associated with working within the clinical setting, such as the high demand and short supply of participants' time, and the direct relationship between the task completion and the requirements for the digital tool, which allowed for a natural and unobstructed data collection.

Participant Recruitment

Our participant recruitment followed a mixture of convenience and snowball sampling comprising an invitation email sent to the staff working in the ICU who had prior experience with mechanical ventilation treatment and signposting through the internal network at our research site—University Hospitals Bristol and Weston NHS Foundation Trust. This recruitment process yielded a sample size of 7 participants across 2 distinct job roles (6 junior doctors and 1 doctor), which provided limited feasibility for suitable analysis of the interrole differences in approach to annotation but was sufficiently rich for establishing the software requirements for the tool we set out to design. Comparative sample sizes can be observed in similar research in the field [24-26]. Before data collection, the annotation task was piloted with a clinical member of our team experienced in mechanical ventilation treatment, as well as 2 other members of our team from the ML background. The insights collected from the pilot activity allowed us to refine the set of clinical parameters used throughout the activity, devise the inclusion criteria for the underlying admissions, and diversify the data extracts to form a sample representative of a typical dataset. Our research site had a preestablished research partnership with the University of Bristol and a technologically enhanced ICU with widespread adoption of digital systems.

Theoretical Framework

To analyze the participants' actions performed during the simulated activity, we used a framework that served as a basis for characterizing the data annotation process and identifying the challenges and opportunities associated with performing the task. Our framework followed the Norman's Interaction Cycle (NIC) model which assumes that the interaction is a process of evaluation and execution between the user and the technology [27]. It outlines a 7-step process that begins at the goal and, through evaluation of available means and strategies, as well as the execution of these strategies, leads to achieving that goal in practice. The framework emphasizes the breakdown of the preproduction stage into planning (formulating the problem that needs to be solved), specification (outlining the strategies that can be used to tackle the problem), and performance (specifying actions that need to be taken to deploy the strategy). Furthermore, it highlights the importance of presenting the user with feedback over 3 separate stages including perception (tracking the outcome of performed actions), interpretation (analyzing the effect of the outcome), and comparison (evaluating whether their actions resulted in achieving the goal) [27]. Finally, the model captures the disparities between user intentions and actions permitted by the technology (gulf of execution) and the effort required to correctly interpret the results of their actions with regard to the desired outcome (gulf of evaluation) [27,28].

Data Collection

To facilitate data collection, we simulated a data annotation activity involving manual annotation of real intensive care patient data using pens and highlighter pens on excerpts of data

XSL•FO
RenderX

printed on paper sheets. The data were formatted to resemble the clinical information system present at the research site and displayed patient demographics in addition to a table with time-series data. Each column of the table corresponded to an hour of the day and each row corresponded to a specific parameter; the table's cells contained the readings of a parameter for a given hour (Figure 2). The outline brief for the activity prompted participants to create annotations, allowing them to create multiple annotations for a single admission. Crucially, no additional instructions were provided regarding the annotation format. Before the data collection, the activity was piloted internally with an experienced intensive care consultant (CB) and 2 ML experts (RSR and CMW), which helped us establish inclusion criteria for the selected admissions, broaden the characteristics of our admission sample, and refine the included parameters. The activity took place as a single in-person workshop, lasting approximately 45 minutes, during which each of the 7 participants annotated the same set of 5 unique admissions (Figure 3).

Participants were observed for the duration of task completion by a single observer who took field notes throughout the entire activity. These field notes captured the interactions of the participants with the annotation tasks and described the actions taken when annotating specific admissions, how multiple admissions were annotated, and questions asked by the participants during the task. The collected notes were then aggregated across the different stages of NIC and the annotated printouts were collected and used to supplement the analysis of the methods used by the participants to label the data.

Task Selection

Capturing data labels in a manner representative of the general annotation process relied on selecting an appropriate task. On the one hand, the desired label could not be trivial and needed to pose a significant challenge, complex enough to prompt an in-depth analysis of the data. On the other hand, this task also needed to fall within the subset of domain knowledge that participants were familiar with and could therefore solve with a relative degree of confidence. Annotating weaning from mechanical ventilation satisfies both of these criteria due to its challenging nature and the relative bias of the person who performs it. The process of weaning can be characterized by great variability in practice [29], in which both the timing of when the weaning begins and the method in which it is delivered largely depend on the clinician in charge of the treatment [29,30]. Together with the lack of personalized guidelines [31] and a wide variety of ways in which patients can be weaned, mechanical ventilation weaning constitutes a label that is difficult to derive from data and requires domain expertise, which makes it suitable for this task. While in the context of mechanical ventilation the term "weaning" comes with an inherent ambiguity due to a number of conflicting definitions [32-36], for the purpose of this activity it was explicitly defined as "the reduction of support delivered by the mechanical ventilator with an end goal of extubation." Consequently, the activity brief prompted participants to annotate periods during which mechanical ventilation weaning takes place and allowed multiple annotations for any individual admission.

Admission Data

The data used in the activity came from a deidentified intensive care dataset called "Medical Information Mart for Intensive Care IV version 2.0" [37]. The eligibility criteria required that subjects were at least 18 years of age at the time of admission, had undergone an invasive mechanical ventilation treatment that lasted for a minimum of 24 hours, their stay in the ICU lasted for a minimum of 4 days, and that their stay did not end with death, including up to 48 hours after discharge. The time-series parameters used in the data extract were limited to those relevant to mechanical ventilation weaning and were selected by 2 independent clinicians working in the ICU. The data were extracted using a structured query language script run on the PostgreSQL installation of Medical Information Mart for Intensive Care IV version 2.0 with the concept tables computed [38]. The script aggregated the selected parameters on an hourly basis for each eligible admission and limited it to the range surrounding the period of mechanical ventilation treatment.

Ethical Considerations

This work was approved by the Faculty of Engineering Research ethics committee at the University of Bristol (case 2022-150, research ethics committee reference 22/HRA/2166). Information regarding the study was circulated with the invited participants electronically alongside the recruitment email. Informed consent was captured electronically using digitally signed consent forms prior to enrollment in the study. Data obtained from this study were deidentified and stored securely in an encrypted database. The access to the database was password-protected and only the research team had access to these data. All participants were able to quit without any explanation at any point during the study. Participation in the study was voluntary, and no financial or other form of compensation was provided to the participants.

Results

Data Annotation Analysis

During the simulated data annotation activity, we observed participants following a series of discrete steps when annotating data. To understand how these actions fit into the annotation process, we analyzed the observations in the context of NIC and aggregated them into the distinct phases of the model.

Planning

Following the distribution of the printout sheets containing the admission data, participants began the process of familiarizing themselves with the data. This stage involved selecting a single excerpt from the available admissions, analyzing the patient demographics, and browsing through the time-series data. During the process, participants frequently cycled through the entire length of the time-series data from the initial admission until discharge and back.

Specifying

Upon familiarization with the specific admission, participants began searching for individual points in time suggestive of the weaning taking place. Some participants preferred to start with the end of treatment, where weaning led to extubation, while others analyzed the data to find the points in time when weaning began. This involved focusing on specific parameters (as suggested by following the specific rows with the pen tip) while browsing through the time-series data across different columns.

Performing

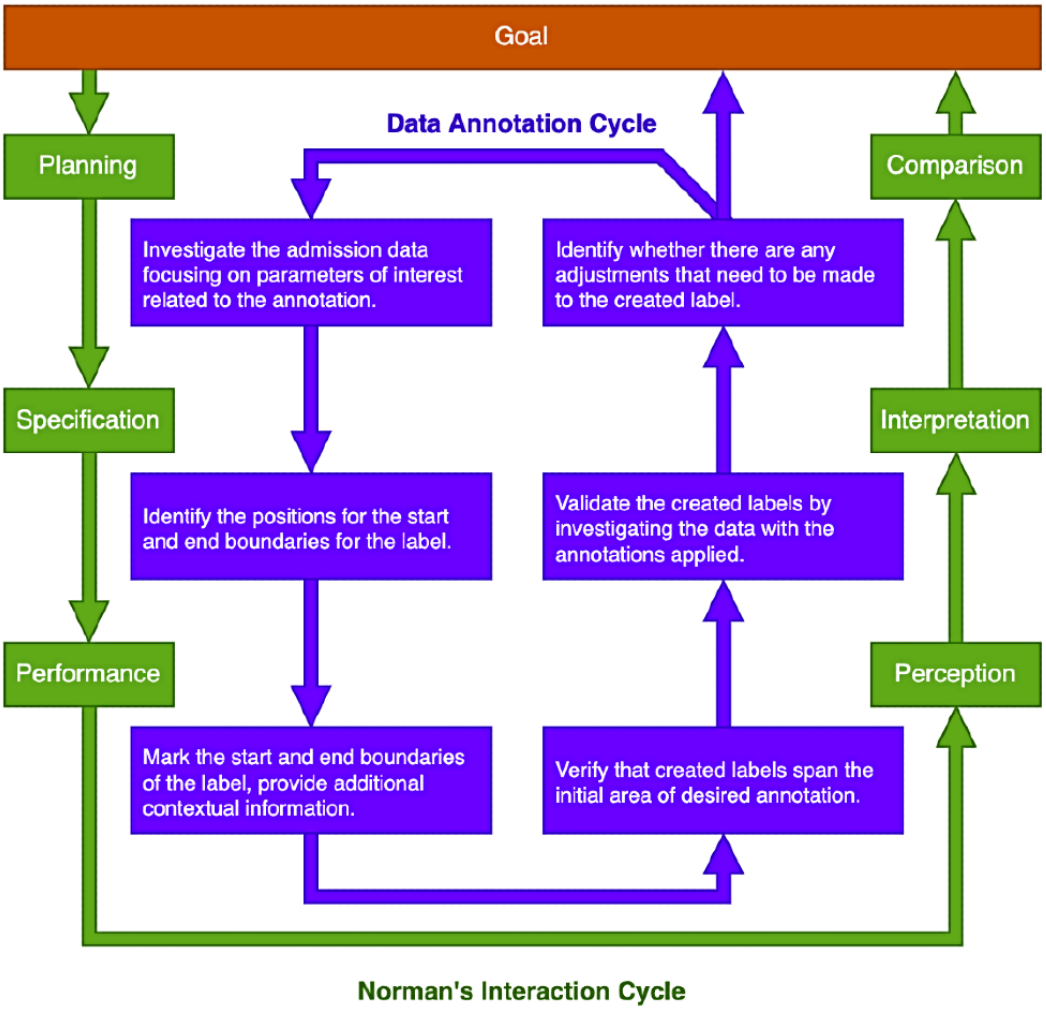
Upon finding the thresholds for the start or end of weaning, the participants annotated the printed sheets directly. To create the labels, a variety of techniques were used, which differed both between the individual annotators and the distinct admissions. These included circling the start and end dates in the header row of corresponding columns, drawing vertical lines on the edges of the columns to mark the start and end periods, and drawing a box around the portion of the dataset spanning the duration of the label. Similarly to the analysis process, some participants preferred to first annotate the end of the weaning process, rather than its start. In some cases, participants also provided additional information in the form of written comments that justified the created label (eg, "mode of ventilation changed from A to B" or "delivered oxygen reduced—indicative of weaning") and underlined values within cells of parameters that prompted annotation.

Perceiving

Following the act of annotating the data, participants frequently verified their labels. This was expressed by browsing through the time-series data again and ensuring that the start and end dates corresponded to the parameter readings that suggested the annotation in the first place.

XSL•FO
RenderX

Interpreting



In some cases, participants derived additional insights from the data when investigating them with their labels already present. These insights frequently manifested in the form of retracing the admission data over the span of the created label, which resulted in a reevaluation of the created label and its underlying data.

Comparing

Finally, participants who identified the need for amendments returned to the planning stage to repeat the annotation process, whereas those satisfied with their annotations frequently sought feedback from the activity facilitator on the desired annotation count and the next steps involved in the process.

Crucially, by contextualizing the annotation process within the NIC model we identified that the overall approach to annotation followed a cyclic process of investigation of the data, creation of the labels, reevaluation of the data with the labels applied, and refinement of previously created labels (Figure 4).

Figure 4. Data annotation followed a cyclic process involving investigation of data, label creation, reevaluation of data with labels applied, and refinement of created annotations.

User Requirements

Observations from the workshops captured key characteristics of participant interactions with the task, forming a basis for establishing the functional requirements of the digital tool. Coupled with the operational constraints of data annotation in clinical settings and the specific needs for future label use in the ML context, these characteristics informed the user requirements for the digital annotation tool.

Annotation of Individual Admissions

Familiarization with admission data during the planning and specification stages suggested that the primary goal of participants at the early stage of the process was to obtain a high-level overview of the patient's characteristics and their stay in the ICU. This was supported by the frequent cycling through different parts of the admission, allowing participants to establish a broad timeline of events and the overall treatment trajectory without focusing on the minutia of its delivery. The interface of the tool should allow end users to conduct a similar analysis digitally, incorporating both the patient demographics and the time-series data.

Once familiarized with the admission data, participants shifted their focus to a more task-oriented analysis by narrowing the list of parameters to a subset significant for the task, suggesting

XSL•FO
RenderX

different relevance of specific parameters to the target label. Furthermore, the fact that in certain cases participants found it easier to first search for the end of weaning, rather than its start, suggests that their confidence in the accuracy of the created label, its precise start or end, might be different across annotations. Similarly, each of the participants displayed different preferences for creating annotations favoring first marking either the start of the weaning process or its end. Despite this, they all shared a common set of actions of marking the beginning and end of the label, even when the order of these operations was not the same. To make the annotation process as unobtrusive as possible, the digital data annotation tool should therefore allow flexibility in not only how the data are viewed and analyzed but also how the annotations are being created. As such, the interface needs to display a continuous dataset without constraining it to a subset of time or parameters and allow the end users to freely mark the boundaries of the label in the order of their preference.

Following the creation of a label, participants frequently continued to investigate the underlying data and further adjusted the labels, indicating the need to reflect on their immediate performance and refine the annotations. Adjusting labels upon their reevaluation indicates that when the data are viewed with the annotations applied, the annotator's perception of these data changes allowing for additional insights to be derived. As such, the digital tool should allow for the display of the created annotations on top of the data and facilitate a similar ability to adjust and modify them once they are created.

Participants also frequently provided additional information to support their labels, such as comments or specific parameters that led them to create the annotation. This contextual information could be used as a surrogate for the thought process of the annotators and further inform the importance of specific parameters on the target label. The digital tool should therefore incorporate the ability to provide additional data, such as parameters of interest, confidence in the accuracy of created labels, and free-form text that provides further context.

Finally, the feedback sought upon completing the annotation indicated the need for both a progress indicator and the importance of preservation of the continuity of the annotation process on retaining participants' focus. A digital tool could account for this by displaying the count and information about the already created labels and making it easy and efficient for participants to annotate consecutive admissions. As such, the functional requirements for the digital data annotation tool can be specified as follows:

- R1: Data analysis in which participants are free to navigate through the entire span of the admission data, as well as underlying patient demographics.
- R2: Label creation functionality which is flexible enough to allow end users to select the start and end of annotation independently and in any order.
- R3: Label adjustment capability that facilitates an easy and convenient way to amend the created label, particularly with that label presented on top of data.
- R4: Label supplementation feature that allows participants to provide additional context for the created annotation, including confidence in the label accuracy and relevance of different parameters.
- R5: Workflow continuity that ensures a cohesive process of annotation and keeps the end users engaged and focused on the task.

Semiautomated Annotation

Facilitating a semiautomated approach to annotation that allows for creating labels for an entire dataset is a separate but closely related task. As such, it can benefit from the analysis of the manual annotation process and use it to further inform the requirements for the digital tool. The annotation of a single admission could be described as a bottom-up approach, in which end users are presented with data specific to a single admission and asked to annotate them directly (optimally until the entire dataset is annotated). Conversely, adopting an approach that automates the process would likely involve the annotation of an entire dataset based on a single user input, constituting a top-down approach. A semiautomated approach would therefore focus on creating labels for the whole dataset without focusing on individual admissions during their creation but potentially using them to evaluate the annotations and refine them upon further analysis. To that extent, the digital tool needs to allow its end users to establish annotation strategies that are independent of individual admissions during their formulation.

The process in which participants interacted with the individual admissions suggested several key requirements that needed to be adapted for the semiautomated approach. To close the loop of investigating, annotating, evaluating, and refining that the participants exhibited during the simulated activity, the semiautomated annotation approach facilitated by the platform should also allow for analysis of the effectiveness of the annotation in the context of both the entire dataset and individual admissions. In particular, the interface should allow the end users to view individual admissions with the created annotations applied, providing additional explanations for why the label was created, and in turn, allowing them to refine their annotation strategies. Consequently, the requirements for the digital tool facilitating a semiautomated annotation are defined as follows:

- R6: Annotation and evaluation loop captured as one continuous process that preserves the focus of the end users and facilitates effective annotation.
- R7: Label analysis of individual admissions with the overlay of created annotations on the time-series data and justification for their presence.
- R8: Dataset-wide performance metrics that capture the effectiveness of the annotation in the form of aggregate statistics computed across the entire dataset.

Operational Constraints

In addition to the requirements identified through the analysis of participants' approach to the annotation task, there are further operational constraints that need to be reconciled to deliver an effective annotation workflow. To accommodate the busy schedules of the ICU staff, the tool should allow its end users to access it in a way that suits their needs and does not impose strict time commitments. As such, end users should be able to perform the annotation asynchronously and access the platform

XSL•FO
RenderX

remotely. Furthermore, to preserve the focus and ensure that the end users' time is used efficiently, the system should provide a responsive and time-efficient workflow that enables them to create and evaluate annotations in a short span of time. This is particularly important for the semiautomated approach in which the timely annotation of a large volume of data is critical to preserve the continuity of the annotation and evaluation loop. The operational requirements for the annotation tool are therefore defined as follows:

- R9: Asynchronous and remote annotation that allows the end users to perform the task at their convenience without further complicating their busy schedules.
- R10: Responsiveness of the system that provides feedback on the created annotations in a timely manner, particularly in the case of the semiautomated annotation.

Labels for ML

Finally, having identified the functional and operational requirements, we analyzed the platform in the wider context of using the created labels in ML workflows. To that extent, the discussion between data science experts within our research team surfaced several key factors that the tool should account for to ensure that the captured data can seamlessly integrate into ML pipelines.

The most important one to consider is the need to achieve a careful balance between the number of annotated admissions and the confidence in the created annotations. On one hand, increasing the total number of annotated admissions and their diversity would result in a larger training dataset and, consequently, improve the performance of the resulting ML model. On the other hand, to account for the biases of individual annotators, there needs to be some overlap of admissions annotated by distinct annotators that would allow for a comparison of their approaches and biases. Furthermore, for this to happen, additional metadata surrounding the confidence in the specific annotations and relating the created annotations to their authors also needs to be collected. Only then, will the data scientists be able to evaluate each of the annotators individually, compute their biases, and adjust their annotations accordingly to improve the robustness of the training dataset.

Depending on the volume of the data that needs to be annotated, the nature of the annotation task, and the number and experience of the annotators, this balance might be substantially different. Because of this, the system needs to facilitate a dynamic and adjustable configuration for how specific data are assigned to the annotators. This suggests that in addition to the previously established requirements, the tool should also aim to satisfy the following ML-specific requirement:

- R11: Flexible data-splitting solution that allows for adjustment of the data assigned to each participant and keeps track of the label authorship.

Discussion

Principal Results

This study aimed to explore how intensive care experts approach data annotation to establish requirements for a digital tool designed for annotating large datasets in intensive care. We conducted a manual data annotation activity, observing participants as they completed the task and analyzing their actions to gain insights into their annotation strategies. This analysis informed the development of software requirements for a digital data annotation platform.

Our findings revealed that the time-series annotation process follows a cyclical annotation-evaluation loop, which includes data investigation, label creation, reevaluation of data with the labels applied, and refinement of the created labels. From this analysis, we constructed 11 key requirements: 5 directly related to facilitating the annotation of individual patient admissions, 3 adapted for implementing a semiautomated annotation feature, 2 operational requirements focused on the effectiveness of the annotation workflow, and 1 requirement addressing the future use of labels in the ML context (Table 1).

XSL•FO

Table 1. Requirements generated from analysis of observations made during simulated annotation activity.

Category	Requirement description
Annotation of individual admissions	
R1	Data analysis in which participants are free to navigate through the entire span of the admission data, as well as underlying patient demographics.
R2	Label creation functionality which is flexible enough to allow end users to select the start and end of annotation independently and in any order.
R3	Label adjustment capability that facilitates an easy and convenient way to amend the created label, particularly with that label presented on top of data.
R4	Label supplementation feature that allows participants to provide additional context for the created annotation, including confidence in the label accuracy and relevance of different parameters.
R5	Workflow continuity that ensures a cohesive process of annotation and keeps the end users engaged and focused on the task.
Semiautomated annotation	
R6	Annotation and evaluation loop captured as one continuous process that preserves the focus of the end users and facilitates effective annotation.
R7	Label analysis of individual admissions with the overlay of created annotations on the time-series data and justification for their presence.
R8	Dataset-wide performance metrics that capture the effectiveness of the annotation in the form of aggregate statistics computed across the entire dataset.
Operational constraints	
R9	Asynchronous and remote annotation that allows the end users to perform the task at their convenience without further complicating their busy schedules.
R10	Responsiveness of the system that provides feedback on the created annotations in a timely manner, particularly in the case of the semiautomated annotation.
Use in machine learning	
R11	Flexible data-splitting solution that allows for adjustment of the data assigned to each participant and keeps track of the label authorship.

Approach to Annotation

The observations made during the manual annotation activity highlighted important characteristics of how experts from a clinical background approach the annotation task. While the sample of our study produced no discernable differences in how participants from different roles approached the task of data annotation, we observed a variety of strategies used to complete the task. These included several techniques for initial familiarization with the data, prioritization of different parameters during the investigation process, and different order of operations when creating the label. Crucially, we observed that irrespective of the specific strategies, annotators followed a cyclic process of investigation, annotation, reevaluation, and refinement when annotating data. By modeling the process using NIC, we were able to analyze the observations made during the task completion stage and formulate the requirements for the software interface of a digital data annotation platform.

In our analysis, we found that the nature of how annotators choose to analyze the data is largely preferential and, therefore, requires a degree of flexibility in how the software presents the data and allows its users to navigate through it. The cyclic nature of the process suggested that to ensure effective annotation, it must facilitate a continuous and intuitive loop of annotation, allow users to perform actions in varying order, and seamlessly adapt to different stages of the process. Since these requirements were derived from the simulated annotation of individual admissions but captured the characteristics of the overall problem of data annotation, the requirements for the semiautomated approach were adapted to ensure the continuity of the annotation-evaluation loop and flexibility in analysis.

Finally, the fact that annotators frequently sought feedback after creating labels further emphasized the importance of ensuring a seamless and uninterrupted annotation workflow and suggested the need to integrate progress indicators within the digital platform. Together with individual preferences for focusing on different parameters during the analysis and supplying additional information as part of the created labels, this also highlighted the need to capture contextual information alongside labels, which could be beneficial for their later use in the ML pipelines.

Design Implications

This literature on involving clinical staff in the collaborative design of software interventions shows that it can have profound effects on user acceptance and uptake upon release [23,39]. However, it is important to highlight that effectively engaging in such collaboration can be a challenging task, particularly when research activities require substantial time commitment [40]. Collaborating with intensive care clinicians, whose time is in high demand and short supply, may therefore require additional accommodations to be effective. In the context of annotating data, these accommodations translate into additional

XSL•FO
RenderX

requirements that adapt the process to the busy schedules of the clinical staff by allowing them to annotate data both asynchronously and remotely. This further reinforces the need to ensure that the software delivers an intuitive and time-efficient annotation workflow and places additional constraints on its design. Specifically, to facilitate the responsiveness of the annotation-evaluation loop in the semiautomated approach, where users can frequently simultaneously annotate the entire dataset, the software should incorporate a solution that dynamically adapts to both the number of active users and the volume of data that needs to be processed.

Limitations and Future Work

The activity focused on capturing the approach to data annotation was conducted with a limited number of participants, which resulted in a limited diversity of clinical roles and, potentially, perspectives from the ICU. This suggests that some of the requirements established in this research could be particularly applicable to annotators in junior doctor positions and therefore not necessarily generalizable across entire staff working in ICUs. The selection of the task for the manual annotation activity was made to provide an annotation experience that could be extrapolated beyond the specifics of the task. Despite this, we acknowledge that the results it produced could be biased specifically toward the annotation of weaning from mechanical ventilation.

Furthermore, our approach to capturing the annotation process during the simulated activity with only a single observer had a significant impact on the quantity and quality of observations that were collected. Due to the imbalance in the number of annotators and observers, some of the actions undertaken by the participants during the annotation could have gone unnoticed. Furthermore, the presence of a single observer created an inherent bias in the collected observations, as the observed actions could have been perceived differently by observers with different backgrounds or characteristics. These limitations suggest that the observations collected during the activity come with a degree of incompleteness and inaccuracy, which may have impacted the elicited requirements.

We acknowledge that further work in establishing the requirements for the digital tool could strengthen the understanding of how clinicians approach the data annotation task. To that extent, we suggest that further research in this area focuses on capturing the requirements that expand beyond the confines of a single annotation task and within a broader and more diverse population from the ICUs. Capturing a wider range of perspectives could inform the applicability of the elicited requirements and, in consequence, strengthen the resulting design of the digital tool.

The nature of the activity itself was focused strictly on the direct annotation of individual admissions rather than the use of any assistive or automated technologies. Although several requirements elicited in this context applied to the overall annotation process, including a semiautomated approach, additional requirements not captured in this study may also exist. Further research should therefore focus on the evaluation of the proposed requirements and their use and limitations in real-world applications. Therefore, these requirements should be used to design and implement a digital data annotation platform that should be trialed within a clinical setting. Conducting a study that investigates the feasibility of a semiautomated approach to the data annotation, particularly in comparison with the direct annotation of individual admissions, could further inform the requirements for data annotation tools.

Conclusions

In this study, we investigated how clinical staff from ICUs approach the task of data annotation and established 11 key requirements for a digital data annotation tool that could be deployed within the health care setting. Our findings revealed that data annotation is a cyclic process that demands flexibility in how annotators investigate and annotate the data. Preservation of the workflow continuity across different admissions and fluid transition between analysis, annotation, and refinement of the label are essential to facilitating effective data annotation in the clinical domain. Adaptations for the semiautomated annotation need to consider these factors by providing a responsive interface that dynamically adapts to the volume of data and allows for analysis on both an individual and a dataset-wide basis. The significance of these findings is evident in their potential to guide the development of a data annotation tool that capitalizes on the considerable data generated in the ICUs and the expanding use of computational methods in health care.

Acknowledgments

This work was partly supported by the Engineering and Physical Sciences Research Council Digital Health and Care Centre for Doctoral Training at the University of Bristol (UK Research and Innovation grant EP/S023704/1 to MW). The work of RSR was funded by the UK Research and Innovation Turing AI Fellowship (grant EP/V024817/1). The project received an AWS Cloud Credit for Research grant.

Authors' Contributions

MW was involved in the study design, workshop facilitation, and writing. RSR, CMW, and CB were involved in the study design and critical revision.

Abstract

Background: Internet-based cognitive behavioral therapy (CBT) provides psychological interventions to individuals with mild depressive symptoms.

Objective: This study aimed to examine the potential cost-effectiveness of internet-based guided-CBT in university students with mild depressive symptoms from the perspective of service providers in Hong Kong.

Methods: The outcomes of low-intensity guided internet-based CBT and in-person CBT in a hypothetical cohort of university students with mild depressive symptoms were examined using a 5-year decision-analytic model. Model inputs were obtained from published literature and local data. Model outcomes included direct medical cost, school dropouts, and quality-adjusted life years (QALYs). Sensitivity analyses were conducted on all model parameters.

Results: Compared to the in-person group, the internet group gained higher QALYs by 0.0211 QALYs, lowered school dropouts by 0.052%, and saved US $249 in the base-case analysis. In one-way sensitivity analysis, the internet group gained higher QALYs at a lower cost than the in-person group throughout the variation of all model inputs. Probabilistic sensitivity analysis showed that the internet group was cost-effective (at willingness-to-pay threshold was US $48,119/QALY) in 99.7% of the 10,000 Monte Carlo simulations.

Conclusions: Internet-based CBT appears to be the cost-effective option when compared to in-person CBT for university students with mild depressive symptoms from the perspective of service providers in Hong Kong.

internet; cognitive behavioral therapy; telehealth; depression; university students; health economic analysis

Introduction

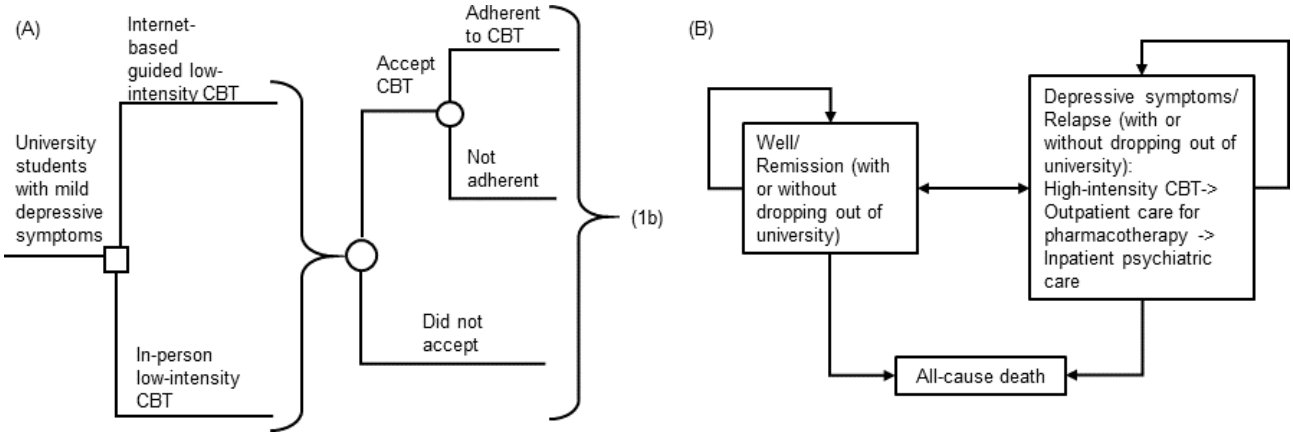
Depression is a leading cause of disability worldwide. The World Health Organization (WHO) reported that approximately 33% first-year college students in 8 countries were screened positive for a common *DSM-IV* (*Diagnostic and Statistical Manual of Mental Disorders IV*) mental disorders [1]. The pooled depression prevalence in university students from 81 studies (near 1.5 million subjects) was estimated to be 34% [2].

Cognitive behavioral therapy (CBT) is a widely used psychological therapy for symptoms of depressive disorders and has been traditionally administered as in-person interventions. Young adults with mild symptoms of depression typically delay face-to-face intervention with a therapist, plausibly associated to several possible reasons. Perceived stigma and embarrassment at face-to-face intervention is one potential barrier [3]. Also, the accessibility of face-to-face psychological interventions may also be limited by monetary or time requirements, as well as by the service delivery barriers, such as insufficient psychological services and inadequate workforce numbers [3]. Internet-based CBT interventions provide alternative options that are self-paced and highly accessible, and computerized low-intensity CBT is recommended by the National Institute for Health and Care Excellence (NICE) as an option for mild depression [4]. Low-intensity CBT is a structured self-help program, including 6 - 8 brief sessions (20 - 30 min per session) over 9 - 12 weeks [4]. Meta-analyses reported superior efficacy of internet-based

XSL•FO
RenderX

CBT when compared to the waitlist or usual care [5,6]. Offering guided internet-based low-intensity CBT could enhance the treatment and health economic outcomes of mental health management for university students with mild symptoms of depression. In addition to clinical evidence, health economic findings are important evidence to facilitate the informed decision-making process for policy makers on the uptake of a health technology. This study aimed to examine the potential cost-effectiveness of internet-based guided CBT in university students with mild depressive symptoms from the perspective of service provider in Hong Kong.

Methods



Ethical Considerations

The protocol of retrospective review had been approved by the Joint Chinese University of Hong Kong–New Territories East Cluster Clinical Research Ethics Committee. The need for informed consent was waived by the Joint Chinese University of Hong Kong–New Territories east Cluster Clinical Research Ethics Committee. Data deidentification was performed in the retrospective data review process, and no compensation was provided.

Model Overview

A decision-analytic model (Figure 1A–B), including a short-term decision tree model followed by a 5-year Markov model, was designed to evaluate the potential health economic outcomes of a hypothetical cohort of university students with mild depressive symptoms managed by two strategies: (1) therapist-guided, internet-based low-intensity CBT (internet group) or (2) conventional in-person low-intensity CBT (in-person group). Depression symptom classifications adopted the Patient Health Questionnaire-9 (PHQ-9) [7]: mild (PHQ-9 score 5 - 9), moderate (PHQ-9 score 10 - 14), or severe (PHQ-9 score ≥15).

Figure 1. (A-B) Simplified decision-analytical model. Depressive symptoms/relapse status included cases of mild, moderate, or severe depressive symptoms. CBT: cognitive behavioral therapy.

Low-intensity CBT (delivered in-person or via the internet guided by a therapist) recommended by NICE for mild depressive symptoms is a structured self-help program that includes 6 - 8 sessions over 9 - 12 weeks. In the in-person group, the participants work through the CBT-based self-help workbooks with brief support from the therapist in face-to-face sessions (20 - 30 min per session). In the internet-based CBT, the low-intensity CBT program was offered via the internet platform. The participants work through the CBT-based self-help materials (resembling the structure of face-to-face CBT) delivered by online modules, and the therapist provided written feedback to the participant's self-help work by emails or texting [4].

All hypothetical students with mild depressive symptoms entered a short-term model mirroring the duration of the low-intensity CBT program (Figure 1A). The hypothetical student (in both groups) might accept the CBT program, and those who accepted the therapy might adhere with the course of CBT. Upon the completion of low-intensity CBT, the student might recover well or deteriorate (showing moderate or severe depressive symptoms), and all were advanced to a 5-year Markov model (Figure 1B).

In the Markov model (Figure 1B), the hypothetical subjects proceeded through health states (Markov states) in each model cycle according to transition probabilities [8]. The present Markov model consisted of three key Markov states (well/remission, depressive symptoms/relapse, and all-cause death). Within the depressive symptoms/relapse status, cases are further differentiated (by proportion) into depressive symptoms of mild, moderate, or severe. The students who deteriorated or did not achieve remission with the low-intensity CBT program were stepped up to high-intensity CBT and outpatient psychiatric care for pharmacotherapy [4]. Students with severe depressive symptoms might be admitted to hospital for inpatient psychiatric care. In each model cycle, all hypothetical students (those in remission and those with depressive symptoms) might (or might not) permanently dropout from the university study. The model outcomes included direct medical cost, dropout, and quality-adjusted life years (QALYs). The model time horizon was 5 years, and the cycle length was 1 month. With the non-responding and recurring nature of depressive symptoms, a timeframe of 5 years was adequate to capture the outcomes of internet-based and conventional in-person low-intensity CBT, and the downstream costs and QALYs associated with deteriorated and non-responsive depressive symptoms.

Clinical Inputs

The clinical model inputs (Table 1) were retrieved from published clinical studies. A MEDLINE search (2000 - 2023) was performed using keywords such as “depressive disorders,” “internet,” “telehealth,” “telemedicine,” “cognitive behavioral therapy,”“cognitive behavioral therapy,” “pharmacotherapy,” “uptake,” “compliance,” “remission,” and “deterioration.” Selection criteria of published studies included: (1) Reports published in English language, (2) adults with symptoms of depressive symptoms, (3) event rates of remission and/or deterioration, and (4) individuals’ uptake of the delivery platform and (5) compliance of delivery platform (online and in-person) for CBT were reported. Meta-analyses and randomized controlled trials were the preferred types of studies. When multiple clinical randomized trials were available for the same model input, the base-case value was derived by the weighted average of the reported findings.

[a]CBT: cognitive behavioral therapy.

[b]Parameter-specific distribution used in probabilistic sensitivity analysis.

The effectiveness of low-intensity CBT for mild depressive symptoms was retrieved from the findings of a prospective, pre- and post-treatment study of low-intensity CBT; they reported the recovery (63.9%) and deterioration (5.3%) rates for individual with mild common mental disorders (depressive disorders and anxiety disorders) in Hong Kong [9]. A systematic review (including 17 studies) reported that electronically delivered CBT was more effective than face-to-face CBT at lowering severity of depression symptoms and concluded that electronically delivered CBT was at least as effective as in-person CBT [10]. The relative difference in the effectiveness of CBT delivered via internet versus in-person was therefore assumed to be 1.00 in the present model. A recent Canada health technology assessment study on the cost-effectiveness of internet-delivered CBT for major depression had applied a spontaneous recovery rate of 25% for individuals who did not receive any treatment [11], and the present model adopted the spontaneous recovery rate for individuals with no intervention (who did not accept or were non-adherent to the CBT) in both study arms. The occurrence rate of deterioration in the individuals with no interventions was obtained from an individual participant data meta-analysis on internet-delivered CBT (including 16 trials with total 3805 participants), reporting that clinically significant deterioration had occurred in 9.1% participants in the control groups [12]. The preference of university students for digital technology versus in-person interventions when encountered mental health needs was examined in a survey study (n=572), and the likelihood of seeking help through online and in-person methods was 75.4%% and 63.3%, respectively [13]. The compliance to CBT was retrieved from the findings of a meta-analysis on adherence to internet-based (80.8%) and face-to-face (83.9%) CBT for depression (including 24 trials) [14].

The monthly probability of mortality in the subjects with depressive symptoms was approximated by all-cause mortality from age-specific mortality [15,16] and relative risk of mortality in individuals with depression (1.18) reported by a meta-analysis (including 25 studies and n=106,628) on excess mortality associated with depression [17]. The monthly probabilities of

XSL•FO
RenderX

relapse from well (2.44%) and remission from depressive symptoms (0.54%) after the completion of low-intensity CBT in both study arms were estimated from the findings of a long-term follow-up study of depression in primary care setting over 3 - 5 years (n=248; median 46 months, IQR 43-51 months) [18]. Of the relapsed cases from those who recovered well, the proportion of relapsed cases with mild symptoms (24.3%) and the proportion of relapsed cases with moderate symptoms (50%) among the relapsed cases with moderate-to-severe symptoms were retrieved from a retrospective cohort study (n=687) of the recurrence among patients with a history of major depressive disorder [19]. The monthly probability of psychiatric hospitalization (1.78%) among those with severe depressive symptoms was estimated from the 12-month psychiatric hospitalization rate reported by a retrospective database analysis (n=248) on hospital utilization in patients with major depressive disorder [20]. The monthly probabilities of school dropout among students with remission (0.124%) and those with depressive symptoms (0.193%) were approximated from the findings of a long-term follow-up study (for 4.8 years) on mental health and school dropout in over 3000 individuals aged 16 - 29 years [21].

Utility Inputs

The QALYs gained by each hypothetical student was calculated by the time spent in various health states, adjusting by the health state-specific utility (Table 1). The QALYs gained were discounted to the current year using a 3% annual discounting rate. A study reported the age-specific scores for quality of life from a US population-based survey [22], and we adopted the US age-specific score as the utility value in the present model. The utility values of remission and mild-to-severe symptoms of depression were adopted the corresponding values applied in cost-effectiveness analyses on the management of depression [23,24].

Cost Inputs

The cost analysis was conducted from the perspective of service providers in Hong Kong. The direct cost items (Table 1) were costs for in-person low-intensity CBT, internet-supported guided low-intensity CBT, in-person high-intensity CBT, and costs of psychiatric outpatient and inpatient treatment for depressive symptoms. The cost of in-person CBTs were estimated by the number of sessions (per intensity level) [4] and the local hourly wages of the psychotherapist. The overhead for internet-supported CBT in our model adopted the overhead cost of an online-guided CBT program for depression examined in a randomized controlled study [25]. The percentage of the psychotherapist's time (9.23%) for guided CBT versus in-person CBT was retrieved from the report of randomized controlled trials of internet-delivered versus in-person CBT for depression [26]. The cost per psychiatric hospitalization was approximated by the length of hospital stay for depression and cost per day of psychiatric hospitalization [27,28]. We conducted a retrospective review of psychiatric resource utilization in a cohort of local university students who received ambulatory psychiatric care for depressive symptoms. A cohort of students of the Chinese University of Hong Kong who had been referred by the University Health Services in 2017 - 2020 to outpatient psychiatry care for depression symptoms (n=100; 32% men, median age 21 [IQR 20 - 22] years) were reviewed on the psychiatric care reimbursement claims. The investigators had no access to information that could identify individual students during or after data collection. The median cost per patient month (US $231; 25th and 75th percentile US $160 and US $335) were applied as psychiatric outpatient costs (per patient month) for depressive symptoms. The costs were adjusted to the current year by an annual discounting rate of 3%.

Data Analysis

The expected cost and QALY of both study arms were generated in the base-case analysis. A CBT strategy was the dominant strategy if it gained higher QALYs at a lower cost than the comparator. When a strategy gained higher QALYs at a higher cost than the comparator, incremental cost per additional QALY gained (ICER) was calculated as follows: Δcost/ΔQALYs. The WHO recommended that ICER less than 1×gross domestic product (GDP) per capita to be highly cost-effective [29]. The 2023 GDP per capita of Hong Kong (US $48,119) was adopted as the willingness-to-pay (WTP) threshold (cost per additional QALY gained) in the present analysis [30]. A CBT strategy was accepted as cost-effective if (1) it was the dominant option (the strategy was less costly and more effective), or (2) the strategy was more costly and more effective, and its ICER versus the comparator was less than the WTP threshold.

The robustness of the base-case results was examined by sensitivity analysis. One-way sensitivity analysis was conducted for all model inputs. The range for sensitivity analysis of each model input was either the 95% CI range, high/low values of the variable, interquartile range, standard deviation, or (if above were not reported) varied by 20% of the base-case value. Probabilistic sensitivity analysis examined the impact of simultaneous variation of all model inputs. The cost and QALYs were generated for 10,000 times using the Monte Carlo simulation by randomly drawing each model input from the parameter-specific distribution (Table 1). The incremental cost and incremental QALYs of the internet group were presented in a scatter plot. All analyses were performed using TreeAge Pro 2023 (TreeAge Software Inc) and Excel 2016 (Microsoft Corporation).

Results

The internet group gained higher QALYs (by 0.0211 QALYs) and lowered dropout rate (by 0.0528%) at a reduced cost (US $249 saved) versus the in-person group in the base-case analysis (Table 2), and therefore was the (dominant) cost-effective option at ICER −11,801 US $/QALY.

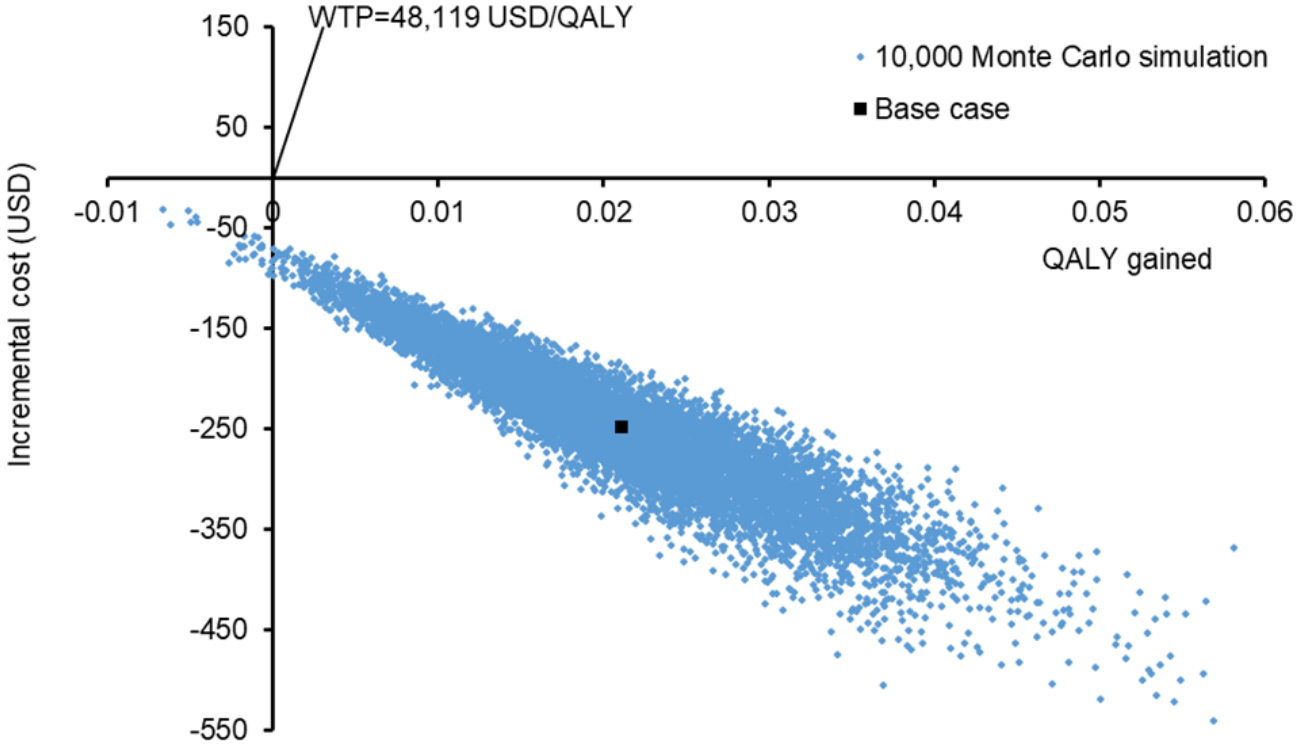
Table . Base-case analysis results.

	Costs (US $)	Incremental cost (US $)	School dropout	Incremental Dropout	QALYs[a]	Incremental QALYs
Internet group	8498	−249	9.8645%	−0.0528%	2.5627	0.0211
In-person group	8747	-	9.9174%		2.5416	-

[a]QALYs: quality-adjusted life-years.

In one-way sensitivity analysis, the internet-based group remained to gain higher QALYs at lower costs than the in-person group throughout the variation of all model inputs, and no threshold value was identified. The compliance rates to internet-based CBT and in-person CBT were the most influential factors on the ICER of internet-based CBT. When the compliance rate to internet-based CBT varied over the range of sensitivity analysis (from 73.0% to 88.7%), the ICER reduced from −10,116 USD/QALY to −23,892 USD/QALY. When the compliance rate to in-person CBT changed from 75.7% to 92.1% (range for sensitivity analysis), the ICER of internet-based CBT increased from −20,254 USD/QALY to −10,117 USD/QALY. To further explore the interacting impact of the compliance to the two delivery forms of CBT, a two-way sensitivity analysis was performed on extended range (50 - 100%) for both parameters. The findings of the two-way sensitivity analysis are shown in Figure 2. The gray area indicated the combination of compliance rates of internet-based and in-person CBT to prefer the internet-based CBT as the cost-effective option. The white area indicated the combinations of compliance rates leading to the in-person CBT as the cost-effective strategy.

Figure 2. Two-way sensitivity analysis of compliance to internet-based and in-person CBT. Gray zone: Combinations of parameters led to the internet group as the cost-effective option. White zone: Combinations of parameters led to the in-person group as the cost-effective option. CBT: cognitive behavioral therapy.



The internet platform cost and percentage of psychotherapist's time were previously reported to be major cost drivers of internet-based CBT [31,32]. The impact of these two parameters on the present base-case results were further evaluated by an extended sensitivity analysis, conducted by increasing the upper limit of internet platform cost from US $29 to US $2000, and the upper limit of psychotherapist's time from 11.1% to 50%. The extended sensitivity analysis found a threshold value for the internet platform cost at US $1745, and no threshold was identified for psychotherapist's time contribution.

XSL•FO
RenderX

The probabilistic sensitivity analysis recalculated the cost and QALYs for each study group 10,000 times using the Monte Carlo simulation. The incremental cost and additional QALYs gained by the internet group versus the in-person group in all Monte Carlo simulations are shown in Figure 3. The internet group was cost-saving in 100% of the 10,000 simulations, and gained higher QALYs 99.7% of the times (and therefore accepted as cost-effective in 99.7% of all simulations). The mean cost saved and additional QALY gained by the internet group were US $244 (95% CI US $242-246) and 0.0211 QALYs (95% CI 0.0209 - 0.0213), respectively. The internet group remained the cost-effective option when the WTP was lowered from US $48,119/QALY to 0.

Figure 3. Scatter plot of increment cost and QALY saved by internet-based CBT group versus in-person CBT group. CBT: cognitive behavioral therapy; QALY: quality-adjusted life-year; WTP: willingness-to-pay.

Discussion

Principal Results

This is the first study to report the cost-effectiveness of guided internet-based low-intensity CBT versus in-person CBT for mild depressive symptoms in university students. The present findings showed that the strategy of offering guided internet-based CBT gained higher QALYs and reduced school dropouts at a lower cost than the strategy of offering in-person CBT. The sensitivity analyses supported the robustness of these findings that the probability of the internet group to be accepted as cost-effective was 99.7% at the WTP threshold of US $48,119/QALY.

Limitations

This study was limited by the nature of model-based analysis that the model structure only included the key clinical treatment outcomes of depressive symptoms. The model inputs were retrieved from multiple clinical studies with heterogeneity in the study subjects. The findings from studies of CBT for depressive symptoms in Hong Kong or Chinese population do not fully meet the needs of the present model, and some of the clinical model inputs were therefore obtained from findings published in Western populations [10-14,17-21]. The sources of model inputs might weaken the generalizability of the study results to the university students in Hong Kong. Also, the compliance to internet-based CBT was retrieved from a meta-analysis of studies on CBT among depressed adults, including students and older participants [14]. University students are likely to have a higher affinity (vs older) for internet-based therapy due to higher digital literacy [33], and the compliance estimate (including both student and older samples) might therefore have underestimated the compliance in students, thus the cost-effectiveness benefits of internet-based CBT in students. Sensitivity analysis was therefore conducted on all model inputs to examine the impact of model parameter variation on the model findings. The cost-effectiveness findings generated by the present model were found to be highly robust to the variation of all model inputs. The psychiatric outpatient cost estimation from a local cohort of university students did not differentiate the severity of depressive symptoms and might underestimate the total direct cost related to severe depression. Indirect cost (loss of productivity) and the quality-of-life change associated with depression-related university drop-out were not considered in the present model, and might therefore undervalue health economic benefits generated by the guided internet-based low-intensity CBT.

Comparison With Prior Work

The individual compliance rates to the two CBT delivery modes were identified to be the most influential parameters in the

XSL•FO
RenderX

one-way sensitivity analysis. The base-case values of CBT compliance were adopted from a meta-analysis on 24 studies comparing the adherence to guided internet-based CBT with the adherence to face-to-face CBT. Even though the average adherence of face-to-face CBT (83.9%) was higher than that of internet-based CBT (80.8%), the difference between adherence rates did not achieve statistical significance (*P*=.59) [14]. The impact of uncertainty in the difference between the compliance rates on the cost-effectiveness of the two CBT delivery modes was further elaborated by a two-way sensitivity analysis on the compliance rates of internet-based and in-person CBT. The findings of two-way sensitivity analysis provided information on the combinations of compliance rates required for internet-based and in-person CBT to be cost-effective. In cohort with low compliance to in-person CBT (<60%), the internet-based CBT was a cost-effective option if the compliance to internet-based CBT was at least 50%. In individuals with high compliance to in-person CBT (>90%), the internet-based CBT needed to achieve a compliance rate of >75% in order to be accepted as the cost-effective alternative. The CBT delivered by the internet-based technology was previously reported by a 6-month decision model in Australia to be less costly and more effective than "treatment as usual" (using antidepressant medication) for an acute depressive episode. Similar to the present findings, the compliance rate of internet-supported CBT was also identified as the most influential factor on the cost-effectiveness of the technology-based CBT [34].

A life-long model-based health economic analysis demonstrated that an internet-based CBT was more effective in gaining higher QALYs at higher cost than "treatment as usual" for depression in Spain, and the high cost (approximately US $500) of technology platform and recurring cost (approximately US $3000 per individual) were the major cost drivers of internet-based CBT [32]. A 3-year model-based health economic analysis in Germany reported that the internet-based CBT gained higher QALYs at a lower cost than in-person CBT for unipolar depression. The Germany study included a low-cost (US $53) technology platform and low staff cost (psychotherapist-time approximately 40% of in-person CBT) [31]. Similarly, the internet group in the present model adopted a low cost for the internet platform to deliver the low-intensity CBT materials (US $24) [25] and approximately 10% psychotherapist's time of in-person CBT [26]. The cost-effectiveness of internet-based CBT was robust to high percentage (50%) of psychotherapist's time, and it remained cost-effective if the internet platform cost was less than US $1745, as indicated by the findings of extended sensitivity analysis in the present study.

University students belong to a vulnerable group of depressive symptoms. The latest report of WHO showed the statistics of World Mental Health Surveys International College Student Project (n=13,984) that the prevalence of depressive episode was the highest of all common mental disorders. The lifetime prevalence of major depressive episode was 21.2% and the 12-month prevalence was 18.5% among the surveyed students [1]. CBT is the recommended intervention for mild depressive symptoms, yet the acceptance rate of professional treatment among young adults had been low (<30%) due to embarrassment and preferring to handle the issue alone [3,35]. The internet-based CBT, as a NICE recommended intervention, has been showed to enhance acceptance by university students for emotional needs [13] and therefore could meet the needs of university students with mild depressive symptoms. Our prior study on the cost-effectiveness of internet-supported CBT for mild symptoms of anxiety for university students reported that the internet-supported CBT gained higher QALYs with cost-saving from the societal perspective of Hong Kong [36]. The findings of the present study further indicated that offering internet-based CBT (versus in-person CBT) for mild depressive symptoms was effective in gaining higher QALYs and lowering dropout rate with cost-saving. The improvement in QALYs achieved statistical significance (as indicated in 10,000 Monte Carlo simulations), yet the improvement (by 0.0211 QALYs) was modest. The health economic benefits of guided internet-based low-intensity CBT were mainly generated by the cost-saving and similar effectiveness to in-person CBT. The internet-based low-intensity CBT therefore is an alternative for university students with mild depressive symptoms for the policy makers to consider, especially when manpower resources are limited and penetration of internet-based programs is adequate. To transfer the internet-based CBT cost-effectiveness demonstrated in the present study to university students in Hong Kong, cultural adaptation of the internet-based CBT is essential to address differences (that may influence the effectiveness and acceptability) in communication styles, stigma, and social values in the context of locality [37]. The effectiveness of culturally adapted internet-based CBT for Hong Kong adults (18 - 70 years) with mild-to-moderate depressive symptoms has been recently demonstrated in a randomized clinical trial (n=402). The findings demonstrated a satisfactory recovery rate and supported that culturally and linguistically adapted internet-based CBT is an effective and feasible treatment for Hong Kong Chinese adults [38]. To further inform the decision-making process of resource allocation, future research to evaluate the culturally adapted internet-based CBT for university students with mild depressive symptoms together with feasibility study are highly warranted.

Conclusions

The guided internet-based low-intensity CBT was found to gain higher QALYs and reduce dropout rate at a lower cost, when compared to in-person CBT, for mild depressive symptoms in university students from the perspective of service providers in Hong Kong.

Abstract

Background: Although various apps have been developed to support health behaviors, they are mostly commercial, possibly limiting the number of users. The ME-BYO index was developed by Kanagawa Prefecture in 2019 to comprehensively and numerically measure and visualize an individual's current health status and future disease risk by quantifying data. The ME-BYO index is free of charge, so it can be made available to as many prefectural residents as possible for health promotion. Effective online strength training programs are being developed that, when combined with ME-BYO index measurements, will help with both exercise habits and health management.

Objective: In this study, we aimed to validate the fidelity, feasibility, and acceptability of self-measurement using the ME-BYO index during the implementation of an online strength training program.

Methods: Participants were 23 adults aged 40 years or older who did not regularly perform muscle strengthening exercises. The strength training program was performed twice a week for 8 weeks (16 sessions in total), and the ME-BYO index was explained to the participants so that they could self-measure the ME-BYO index with a smartphone on the day of the strength training program, before its implementation. The ME-BYO index during the study period was continuously collected from the app, and the ME-BYO index adherence rate was calculated. Questionnaires were used to assess the feasibility (difficulty of measurement and motivation to improve lifestyle) and acceptability (intention to maintain measurement and appropriate frequency of measurement) of implementing and continuing the ME-BYO index measurements. Changes in the ME-BYO index between the first and second halves of the program period, examination of items strongly related to changes in the ME-BYO index, and a comparison of physical fitness and health outcomes before and after the program period were conducted.

Results: The mean ME-BYO index adherence rate during the strength training program was 89.4% (SD 17%). Regarding acceptability, the participants were highly motivated to continue measuring the ME-BYO index (77%), and the appropriate frequency of measurement was once a week and twice a week (31% and 31%, respectively). Panel data analysis of the self-measured ME-BYO index showed no significant change in the ME-BYO index score; however, it increased to a higher score. Examination of the items that increased the overall score indicated that systolic blood pressure, mental resilience, and Mini-Cog scores were the relevant factors. The pre- and postprogram measurements showed no significant changes in items other than physical fitness.

Conclusions: The fidelity, feasibility, and acceptability of measuring the ME-BYO index during a regular online strength training program were high, suggesting that self-measurement of the ME-BYO index could be used to implement and maintain healthy behaviors. These findings suggest that the ME-BYO index can be recommended as a basic health app.

Introduction

Appropriate health behaviors are important for maintaining and improving health. In recent years, there have been remarkable developments in mobile health to support healthy behaviors, with various apps being developed [1]. Reviews on the effectiveness of these apps have examined healthy behaviors such as changes in physical activity [2,3], dietary management [4], smoking cessation [5], weight management [6], diabetes management [7], hypertension management [8-10], and medication adherence [11,12], as well as their combined effects with other interventions. However, most of these apps have been commercially developed. Users of smartphone health apps have high health literacy and financial affordability [13,14], and these factors may limit the available population. A review of apps for mental health among underserved young people found that, while acceptance was high among economically disadvantaged residents (with positive evaluations and high satisfaction), they did not intend to continue using the apps. This population was also reluctant to pay for the apps [15].

Furthermore, while commercially available apps have high download numbers and receive positive evaluations regarding ease of use and engagement, significant variations in quality have been reported. Many of these apps are not evidence-based, are inconsistent with public health guidelines, lack empirical evidence of effectiveness or validation of measurement tools, lack theoretical grounding, lack expert and user involvement, and fail to provide assurances around privacy, security, or health risks [16]. Therefore, it is valuable for local governments to develop apps that address these challenges and that all residents can use with confidence.

Kanagawa Prefecture, one of Japan's largest local governments, defines "ME-BYO" as a state of continuous change between health and disease, rather than a clear distinction between health and disease, and promotes efforts to improve presymptomatic conditions based on three pillars: diet, exercise, and social participation. In March 2020, the prefecture's health management ME-BYO index, which allows individuals to measure their state of ME-BYO, was released on the smartphone app "My ME-BYO record" [17]. The ME-BYO index is a simple and comprehensive index that can be calculated by entering and measuring 15 items across the areas of metabolic function, locomotor function, cognitive function, and mental resilience. It is expected to promote behavioral changes in individual health and the construction of new systems in society through the concrete quantification of health status [18].

It is unique in that it includes risk factors for dementia (BMI, blood pressure, and mental health) and the Mini-Cog for screening cognitive function. To date, a new longitudinal study based on the Kanagawa Prospective ME-BYO Cohort Study has been initiated to verify the validity and reliability of the measurement method [19,20] and incorporate a future prediction function. However, the real-world feasibility of the ME-BYO index has not yet been validated.

The ME-BYO index was developed for health promotion among residents. This app is provided free of charge to enable widespread use. Therefore, disseminating the app and verifying its feasibility are crucial for addressing health disparities.

Epidemiological studies on physical activity have recently focused on strength training, low-intensity physical activity, and sedentary behaviors. Among these, meta-analyses have shown that strength training reduces the risk of all-cause mortality and development of cardiovascular diseases, cancer, and diabetes [21]. The COVID-19 pandemic has led to the development of various online exercise programs. In particular, online strength training programs, which are convenient and can be completed relatively quickly, are as effective as in-person training and a promising approach for busy working populations [22]. Therefore, combining the measurement of the ME-BYO index with online strength training programs may contribute to motivation to practice exercise and health management.

Therefore, in this study, we aimed to examine the fidelity, feasibility, and acceptability of the ME-BYO index during the implementation of an online strength training program, which is a promising approach for exercise continuity in the working-age population.

Methods

Study Design and Participants

This was a prospective single-arm study. The participants were 23 adults aged 40 years or older (41 - 68 y) who did not regularly perform muscle strengthening exercises at least twice per week. Information on muscle strengthening exercise habits was collected through self-report.

Ethical Considerations

This study was approved by the Ethics Committee of the Nippon Sports Science University (023-H043) and by the Ethics Committee of Kanagawa Cancer Center (2023KEN-10). The purpose and content of the study were explained to the participants, and written informed consent was obtained before the study was conducted. Data were collected in a face-to-face setting, and all user data were deidentified before analysis.

Strength Training Programs

The strength training program was performed twice weekly for 8 weeks (16 sessions in total). Strength training consisted of six exercises (squats, rear raises, dips, lunges, single-leg Romanian deadlifts, and push-ups; Multimedia Appendix 1) and lasted approximately 60 minutes per session. The load was applied with body weight or Therabands, and the number of repetitions per set was 10 to 20, with 1 to 3 sets (low intensity) titrated during the training period. The rest period between sets was 2 minutes. A video call app (ZOOM) was used, and the instructor-to-subject ratio was set at 1 to 5 - 7. The strength training program was delivered by well-trained staff [22,23]. The staff members measured the following before and after the strength training program: the ME-BYO index, cognitive function, well-being, psychological distress, physical fitness, body composition, and physical activity.

XSL•FO
RenderX

Measurement Items

The ME-BYO Index

The ME-BYO index was measured by the staff before and after the implementation of the strength training program. During the study period, self-measured ME-BYO index was continuously obtained through the My ME-BYO record app, which was created by Kanagawa Prefecture. The ME-BYO index was measured after a thorough explanation was provided during the preprogram assessments. Instructions for self-measurement were distributed and explained. For this study, data were anonymized, and only information from the study participants was collected.

The ME-BYO index is scored based on a 15-item measure across the following four domains: metabolic function, locomotor function, cognitive function, and mental resilience [18,24]. The World Health Organization categorizes intrinsic capacity into five categories: physical mobility, vitality, psychosocial, sensory, and cognitive [25]. The ME-BYO index was designed using this approach and calculated by summing the weighted partial scores that assessed the status of the four domains. The overall score ranges from 0 to 100 points, with higher scores indicating better health. Various scientific indicators were collected using a survey to construct a scoring formula for domain-specific assessments. The following measurement indices were used to calculate the ME-BYO index: sex, age, BMI, and systolic blood pressure to evaluate metabolic function; the 5-question Geriatric Locomotive Function Scale questionnaire [26] and walking speed measured by a smartphone [19] to assess locomotor function; the 3-question version of the Mini-Cog [20,27,28] to evaluate cognitive function; and individual voice information to evaluate mental resilience. A mind monitoring system (MIMOSYS; PST Inc) was recently developed [29-31] and implemented to evaluate mental resilience using smartphone apps [18].

My ME-BYO record can be installed and used free of charge in the App Store and Google Play. My ME-BYO record and ME-BYO index Terms of Use, Privacy Policy, and Security Policy are available within the app and on the Kanagawa Prefectural Government website [32-34].

Fidelity, Feasibility, and Acceptability of the ME-BYO Index Measurement

This study was conducted based on Proctor et al.'s [35] implementation outcome framework (IOF). We examined the individual-level implementation outcomes outlined in the IOF: fidelity, feasibility, and acceptability.

The ME-BYO index self-measurement frequency and adherence rate were calculated as fidelity. The adherence rate was calculated individually as the percentage of the self-measurement to the participation sessions throughout the intervention period, and the average adherence rate was obtained.

In feasibility, they were evaluated using a questionnaire regarding the difficulty of measuring the ME-BYO index twice a week (quite difficult, somewhat difficult, not very difficult, or not at all difficult) and their motivation to improve their lifestyle through regular ME-BYO index measurements (not at all motivated, not very motivated, somewhat motivated, or quite motivated).

The acceptability of the ME-BYO index was evaluated using a questionnaire with the following two items: (1) intention to maintain regular ME-BYO index measurements after the end of the study (not at all, not very much, somewhat agree, or strongly agree); and (2) frequency of ME-BYO index measurement appropriate for the participant (once a year, once every few months, once a month, twice a month, once a week, or at least twice a week). The questionnaire on feasibility and acceptability is detailed in Multimedia Appendix 2.

Fidelity and Acceptability of Strength Training Programs

Fidelity was assessed regarding the time required for participation and the adherence rate in the strength training program. Acceptability was evaluated using the following questionnaire on technical difficulty and time allocation of the strength training program: For technical difficulty, participants were asked to choose from the following options: quite difficult, somewhat difficult, not very difficult, or not at all difficult. Time allocation was selected from the following options: not at all appropriate, not very appropriate, somewhat appropriate, and quite appropriate.

Cognitive Function

We used the Japanese version of the mild cognitive impairment (MCI) screen, a simple cognitive function scale developed by the Medical Care Corporation, Inc., in the United States, to detect MCI early [36]. The assessment was based on the Memory Performance Index (MPI) score. The MPI score is a unique index that objectively expresses the health status of the brain and is evaluated and calculated using the statistical analysis algorithm of the MCI screen. The higher the MPI score, the higher the patient's cognitive health status, expressed quantitatively as a number from 0 to 100 [37].

Well-Being and Psychological Distress

The World Health Organization-5 Well-Being Index was used to measure the subjective psychological well-being [38]. The respondents answered five statements regarding their feelings over the past 2 weeks. The total score ranged from 0 to 25, with higher scores indicating higher psychological well-being. Scores <13 indicate poor well-being and suggest depression according to the International Statistical Classification criteria [39]. To assess the quality of life, we multiplied the raw score and calculated the percentage ranging from 0 to 100 (low to high quality of life).

The Psychological Distress Scale (K6) score, a robust nonspecific psychological distress measurement tool [40,41], was calculated from six items using a 5-point Likert scale, with the total score ranging from 0 to 24, with higher scores indicating more severe distress. We used the Japanese version of the scale [41], translated and validated from the original scale developed in English [40].

Physical Fitness and Body Composition

Grip strength was assessed using a hand grip dynamometer (Takei Scientific Instruments). Participants were allowed two

XSL•FO
RenderX

attempts to attain the highest possible rating. They took a standing position and squeezed the dynamometer as hard as possible with one hand, and then repeated the test with the other hand.

A push-up test was performed to evaluate upper extremity muscle function. Participants were required to touch a 10 cm foam pad placed on the floor with their knees on top. The participants were then asked to alternately perform push-ups repeatedly for 30 s, and the number of times they could come to the start position was counted and recorded.

The 5-times chair-standing test required the participants to stand up from a chair without using arms and sit down as quickly as possible. The time required for participants to perform this action was measured 5 times using a stopwatch [42].

Squat and countermovement jumps were measured using a MULTI JUMP TESTER instrument (DKH Co., Ltd). All the participants were instructed to jump as high as possible and were not allowed to use their arms. The highest score of the two trials was accepted as the jump score (cm).

The sit-and-reach flexibility test is widely used as a general test of trunk flexibility and is performed using a digital measuring device (Takei Scientific Instruments). The participants were instructed to sit on the floor and stretch their torso and arms out in front of them with their knees straight. The participants were allowed 2 to 3 attempts to attain the highest possible rating.

Body composition was measured in terms of muscle thickness and body fat content. The muscle thickness (cm) of the triceps brachii (ie, 60% distal between the lateral epicondyle of the humerus and the acromial process of the scapula) was measured using B-mode ultrasound (FAMUBO-D; SEIKOSHA). Body fat (%) was measured using a body composition measuring device (Inbody270; InBody Japan Inc). Height (seca 213; seca Nihon) and weight (HD-665; TANITA corporation) were measured, and BMI (kg/m^2) was calculated. Systolic blood pressure and diastolic blood pressure (mmHg) were measured using a sphygmomanometer (HEM-7120; OMRON Healthcare Co. Ltd). Participants rested for at least 5 minutes in a seated position before the measurement was taken. They took two readings themselves. If there were no issues, the second reading was used.

Physical Activity

Physical activity was measured using a validated accelerometer (Active Style Pro HJA-750C; OMRON Healthcare) [43-45]. Participants were instructed to wear the accelerometer on their waist for 7 consecutive days from when they walked up to when they went to bed, except when bathing, swimming, or other water exposure. The time the accelerometer was worn was calculated by subtracting the time the accelerometer was not worn from 24 h per day. Those with at least 4 days of at least 10 hours of wear per day were included. The outcome measures were average moderate-to-vigorous physical activity time (minutes per day, ≥3.0 METs) and average sedentary time (minutes per day, ≤1.5 METs). A macro program (version 190829), developed and distributed by the Japan Physical Activity Research Platform [46], was used to process the accelerometer data.

Statistical Analysis

For the panel data analysis of the ME-BYO index self-measured, the means of the first 4 weeks of the program and the second 4 weeks of the program were compared for the overall score, metabolic function score, locomotor function score, cognitive function score, and mental resilience score using an appropriate *t* test. A multilevel analysis was also performed, with the ME-BYO index overall score as the dependent variable; BMI, systolic blood pressure, mental resilience score, Mini-Cog score, 5-question geriatric locomotive function scale, and walking speed as the independent variables; and sex and age as the adjusted variables. Paired *t* tests were used to compare the means of each item in the pre- and postprogram measurements. Statistical analyses were performed using SPSS version 27 software (IBM Corp). The significance level was set at 5%.

Results

Of the 23 participants, 19 participated in the premeasurement period. Therefore, the 19 participants for whom pre- and postassessments were available were included in the analysis. The baseline characteristics of the study participants are shown in Table 1. The mean age was 57.6 (SD 7.8) years.

The results of the fidelity, feasibility, and acceptability of the ME-BYO index measurement and strength training program are shown in Table 2. Regarding the number of self-measurements and the adherence rate of the ME-BYO index, 13 participants were included in the evaluation because 8 participants had not yet taken the measurement owing to inadequate smartphones or measurement environments. The mean number of measurements was 14.1 (SD 3.1), and the ME-BYO index adherence rate was 89.4% (17%). Regarding self-measurement of the ME-BYO index twice a week during the study period, a few participants had difficulty measuring it (n=5, 39%), and many participants were motivated to improve their lifestyle (n=8, 61%). The intention to maintain the ME-BYO index twice a week was high (n=10, 77%), and the most common appropriate frequency for measuring the ME-BYO index was once or twice a week (n=8, 62%). The adherence rate in the strength training program was 94% (8.5%). The technical difficulty was somewhat difficult (n=9, 47%) but not very difficult (n=7, 37%). Time allocation was appropriate (n=16, 84%).

When comparing the mean scores of the ME-BYO index self-measurement between the first and second 4 weeks, there was no significant difference, but there was a change to a higher value (Table 3).

A multilevel analysis using panel data in the self-measured ME-BYO index to examine the measures that increased the overall score revealed that systolic blood pressure, mental resilience, and the Mini-Cog score were significantly associated factors. An increase of 1 mmHg in systolic blood pressure tended to decrease the overall score by 0.15 points. A 1-point increase in mental resilience tended to increase the overall score by 0.10 points. A 1-point increase in Mini-Cog score tended to increase the overall score by 3.57 points (Table 4).

Significant improvements in physical fitness were observed in the postprogram measurements compared with the preprogram measurements, including push-ups, 5-time chair standing test, squat jump, and countermovement jump. No significant changes were observed in the other items (Table 5).

Table . Changes in the ME-BYO index self-measurement scores[a].

Item	First half of the program, mean (SD)	Second half of the program, mean (SD)	*P* value
Overall score (points)	91.6 (4.2)	92.9 (4.1)	.15
Metabolic function score (points)	90.2 (8.1)	90.2 (8.2)	.99
Locomotor function score (points)	97.3 (7.9)	97.2 (6.6)	.91
Cognitive function score (points)	96.5 (8.0)	98.7 (2.2)	.22
Mental resilience score (points)	70.3 (19.7)	78.2 (11.2)	.08

[a]Paired *t*-test: panel data on ME-BYO index self-measurement to compare mean scores for the first 4 weeks and second 4 weeks of the program.

Table . Measures associated with an increase in the overall score of the ME-BYO index[a].

	Estimated value	SE	*P* value	95% CI
BMI (kg/m^2)	−0.25	0.31	.43	−0.95 to 0.44
Systolic blood pressure (mmHg)	−0.15	0.02	<.001	−0.19 to −0.12
Mental resilience score (points)	0.10	0.01	<.001	0.08 to 0.12
Mini-Cog score (points)	3.57	0.71	<.001	2.15 to 5.00
Five-question geriatric locomotive function scale (points)	−1.54	1.18	.20	−3.91 to 0.83
Walking speed (m/s)	−0.01	0.07	.87	−0.16 to 0.14
Sex: women (reference: men)	−1.68	3.23	.62	−9.24 to 5.88
Age (years)	−0.04	0.21	.85	−0.54 to 0.46
Intercept	95.45	12.60	<.001	66.99 to 123.91

[a]Multilevel analysis: Using panel data in the self-measurement of the ME-BYO index, the overall score was the dependent variable; BMI, systolic blood pressure, mental resilience score, Mini-Cog score, 5-question geriatric locomotive function scale, and walking speed were the independent variables; and sex and age were the adjusted variables.

Discussion

Principal Findings

In this study, we evaluated the fidelity, feasibility, and acceptability of self-measuring the ME-BYO Index during an online strength training program. The mean number of measurements was 14.1 (SD 3.1), and the adherence rate was 89.4% (17%), suggesting high fidelity in an 8-week (16 sessions), twice-weekly training program. Although 5 (39%) participants had difficulty measuring the ME-BYO index, 8 (61%) participants were motivated to improve their lifestyle. The importance of daily physical condition and health management was described in the individual questionnaire (Multimedia Appendix 3), suggesting that these factors led to a high number of ME-BYO index measurements. A study on the fidelity of a smartphone nutrition app (MyNutriCart) for making smart and healthy choices when purchasing food in grocery stores found that the average use of the app was 75% for each purchase, with a 69% likelihood of use [47]. This was an 8-week intervention in which participants were instructed to use the app every time they went grocery shopping or at least once a week [48]. Reviews of self-monitoring mental health apps also report adherence rates of 85% to 100%, suggesting high engagement with these apps [49]. Despite differences in input items and duration, this study demonstrated fidelity similar to that of other studies.

Eight participants were unable to self-measure, not due to a lack of interest or motivation but primarily because their smartphones were incompatible. Furthermore, all their baseline characteristics were comparable (Multimedia Appendix 4). Therefore, it is unlikely that this resulted in a biased sample. However, it should be noted that the ME-BYO index measurement was requested on the day of program participation, which may have motivated participants to continue the measurement. Additionally, smartphone literacy may have influenced the results. Concerns remain, particularly among older adults, that limited familiarity with technology may affect outcomes. This highlights the need for further research.

High fidelity was also confirmed for the strength training program (94%), suggesting that the program may be an effective

XSL•FO
RenderX

gateway to exercise habits in the working population. Pre- and postprogram measurements revealed an increase in physical fitness. However, no changes were observed in the mental or psychological factors assessed besides the ME-BYO index. These results suggest that, although the evaluation of the ME-BYO index measures not linked to the program is problematic, combining the program with a regular and highly feasible program is effective for regular ME-BYO index measurements. The intention to continue measuring the ME-BYO index twice a week was high (n=10, 77%), and the appropriate frequency of the ME-BYO index measurement was once or twice a week (n=8, 62%), suggesting that continuous ME-BYO index measurement at short intervals could be used as an indicator of the effectiveness of regular exercise and other programs. A prior study using real-world data from the My ME-BYO Record app reported low engagement among repeat users [50]. In contrast, the present study observed high adherence rates when the app was integrated within a structured online strength training program. These findings suggest that combining the app with guided health interventions may be an effective strategy to enhance user engagement and address the low adherence typically observed in free-living settings compared to structured programs.

When comparing the mean ME-BYO index self-measured scores between the first and second 4 weeks, there was a general change to higher scores, although there were no significant differences. Notably, the mental resilience score showed an upward trend, while the scores of the other indicators remained high. The multilevel analysis showed that the measures that increased overall scores were systolic blood pressure, mental resilience, and Mini-Cog scores. The ME-BYO index app has an immediate feedback and advice function for measurement results, and the ability to self-monitor is thought to be a factor that increases its fidelity, feasibility, and acceptability. Self-monitoring is one of the most commonly used behavioral change techniques in health apps [51]. A meta-analysis by Michie et al [52] on behavior change techniques (BCTs) that contributed to improved physical activity and dietary habits found that the most effective BCT among 122 intervention studies was immediate self-monitoring of behavior, indicating the importance of implementing BCTs. This study demonstrated the importance of implementing BCTs.

In a study evaluating the quality of physical activity apps, only 1 out of 65 randomly selected apps that met the criteria had a noncommercial affiliation (government agency). Privacy and security assessments revealed that 29.2% of the apps had no privacy policy. Most apps collect personally identifiable information and share user data with third parties, and more than half do not specify how to ensure data security [53]. Furthermore, only 12 of the 65 apps had a peer-reviewed study associated with them, and only one app was evaluated for efficacy in a trial. This suggests that the quality of commercially developed apps is inadequate. Importantly, this study confirmed the feasibility of a reliable app provided free of charge by the local government, which can be recommended for use as a basic health app.

Limitations

This study had several limitations. First, it used a before-and-after comparative design, and the influence of psychological bias (the Hawthorne effect) and selection bias cannot be excluded. Second, the sample size was small, which may have resulted in insufficient statistical power. Future studies involving control groups are required. Third, although the evaluation was based on the IOF, the feasibility and acceptability indicators were not validated scales, which may have introduced interpretation bias. Fourth, the study was conducted over a short period. The ME-BYO index includes indices (cognitive and locomotor functions) that do not change easily over a short period. Therefore, it may be difficult to detect the effects of short-term measurements at short intervals, and long-term validation needs to be addressed. The impact on long-term fidelity should also be considered.

Conclusion

We investigated the fidelity, feasibility, and acceptability of self-measurement of the ME-BYO index during the implementation of an online strength training program in adults with no exercise habits. The fidelity, feasibility, and acceptability of measuring the ME-BYO index during implementation were high, suggesting that self-measurement of the ME-BYO index could be used as a tool for implementing and maintaining healthy behaviors. The fact that these findings were confirmed in an app provided free of charge by the public sector is significant and suggests that it can be recommended as a basic health app.

Acknowledgments

The authors thank all participants in this study. The authors thank students from the Graduate School of Physical Education, Health and Sport Studies, Nippon Sport Science University for their assistance with data collection and program implementation. We thank Editage [54] for English language editing.

Funding

This study was supported by the ME-BYO index project of the Kanagawa Prefecture and grants-in-aid for the Japan Society for the Promotion of Science KAKENHI grant (16H06277 [CoBiA]) from the Japanese Ministry of Education, Culture, Sports, Science, and Technology. This study was also supported by the Science and Technology Innovation co-creation center promotion project of the Kanagawa Institute of Industrial Science and Technology.

Abstract

Background: Dementia increases the risk of individuals getting lost due to cognitive decline, impacting daily functioning and heightening caregiver worry. Traditional search methods are often time-consuming and stressful, whereas GPS-based technologies face limitations such as battery dependency. A crowdsourcing Internet of Things (IoT) technology using energy-efficient Bluetooth Low Energy (BLE) offers a potential solution to locate missing individuals with dementia more effectively by harnessing the power of the crowd and fostering a caring and inclusive community.

Objective: This study aimed to evaluate the effectiveness of a BLE-based privacy-preserving crowdsourcing IoT system consisting of a BLE tag and an Android and iOS app in improving lost-related behavior and psychological well-being by facilitating searches, after-care arrangements, and reducing caregiver worry, as well as to assess its usability among caregivers of individuals with dementia in Hong Kong.

Methods: A single-arm, prospective observational study was conducted from November 2020 to October 2023. Caregivers (N=1034) of individuals with dementia used a staff-assisted crowdsourcing IoT technology comprising a BLE tag, mobile app sensor, and location cloud server. Outcomes included search strategies, post–getting lost care arrangements, caregiver worry and distress (10-point scale), and usability (modified Quebec User Evaluation of Satisfaction with Assistive Technology 2.0 survey). Data were collected at 6- and 12-month follow-ups and analyzed using generalized estimating equations and linear mixed models.

Results: Of the 1034 participants, 143 (13.82%) reported lost episodes, with 51 (35.7%) using BLE tags for searches. Worry about future lost episodes decreased significantly over time (P=.008), especially among BLE tag users (P=.04). There was an association between BLE tag use and adoption of proactive search strategies (eg, going out to search: adjusted odds ratio 2.78, 95% CI 1.33-5.82; P=.007) and preventative measures (eg, IoT devices or CCTV: adjusted odds ratio 2.92, 95% CI 1.61-5.29; P<.001). Usability satisfaction was high for design and data security, whereas approximately half of the participants (309/707, 43.7%) were satisfied with accuracy.

Conclusions: The BLE crowdsourcing system may reduce caregiver worry and encourage proactive search behaviors, although accuracy depends on broader community adoption. Integration into dementia care plans could enhance safety and autonomy. Further research with a randomized controlled trial design is needed to confirm these findings.

dementia; getting lost; IoT; Internet of Things; crowdsourcing IoT technology; caregiving worry; caregiving distress

Introduction

Dementia is a neurodegenerative syndrome characterized by progressive impairments in cognitive domains, including memory, judgment, and orientation, significantly impacting daily functioning [1]. Individuals with dementia are at an increased risk of becoming lost due to compromised perceptual-motor and visuospatial abilities [2-5], as well as difficulties in acquiring and retaining new information [6]. Cognitive deterioration, particularly in orientation and executive function [7,8], along with psychological factors, such as depression, agitation, and stress-related coping mechanisms, is

XSL•FO
RenderX

a key contributor to this risk [9-11]. The consequences of getting lost can be severe, leading to psychological distress, heightened fear [12,13], and increased risk of serious injury or mortality, especially if the individual remains missing for an extended period [14,15]. Moreover, such incidents often result in premature admission to nursing homes [5], negatively affecting the overall quality of life for individuals with dementia.

The impact of these episodes extends beyond the individuals themselves, as caregivers frequently experience heightened stress, worry, exhaustion, and fatigue due to prolonged surveillance [13,16]. The fear of getting lost often prompts caregivers to adopt restrictive measures, such as limiting outdoor activities, which can compromise the autonomy and quality of life of individuals with dementia [17,18]. Traditional methods for locating lost individuals, such as neighborhood searches and contacting authorities, are time-consuming and often yield limited success. Recent technological advancements, including GPS tracking using mobile phones or dedicated wearable devices such as watches, offer more efficient solutions but are not without challenges, such as the need for regular battery charging for the wearable devices, which individuals with dementia who live alone may forget.

In response to these challenges, a search technology was developed that harnesses the power of the crowd and uses more energy-efficient Bluetooth devices. This technology aims to provide a more reliable and community-driven solution for locating individuals with dementia who become lost. This study sought to evaluate the effectiveness of this technology in facilitating searches and reducing caregiver worry during dementia-related lost episodes. Additionally, it aimed to explore the potential benefits and limitations of this technology in real-world scenarios, contributing to the development of more effective support systems for individuals with dementia and their caregivers.

Methods

The Crowdsourcing Internet of Things (IoT) Technology

This study used a crowdsourcing IoT technology developed by the co-authors at the Hong Kong University of Science and Technology [19]. The primary objective of this system was to locate individuals using a software-based crowdsourcing. The technology's development began in 2019, with deployment starting in 2020, predating the launch of Apple's AirTag [20]. The technology comprises 3 main components: a Bluetooth Low Energy (BLE) tag, a mobile app for both Android and iOS platforms, and a location cloud server. The BLE tag, designed and customized as a walking stick holder, keychain, or smart card, emits a signal detectable by the sensor within a range of 30 to 100 meters (Figure 1). While AirTag's "Find My" network relies on the iOS ecosystem [21], our technology engages both Android and iOS communities, broadening the search network and supporting our aim of the project to foster a dementia-friendly community through the active participation of caregivers and volunteers (referred to as "Dementia Angels") in the search.

XSL•FO
RenderX

Figure 1. The Bluetooth Low Energy tag in different designs. (A) Overview, (B) walking stick holder design, (C) keychain design, and (D) smart card design.

The Dementia Angels download the sensor app, which uses GPS for positioning. The graphical user interface of the app is shown in Figures 2–3. The app consists of 2 primary interfaces: "report lost" interface for caregivers (Figure 2) and the "missing person report" interface for Dementia Angels (Figure 3). The "report lost" interface provides the location where and when the BLE tag was last tracked. When the caregiver reports a lost episode and activates a search, they input the lost episode–related information to aid Dementia Angels' searching. The "missing person report" interface displays recent missing reports and successful recoveries. The app incorporates large, touch-friendly buttons and icons and uses different color schemes to distinguish the 2 interfaces. The app is in Chinese, and Figures 2–3 show a translated version for illustration purposes.

XSL•FO
RenderX

Figure 2. "Report lost" interface for caregivers.

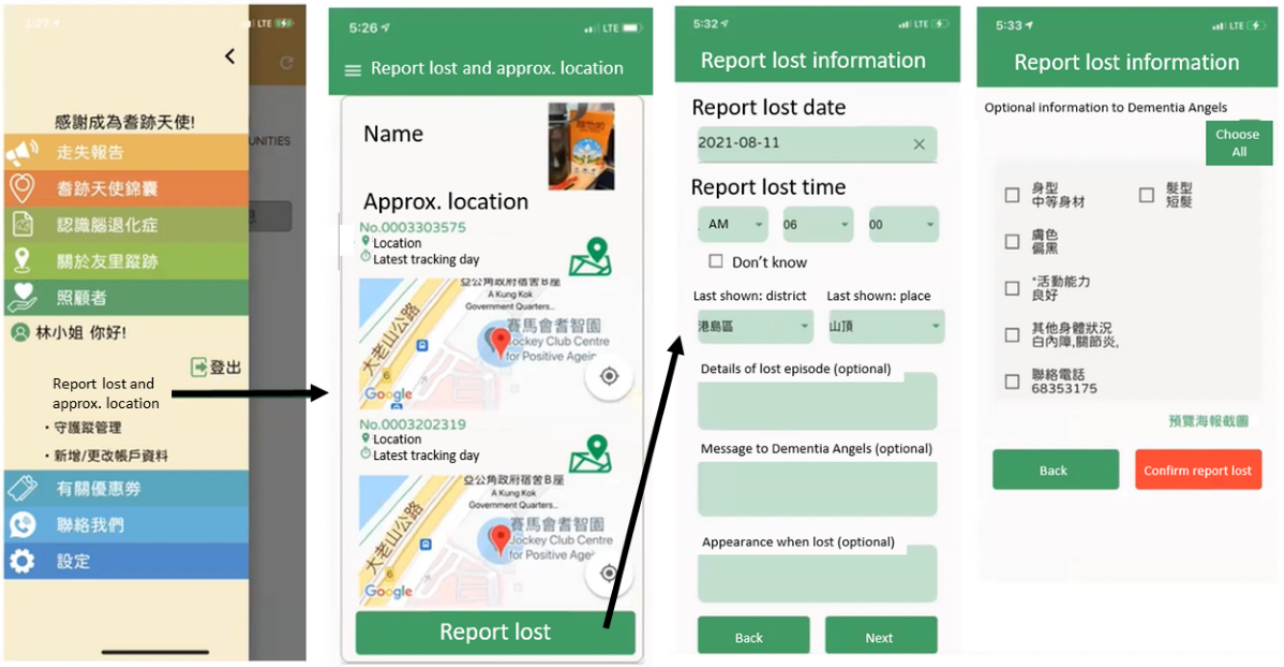

Figure 4 illustrates the mechanism of the technology. When a care recipient goes missing, the caregiver can activate a search notification. This prompts caregivers and Dementia Angels to enable Bluetooth and GPS on their devices to detect the BLE tag signal. Upon detecting the signal, the mobile devices anonymously relay their location to a location cloud server, where a localization engine determines the location of the BLE tag. This information is then communicated to caregivers to aid in the search. The accuracy of the positioning, therefore, depends on the number of scans from Dementia Angels.

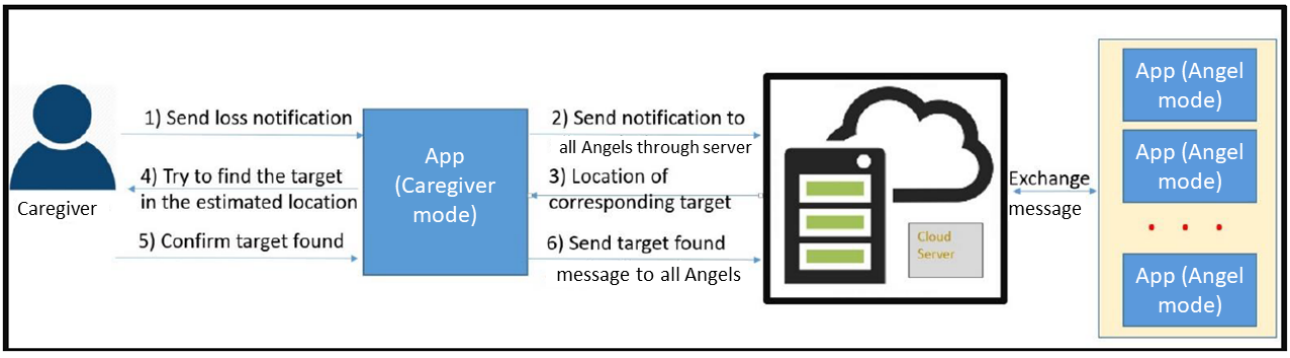

This technology adopts the privacy by design approach. The key advantages of the technology include real-time and on-demand positioning capabilities, which protect the care recipients' rights when the positioning is only performed when they are in a safety threat. The BLE tag is water-resistant, with a battery life of up to 1 year and low battery notification on the caregiver interface to ensure timely replacement by caregivers, in contrast to GPS-based trackers commonly used during the technology's development, which typically require more frequent recharging due to higher power consumption. Furthermore, the search function is only activated when necessary, minimizing inconvenience for caregivers and Dementia Angels. All location data are anonymized to protect the privacy of the searchers.

Study Design and Hypotheses

This study adopted a single-arm, prospective, observational study design. The research hypotheses were that participants would (1) adopt more proactive search strategies and post–getting lost care arrangements when using the IoT technology, (2) have less lost episode–related distress and worry when using the IoT technology, and (3) be satisfied with the usability of the IoT technology.

Participants

The participants in this study were caregivers of individuals with dementia. The inclusion criteria were (1) citizens residing in Hong Kong, (2) aged ≥18 years, (3) providing care to individuals diagnosed with dementia, (4) smartphone users, and (5) willing to participate in the study by giving informed consent. The exclusion criteria were (1) inability to participate in research due to visual, hearing, physical, or psychological issues; and (2) refusal to provide informed consent. The participants were recruited through self-enrollment in the program, networking, and referral from other organizations; as this was a usability test, we adopted a maximum recruitment rationale and included all participants who were willing to contribute to this study.

Outcomes

The primary outcome of the study was the difference in search strategies and post–getting lost care arrangements with the use of the IoT technology, measured by a survey containing a set of predesigned strategies and arrangements with binary "yes or no" responses and an open-ended "others" option.

The secondary outcomes were (1) caregiving worry toward future lost episodes after a getting lost episode, measured by the question "How worried are you about future lost episodes?," with a 10-point rating scale in which a higher score indicated higher worry; (2) caregiving distress toward the getting lost episode, measured by the question "How distressed are you about this getting lost episode?," with a 10-point rating scale in which a higher score indicated higher distress; (3) factors associated with getting lost in the dementia context by analysis based on the demographic data; and (4) usability of the IoT technology, measured by a survey modified from the Quebec User Evaluation of Satisfaction with Assistive Technology 2.0 [22]. The original scale has 12 items, including dimensions, weight, adjustments, safety, durability, simplicity of use, comfort, effectiveness of service, delivery, repairs and servicing, professional services, and follow-up. A 5-point Likert scale, ranging from "very satisfied" to "not satisfied at all," was used. The survey used in this study was modified to suit the technology trialed in this study, and the items evaluated included size, weight, willingness of the care recipient to carry the BLE tag during and after the trial, durability, design, ease of app operation, accuracy of the technology, and data security. In addition, the number of caregivers who installed the sensor app for use and whether the paid helpers of the care recipients installed the sensor app were recorded to evaluate the caregiver engagement with the technology.

To complement the structured survey-based outcomes, real-life data on the usage of the IoT technology were collected during the study period. These data, primarily consisting of scan counts by Dementia Angels, served as an indicator of the technology's deployment in a naturalistic setting.

Study Procedures

The social worker, project staff (interveners), or researchers of 2 nongovernmental organizations explained the study details to potential participants and obtained their consent for research participation. The participants were then distributed 1 to 2 BLE tags and a note about how to install the sensor mobile app and how to pair the BLE tag with their sensor accounts. They then tested the BLE tag in daily lives, whereas the interveners provided technical support, such as installation, pairing, and use, as well as support during lost episodes if needed by the caregivers. The participants were notified by the mobile app at 6-month and 12-month time points from baseline to self-administer a survey to provide information about use and getting the lost episodes, if any. The participants who did not respond were contacted by the researchers 3 times at different time slots on different days before they were regarded as "did not complete posttest." The data collected from the latest interview were included in this study.

Statistical Analysis

The baseline characteristics of participants were presented using descriptive statistics, whereas between-group differences were analyzed using the chi-square test. The outcome of factors associated with getting lost was analyzed by generalized estimating equations with a binary logistic model and time as a within-subject effect; demographic variables were the predictors. The outcomes of search strategies and post–getting lost care arrangement were analyzed by generalized estimating equation with a binary logistic model and time as within-subject effect, with BLE tag use as the predictor. Paired comparison of changes in these 2 outcomes was conducted using the 2-sided McNemar test. The outcome for caregiver worry and caregiver distress was analyzed using a linear mixed model, with time effect, group effect, and group×time interaction effect using first-order autoregressive covariance structures because it had the smallest Akaike Information Criterion. All analyses were adjusted for caregiver age, caregiver sex, care recipient age, and care recipient sex. The usability outcomes were presented descriptively, with "very satisfied" and "satisfied" grouped as the "satisfaction." Missing data were left missing. All statistical analyses were performed using the statistical package SPSS version 26 (IBM Corp). Significance was set at P of .05.

Ethical Considerations

This study was approved by the Survey and Behavioral Research Ethics Committee of the Chinese University of Hong Kong (reference 175 - 19) [23]. The study was conducted according to the Declaration of Helsinki—ethical principles for medical research involving human participants. Informed consent for participation in this study was obtained from the participants, covering the use of demographic data and their reports of lost episode–related experiences. In addition, both participants and their care recipients provided written program-level informed consent before program participation. The program consent form introduced the program objectives, explained the use of

XSL•FO
RenderX

the tracking device, and specified that data collected through the program would be used for evaluation purposes. All participants and their care recipients were informed of the program details verbally and in writing before signing the program consent. Participants did not receive any financial or nonfinancial compensation for participating in this study, and there was no cost to the participants for any study procedure. The confidentiality of personal data was maintained in accordance with the Personal Data (Privacy) Ordinance of Hong Kong. Data security was ensured through encryption protocols and secure storage practices, and care recipients' data were contributed in deidentified form through the program's tracking record.

Results

Overview

Data were collected from November 2020 to October 2023. As shown in Figure 5, 1252 caregivers joined the trial for 6 to 12 months, 1034 (82.58%) of them completed the 6- or 12-month posttest and were included in this study. Among the 1034 participants, 143 (13.82%) reported a lost episode of care recipients during the trial, and 51 of the 143 (35.7%) participants used a BLE tag to help with the search during the lost episode.

Figure 5. Participant flowchart. BLE: Bluetooth Low Energy.

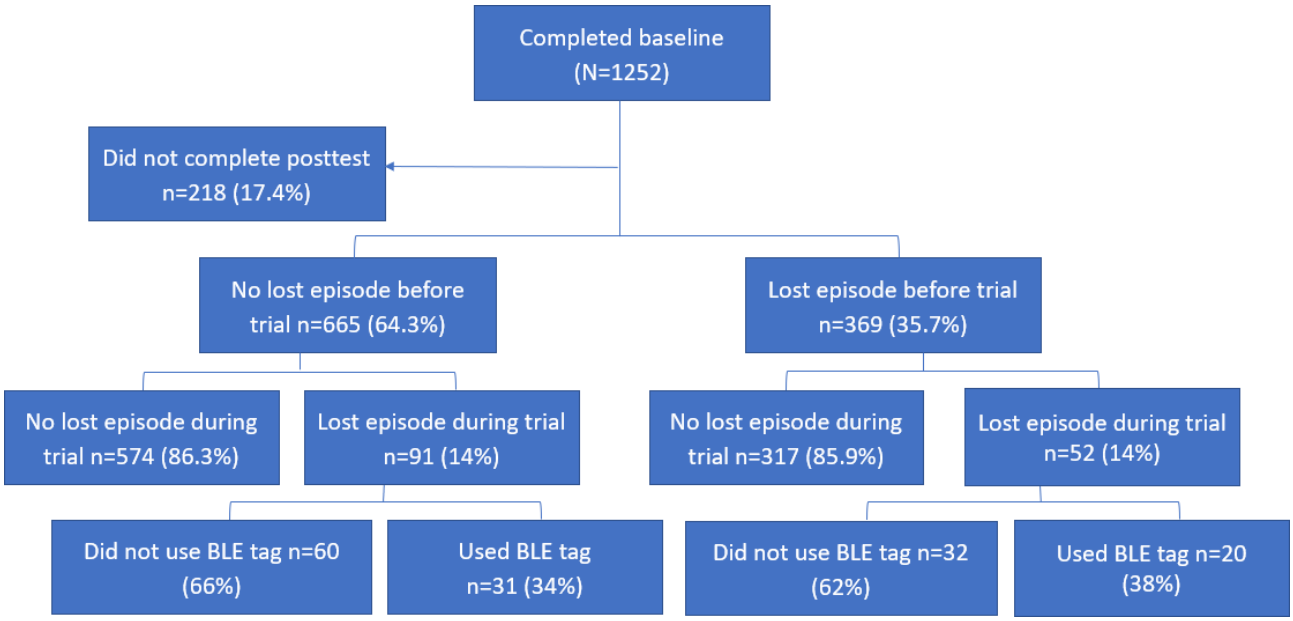

Table 1 presents the baseline participant characteristics. Approximately 20% (189/1034) of the caregiver participants were aged ≥65 years, and a quarter of the participants (256/1034, 24.75%) were male participants. They were mainly the children of the care recipients with dementia, and half of them (512/1034, 49.51%) lived with the care recipients. Of the 1034 participants, 59.86% (n=619) of care recipients were aged ≥80 years, and nearly half of them (n=480, 46.42%) had moderate or late-stage dementia, while 370 (35.78%) of them had experienced lost episodes before the trial. There was no significant difference in baseline characteristics between those who experienced lost episodes during the trial versus those who did not, except baseline worry about future lost episodes (mean 8.7, SD 1.6 vs mean 8.0, SD 2.1; *P*=.03).

Factors Associated With Getting Lost

After adjusting for covariates, care recipients in moderate or late-stage dementia were more likely to get lost (adjusted odds ratio [AOR] 1.84, 95% CI 1.49-2.27; *P*<.001). Care recipients who lived alone were less likely to get lost before adjustment (Table 2).

Intervention Effects on Search Strategies and Post–Getting Lost Care Arrangement

A total of 143 caregivers had experienced episodes of lost care recipients during the trial. Among them, 31 (21.7%) reported that the getting lost episodes happened in the morning (6 AM to 12 PM), 80 (55.9%) in the daytime (12 PM to 6 PM), and 32 (22.4%) in the nighttime (6 PM to 6 AM). Of 143 caregivers, 52 (36.4%) reported that the getting lost episode happened on the street; 51 (35.7%) at home; and 21 (14.7%) at shopping malls, markets, or retail shops.

Of 143 caregiver participants, 51 (35.7%) used the BLE tag to aid searching. There was no significant baseline difference between the BLE tag users and nonusers. Of 51 lost care recipients using the BLE tag, 17 (33%) were found within 1 hour, whereas 36 (39%) of 92 lost care recipients without using BLE tag were found within 1 hour (*P*=.49). Of 51 BLE tag user cases, 49 (96%) and 90 (98%) of 92 nonuser cases were found within 24 hours (*P*=.62).

Table 3 presents the comparison of the search strategies and post–getting lost care arrangement between BLE tag users and nonusers. The results revealed that BLE tag users had higher adjusted odds of going out to search for lost care recipients (AOR 2.78, 95% CI 1.33-5.82; *P*=.007), contacting police (AOR 2.59, 95% CI 1.26-5.35; *P*=.01), and using media or social media to aid search (AOR 22.45, 95% CI 2.62-192.38; *P*=.005); paired comparisons on search strategies pretrial and during trial (Multimedia Appendix 1) showed an insignificant, directional increase among BLE users for using these strategies, whereas nonusers had an insignificant, directional decrease in using these measures except for an insignificant increase in police calls.

After the lost episode, BLE tag users had higher odds of using an IoT device or installing CCTV to prevent future lost episodes (AOR 2.92, 95% CI 1.61-5.29; *P*<.001); paired comparison (Multimedia Appendix 1) showed an increase among BLE tag users and a decrease among nonusers in using this measure from pretrial to posttrial, but neither change reached statistical significance.

Intervention Effects on Caregiver's Worry and Anxiety

A total of 52 caregivers had experienced episodes of lost care recipient both before (baseline) and during the trial (posttest). BLE tag users had significantly higher worry about future lost episodes (*P*=.04) and distress toward recent lost episodes (*P*<.001) than nonusers, regardless of time. Analysis of baseline and posttest scores revealed that worry toward future lost episodes decreased significantly over time, regardless of groups (*P*=.01). There was no group×time interaction effect on the 2 outcomes, although BLE tag users reported a significant reduction in worry about future lost episodes (*P*=.04); in contrast, the decrease in worry in nonusers was not statistically significant. No significant result was observed in the reduction in distress (Table 4).

Usability Outcomes

A total of 1034 participants who completed the posttest were included for usability analysis. More than 80% of the care recipients were observed to be willing to carry the BLE tags during (780/952, 81.9%) and after the trial (521/631, 82.6%). More than 70% (691/954) of participants trusted the data security, but less than half of the participants (309/707) were satisfied with the accuracy of the technology (Table 5).

XSL•FO
RenderX

Table . Usability outcomes (N=1034).

Usability outcomes	Valid [a], n (%)	Satisfaction[a], n (%)
Satisfaction of care recipients toward the size of BLE[b] tag	957 (92.55)	652 (68.1)
Satisfaction of care recipients toward the weight of BLE tag	956 (92.45)	668 (69.9)
Care recipients were willing to carry BLE tag during the trial	952 (92.06)	780 (81.9)
Care recipients will be willing to carry BLE tag after the trial	631 (61.02)	521 (82.6)
Satisfaction of participants toward the durability of BLE tag	956 (92.45)	763 (79.8)
Satisfaction of participants toward the design of BLE tag (convenient for care recipients to carry)	954 (92.26)	814 (85.3)
Satisfaction of participants toward the easiness of app operation	951 (91.97)	671 (70.6)
Satisfaction of participants toward the accuracy of the technology	707 (68.37)	309 (43.7)
Satisfaction of participants toward the data security	954 (92.26)	691 (72.4)
Paid helpers install the app to use the technology during the trial	268 (25.91)	39 (14.6)
Number of caregivers who installed the app to use the technology during the trial	805 (77.9)	1.71 (1.13)[c]

[a]Missing and "not applicable" are excluded from the analysis; therefore, the percentage is based on valid responses.

[b]BLE: Bluetooth Low Energy.

[c]This data point is a mean (SD) value.

Real-Life Use

The program delivered 4836 BLE tags to 3259 individuals with dementia (including those who did not consent to participate in the study), averaging 1.5 BLE tags per person. There were 47,012 Dementia Angels who downloaded our app to detect signals from the BLE tags (20,269 iOS, 43.1%; and 26,743 Android, 56.9%). Additionally, more than 900 Dementia Angel sensors (physical boxes and mobile app) were installed across shopping malls, public transport hubs, and retail shops, reflecting significant community engagement.

Among the 1252 study participants, caregivers initiated 111 lost episodes, whereas 51 (45.9%) self-reported using the BLE tag during searches for missing care recipients. This discrepancy might be attributed to factors such as multiple searches by some caregivers and variation in reporting. Despite these differences, the real-life data provide valuable insights into use patterns, which are presented in this section.

Table 6 presents the characteristics of the 111 lost episodes initiated by caregiver participants in the mobile app. The majority of caregivers who initiated searches were women aged <65 years, predominantly children of the care recipients. Approximately half of the care recipients (62/111, 56%) were aged ≥80 years. More than 60% (69/111) of them were in the moderate or late stage of dementia, and more than 70% (82/111) maintained good mobility. On average, each search involved 18.59 (SD 52.56) scans by the Dementia Angels.

Discussion

Principal Findings

This observational study indicates that crowdsourcing technology has mixed effects on caregivers of individuals with dementia at risk of getting lost. The technology was associated with a modest reduction in caregiver worry, a higher adjusted odds of proactive search efforts, and a higher adjusted odds of adoption of an IoT device or CCTV as a preventative strategy; however, paired comparison among BLE tag users showed only directional but nonsignificant increase in use of these measures. In addition, approximately 50% of real-world missing cases reported to have used the BLE tag to aid search, and the technology did not demonstrably reduce the time required to locate missing individuals. In terms of risk factor analysis, the progression of dementia emerged as a significant risk factor for getting lost.

Risk Factor for Getting Lost

Our findings align with existing research, revealing that approximately 35% of community-dwelling individuals with dementia have experienced getting lost [24,25]. The finding that individuals in the moderate or late stage of dementia are at higher risk of getting lost in the community, compared with individuals in the mild stage of dementia, is consistent with other studies [12,26,27]. This increased risk is likely due to the progressive impairment of insight [28] and the exacerbation of behavioral and psychological symptoms, such as agitation, apathy, and irritability, commonly observed in major types of dementia [29,30]. These symptoms are known as risk factors for wandering [31], emphasizing the need for tailored support and preventative strategies for caregivers throughout their caregiving journey.

Intervention Effects on Behavioral and Psychological Changes

The crowdsourcing technology trialed in this study was associated with a reduction in caregiver worry and higher adjusted odds of promoting proactive engagement in search and prevention. Consistent with previous systematic reviews, our study suggests that IoT technology provides a sense of reassurance, mitigating caregiver anxiety by offering a means to locate care recipients who become lost [32].

The observed group effect, wherein BLE tag users exhibited higher levels of worry and distress related to getting lost, underscores their propensity to use the technology during such episodes and highlights the need for targeted support for these caregivers. The subsequent decline in worry and distress over time, particularly the significant time effect in the worry outcome, regardless of BLE tag use, may be attributed to the availability of study interveners who provided practical, solution-focused support during missing episodes. This underscores the potential benefits of a facilitator-aided approach in managing getting lost events.

Notably, while worry significantly decreased over time for BLE tag users, the reduction in distress was not significant. This disparity may reflect the distinct nature of these constructs: distress being an immediate affective response, while worry is a more cognitive construct linked to problem-solving and control [33]. The technology may not immediately alleviate distress, but it empowers caregivers to access resources, thereby reducing worry. This is supported by the finding that BLE tag users had a higher adjusted odds of adopting proactive search measures, such as going out to search, calling police, or using media or social media, potentially enhancing their sense of control over the situation and reducing anticipatory worry. Paired comparison among BLE tag users also showed a directional increase in using these measures, but the increase did not reach statistical

XSL•FO
RenderX

significance, possibly because of the small subsample size. The higher adjusted odds of seeking help from media or social media among BLE tag users may be because they are more likely to normalize tracking technology through exchange with other dementia caregivers on these platforms [34]. Social media is also a primary and rapid channel used by police to mobilize the public during missing-person incidents [35]; therefore, it naturally complements BLE-enabled search routines. However, this association should be interpreted cautiously because the low event count (<10) may result in imprecise and unstable odds ratio, suggested by the wide CI.

Moreover, BLE tag users had a higher adjusted odds of adopting person-centered preventative strategies over time. Caregivers often prioritize safety over liberty [36,37], sometimes resorting to restrictive measures, such as forbidding the care recipients to go outdoors [13], that negatively impact the quality of life of individuals with dementia. The technology developed in this trial aims to address this by providing a positioning solution that is acceptable to individuals with dementia, thereby encouraging caregivers to shift toward less restrictive strategies, such as using CCTV or IoT devices rather than preventing outdoor activities altogether. Paired comparison showed an insignificant, directional increase in the use of IoT device or CCTV among BLE tag users. However, the proportion of BLE tag users who continued to use the prevention of outdoor activities as a preventive measure remained unchanged, which may reflect the higher worry and distress observed in this group. While the results of paired comparison should be interpreted cautiously because of small subsample size, these results suggest that technology adoption alone may be insufficient to reduce restrictive practices, and additional caregiver support may be needed to fully promote greater autonomy and quality of life for people living with dementia. In terms of privacy concerns, the crowdsourcing technology balances safety concerns with privacy by activating positioning only during a missing episode, initiated by the caregiver. This design respects the autonomy of individuals with dementia while providing a safety net [38,39].

The majority of both BLE tag users and nonusers located their missing care recipients within 24 hours, with 30% to 40% of missing care recipients found within 1 hour. However, there was an insignificantly higher portion of missing care recipients who did not use the BLE tag that were found within 1 hour. This may be due to the effectiveness of overall search strategies and the study being conducted in a densely populated area, which inherently shortens the time of searching. The significant difference in time taken to find the missing care recipients may be related to the underlying risk profiles of those using or not using the BLE tag, as suggested by the higher caregiver worry observed in the BLE tag group.

Usability and Acceptance

Findings on usability and acceptance indicated a high willingness among individuals with dementia to carry the BLE tag and a high level of caregiver trust in data security. The design of the BLE tag as a keychain, pass, or attachment to mobility aids likely contributed to its acceptance. This aligns with literature suggesting that small, unobtrusive designs enhance user acceptance [39,40]. Our BLE tag design adheres to this principle, ensuring that individuals with dementia only need to carry the device naturally, with caregivers initiating the search if a missing episode occurs. Additionally, the reassurance provided by the technology may alleviate distress associated with outdoor activities. A systematic review revealed that individuals with dementia feel distressed when confined indoors but also fear getting lost [41], leading them to restrict their outdoor activities [42,43]. Technology offering reassurance can reduce this fear and distress, encouraging more frequent and extensive outdoor activities [37,44], thus promoting autonomy, a key element of quality of life. Indeed, some individuals with dementia expressed a discrepancy between their perception of their outdoor capabilities and the restrictive measures imposed by caregivers due to safety concerns [45]. IoT technology can mitigate this potential conflict by providing reassurance to both caregivers and care recipients.

However, caregivers expressed lower satisfaction with positioning accuracy, a key determinant of use satisfaction and adherence [46]. This limitation arises from the technology's reliance on wide coverage of sensors to detect the BLE tag and relay location information. Greater sensor coverage would result in more accurate positioning. This project aimed to promote dementia-friendliness and invited citizens to install the mobile app, turning them into mobile sensors. Despite more than 47,000 downloads, coverage was insufficient, and technology usage was mainly by caregivers themselves during lost episodes. Given that individuals with dementia who get lost in the community are often found by people other than caregivers [15,24], our findings suggest the vital importance of public education on dementia-friendliness to build wider sensor coverage and increase the accuracy of this technology.

A key postprogram initiative to enhance coverage and improve positioning accuracy involved collaborating with corporate partners to deploy sensors across public spaces frequently visited by people with cognitive impairment, such as shopping malls, transport hubs, and retail shops [47]. Beyond installing sensors to support search efforts, we also implemented tailored training programs for staff in the transport, banking, and property sectors. These trainings aim to improve their ability to respond to missing-person incidents, fostering a more dementia-friendly community.

Real-Life Use

The real-life data revealed that approximately 50% of lost episodes used the technology to aid the search, and these searches were predominantly conducted by caregivers aged <65 years, mostly women and often children of the care recipients, suggesting that this crowdsourcing technology is concentrated among younger, tech-savvy family members with direct caregiving responsibilities. The predominance of female caregivers and adult children further suggests that this demographic, often balancing multiple responsibilities, may derive particular benefit from such technology.

The care recipients are typically older adults who are often in the moderate or late stage of dementia but maintain good mobility. These traits highlight a target group prone to wandering and physically capable of straying significant

XSL•FO
RenderX

distances, amplifying the need for an effective positioning solution. Beyond this cohort, the system's reliance on a battery-saving tag, a mobile sensor interface, and a community endeavor for searching suggests its potential for scalability across broader dementia care apps, such as in residential facilities or community settings where the risk of getting lost persists.

Clinical Implications

The findings of this study underscore the importance of implementing IoT technology as part of comprehensive dementia-friendliness plans for individuals with dementia who are at risk of getting lost. Health care providers should consider recommending such technology as part of a care plan for community-dwelling individuals with dementia. It is crucial to educate and encourage caregivers about the potential benefits and limitations of positioning technology, such as the BLE tag, so that they can effectively use these tools to aid in the search for lost care recipients, potentially reducing the duration of lost episodes. The real-life data show that caregivers aged >65 years, who may be less tech-savvy, could underuse the system. As the population ages and the number of older adult caregivers, who have higher worry about their literacy in using assistive technology, increases [48,49], training and support programs should be available to help caregivers navigate and effectively use assistive technology, mitigating initial worry and improving overall outcomes [39,50].

Several risk factors for getting lost in the context of dementia were identified in this study. Health care providers could identify at-risk individuals with dementia and tailor interventions or support accordingly. Additionally, as caregivers may not always be aware of the preceding signs of getting lost [11], health care providers should facilitate caregiver awareness through education and case management. Getting lost is often an adverse outcome for individuals with dementia who may seek to fulfill unmet physical or psychological needs [10]; rather than restricting mobility, a more person-centered care approach should address these needs in an unobtrusive way that facilitates autonomy while ensuring safety. This approach should include education and assessment of ethical issues, ensuring that the privacy and liberty of individuals with dementia are respected [51].

The study found that individuals with dementia were willing to use assistive technology, likely because they were aware of the risks and sought to manage these risks independently without burdening their caregivers, and this attempt should be respected and supported [52]. Additionally, research exploring the daily mobility patterns of individuals with dementia suggests that they tend to navigate predictably based on their daily routines [53], implying that caregivers who are knowledgeable about the daily whereabouts of their care recipients are more likely to find their missing care recipients. Furthermore, the benefit of assistive IoT technology during lost episodes can be multiplied when the search area is more confined.

Strengths and Limitations

This study has several strengths. First, it was conducted in a real-world setting, which enhances the generalizability of the findings. Second, the large sample size provides robust results on the usability outcomes and factors associated with getting lost. Third, it included the usability and acceptance outcomes, such as device comfort and ease of use of the app [54], which added evidence to the daily life usability testing in prior studies [55]. However, the study also has limitations. First, the single-arm study design, as opposed to a randomized controlled trial design, limits the ability to draw causal inferences and account for potential confounders into consideration. We adopted the observational study design because we would like to observe the use of this technology in a naturalistic and exploratory manner; the findings of this study support further examination using a more robust study design. Second, the participants in this study were caregivers of individuals with dementia. Their responses regarding the satisfaction of care recipients may be subject to bias, as they are informants rather than the direct recipients of the intervention. Third, this study only captured data on the most recent episode of getting lost; outcomes related to after-care arrangements, caregiver distress, and worry may be time dependent. Therefore, future studies should consider a longitudinal design to examine the trajectories of these outcomes over time.

Conclusions

This study suggests that BLE-based crowdsourcing technology may support caregivers of individuals with dementia by reducing worry about future getting lost episodes over time and encouraging proactive search strategies. Caregivers reported high satisfaction with usability and data security, although concerns about positioning accuracy highlight the need for broader community adoption to enhance effectiveness. While the technology did not significantly shorten the duration to find the missing care recipients, its integration into dementia care plans could complement existing strategies, balancing safety with autonomy. Limitations, including the observational design and reliance on caregiver reports, underscore the need for randomized controlled trials and perspectives from individuals with dementia to confirm these findings and evaluate long-term benefits.

Abstract

Background: Diagnostics, treatment, and research of persisting postconcussion symptoms are challenging. Assessing symptoms is essential, but currently implemented methods only allow for retrospective reporting of symptoms. A mobile health (mHealth) symptom mapping app for adults with persisting postconcussion symptoms may be an accessible and cost-efficient alternative.

Objective: This study aimed to develop a research-based mobile app for symptom mapping for adults with persisting postconcussion symptoms and investigate its usability, feasibility, and safety.

Methods: This was a mixed method development and usability study consisting of three iterative cycles, each including (1) app design and programming, (2) app usability evaluation by the user group, and (3) app review by the clinician group. The outcomes were the mHealth App Usability Questionnaire and Mobile App Rating Scale scores, the number of days with logged symptom data during a home-testing period, and descriptions of adverse events throughout the study period. Semistructured interviews were conducted to explore the user group's experiences further.

Results: Twenty-three adults with persisting postconcussion symptoms (median age 52, IQR 34-59 years; 70% female) were included in the user group. Six clinicians (median age 53, IQR 35-60 years), including 3 (50%) females, with a mean of 13 (SD 7) years of experience working with individuals with persisting postconcussion symptoms, were included in the clinician group. The app received a mean score of 5 (SD 1.1) on the mHealth App Usability Questionnaire (7-point Likert scale) from the user group and 4.1 (SD 0.4) on the Mobile App Rating Scale (5-point Likert Scale) from the clinician group. During the 28-day home-testing period, the adherence rate among the participants in the user group was 89% (IQR 78 - 96), and two adverse events related to increased symptom awareness were registered. Three themes were created through reflexive thematic analysis of the qualitative data: (1) Visualizing the invisible—Enabling reflection and insight; (2) Personalized yet simple—Balancing relevance and usefulness; and (3) More than just a number—The complexity behind the symptom scores.

Conclusions: We developed a research-based symptom mapping app for people with persisting postconcussion symptoms. The app received high usability ratings from both the user and clinician groups. The app is a feasible alternative to traditional symptom mapping methods, and it is safe to use for its intended purpose.

Trial Registration: ClinicalTrials.gov NCT05635656; https://clinicaltrials.gov/study/NCT05635656

Introduction

Mild traumatic brain injury (mTBI) can be defined as a trauma to the head accompanied by acute signs of reduced cerebral functioning, such as brief loss of consciousness, confusion, or amnesia for the event, but often with no neuroradiological findings [1]. Common causes of civilian mTBI are falls, bicycle accidents, sports, motor vehicle accidents, being struck by objects, and violence [2]. People with mTBI can experience symptoms such as headaches, dizziness, nausea, fatigue, light sensitivity, sound sensitivity, trouble concentrating, attention problems, sadness, irritability, anxiety, depression, and sleep problems [3,4]. Most people recover within a few weeks after the injury, but a considerable proportion develop persisting postconcussion symptoms (PPCS) where symptoms persist for more than 3 months [5]. The reported prevalence of PPCS differs between contexts and study procedures, and a recent review found an estimated prevalence between 18.3% and 31.3%, depending on the applied definition of PPCS [6,7].

Despite the high prevalence, the etiology of PPCS is largely unknown and is an ongoing topic of debate among experts in the field [4,8]. Several factors, including pre, peri, and postinjury factors, are believed to influence or contribute to PPCS [9], and a biopsychosocial framework is often applied to understand these intricate processes [10,11]. PPCS is associated with reduced health-related quality of life [12], reduced return-to-work rate [13-15], and reduced participation in social life [16]. Regardless of the pathophysiological mechanisms involved, PPCS is a substantial health problem affecting the lives of many people.

Despite the high burden, we lack consensus on the diagnosis and classification of PPCS [4,17]. No single test can confirm PPCS; the diagnosis is established after careful evaluation of the medical history and self-reported symptoms [18,19]. Differential diagnosis can be particularly challenging, as similar symptoms to PPCS have also been reported in the general population [20].

Self-reporting of symptoms is essential in diagnosing and treating PPCS and is an important data source in research aiming to expand our understanding of the condition and evaluate treatment effects. Existing validated and widely used instruments for assessment of postconcussion symptoms, such as the Rivermead Postconcussion Symptom Questionnaire (RPQ) and the British Columbia Postconcussion Symptom Inventory, only allow for retrospective reporting, using a timescale of days or weeks [7,21,22]. While retrospective symptom assessment has pragmatic advantages, it may introduce recall bias, where the person reporting their symptoms fails to accurately recall the symptoms' occurrence or intensity [23]. This can potentially lead to an incomplete representation of the person's experienced symptoms, complicating the diagnosis and treatment of PPCS, as well as impeding research developments. Prospective symptom assessment, by comparison, has the benefit of the person reporting closer in time to symptom occurrence and may provide a more nuanced representation of symptom fluctuation and reduce the risk of recall bias [24].

An mHealth app for mapping PPCS is a highly warranted tool. It allows symptom registration in real time, capturing day-to-day fluctuations, and has the potential to support people with PPCS to take ownership of and manage their condition [25], support the clinician in diagnosing and evaluating treatment effects, and provide prospectively collected data for clinical trials. Furthermore, a mobile app is easily distributed, making it an accessible and cost-efficient alternative to traditional methods [26]. Therefore, we aimed to develop a mobile app for symptom mapping for people with PPCS and investigate its usability, feasibility, and safety.

Methods

Study Design and Participants

This was a mixed method iterative development and usability study carried out at St. Olavs University Hospital from December 25, 2022, to March 5, 2024. The mobile app was developed throughout the study based on feedback from people with PPCS (user group) and clinicians with expertise in PPCS (clinician group) at 3 different time points. The primary objective was to assess the app's usability, and the secondary objectives were to assess feasibility and safety.

The study participants in the user group were recruited from an outpatient rehabilitation clinic, through announcements on the hospital's official website, the Norwegian Center for Headache Research website, and user organizations and their social media. Inclusion criteria were: (1) age 18 years or older, (2) mTBI as defined by having sustained a head injury with observed or self-reported alteration of consciousness, amnesia, or other relevant acute symptoms, such as drowsiness, (3) PPCS according to the *International Classification of Diseases* research criteria operationalized as reporting 3 or more symptoms (including headache) on a moderate or greater intensity level on the RPQ, (4) posttraumatic headache according to the *International Classification of Headache Disorders 3rd edition*, (5) proficiency in the Norwegian language, and (6) signed written informed consent. Exclusion criteria were (1) severe psychiatric or somatic disease or other patient-related factors that would provide obvious challenges for adhering to the study protocol, including using the app, (2) having no access to an iOS (Apple Inc) or Android smartphone (Google LLC), or (3) having less than 3 months of smartphone experience. An experienced research nurse screened participants for eligibility by collecting relevant medical information and symptom history directly from the participants.

The study participants in the clinician group were identified based on their expertise in the field of PPCS and were recruited through convenience sampling using professional networks of the authors at Norwegian universities, hospitals, and clinics, aiming to include clinicians from diverse multidisciplinary backgrounds.

Study Measures

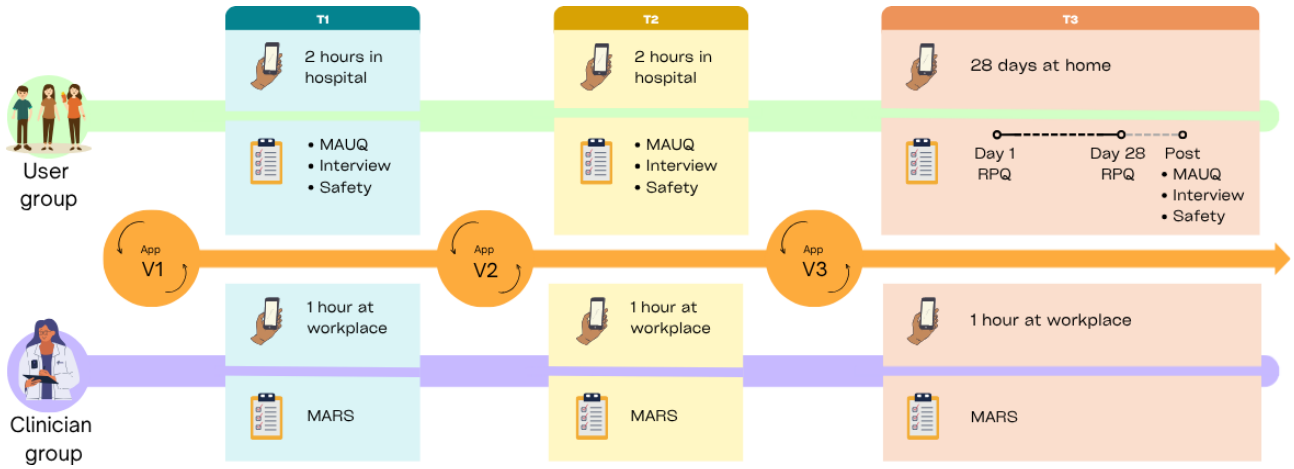
The primary outcome was app usability, which was measured using the mHealth App Usability Questionnaire (MAUQ) and Mobile App Rating Scale (MARS). The MAUQ consists of 21 statements divided into 3 subsections: Ease of use and

XSL•FO
RenderX

satisfaction, Interface and satisfaction, and Usefulness. The questionnaire has a 7-point Likert scale from 1 (strongly disagree) to 7 (strongly agree). The MARS is an app quality rating tool that assesses app quality on 4 dimensions: Engagement, Functionality, Aesthetics, and Information quality. The questionnaire uses a 5-point Likert scale, ranging from 1 (Inadequate) to 5 (Excellent). The total mean score describes the app's overall quality, while mean subscale scores within the dimensions can be used to describe specific strengths and weaknesses. Professional translators translated the MAUQ and the MARS into Norwegian using a forward-backward translation method. Experts in the field of mTBI performed the harmonization of the translations.

The RPQ was completed as part of the screening and inclusion of study participants in the user group, as well as before and after the home testing period. The RPQ contains 16 items representing different symptoms and operates on a 5-point Likert scale from 0 (no experience at all) to 4 (severe problem). When summing up the scores, responses of 1 (no more of a problem than before) were recoded to 0, with a total score range of 0 - 64. The Norwegian version of the RPQ has been translated from the original English version by the Collaborative European NeuroTrauma Effectiveness Research in Traumatic Brain Injury (CENTER-TBI) Consortium [27] and has been validated [28].

The secondary outcomes were feasibility and safety. To assess feasibility, we recorded the percentage of days with logged symptom data in the user group during the home-testing period of 28 days, referred to as adherence. For participants experiencing technical issues in the app hindering them from using it, the percentage was calculated as days with logged symptom data divided by the number of days it was possible to use the app. The app safety was assessed with the frequency of adverse events (AE), serious adverse events, and unexpected serious adverse events throughout the whole study period.



To further explore the app's usability, feasibility, and safety, semistructured interviews were conducted with all participants in the user group as part of each iteration.

Study Procedure

The study consisted of 3 iterative cycles. Each iteration included (1) app design and programming, (2) usability evaluation by the user group, and (3) review by the clinician group. During usability evaluation (2), the user group completed the MAUQ and conducted a semistructured interview, while the clinician group filled out the MARS during the app quality review (3). Before filling out the questionnaires, both the user and clinician groups had the opportunity to explore the app independently. Thereafter, they were instructed to perform specific tasks, typically describing an overarching goal, that is, "perform a registration of the symptoms you are experiencing today."

The study participants' immediate reactions and issues that emerged during the usability testing were also documented. The feedback from the user and clinician groups during usability testing was used to develop the next app version for the following iteration. In the first 2 iterations, the participants in the user group attended 2-hour individual sessions in a hospital setting to evaluate the app's usability. While in the third iteration, they used the app for 28 days at home (Figure 1).

Figure 1. Illustration of the study procedure. The study participants evaluated the different versions of the app (v1, v2, and v3) as part of every iteration. In the first two iterations, the user group evaluated v1 and v2 during 2-hour sessions at the hospital, completing the mHealth App Usability Questionnaire, an interview, and a safety assessment. In the third iteration, they used v3 at home for 28 days, completed the Rivermead postconcussion symptom questionnaire on the first and last day, and completed the mHealth App Usability Questionnaire, an interview, and a safety assessment within 2 weeks after the last day. The clinician group evaluated v1, v2, and v3 in 1-hour sessions at their workplace, completing the Mobile App Rating Scale during all iterations. MARS: Mobile App Rating Scale; MAUQ: mHealth App Usability Questionnaire; RPQ: Rivermead Postconcussion Symptom Questionnaire.

During the home testing, the user group was asked to use the app to register their symptoms daily. The app was preconfigured to send a notification every evening at 8 PM with the message "Did you experience symptoms today?" The study participants could adjust the notification time or disable it in the settings. They were able to register symptoms experienced within the last 48 hours but were not able to edit or add symptoms beyond that timeframe. Study personnel made 3 planned phone calls (approximately once a week) to assess any technical issues with the app. Additional phone calls were scheduled for further troubleshooting if technical issues were not solved immediately.

The clinician group evaluated the app's usability in 1-hour sessions in their work environments in every iteration.

Parallel to investigating the usability, feasibility, and safety of the symptom mapping app, the study participants also evaluated

XSL•FO
RenderX

a digital solution for biofeedback, as described in the preregistration of the research study Digital Solutions for Concussion [29]. The findings related to the biofeedback device will be reported elsewhere.

Data Analysis

The outcome measures for each cycle were summarized statistically. Continuous variables were summarized as mean (SD) or median (IQR) according to distribution. Categorical variables were summarized as frequencies (percentages). No statistical hypothesis testing was conducted.

The qualitative interviews were analyzed using reflexive thematic analysis, as described by Braun and Clarke [30], underpinned by a critical realism approach. The first author and fourth author conducted the qualitative interviews, which were later transcribed verbatim by the first author, fourth author, and 2 research assistants. The transcribed interviews were proofread by a research team member other than the transcriber. The first author kept a reflexive journal throughout this process, as well as in the later phases of the analytic process. The first author systematically coded the transcribed data semantically, applying code labels close to the expressed meanings. Next, initial themes were developed by exploring clusters of meaning across the dataset. Through reviewing and further developing the initial themes, the final themes were defined.

The quantitative analyses were performed in SPSS (SPSS Inc) and R (R Development Core Team), and the qualitative analyses were performed in NVivo (Lumivero).

App Development and Deployment

The app was programmed using React Native and made available for beta testing on both iOS and Android devices. St. Olavs Hospital and Norwegian University of Science and Technology (NTNU) contracted Nordic Brain Tech AS and Fominykh Consulting for consultant services on app programming. During usability testing, the study participants used the app on dedicated study phones provided by St. Olavs and NTNU. During the 28-day home-testing period, the user group used the app on their personal smartphones. They received written instructions and a QR code to download the app, and study staff assisted them by phone. Data collected with the app was transferred as deidentified data to Microsoft through the cloud service Microsoft Azure. The data were encrypted in transit and at rest. The identity and credentials were stored with the identity management service Microsoft Azure AD B2C. St. Olavs Hospital and NTNU have full ownership of the app, all data, images, and results created in the study.

Ethical Considerations

The study was approved by the Norwegian Medicinal Products Agency (NoMa 22/16250‐7) and the Norwegian Ethics Committees for Clinical Trials on Medicinal Products and Medical Devices (REC-KULMU 422538) and preregistered in ClinicalTrials (NCT05635656). The participants in the clinician group were identified based on their expertise in PPCS and recruited through convenience sampling using professional networks of the authors at Norwegian universities, hospitals, and clinics, aiming to include clinicians of diverse multidisciplinary backgrounds. Recruitment material for the user group was distributed through the hospital, patient organizations, and the Norwegian Centre for Headache Research (NorHead). Interested individuals made contact by email. All participants received oral and written information about the study, and informed written consent was obtained prior to the first study visit. Consent was collected electronically using eFORSK, a web-based application developed and maintained by Central Norway Regional Health Authority's IT department, Hemit HF. Participants were not compensated for their participation.

Results

Overview

A total of 23 adults (median age 52, IQR 34-59 years; 70% females) with PPCS were included in the user group, and 6 clinicians (median age 53, IQR 35-60 years; 50% females) were included in the clinician group. Table 1 displays demographic and injury-related characteristics of the user group. The most common injury mechanism was being struck by or on an object, whereas 5 cases were sport-related. Two participants in the user group dropped out during the study period. Both dropped out before commencing the home-testing period and stated personal reasons not related to the study as the reason for their withdrawals.

The participants in the clinician group (n=6) had a median age of 53 (IQR 35-60), and 50% (3/6) were women. They were medical doctors, specialists in physical medicine and rehabilitation, or clinical neuropsychologists with a mean of 13 (SD 7) years of experience in the field of PPCS.

[a]RPQ: Rivermead Postconcussion Symptom Questionnaire.

App Development

Three versions of the symptom diary app were developed in the course of the study based on feedback from the study participants during usability testing. The third version of the app was used in the 28-day home-testing by the user group (Figure 2).

XSL•FO
RenderX

Figure 2. Screenshots from v3 of the app. Screenshot 1 shows the initial screen users see when opening the app for the first time. Screenshot 2 shows the first screen of a diary entry. The drop-down menu for each symptom contains 3 different parameters: intensity of symptoms, negative impact on functioning, and negative impact on well-being. Screenshot 3 shows an overview of the current day. Screenshot 4 shows statistics from the diary entries over the past 3 months in a line graph, with customization options to select which symptoms and activities to display. The study participants used a Norwegian version of the app, but for the purpose of this article, the screenshots have been translated into English.

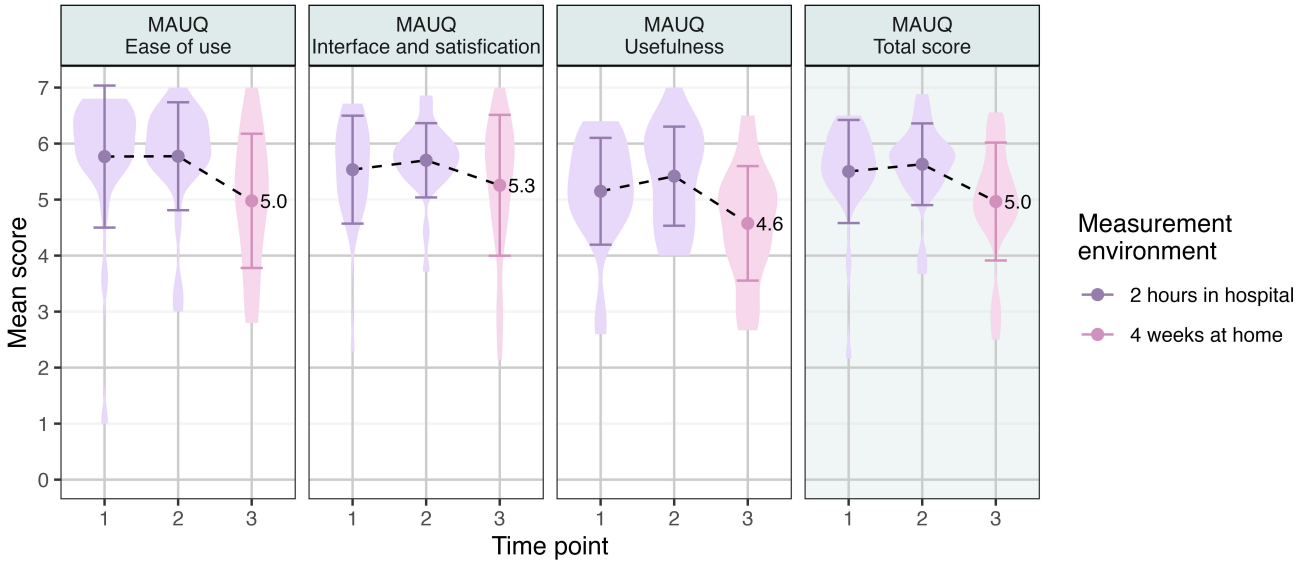
Usability

The user group rated the third version of the app's usability 5 (SD 1.1) out of 7 on the MAUQ, with the highest scoring for Interface and satisfaction, followed by Ease of use and Usefulness (Figure 3).

The clinician group's mean rating of the app on the MARS was 4.1 (SD 0.4) out of 5, with Aesthetics scoring the highest, followed by Functionality, Engagement, and Information (Figure 4).

XSL•FO
RenderX

Figure 3. mHealth App Usability Questionnaire scores for the symptom mapping app, completed by the user group. MAUQ: mHealth App Usability Questionnaire.



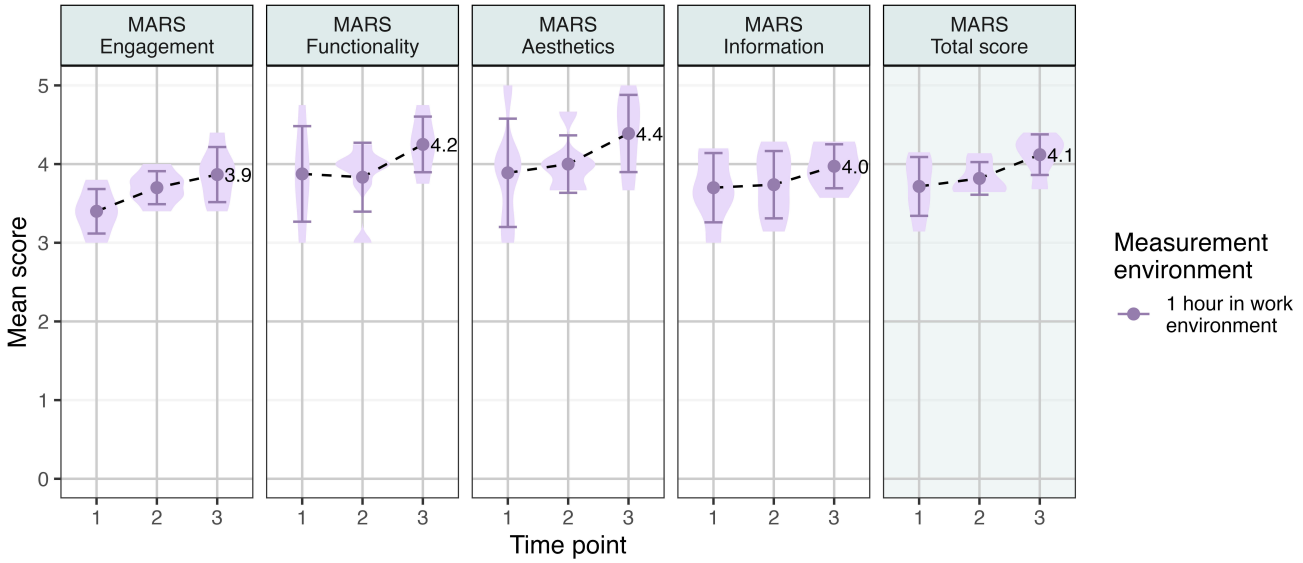


Figure 4. Mobile App Rating Scale scores for the symptom mapping app, completed by the clinician group. MARS: Mobile App Rating Scale.

Feasibility

A total of 21 participants in the user group completed the home-testing period, of whom 16 experienced technical issues of different severities during this time. There were 14 participants who experienced mild technical issues, such as being logged out of the app or the app "freezing," while 2 participants experienced severe technical problems where symptom entries were not saved due to a synchronization issue with the server. Despite the 2 participants' efforts using the app, significant amounts (possibly >85%) were not stored, and it was therefore not possible to accurately calculate their adherence rate. These were therefore excluded from the adherence analysis. The 2 excluded study participants with severe technical problems successfully completed all other study measures and were not excluded from other analyses. The adherence rate for the user group during the home-testing period was 89% (IQR 78-96), n=19. The adherence rate for all analyzed participants, independent of whether they experienced severe technical issues or not, was 81% (IQR 75-96; n=21).

Safety

Two AEs were logged during the home testing period. No severe AEs or unexpected severe events were logged. In both incidents, the study participants reported increased awareness of symptoms as an unwanted effect of using the symptom mapping app.

Qualitative Analysis and Results

Using reflexive thematic analysis through a 6-phase process as described by Braun and Clarke [30], 3 themes were constructed: (1) Visualizing the invisible—Enabling reflection and insight; (2) Personalized yet simple—Balancing relevance and usefulness; and (3) More than just a number—The complexity behind symptom scores.

Visualizing the Invisible—Enabling Reflection and Insight

The first theme surrounds the participants' need for a concrete visualization of their experiences with PPCS. They expressed a need to document their symptoms to confirm for themselves

XSL•FO
RenderX

that this is actually what it is like over time and not something they are exaggerating or understating. The app also gives the opportunity to engage in self-reflection and identify possible adjustments to improve functioning and well-being. One participant stated:

> *It's about getting an overview of your own life and knowing that, okay, I can see the patterns, on the weeks where I sleep less, it gets worse. And then it's a bit reassuring to know, okay, I know this will be a hectic period, so maybe I need to take it a bit easier on other things. It's not necessarily about building your life around this, but it gives you the opportunity to make smarter choices and set yourself up with better conditions.* [Zara, 64, v3]

The participants described how they can use the visual representations of their reality to take ownership of their condition and proactively manage their own lives. They want to make informed decisions and set priorities that align with their values.

Many also see the potential of sharing such a visual representation of their PPCS experience with health professionals to facilitate communication and create a shared understanding of their symptom burden. One participant explained:

> *When you are at the general practitioner's office, you have very limited time to communicate everything that has been going on for the past two or three months; it is hopeless, actually. The doctor could rather just go in [the app] by themselves, watch the log, and then see how you have been.* [Omar, 53, v3]

Another participant said:

> *When you are in treatment and you get the question 'how have you been lately?' it's not so easy to remember because you are standing so close to it. So, to be able to show your registrations to get it more…in writing, that is usually very helpful* [Tamara, 56, v1]

They explained that it can be helpful to zoom out and show gradual and nonlinear recovery. Tracking their journey to recovery was thus another potential of the symptom diary pointed out by the participants.

Notably, several participants had already tried to create a visualization of their PPCS experience, using, for instance, Microsoft Excel or Post-It notes. Several participants also mentioned they have searched the internet for an app to keep track of their symptoms. Many had experience with headache diary apps, and some had tried symptom-tracking apps for various chronic illnesses. They had not yet experienced finding an app that took "the whole picture" into consideration, allowing them to track the symptoms and activities perceived as relevant to them. As 1 participant pointed out when talking about the headache diaries:

> *I feel like it is not enough to just log the headache. I have several types of headaches, but that is not the biggest challenge in my life. The fatigue, the sleep problems, the periods with bad memory have been far more challenging [...] There is so much more to it (than the headache).* [Valerie, 47, v1]

Personalized Yet Simple—Balancing Relevance and Usefulness

This theme represents the fine line between a useful and a cumbersome tool. A useful tool is perceived by the study participants as an app containing the necessary elements to log the aspects relevant to their functioning and well-being, while still being as simple as possible, making it low-threshold to use daily.

Many participants found the app relevant and easy to use, though some found it cumbersome and time-consuming. They expressed a need to minimize the available options and the clicks necessary to complete a symptom registration. They also highlighted the importance of always being able to edit their preselected symptoms.

The symptoms that users wanted to log seemed to be connected not only to symptom intensity, but also to their impact on their functioning, well-being, and symptom fluctuation.

> *It can be something that doesn't occur very often, but it is very intense when it does, or the opposite, something that is present most of the time without being extremely critical, but it's always there, simmering in the background in a way. So as long as you can choose [...] because people are different* [Sophie, 25, v2]

The activities perceived as relevant seemed to be connected to their perception of what influences symptom burden, but also activities enhancing their overall well-being without necessarily actively decreasing symptom intensity. For instance, 1 participant said:

> *Working in the garden is something that gives me peace of mind, and you need that on a bad day. Yeah, working in the garden would be nice to have as a distinctive activity to register* [Omar, 53, v3]

Several participants expressed how different contexts could generate different perceptions of what is relevant to track, for instance, starting a new treatment, returning to work after sick leave, or when experiencing a particularly stressful period in their personal lives. The feeling of purpose seemed to be essential for the perception of relevance.

Thus, there was great variation in which symptoms and activities were perceived as relevant. This underlies the importance of a flexible layout allowing for personalization, where the user of the app defines what is relevant in their unique case, enhancing the user's perception of the app's usefulness.

More Than Just a Number—the Complexity Behind Symptom Scores

The third theme reflects the complexity of PPCS and how the mapped symptoms in the app will always remain a simplification of reality. One participant put it this way:

XSL•FO
RenderX

> *To me, there is more behind that number than to you, and you can't include every person's life story, you need a number, so I get that* [Pedro, 58, v1]

Many participants found it challenging to sum up their experiences in a score. They acknowledge that there is no correct answer to "what a score of 5 means," and that they operate the scale based on their perception of what the scores represent, which is not static. One participant explained how they found their scoring became more consistent over time and that they needed about 14 days of "calibration" during the home testing. Another participant highlighted how their perception is, in fact, dynamic:

> *If it's been a long time since you had a 9 - 10, and you are in more pain than usual, you might put down a score of 8. But during a bad period, that score of 8 would've actually been a 5. So, that is something to keep in mind: a 5 is not always a 5.* [Eve, 40, v2]

The participants reflected on several aspects complicating their action of scoring, including the frequent fluctuations of symptoms, the intertangled relationship between symptoms, and other factors influencing the experienced symptom burden. Some pointed out internal factors influencing their perception of today's score, (eg, how they slept), as well as external factors (eg, if they went outside and were exposed to a lot of noise or stayed home that day). One person said they generally hesitated to score a 10 as they felt others probably had it worse.

Some also reflected on what they compared themselves to when scoring, for instance, life before the injury or to their peers.

While recognizing the challenging act of scoring and acknowledging that it inevitably always will be a simplification of their experiences, several participants still eyed the potential benefits of scoring their symptoms:

> *It is difficult to register [symptoms] based on a number, but at the same time, it makes it much more measurable and easier to spot patterns* [Sophie, 25, v1]

Discussion

Overview

We developed a research-based mHealth app for symptom mapping for people with PPCS. The app was created by combining rigorous research methods with iterative usability testing, together with people with PPCS and experienced clinicians in the field. We investigated the app's usability, feasibility, and safety. The app received high usability ratings from both the user and clinician groups and achieved a high adherence rate during home testing. Two AEs related to increased symptom awareness were logged during the study period.

Usability

The app received generally favorable usability scores and app quality scores from both the user and clinician groups. After 28 days of home testing, the final version received a mean score of 5 (SD 1.1) on the 7-point Likert scale in MAUQ by the user group and 4.1 (SD 0.4) on the 5-point Likert scale in MARS by the clinician group. Previous studies have evaluated apps for tracking symptoms in various conditions, including concussion and chronic pain, using the same questionnaires, with mean MAUQ scores ranging from 4.7 - 6.1 [31,32] and mean MARS scores ranging from 1.42 - 4.1 [33,34], implying that the app is considered acceptable in regards to usability and app quality by both people with PPCS and clinicians working in the field of PPCS. Notably, the user group rated the first 2 versions of the app higher than the third and final version (Figure 3). The differences in the study setting may partly explain this, as the user group tried the first 2 versions of the app in 2-hour sessions at the hospital, while using the third version at home for 28 days. The participants may have encountered challenges with the app when using it more extensively at home than during the limited time they had at the hospital. Furthermore, many of the participants experienced technical issues in the app during the home-testing period, possibly also affecting their experience of usability. Notably, the completion of the MAUQ did transpire in identical settings at all times, always situated in the hospital.

Feasibility

The adherence during the 28-day home-testing period was 89% (IQR 78 - 96). A meta-analysis of 99 mHealth apps for preventing or managing noncommunicable diseases revealed an average adherence rate of 56% [35]. A study similar to this study developed an app for people in the acute phase of concussions and observed an adherence rate of 28% during a 5-week period [31]. They recruited participants within 14 days of their concussion and thus aimed at a slightly different patient population than in this study, which may partly explain the difference in adherence rate. The high adherence rate in this study implies that the symptom diary app is a feasible approach for logging PPCS despite the relatively high frequency of technical issues for many of the study participants. In this study, we programmed the app to send a daily notification to register symptoms, based on feedback from the user and clinician groups, in order to ensure sufficient data density while also minimizing the experienced burden on the user. Given the high observed adherence rate, future studies can consider exploring multiple registrations per day to enhance data density. However, this should be done while carefully evaluating the user's experienced burden.

Safety

Regarding the app's safety, 2 AEs were registered concerning increased awareness of symptoms during home testing. Both participants completed the home testing but stated during their last encounter with the study personnel that they became more aware of their symptoms, which had a negative impact on their well-being. They both emphasized the value of keeping track of their symptoms but acknowledged that it can also function as a negative reminder. One participant emphasized the importance of receiving guidance from a health care provider in interpreting their symptom logs. This is an important finding, as the effects of symptom tracking in PPCS are understudied. This is, however, not unique to the field of PPCS; the effects of symptom mapping are, in general, understudied. In a small study with healthy individuals, it was shown that subjects tracking their symptoms daily for 2 weeks had increased recall

XSL•FO
RenderX

of symptoms and perception of symptom severity compared to the control group [21]. Still, we should not discard the reported experiences of the app's usefulness despite these incidents. It is plausible that a subgroup of the study population is prone to experiencing unwanted side effects related to increased awareness of symptoms. Future studies should focus on identifying such subgroups and determining which clinical implications symptom tracking apps should have. Developers of mHealth apps or wearable devices measuring symptoms should be aware of their ethical responsibilities, and clinicians recommending such tools and individuals using them should be made aware of the potential side effects [36-38].

Qualitative Analysis and Results

In the qualitative analysis, 3 overarching themes were created, which together informed the quantitative findings on the apps' usability, feasibility, and safety. The first theme, Visualizing the invisible—Enabling reflection and insight, actualizes a need for visual representations of PPCS experiences. It is essential for the usefulness of a mHealth app that its purpose is rooted in users' needs, as a good fit between a mHealth app's purpose and the user's needs increases the likelihood of continuous use [39].

The research field of personal visualization offers perspectives on the expressed need for visual representations of PPCS experiences. Visual representations of personal data can empower people with improved access and comprehension of their own data [40]. A systematic review of information visualization found visual tools essential in helping people understand and make sense of their personal health information, which is necessary to improve self-management of their health condition. For chronic illnesses, the "management" is oftentimes not focused on curing the condition but rather on coping and maintaining everyday life [41]. Coping and maintaining everyday life as an overarching goal is in line with the study participants' reflections on the purpose of the symptom diary app. They describe a need for a tool to visualize their PPCS experiences, create insight, engage in self-reflection, and make informed decisions aligned with their personal values and goals, as well as to facilitate communication with health care providers.

The second theme, Personalized yet simple—Balancing relevance and usefulness, touches upon both aspects of usability and feasibility of the symptom diary app. Experience of relevance seems to be vital to the perception of the app being useful, which again is essential for the probability of a mHealth app actually being used [39,42]. What is perceived as relevant is highly individual, as reflected in this second theme. The diverse views on relevance highlight the importance of a personalized layout in the app, allowing the user to define which symptoms and other variables are relevant to log and visualize in graphics. However, there appears to be a fine line between including many options to ensure perceived relevance and including too many options, making the app overly cumbersome. Thus, this requires careful navigation when developing mHealth apps for people with PPCS.

Finally, the third theme, More than just a number—The complexity behind symptom scores, addresses a more overarching concept, informing all 3 study objectives: usability, feasibility, and safety. Even though most study participants appreciated a visual representation of their PPCS experience and leveraged it to create overview and insight, many acknowledged the challenge of quantifying their experiences. They elaborated on how their interpretation of the scale is dynamic, depending on both internal and external factors. It is an important reminder that the visual representation of a person's PPCS experience in the app, or any other symptom-tracking instrument, will always remain a simplification of reality. A person's experience will always be richer and more complex than what can be expressed in numbers and summarized in graphics [43]. However, this does not diminish the usefulness of a visual representation for coping and managing everyday life, as described in the first theme.

Still, an important aspect to consider is how simplifying and quantifying someone's experience with PPCS may contribute to how they perceive their own experiences. From a critical realist perspective, PPCS exists as a real phenomenon independent of our descriptions of it. However, the conceptual framework embedded in the app, ie, the words we use, the categorization of symptoms, and the operationalization of numerical scales, will to some extent shape how the users of the app perceive, understand, and communicate their experiences. Creating a simplified visual representation can be useful for people with PPCS in gaining an overview and insight into a complex condition, as well as in communicating their PPCS experiences to others. It can support the user of the app in understanding and making sense of their condition, which again is crucial to health management and improving quality of life [41]. Still, this highlights the ethical responsibility of mHealth app developers to create research-based layouts and content [44]. Our findings regarding the symptom diary's safety illustrate the importance of not taking this ethical responsibility lightly. An mHealth app can have unwanted side effects for some individuals, just as any other health intervention, and requires a research-based approach.

Limitations

The questionnaires we applied to investigate app usability (MAUQ) and app quality (MARS) have been used extensively and validated in many languages [45,46]. For the purpose of this study, professional translators translated both the MAUQ and the MARS questionnaires into Norwegian using forward-backward translation, followed by harmonization of the translation by experts in the field of PPCS. However, no formal validation of the psychometric properties in a Norwegian context has been done, so direct comparisons of scores in this study with studies using the original English version should be interpreted with caution.

The number of technical issues encountered in the app during the home testing may represent a limitation regarding the feasibility assessment. Yet, adherence was not drastically affected when including the 2 participants who experienced severe technical issues (adherence 89% vs 81%), indicating good adherence despite the technical obstacles. Still, another fourteen participants experienced less severe technical problems, where no data were lost, but it may have affected their daily adherence to the app. Thus, the adherence to the app may be

XSL•FO
RenderX

underestimated, but it is, despite this, considered high compared to similar studies investigating the feasibility of mHealth apps in similar study populations [31,35]. The ongoing app development and refinement will further examine technical issues and how to mitigate them in the future.

Finally, in our study sample, 70% were female. Since this study focused on development and usability within a small sample, it was not designed to generalize to the whole PPCS population. Furthermore, women are overrepresented in the PPCS population, with female gender identified as a known risk factor for PPCS [47-49]. Future research should investigate how applicable the findings of this study are to a broader PPCS population.

Conclusions

The symptom diary app for people with PPCS is considered usable, feasible, and safe for its intended use and is ready for testing in larger-scale clinical trials.

Acknowledgments

The authors thank all study participants for their valuable contribution to this research study and the development of the symptom diary app. We also thank our research assistants, Nathalie Bergh and Sunniva Traa Carlsen, and the research coordinator Janne-Birgitte Bloch Bjerkhaug, at the Rehabilitation Clinic, St. Olavs Hospital, for their efforts.

Funding

This study was funded by the Liaison Committee between the Central Norway Regional Health Authority (RHA) and the Norwegian University of Science and Technology (NTNU) (2020/28373), the Central Norway Regional Health Authority (RHA) (innovation funding), and the Norwegian Research Council (328615). The funder had no influence on the study design, data collection, data analysis, data interpretation, or writing of the article.

Abstract

Background: Digital health applications (DiGA) have been integrated into Germany's health care system since 2019, offering certified medical devices for various health conditions. This study focuses on deprexis and Selfapy, the first 2 permanently approved DiGA for depressive disorders in Germany, to evaluate their usability for people ≥60 years. The study's significance is underscored by the underrepresentation of older people in previous DiGA studies, accompanied by an emergent risk of inequalities in distribution for this vulnerable population.

Objective: This study assessed the usability of DiGA deprexis and Selfapy for adults aged ≥60 years with mild to moderate depression. The more user-friendly option will be chosen for the DiGA4Aged project's upcoming randomized controlled trial.

Methods: The prospective observational study uses the People at the Centre of Mobile Application Development (PACMAD) usability model in a mixed methods design. The study's multistage data collection encompasses sociodemographic data and quantitative questionnaires about health literacy (European Health Literacy Survey Questionnaire [HLS-EU-Q16]), electronic health literacy (revised German eHealth Literacy Scale [GR-eHEALS]), media affinity, depressive symptoms (9-item Patient Health Questionnaire [PHQ-9]), and perceived usability (System Usability Scale [SUS]), as well as a qualitative think-aloud and semistructured interview. Participants were equally allocated to use either deprexis or Selfapy. Recruitment of 18 participants was conducted at 3 hospital departments (ie, psychiatry, psychosomatics, and geriatrics) in spring 2024. Participants were eligible if they were aged ≥60 years, were diagnosed with mild or moderate depressive disorder, owned a digital device, and gave written consent to participate.

Results: Quantitative analysis revealed age, gender, depressive severity, and health literacy parity between both groups. Selfapy users displayed marginally lower technical proficiency and lower usability scores. Qualitative data showed lower usability among participants in the Selfapy group due to design-related errors and higher cognitive load. Despite visual, psychomotor, and cognitive challenges, participants endorsed both DiGA for older users, stressing the importance of assistance and practicing the usage.

Conclusions: Reported difficulties in usability may help to improve future DiGA development for older people, especially as the willingness to use DiGA exists.

Introduction

Depressive disorders represent an increasingly urgent public health issue, having already been identified by the World Health Organization as the condition most likely to rank second in the disability-adjusted life years index by 2030 [1]. Depressive disorders are associated with a significant reduction in quality of life and performance, along with major economic consequences [2].

Between 2001 and 2020, the point prevalence of self-reported depressive symptoms stood at 34% worldwide [3]. A survey was conducted across Europe to determine the prevalence of depressive symptoms within the past 2 weeks (assessed via self-report using the 8-item Patient Health Questionnaire [PHQ-8]). The result was a prevalence of 6.6% for the European Union as a whole (men 5.2% and women 7.9%), whereas in terms of age-standardized prevalence, people aged ≥65 years and above (9%) were most affected in the European Union. In Germany, a comparatively higher prevalence of 9.2% was recorded (women 10.8% and men 7.6%). People in the 15 to 29 years age group in Germany were particularly affected (11%), whereas approximately 7% of individuals aged ≥65 years showed signs of depressive symptoms [4].

There are already considerable shortcomings in treatment in Germany [5]. In particular, the demand for psychotherapy is still insufficiently met, leading to long waiting times before treatment begins [6].

Internet-based interventions may be one way of providing low-threshold access to treatment. While more than 10,000 smartphone apps are available for mental or behavioral health, evaluating these apps to ensure privacy protection, usability, and interoperability is a major challenge [7].

In Germany, efforts are underway to precisely ensure this evaluation through a standardization process, thereby giving patients direct access to quality-assured applications. Therefore, digital health applications (DiGA or Digitale Gesundheitsanwendungen) have been integrated into Germany's health care system since the German Digital Healthcare Act came into effect in 2019. DiGA, offered as apps and web-based applications, are certified as low-risk medical devices that can be prescribed by physicians and psychotherapists or dispensed after approval by health insurance companies [8]. A prescription is possible after successfully passing an assessment procedure of the Federal Institute for Drugs and Medical Devices. This is accompanied by the entry in the DiGA directory either as temporarily approved DiGA for 1 year pending reassessment or as permanently approved [9]. The approval by the Federal Institute for Drugs and Medical Devices requires evidence of the so-called positive care effect, meaning that the DiGA has been proven to contribute either to an improved management of the disease or to enhanced patient health [10].

Currently, 26 of the overall 56 listed DiGA address indications in mental health, making this category the largest of 12. To this date (July 5, 2024), 4 DiGA (ie, deprexis, edupression.com, Novego, and Selfapy) are permanently listed for use in depressive disorders, and another 3 DiGA are temporarily approved for 1 year (elona therapy Depression, MindDoc auf Rezept, and My7steps App) [11].

The first 2 permanently approved DiGA for treating depressive disorders were deprexis and Selfapy [11]. While these DiGA offered patients an opportunity to take advantage of treatment options for depressive symptoms, not all patients could be reached through this channel. The usage behaviors of certain age groups differ according to a report on the implementation and development of DiGA between 2020 and 2022. During the period under review, deprexis was prescribed approximately 10,000 times, with the frequency of use decreasing steadily among those aged ≥65 years. During the same period, Selfapy was prescribed about 9000 times in total, with almost no users in the age group >60 years [12]. Moreover, the approval studies of both deprexis [13,14] and Selfapy [15] did not include participants aged >65 years.

These findings illustrate the necessity of incorporating accessibility and participation considerations for the older population because depressive disorders are among the most common mental illnesses in older people [16]. Approximately 4% to 5% of individuals aged 65 to 79 years in Germany are affected by depressive symptoms [17]. Owing to the global trend of an aging population [18], the prevalence in this population group will steadily increase. Although, as mentioned earlier, other age groups in Germany are more severely affected by depressive symptoms, it is crucial to ensure that DiGA, as a state-supported concept, are beneficial and accessible to all individuals and that no one is excluded from this growing path of digital health care.

While expanding digital health care services such as DiGA could address these deficits, at the same time, inequalities in distribution might be reinforced, especially for vulnerable groups such as older people [19]. To ensure they can also benefit from such offers, the usability of DiGA should meet the needs of this user group. Various studies (eg, [20,21]) have shown that older people face specific challenges when using mobile apps: visual, psychomotor, and cognitive limitations due to aging and disease can impair usability. For instance, font size, visual contrast, small screens, and complex menu navigation pose considerable obstacles to use [20,21].

This study aimed to evaluate the usability of the DiGA deprexis and Selfapy for people aged ≥60 years with mild or moderate depressive disorders. The evaluation is based on the People at the Centre of Mobile Application Development (PACMAD) usability model [22]. The more user-friendly DiGA will be selected for the following randomized controlled trial (RCT) in the overall project DiGA4Aged.

Methods

Study Design and Participants

This prospective observational study adopted a convergent mixed methods design, involving the combination of both quantitative and qualitative data to obtain a more comprehensive understanding of the research topic. The design was stated as concurrent, with greater emphasis placed on qualitative data and triangulation of data occurring on the level of interpretation.

XSL•FO
RenderX

Both quantitative and qualitative data were collected at a single time point (single phase) [23].

Owing to the recent integration of DiGA into Germany's health care system since 2019, hardly any evidence was available before this study's conception in 2022. We searched the database of the Federal Institute for Drugs and Medical Devices for approval studies of the DiGA manufacturers and reports about the prescription and usage of DiGA. Furthermore, we searched PubMed for articles published from database inception to October 1, 2022, using the keywords ("depression" OR "depressive disorder" OR "mental health") AND ("DiGA" OR "health app" OR "eHealth" OR "mobile app" OR "smartphone app") without language restrictions. We identified systematic reviews on mobile apps with regard to mental health; however, none of them specifically included DiGA. Even now, the body of evidence on DiGA is only growing slowly.

The recruitment and assessment periods took place from February to April 2024 in 3 hospital departments: psychiatry, psychosomatics (both from Landwirtschaftsverband Westfalen-Lippe–University Hospital Bochum), and geriatrics (Marien Hospital Herne). In an endeavor to recruit a heterogeneous sample, the purposive selection by physicians and researchers at these departments was based on sociodemographic characteristics, health, and perceived electronic literacy, as well as perceived media affinity, alongside the eligibility criteria (Textbox 1). No distinction was made in terms of gender. In each department, the first 3 participants included in the study used Selfapy, followed by the next 3 using deprexis.

Textbox 1. Eligibility criteria for participation.

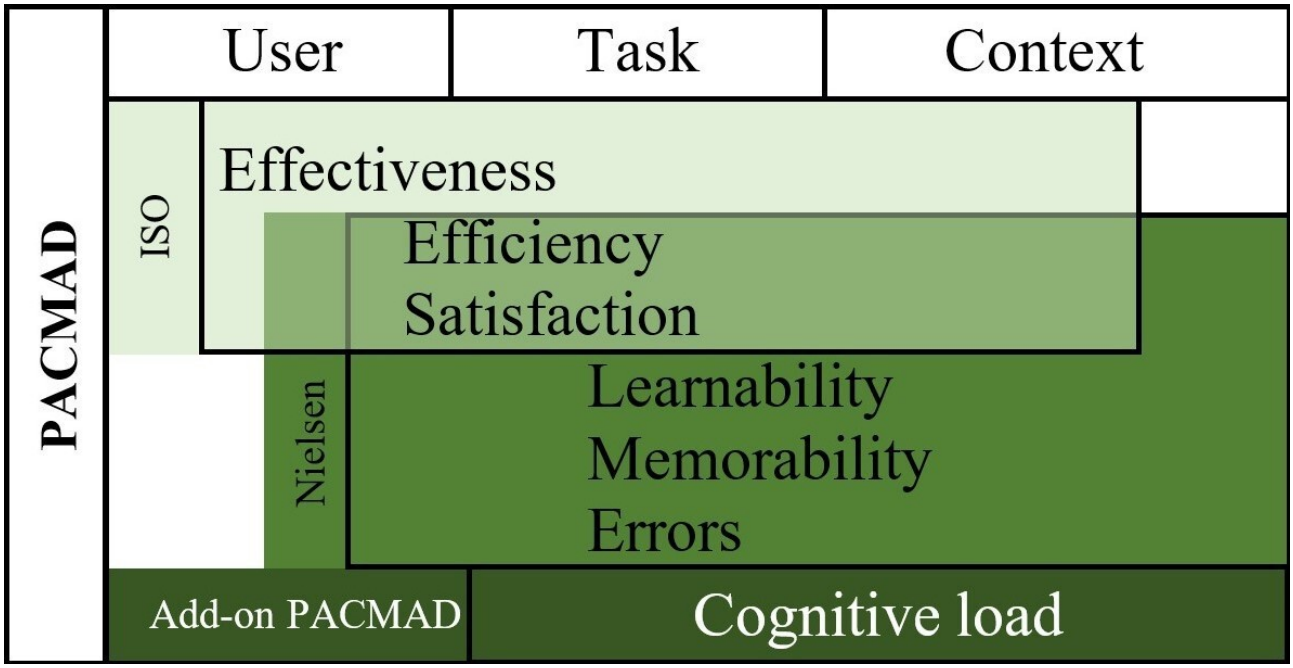
Inclusion criteria

- Aged ≥60 years
- Diagnosis of mild or moderate depressive disorder
- Ownership of a digital device suitable for digital health applications (DiGA) use
- Written consent to participate

Exclusion criteria

- Acute psychotic symptoms
- Acute suicidal tendencies or self-endangerment that results in an immediate need for treatment
- Severe intellectual impairment
- Motor and sensory impairments that prevent the use of a digital device
- Insufficient knowledge of the German language
- Advanced and incurable disease
- Diagnosis of bipolar disorder or schizophrenia
- Current participation in another intervention study
- Current use of a DiGA for the treatment of depressive disorder

Ethical Considerations



The study received ethical approval from the Ethics Committee of the Ruhr University Bochum (23 - 7901). The reporting adhered to the GRAMMS (Good Reporting of a Mixed Methods Study) guideline for mixed methods studies in health services research [24] and to the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) statement [25]. Participants were compensated with an expense allowance of €25 (US $29.24) per hour for their participation in the study. All participants were informed about the objectives of the study and the possible risks. They gave their written consent and were able to ask questions on site. Participation was voluntary, and they could withdraw at any time without suffering any disadvantages. None of the participants took advantage of this option. After the survey, the data were pseudonymized. All data was anonymized for the manuscript.

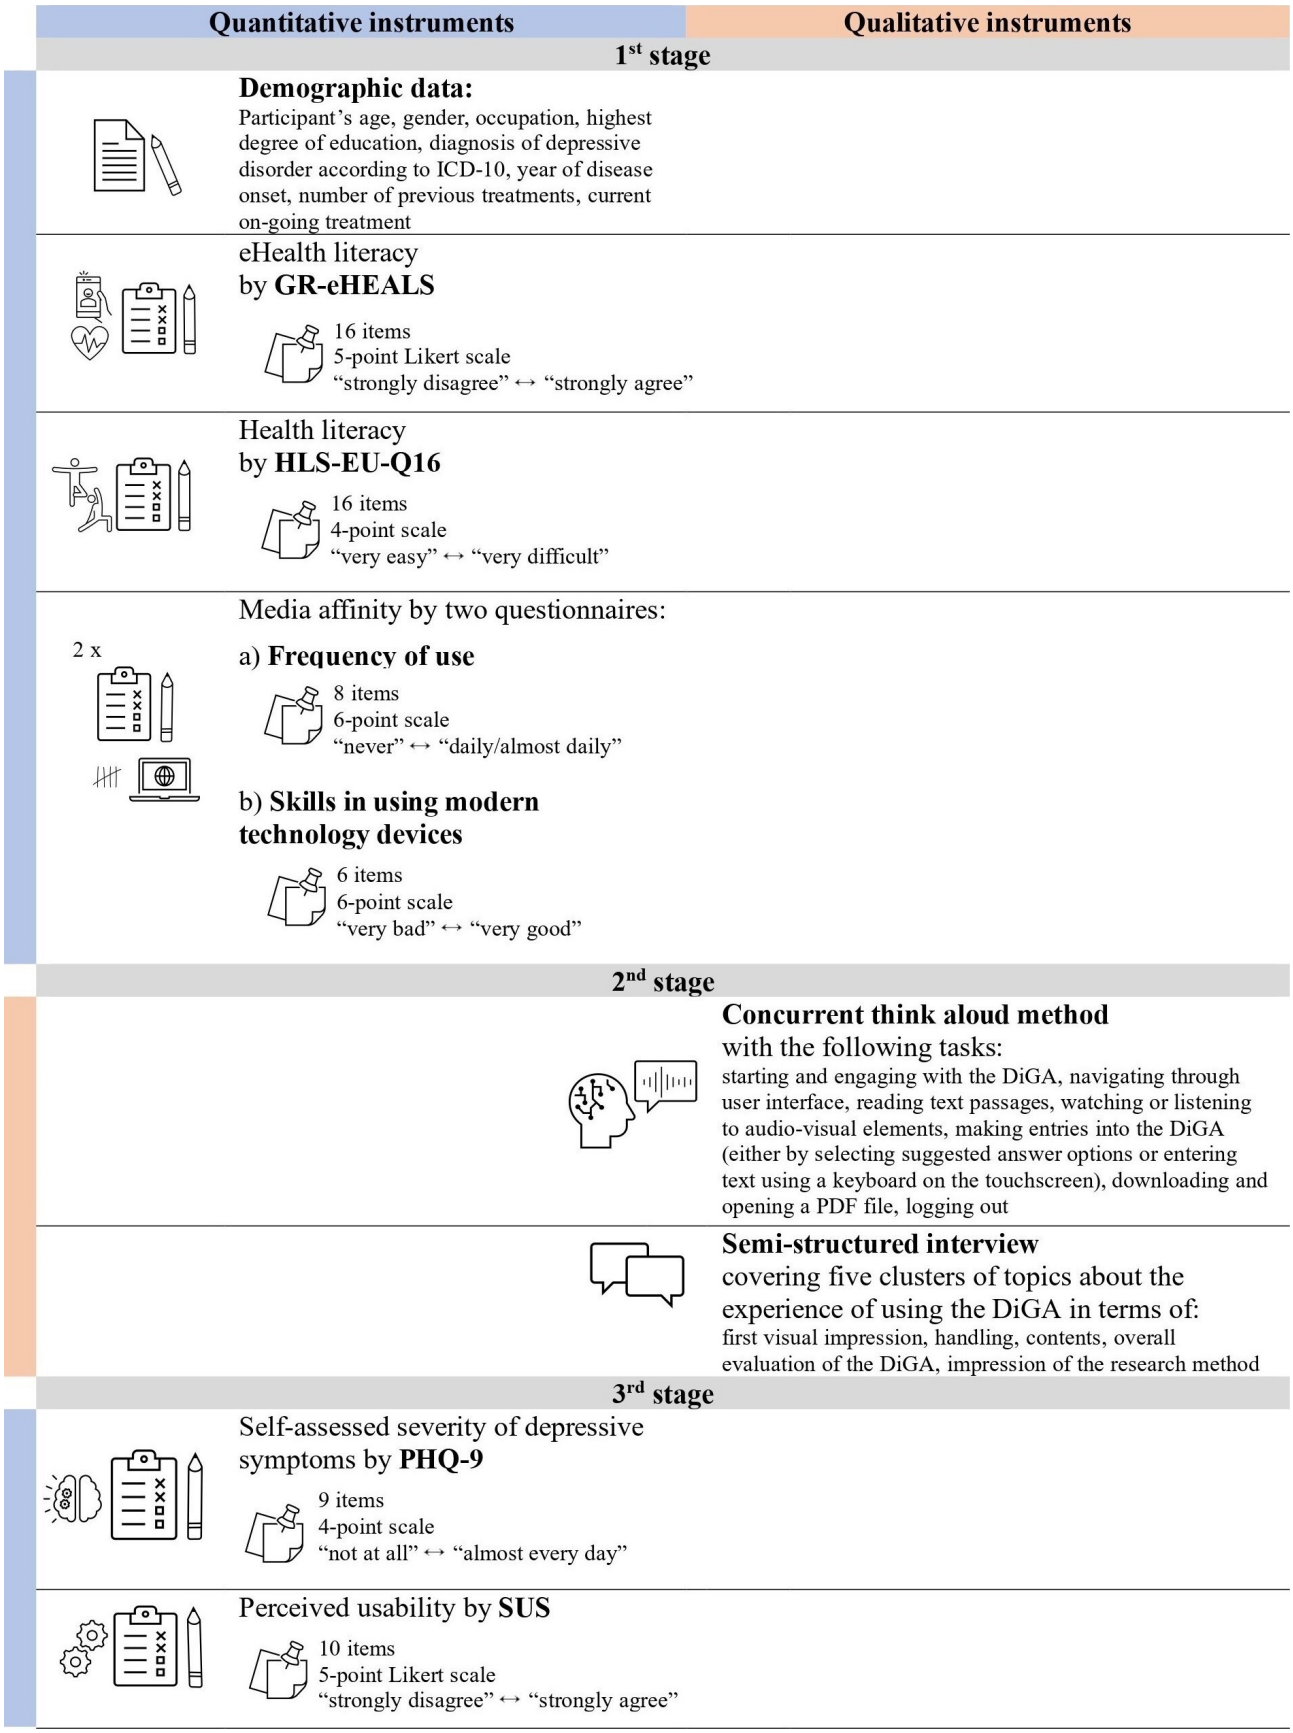
Procedures

The evaluation of the DiGA is based on the PACMAD usability model (Figure 1 [22]), which combines usability models developed by the International Organization for Standardization [26] and Nielsen [27] with an additional focus on mobile applications [22].

XSL•FO
RenderX

Figure 1. PACMAD usability model (own representation, based on a study by Harrison et al). ISO: International Organization for Standardization; PACMAD: People at the Centre of Mobile Application Development.

The PACMAD usability model addresses 7 usability attributes in total: effectiveness, efficiency, satisfaction, learnability, memorability, errors, and cognitive load [22]. The latter attribute, as an additional component to existing usability models, is considered the main contribution of the PACMAD model. Within the scope of those attributes, 3 further factors can influence the overall usability: user (eg, previous experiences interfering with overall usability), task (eg, goals of users), and context of use (eg, environment of use) [22].



The data collection incorporated quantitative instruments in the first and third stages and qualitative instruments in the second stage (Figure 2) [28-32].

The revised German eHealth Literacy Scale (GR-eHEALS), the European Health Literacy Survey Questionnaire (HLS-EU-Q16), and the System Usability Scale (SUS) were used. During the third stage, a validated questionnaire was used for the self-assessment of the severity of depressive symptoms. The PHQ-9 is a widely used screening instrument for assessing depressive symptoms, based on *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*) criteria. Its brevity, diagnostic utility, and ease of administration make it especially suitable for use in population-based studies, including those involving older adults. The German version of the PHQ-9 was developed through a rigorous process of translation and back-translation, ensuring cultural and linguistic equivalence. Validation studies conducted in Germany have confirmed the semantic and conceptual appropriateness of the questionnaire for older German speakers [31]. In the German older adult population, the PHQ-9 has shown good criterion validity, with sensitivity and specificity levels that are consistent with its performance in younger populations. For instance, Kocalevent et al [33] reported a sensitivity of 81% and specificity of 89% at the standard cutoff score (≥10) when compared with structured clinical interviews. On the basis of these findings, the PHQ-9 can be considered a valid and reliable instrument for assessing depressive symptoms in older adults in Germany.

The concurrent think-aloud method [34] is a common procedure in the field of digital health care for testing technologies in terms of usability, content, and accuracy of fit [27]. It enables researchers to trace the user's course of action and reveals emerging usability issues [35] while offering insight into the users' cognitive and emotional reactions and processes [36]. The tasks were based on typical activities during initial use. Furthermore, semistructured interviews were conducted to gather participants' individual experiences and impressions after using the DiGA, enabling comparability while accommodating participants' personal perspectives [37]. The second stage included audio recording as well as video capturing of the participant's screen activity during DiGA use.

XSL•FO
RenderX

Data Analysis

Quantitative data were analyzed by descriptive statistics using the statistical software package SPSS Statistics 27.0 (IBM Corp). Measures of central tendency were calculated for the comparison of individual items or sum scores between individual participants or between the groups. Reporting includes both the mean with SD and the median with IQR. To prevent case exclusion due to missing values, median imputation was applied to 2 individual responses within the eHEALS and SUS instruments.

The extraction and synthesis of qualitative data were carried out according to Rädiker and Kuckartz [38] using the software MAXQDA 2022 (VERBI Software GmbH). The predefined attributes of the PACMAD model were used as the main category system, supplemented by an additional category on methodology.

Initially, 2 researchers (MC and TSB) independently coded 1 Selfapy assessment and discussed the resulting variations and discrepancies to set a standard. The remaining 17 assessments were coded (MC), and uncertainties across all videos were discussed (MC and TSB).

To ensure interrater reliability, 4 assessments were reevaluated by 2 researchers (ICO and TSB), with each researcher rating 1 Selfapy and 1 deprexis assessment from 2 distinct hospital departments. In total, 5 of 18 assessments were viewed twice.

The triangulation of both quantitative and qualitative datasets (Figure 3) [22,28-32] ensured a comprehensive interpretation of the PACMAD usability model. The factors user, task, and context of use are interconnected and compared across DiGA groups.

Figure 3. Triangulation matrix (own representation). GR-eHEALS: revised German eHealth Literacy Scale; HLS-EU-Q16: European Health Literacy Survey Questionnaire; PACMAD: People at the Centre of Mobile Application Development; PHQ-9: 9-item Patient Health Questionnaire; SUS: System Usability Scale.

gender	age	PHQ-9	HLS-EU-Q16	GR-eHEALS	frequency of use	skills of use	SUS	PACMAD	evaluation of the think aloud method

Results

Overview

A total of 18 evaluable assessments were conducted; 1 additional assessment could not be evaluated due to a technical malfunction of the recording equipment. Thus, each DiGA is represented by 9 assessments, equally covered by 3 per hospital department. All assessments were carried out with a study tablet, using the web-based application of both DiGA.

Quantitative Findings

Quantitative data were analyzed for 18 participants aged 61 to 88 years, with an almost equal distribution in both groups. The participants' average age was 68.3 (SD 9.6) years, and the majority (n=14, 78%) were women. Each group consisted of 7 women and 2 men. All but 3 participants were no longer employed (n=15, 83%).

On average, participants scored 12.4 (SD 5.2) on the PHQ-9, indicating moderate depression. Eight (44%) participants, 3 from the deprexis and 5 from the Selfapy group, were undergoing outpatient depression treatment at the time of data collection.

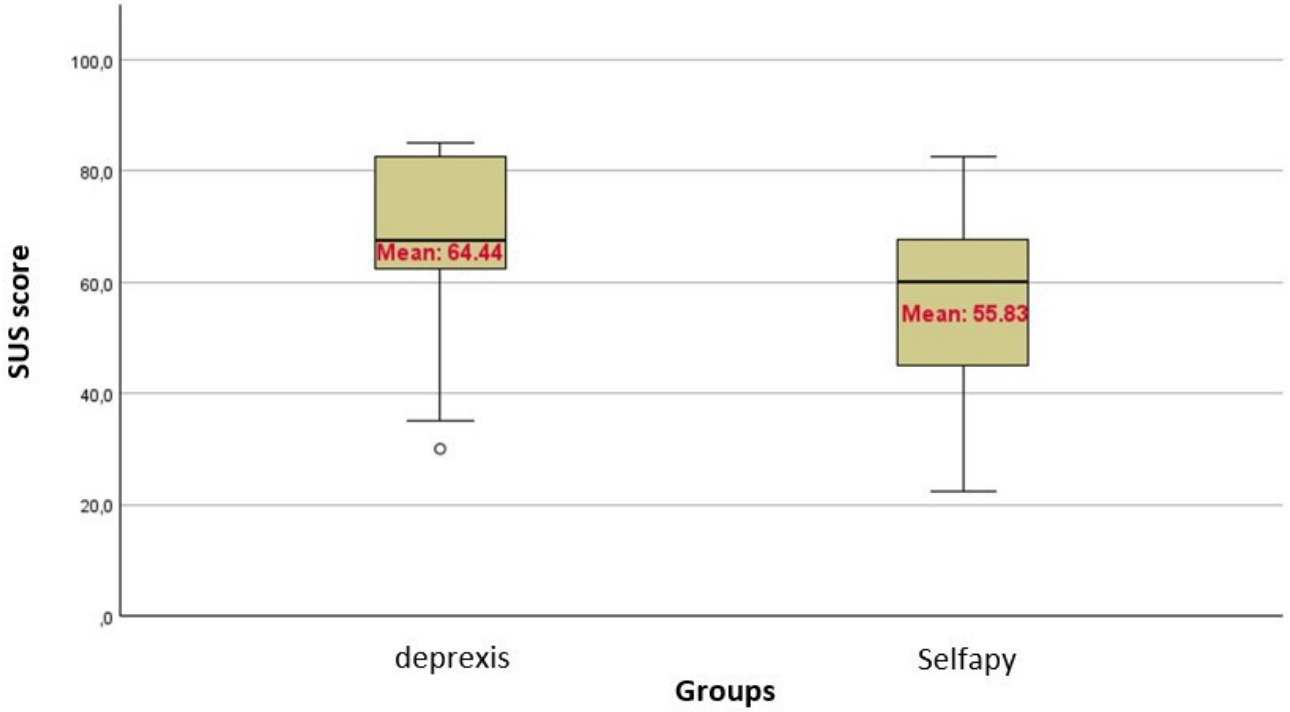
Similar results were observed in both groups for the HLS-EU-Q16, indicating moderate to good health literacy (scale 16 - 64) and for the GR-eHEALS, which represents moderate electronic health literacy (scale 16 - 80; Table 1). A total of 17 (94.4%) participants reported using a smartphone daily or almost daily. Although purposeful sampling was applied, participants in the Selfapy group showed lower media affinity overall, both in terms of usage frequency and self-assessed technology skills. The findings on media affinity are based on the assessment of individual items, as the questionnaires are not validated for a score.

XSL•FO
RenderX

Table . Patient-reported parameters.

	Deprexis (n=9)		Selfapy (n=9)		Total (N=18)	
	Mean (SD)	Median (IQR)	Mean (SD)	Median (IQR)	Mean (SD)	Median (IQR)
Age (years)	68.33 (10.11)	63.00 (62.00-77.00)	68.22 (9.64)	63.00 (62.00-76.50)	68.28 (9.58)	63.00 (62.00-74.25)
Depressive severity (PHQ-9[a]) [31][b]	12.11 (4.59)	13.00 (8.50-15.50)	12.63 (6.19)	12.50 (6.50-16.50)	12.35 (5.23)	13.00 (8.00-15.50)
Health literacy (HLS-EU-Q16[c]) [29]	45.78 (5.65)	48.00 (42.00-50.00)	46.33 (8.79)	46.00 (38.00-54.50)	46.06 (7.17)	47.00 (41.25-50.00)
Electronic health literacy (GR-eHEALS[d]) [28]	51.89 (6.03)	52.00 (47.00-57.50)	48.75 (14.48)	47.00 (41.00-57.00)	50.41 (10.60)	49.00 (46.50-56.00)
System Usability Scale [32]	64.44 (20.03)	67.50 (48.75-82.50)	55.83 (18.29)	60.00 (41.25-68.75)	60.14 (19.13)	62.50 (43.125-75.00)

[a]PHQ: 9-item Patient Health Questionnaire.



[b]For PHQ-9, the sample size was 17 (n=8 for Selfapy) due to missing data from 1 participant.

[c]HLS-EU-Q16: European Health Literacy Survey Questionnaire.

[d]GR-eHEALS: revised German eHealth Literacy Scale.

The usability assessment by SUS showed a higher level of user-friendliness for deprexis with an average score of 64.4 (SD 20.0) compared to Selfapy with 55.8 (SD 18.3). It is important to consider the SUS scores alongside participants' individual skills, as they affect the DiGA's perceived usability. Table 1 provides an overview of the self-reported patient parameters, and Figure 4 shows the SUS score distribution using a boxplot to visualize and compare the scatter, central tendency, and outliers across both groups.

Figure 4. SUS score. SUS: System Usability Scale.

Qualitative Findings

Overview

Qualitative findings are presented using the main categories, combining the results for Selfapy and deprexis. The evaluation dimension of the categories differs: while effectiveness, efficiency, and errors were solely evaluated externally by the researcher, satisfaction represents a category that only the participant could self-assess. Learnability, memorability, cognitive load, and the handling of the think-aloud method could be assessed by the participant's comments and through the researcher's observation.

XSL•FO
RenderX

Methodology

Responses to the think-aloud method varied: Selfapy participants rated it either as not disturbing at all or as stressful. Positive comments in the deprexis group outweighed, although some users struggled with verbalizing their thoughts. A few participants requested that the texts be read aloud, finding it challenging to manage both the printed instructions and the digital device.

Learnability

The category learnability describes the ease with which proficiency can be achieved [22]. Participants in both groups were eager to enhance their proficiency and expressed a desire to gain more confidence. They acknowledged that while learning requires repetition, it was generally manageable. A few participants lacked basic technical understanding and asked, for instance, what a PDF file is or how to adjust the volume. Despite initial challenges, some skills were learned even during first-time use, such as scrolling, identifying the menu icon, opening the keyboard, and zooming. Navigation was found to be learnable, and repetition of certain tasks led to faster performance. Participants recommended more guidance for using DiGA, noting the study conductor's help was valuable. They noted that, especially for older people without technical experience, the first use could be difficult.

Effectiveness, Efficiency, and Errors

The category effectiveness describes whether a task is completed by the user. Efficiency considers the speed and accuracy of completion, reflecting the user's productivity. Furthermore, the PACMAD model proposes an evaluation of the errors made while using an application [22].

Most tasks were completed successfully, although often with the assistance of the study conductor. Both groups faced touchscreen issues, causing frustration (eg, having to tap multiple times). Both DiGA presented navigation challenges, including orienting within chapters, finding PDF files, returning to the main page or the previous section, and the logout process. Reading and comprehension issues stemmed from small font size or unclear instructions and questions within both DiGA.

In Selfapy, the chapter overview layout led to confusion, with participants expecting immediate access to the chapter upon clicking. Other challenges included scrolling, selecting between answer options, and entering text via the touchscreen keyboard. Owing to Selfapy's user interface design, participants often missed the *next* button after completing 1 specific task and were confused about how to proceed. The required choice between 2 video formats (web based or app based) caused uncertainty about which video to watch. Selecting the wrong format resulted in limited visibility. Two participants in the Selfapy group terminated the assessment before completing all the tasks.

Deprexis users encountered similar but fewer issues. Specifically, some users failed to open a PDF file, as they clicked on the adjacent nonresponsive description instead of the PDF icon. They additionally faced difficulties locating the menu, as they were not familiar with the menu symbol. In some cases, the audio file was either overlooked or not played, despite having been noticed.

Satisfaction

The user's attitudes toward the DiGA provided insight into their satisfaction with using it [22]. Difficulties with navigation and the handling of the DiGA were recognized by the participants. One-third of the Selfapy users found the menu navigation and overall user interface pleasant, well structured, and intuitive, whereas the majority criticized the navigation as unintuitive and difficult to understand, requiring assistance in the beginning. Some participants suggested that repeated use could lead to improvement. One participant showed clear signs of frustration due to navigation difficulties.

In contrast, two-thirds of deprexis users perceived the DiGA as well structured and easy to navigate, whereas the remaining third found the navigation to be difficult and unintuitive. The main page and the beginning of the assessment were perceived as positive and accessible. Suggestions included clearer menu labels and a single-column layout of the menu to improve navigation.

Regarding design and layout, participants liked Selfapy's appearance, although some found the font size too small and the color contrast insufficient, restricting visibility. Deprexis was well received for its simple, clear interface, although opinions varied on visual elements and color use. The presentation of information was praised as well arranged, but participants recommended increasing the PDF font size. With regard to the general font size, while no negative feedback was given, 2 participants noted it was sufficiently large.

Content and the functions of both DiGA were generally perceived positively. The information was found to be presented in accessible language, with adequate depth and structure. The content was described as interesting, informative, and helpful; however, participants criticized the text in both DiGA as overly lengthy. They suggested an audio playback feature to resolve this concern. Some participants found the answer options limiting, whereas others praised the possibility of individual choice. Besides Selfapy's diary function and support options, the video was praised for its content, graphics, and brevity, although participants suggested moderating the voice-over pitch and reducing the pace.

Deprexis users appreciated the mood check, despite some criticism of its retrospective nature, and expressed a desire for additional support during completion. The overall guidance and motivation provided by deprexis, along with the relaxation exercises and the required responses, were well received. The audio element was praised for being engaging, clear, and memorable, with a pleasant voice quality and appropriate length.

The adoption of Selfapy for long-term use was met with mixed reactions. Some users were deterred by technical constraints and uncertainty about the effectiveness of managing illness. Others showed readiness to use DiGA, encouraged by its interactive nature and constructive suggestions. However, reluctance persisted due to general skepticism or insufficient technical equipment. Overall, the sentiment toward Selfapy was

XSL•FO
RenderX

cautious yet open to possibilities, with a clear need for support and reliable information.

In contrast, deprexis users approved of the DiGA, finding it a reliable aid. Many participants were open to using it regularly, particularly during critical health periods, and valued its potential at the onset of the disease to bridge therapy waiting times. Participants saw deprexis as a valuable addition to therapy but were unsure about its usefulness for individuals with severe depression. Some preferred personal interaction over the digital interface, whereas others liked the independence it offers. Concerns were raised regarding the data security of the diary feature, despite its perceived benefits. Doubts persisted regarding DiGA's capacity to meet individual needs and its potential to replace consultations with a therapist. A common concern was that using the DiGA alone could be overwhelming, prompting suggestions for an introductory course.

Cognitive Load

Cognitive load addresses the extent of cognitive processing while using an application [22]. Difficulties were prominent in this study: participants struggled with text comprehension and production, felt overwhelmed and insecure, and had memory and concentration lapses. These difficulties impacted their self-assessment. Both DiGA user groups faced these issues, but Selfapy was perceived as particularly challenging.

Selfapy users often struggled to grasp certain terms and instructions within the DiGA, frequently asking additional questions for clarity. They felt overwhelmed by the complexity and amount of content, struggled to articulate their thoughts in written form, were concerned about grammatical or spelling errors, and noted a decline in ability associated with age. Some Selfapy users stated that they had reached their individual limit at times and voiced uncertainty about their ability to concentrate and retain information after a single reading. Selfapy users experienced a powerful sense of self-doubt and insecurity. Despite their efforts, they harshly attributed mistakes to their own reduced intelligence and technical skills, rather than considering external factors or task complexity.

Deprexis users preferred shorter texts than those provided, despite understanding the content, and encountered minor comprehension difficulties with some tasks and instructions within the study. No serious confusion during the usage of deprexis was observed. Challenges included reduced focus due to illness, racing thoughts, and a reliance on routines to manage depression. Participants also expressed concern about self-esteem and mood assessment, which both influence cognitive processing.

Memorability

Memorability is defined as the user's ability to retain how an application is used effectively [22]. A second assessment is typically needed to evaluate memorability, but initial difficulties were evident during first-time use. From the participants' perspective, the video in Selfapy contained an excessive amount of information, with participants unable to remember important instructions, such as how to log off. Some did not recall watching a video at all when asked. Deprexis users also showed a few signs of limited memorability: 1 participant filled out the mood check twice without realizing it, and 2 participants forgot about the audio element when asked about it. A reminder feature was proposed for consistent DiGA use.

Discussion

Principal Findings

This prospective observational study gives new insights into the usability of DiGA for older adults with regard to depression, particularly focusing on deprexis and Selfapy, which were the first 2 permanently approved DiGA for depressive disorders. By focusing on participants aged ≥60 years, this research addresses the disparity in usage among older individuals, who have not been adequately represented in previous research. The study advocates for a user-centered approach in DiGA development on the basis of the PACMAD model. The study used a mixed methods approach. While the user groups were comparable in age, gender, severity of depressive symptoms, and health literacy, Selfapy users reported slightly lower technical proficiency and usability scores. Design flaws and increased cognitive load were reported by the participants of the Selfapy group. Despite visual, motor, and cognitive challenges, participants in both groups emphasized the need for support and practice in the use of DiGA for older adults.

A study by Wildenbos et al [39] on barriers to digital health among older adults identified 4 main categories of age-related barriers that can affect the usability of mobile health: physical abilities, perception, cognition, and motivation. Similar findings emerged from the present qualitative study results, corroborating the slightly lower SUS score for Selfapy compared to deprexis.

Barriers to Physical Abilities

Visual and psychomotor limitations were observed universally in both groups and were also evident in the participants' criticism regarding difficulties in using the touchscreen and navigation. Wildenbos et al [39] also reported that other studies had found slowed movements, reflexes, and tremors to be a challenge. It is assumed that these physical limitations may also affect learning duration, speed of performance, error rate, time retention, and subjective satisfaction.

Barriers to Perception

Barriers of perception were reflected in the early termination of 2 Selfapy assessments, increased error rates due to design limitations, and more moments of confusion and uncertainty with navigation, indicating usability constraints. In addition, small font size and poor color contrast were criticized. Wildenbos et al. [39] highlight the need for enhanced lighting to support visual clarity, as well as implications for video content and alerts due to the age-related decline in hearing ability. Hearing difficulties may also result in lower use of desktop computers and internet services compared to older adults without hearing impairments [40].

Barriers to Cognition

Selfapy users also experienced pronounced cognitive load. Some participants showed reduced concentration and struggled with text comprehension. This area may be less prominent in the present study compared to the study by Wildenbos et al. [39],

XSL•FO
RenderX

identifying potential challenges because this study did not include individuals with cognitive impairments. However, the participants' illnesses must be considered as a contributing factor.

Barriers to Motivation

Motivation is one of the key factors influencing the acceptance of technology [41]. Acceptance theories can provide exciting insights in this regard. Although the present study initially focused on usability, tentative conclusions can be drawn regarding this barrier: Selfapy users were more self-critical when faced with challenges. A reason for this could be the lower level of proficiency with modern technology reported by Selfapy users. Here, the mixed methods approach proved to be helpful in capturing specific impressions during use, in addition to the SUS.

Help with increasing motivation can be found in the literature: a systematic review examined the extent to which characteristics of the design and implementation of digital interventions can increase adherence among vulnerable population groups (older people, people with low socioeconomic status, single parents, social minorities, and people with a migration background). The authors state that multimodal content and direct opportunities for interaction and support between users and intervention providers can increase usage [42].

Interventions for Successful Implementation

Although participants encountered difficulties, they were mostly satisfied with both DiGA and expressed encouragement for long-term use. Successful long-term use depends particularly on actual use in everyday life. It is important to note that digital psychological treatment may have higher dropout rates compared to analog options [43]. A key factor in this area is adherence. A systematic review of adherence to digital interventions for mental health conditions found that female gender, positive treatment expectations, and the availability of personal support can increase adherence. Negative factors include limited time for engagement, personal dissatisfaction with the intervention content, or content perceived as impersonal [44]. The positive assessment of personal support was also evident in this study because both user groups rated their assigned DiGA as suitable for older people, emphasizing the necessity to practice the usage.

Although most of the tasks were successfully completed, participants received light support from the study conductors during use to reduce psychological strain. In traditional postprescription use, such support would not be available. The authors, therefore, expect participants to have more difficulty coping with the application, despite its approval through the DiGA authorization procedure. Structured support could potentially be helpful in this context. For example, it became apparent that a structured support system using weekly brief semistandardized emails achieved a high level of effectiveness for a digital mental health application [45]. Other studies on the use of mobile apps for mental health among older users also support the value of this approach [46-48].

Moreover, explicit guidelines and recommendations for developers could be beneficial in mitigating usability-related challenges. While such recommendations should not be derived solely from pilot studies focusing on usability, such as this study, there is a substantial body of design research that provides well-founded guidance in this area. For instance, Gomez-Hernandez et al [49] conducted a systematic review and thematic analysis on design guidelines for mobile applications targeted at older adults. Their study identified a total of 27 key recommendations, including 2 "golden rules" and 25 design principles, which were organized into 5 thematic categories: support and training, navigation, visual design, cognitive load, and interaction.

Strengths and Limitations

The distributions must be interpreted with caution due to the small sample size: it increases the variability of the data and limits the statistical validity of the results. In particular, outliers can distort the overall picture and thus impair the reliability of the conclusions derived.

This study gives new insights into the usability of DiGA for older adults with regard to depression, particularly focusing on deprexis and Selfapy, which were the first 2 permanently approved DiGA for depressive disorders. By focusing on participants aged ≥60 years, this research addresses the disparity in usage among older individuals, who have not been adequately represented in previous research. The study advocates for a user-centered approach in DiGA development on the basis of the People at the Centre of Mobile Application Development usability model. The distributions must be interpreted with caution due to the small sample size: it increases the variability of the data and limits the statistical validity of the results. In particular, outliers can distort the overall picture and thus impair the reliability of the conclusions derived.

On the basis of the information assessed by the GR-eHEALS and the 2 questionnaires on media affinity, the participants in the Selfapy group showed slightly lower proficiency in using modern technology than those in the deprexis group, which could have influenced the usability assessment.

Although the process of actively verbalizing one's thoughts is assumed to be unfamiliar, the participants were largely unaffected by the methodology. However, it must be taken into consideration that 3 different study conductors (1 per hospital department) were involved in data collection. Although the study settings through uniform training of the involved study members, minor procedural differences were nonetheless observed.

Another limitation arises from the target group of the study. Depressive disorder is characterized by symptoms such as attention deficits and lack of motivation. This may have impacted the perceived ease of use, although this effect cannot be conclusively demonstrated. However, we considered it crucial to focus on this target group to better understand the challenges faced by this underrepresented group. It is also important to note that participants were recruited directly from clinical practice. This approach was criticized in a meta-study on the effectiveness of deprexis, as the participants in those studies were recruited outside the clinical context, potentially compromising the transferability of the results [50].

RenderX

Further Research

Larger controlled studies will be needed to replicate the findings and explore further moderators of usage outcomes. While the PACMAD usability model was designed specifically for assessing the usability of mobile applications and takes cognitive load into account, other factors influencing general technology acceptance are not considered.

The subsequent study of the DiGA4Aged project, which is the pilot study, will also examine technology acceptance and the success of support provided to participants by a digital nurse within an RCT. In the future, studies incorporating an acceptance model such as the Unified Theory of Acceptance and Use of Technology [51], which focuses more on general technology acceptance and less on mobile-specific use, will provide valuable insights. Furthermore, research on the implementation of DiGA for this specific patient group could be undertaken, possibly considering the Consolidated Framework for Implementation Research [52].

Conclusions

The findings of this study highlight the need to enhance the accessibility and usability of DiGA for older adults with depressive disorders, who face unique challenges due to age-related sensory, motor, and cognitive changes. In addition, the results show that usability was perceived as lower in the Selfapy group, primarily due to design-related factors of the application. Users in this group reported experiencing greater cognitive load. Participants in both groups emphasized the importance of receiving support when using the DiGA and expressed their desire to continue using it. However, further research is required to identify potential support measures for the use of DiGA by older adults, as well as factors influencing adherence. This way, DiGA can become more accessible and beneficial, ultimately reducing health care disparities and enhancing the quality of life for this vulnerable group. There is a necessity to take into account the needs of the target groups of DiGA in the authorization process and increase efforts to offer older adults support to bridge the digital divide. Considering the study's results and limitations, the decision of the DiGA to be used in the upcoming RCT was made in favor of deprexis.

Acknowledgments

The authors would like to thank the manufacturers for providing test accounts of Selfapy and deprexis free of charge for the duration of the study as well as the participants for their time. There was no further support, especially no financial support from the manufacturers. The authors would also like to acknowledge all members of the DiGA4Aged research group, in particular Hannes Bergmann and Tanja Roth from the hospital departments, for conducting the study.

This work was funded by the Innovations-FoRUM of the Medical Faculty at Ruhr University Bochum (funding code IF-025-22).

Data Availability

Data can be provided upon reasonable request to the first and last two authors.

Authors' Contributions

AM, GJ, HCV, JDH, NT, RW, and TSB conceived the study. ICO, JB, MC, MP, and TSB designed the study. BU, CG, JDH, and MP contributed to the collection of data. MC did the data analyses, with assistance from KK, who analyzed the quantitative data. ICO and TSB verified the data. MC prepared the first draft of the manuscript. All authors critically reviewed the manuscript before seeing and approving the final version.

Conflicts of Interest

None declared.

Abstract

Background: The use of mobile technologies during high-risk pregnancy, placing patients at the center of care, affords them self-management and easier access to health information.

Objective: This study aims to understand the health perception of pregnant women at the beginning of high-risk antenatal care, the usability of a mobile health app—the Health Assistant—and to compare maternal-fetal outcomes between users and nonusers of the app.

Methods: This is an observational longitudinal cohort study that looked into clusters of high-risk pregnant women admitted to antenatal care at the maternity unit of a public university hospital in southern Brazil between April 2022 and November 2023. Pregnant women who did not have a compatible smartphone to download the app or who did not have internet access were excluded from the study. According to systematic randomization, one patient was allocated to the app group and the other to the control group. They all answered an inclusion questionnaire (Q1), and those in the app group were instructed to use the Health Assistant app to prepare for their first antenatal appointment, which would take place in a few weeks' time, when they would answer the Brazilian version of the Mobile App Usability Questionnaire. After childbirth, maternal-fetal outcomes were assessed. Student 2-tailed *t* test, Mann-Whitney test, Fisher exact test, and the chi-square test were used for statistical analysis. A hierarchical cluster analysis was performed using the Ward method and the Euclidean squared distance measure.

Results: The sample contained 111 pregnant women, of whom 55 (49.5%) were allocated to the app group and 56 (50.5%) to the control group. Of the 55 pregnant women who used the app, 21 (38.2%) demonstrated adherence, with an average Mobile App Usability Questionnaire score of 6.2 (SD 1.0). Clustering included 110 pregnant women, and the dendrogram resulted in three clusters, which show several significant differences in terms of family income, medical history, medication adherence, and lifestyle habits. Cluster 2 had the lowest adherence to the app (P=.08) and attended significantly fewer antenatal appointments (6.9 appointments) as compared with Clusters 1 (10.3) and 3 (9.1; P=.006). Cesarean section was more frequent in Cluster 3 (n=41, 95.3%) as compared with Clusters 1 (n=12, 27.9%) and 2 (n=5, 20.8%), P<.001.

Conclusions: Cluster analysis, revealing different profiles of pregnant women, allowed us to identify groups that would benefit from personalized approaches and digital interventions to improve self-awareness and gestational outcomes. The Health Assistant app showed good usability in this context.

Introduction

Mobile health (mHealth) is defined as medical and public health practice aided by mobile devices such as cellphones, patient monitoring tools, personal digital assistants, and other wireless equipment [1,2]. In Brazil, smartphone price reduction and improved connectivity facilitating access to device functionalities have had a major impact on health care with useful tools for professionals and patients alike [3,4]. As part of patient care, mHealth apps aim to promote well-being, emotional, psychological, and physical growth, to increase accessibility to health services in remote areas, and to make processes faster and more precise [2,4-6]. The use of mHealth technologies during pregnancy and the postpartum period has become more common with the advance of information and communication technologies [7,8].

Despite the great educational potential and the increasing popularity of health apps, rigorous scientific evaluation of their effectiveness is still limited, and there is an insufficient number of studies using standardized methods to guarantee their performance and safety [8,9]. DeNicola et al [8] conclude that these apps should be developed with the cooperation of health professionals. An ideal app, resting on scientific evidence, respecting the law, and protecting privacy, should also be user-friendly, attractive, simple, and functional, deploying device sensors and resources for the good of the patient [10]. The use of this technology can thus prove a valuable strategy for health self-management, transforming patient experience by affording greater autonomy and ease of access to care [11].

High-risk pregnancy—when medical conditions or specific pregnancy factors can compromise the health of the mother or the fetus—has an approximate prevalence of 22% [12,13]. This condition can intensify stress and impact the psychological health of pregnant women, worried about possible interventions, hospitalizations, and treatments [14]. The very label “high-risk pregnancy” can contribute to additional stress, as concerns may focus rather on treatments and tests than on the woman’s overall well-being, but it should also lead to greater medical vigilance, which can be perceived either positively or negatively by the patient [12].

In these cases, patient-centered communication yields positive results, since a more humanized and integrative approach can significantly improve the quality of care [15]. Several studies show that a person-centered approach improves satisfaction, reduces costs, and increases the effectiveness of treatments, especially in patients with chronic conditions [15]. In this context, the use of mobile technologies places the patient at the center of care, offering a new experience that enables health self-management and easier access to information and services [11]. A systematic review identified that in 74.3% of the studies, mHealth intervention was cost-effective, but indicated that more research is needed in low- and lower-middle-income countries for the impact of different types of mHealth to be better understood [16].

Furthermore, cluster analysis, considered a relevant method of classifying women in early pregnancy, is another way of drawing attention to the follow-up of high-risk pregnant patients [17]. By identifying homogeneous groups, it allows risk factors to be detected, as well as patterns and trends in pregnancy outcomes to be understood [18,19].

Since longitudinal follow-up with no information gaps is essential for proper antenatal care, an mHealth app produced by health professionals could help prepare high-risk pregnant women for their first antenatal appointment at a maternity unit of a public university hospital in southern Brazil. An easy-to-use app called Health Assistant was expected to have positive effects on both the pregnant woman and the child.

The aim of this study was to evaluate the health perception of pregnant women starting high-risk antenatal care in a low-income country, the usability of the Health Assistant, and maternal-fetal outcomes among app users and nonusers so that we could identify those groups of patients who benefit most from the app and thus provide focused assistance in order to optimize care and obstetric outcomes.

Methods

Recruitment

Pregnant women were included upon admission to high-risk antenatal care at the maternity unit of a public university hospital in southern Brazil between April 2022 and November 2023. High-risk pregnancies were characterized by chronic conditions or those diagnosed during pregnancy, such as hypertension, gestational diabetes, and mood disorders. Primary care referral was the gateway to this care.

Pregnant women who did not have a compatible smartphone to download the app or who did not have internet access, even when the researchers provided a router, were excluded from the study. After accepting and signing the informed consent form, participants were included in the study and allocated, according to systematic randomization with random start, to one of the groups: app or control. The first patient was drawn at random and allocated to the app group, and the others were then assigned in an interleaved manner: the second to the control group, the third to the app group, the fourth to the control group, and so on. Thus, we created two balanced groups—one invited to use the app and the other not invited—without supervision or imposition of use. Although the allocation was random, the study maintained an observational design, as the actual use of the app was at the discretion of the participants and there was no controlled intervention beyond the invitation.

Every patient answered the inclusion questionnaire (Q1), consisting of 32 questions about their social, economic, and health profile. Those allocated to the app group were instructed to use the Health Assistant app to prepare for their first antenatal appointment, which would take place in a few weeks’ time. The digital tool was used without supervision or direct control by the researchers and allowed patients to answer detailed questions about their current pregnancy and their gynecologic-obstetric history. Our objective was to evaluate, in the context of routine clinical practice, the associations between digital engagement and maternal-fetal outcomes, and not to test a controlled intervention protocol.

XSL•FO
RenderX

At the first antenatal appointment, researchers met with participants from the app group and had adherents to the app answer the Brazilian version of the Mobile App Usability Questionnaire (MAUQ).

Ethical Considerations

This is an observational longitudinal cohort study approved by the Institutional Ethics Committee of the Hospital de Clínicas Complex (47084021.5.0000.0096). All participants provided written informed consent before enrollment in the study. Participants' personal data were anonymized to preserve confidentiality and privacy. No financial or other compensation was offered for participation.

MAUQ

MAUQ was chosen because it is a widely recognized tool in the literature for evaluating the usability of mHealth apps. Developed and validated in English by Zhou et al [20], the MAUQ is highly reliable with a Cronbach α of 0.914. The questionnaire was translated into Portuguese by Machado et al in accordance with the guidelines for translation and cross-cultural adaptation of nontechnical skills assessment instruments, ensuring similarity between the original and the translation. Permission to use the translation was kindly granted to the researchers (personal communication by Machado, 2022). For this study, we used the version of the MAUQ for stand-alone digital health apps intended for patients to control, manage, and improve their health care. The questionnaire assessed the following parameters: ease of use, interface, satisfaction, and usefulness. Participants rated each item using a 7-point Likert Scale, ranging from 1=strongly disagree to 7=strongly agree. The usability of the app was determined by the total score and the averages of all the questionnaires answered, where a higher score indicates greater usability [20]. In our study, the MAUQ was administered to patients who were considered adherent, that is, who reported having used the app.

Outcome Analysis

After the expected date of delivery, researchers retrieved their medical records to analyze maternal-fetal outcomes, including the number of antenatal appointments, the number of emergency room visits during antenatal care, intercurrent events, date of delivery, route of delivery, complications, and length of stay for mother and baby, among others. The information collected was organized and filed in spreadsheets for statistical analysis.

Cluster Analysis

Clustering is a technique for organizing a large amount of information into smaller groups so that hidden patterns and relationships between the data are identified and personalized interventions are developed [21,22]. This method was chosen because of its effectiveness in identifying the hierarchical structure of binary data without the need to specify the number of desired clusters beforehand. It also promotes greater homogeneity within clusters and is easy to replicate, making it applicable to various types of data [21,23,24]. Based on the characteristics and outcomes of each cluster, it is possible to develop antenatal care strategies that optimize patient-centered care.

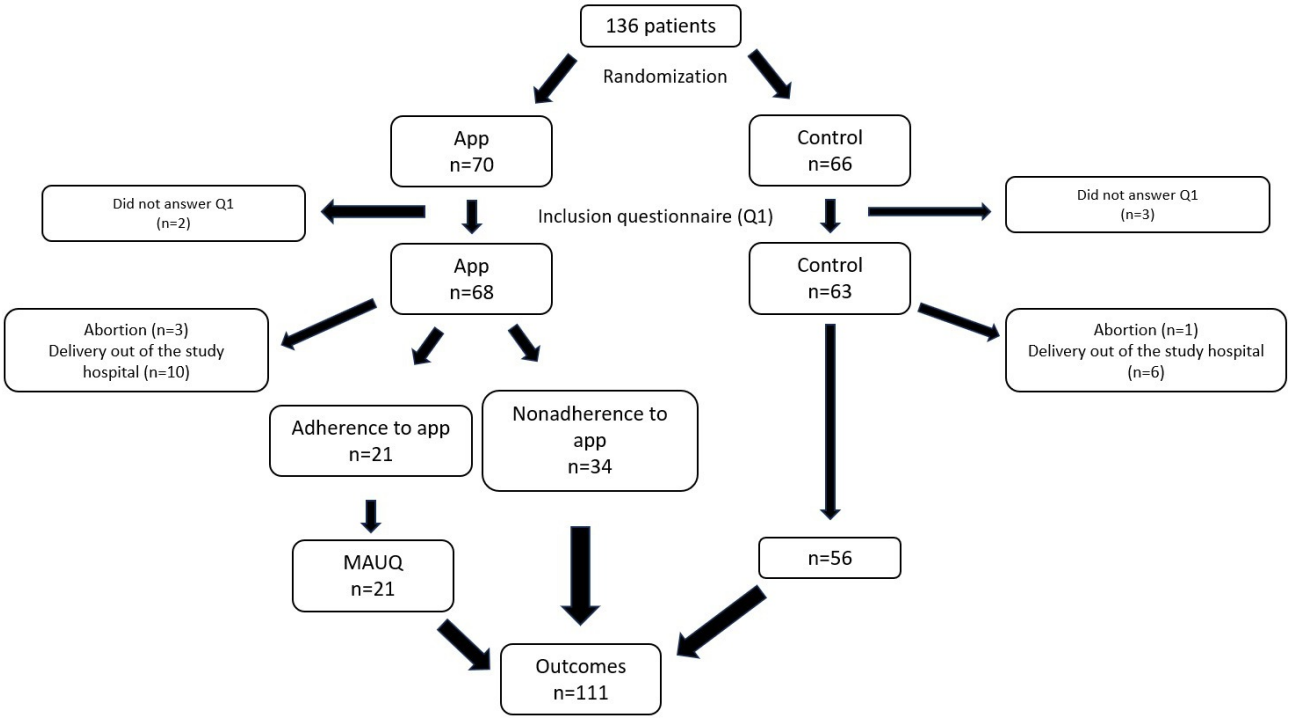
Sample Size Calculation

As an exploratory technique that does not require statistical hypotheses, hierarchical cluster analysis generally dispenses with sample calculation, since there are no standardized methods for it [25]. Dalmaijer et al [26] suggest that a sample of 20 - 30 individuals per expected subgroup is sufficient for cluster analysis, provided that there is a clear separation between the subgroups. Defining the sample in this study aimed to ensure that there was enough data for significant patterns to emerge. Estimating the formation of two or three clusters, depending on the dendrogram, a minimum of 100 patients was therefore proposed, 50 for the control group and 50 for the app group.

Statistical Analysis

Data were organized in an Excel (Microsoft Corp) spreadsheet and analyzed using SPSS Statistics (version 29.0.0; IBM Corp). Descriptive analysis of quantitative variables included the mean, SD, median, and IQR. Categorical variables were expressed in frequency and percentage. Student 2-tailed *t* test for independent samples or the Mann-Whitney nonparametric test was used to compare control and app groups in terms of quantitative variables. The normality of continuous variables was assessed using the Kolmogorov-Smirnov test. Categorical variables were analyzed using Fisher exact test or the chi-square test. An exploratory analysis of the variables in the inclusion questionnaire (Q1) resulted in the exclusion of questions with well-correlated answers or questions that had five or more missing data (blank answers). To determine the clustering of pregnant women, a hierarchical cluster analysis was carried out using the Ward method and the squared Euclidean distance measure. The number of clusters was determined according to the dendrogram. Values of $P<.05$ indicated statistical significance.

Results



Overview

The inclusion questionnaire (Q1) was answered by 131 patients. The team had no access to the outcomes of 20 patients due to abortion or delivery out of the study hospital. Only patients who had answered Q1 and whose outcomes were available were included in the analysis, resulting in a total of 111 pregnant women, as shown in Figure 1.

The MAUQ, restricted to the group that was adherent to the app, was answered by 21 patients and had an average score of 6.2 (SD 1.0) points, with a median of 6.6 (IQR 2.3-7). The internal consistency of the instrument was high, with a Cronbach α estimated at 0.94.

Figure 1. Patient inclusion flowchart. MAUQ: Mobile App Usability Questionnaire; Q1: inclusion questionnaire.

Patient Characteristics

The average age in the control group was 30.5 (SD 5.7) years and the app group was 28.8 (SD 6.2) years, with no significant difference (P=.13). The median number of pregnancies for the control group was 3 (IQR 1-10) and 2 (IQR 0 - 6) for the app group (P=.18). Table 1 shows the categorical variables of Q1 with the characteristics of patients for each group.

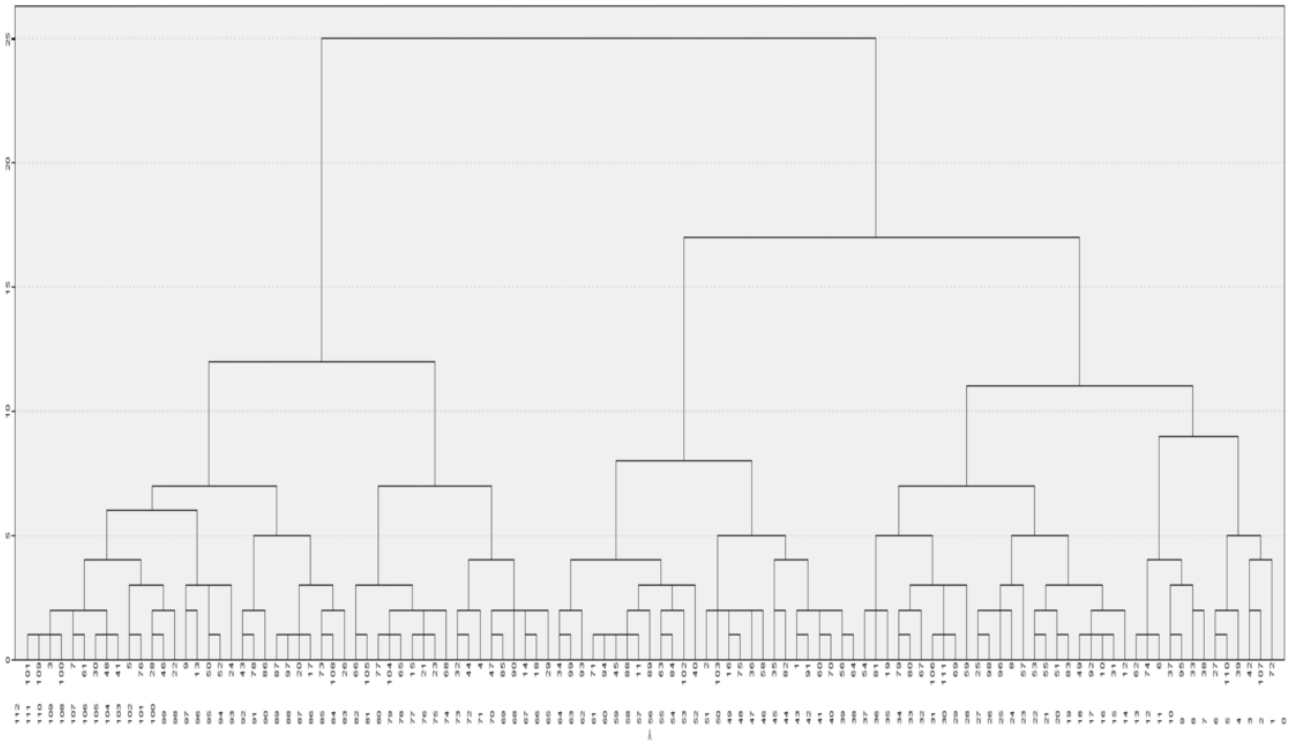
Cluster Analysis

Once it was determined which questions from Q1 would be included in the cluster analysis, one patient who did not adequately answer two or more of them ended up being excluded, which resulted in the analysis of data from 110 pregnant women. According to the dendrogram, the greatest leap in the Ward algorithm was from 86% to 93%, resulting in three groups of pregnant women (Figure 2).

Cluster 1 included 39.1% (n=43) of the participants, Cluster 2 had 21.8% (n=24), and Cluster 3 also included 39.1% (n=43). Pregnant women in Cluster 1 attended an average of 10.3 antenatal appointments, with a median of 11 (IQR 1-23). Participants in Cluster 2 had an average of 6.9 appointments, with a median of 6.5 (IQR 1-12). Finally, Cluster 3 showed an average of 9.1 antenatal appointments, with a median of 9 (IQR 1-24).

Figure 3 shows how significant variables are distributed among clusters, based on the positively significant answers to Q1. A

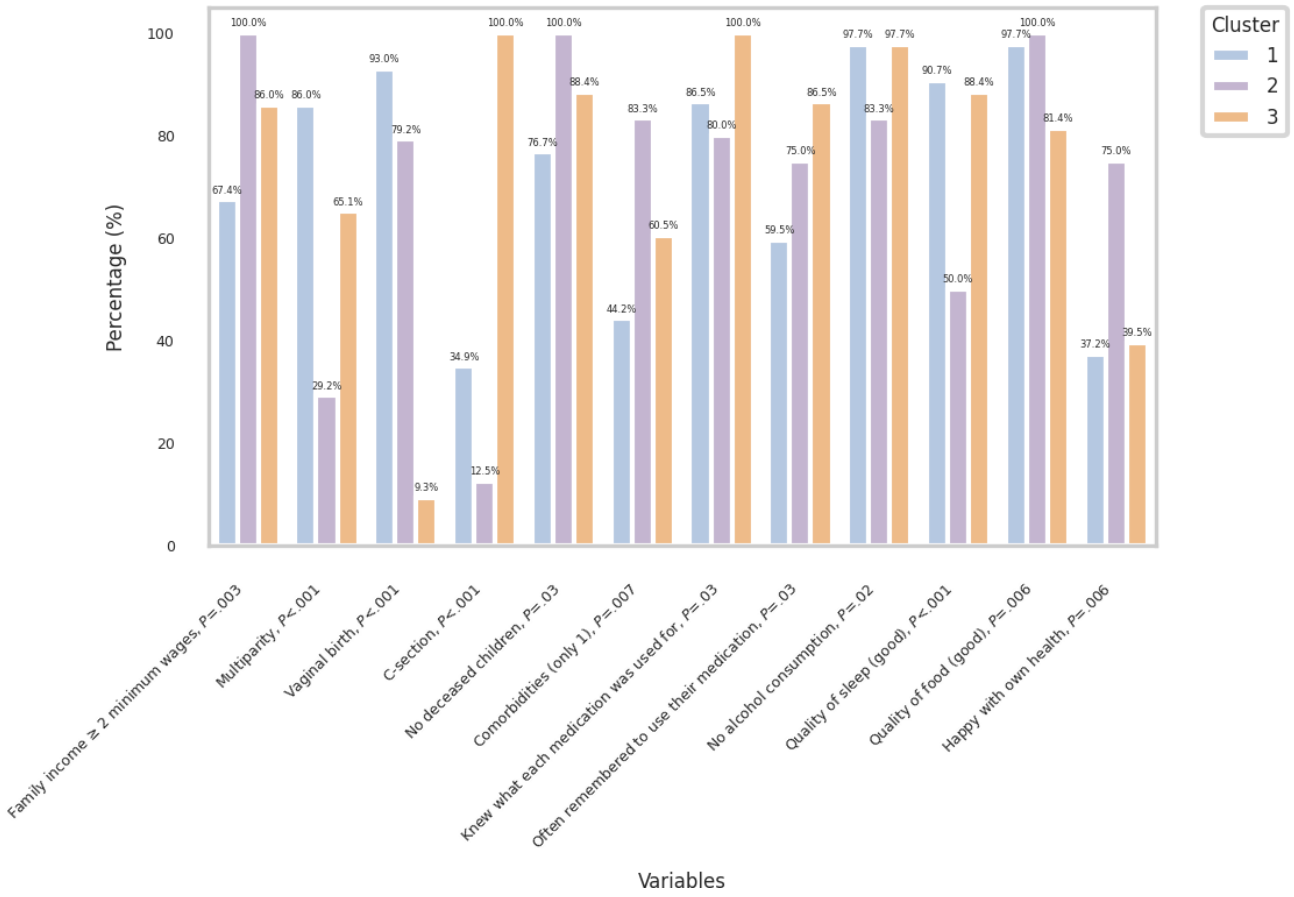
XSL•FO
RenderX



visual representation of the groups in nodes and their connections was created to show the associations between the different variables within clusters (Figure 4).

Acceptance and use of the app varied between the different clusters, with Cluster 1 showing the highest adherence and Cluster 2 the lowest (P=.08). Table 2 shows the differences in adherence to the app among clusters, including participants in the control group.

The outcomes that stood out among clusters were the number of antenatal appointments and the route of delivery. In Cluster 1, 72.1% (n=31) of births were vaginal and 27.9% (n=12) were cesarean. Similarly, Cluster 2 had 79.2% (n=19) vaginal births and 20.8% (n=5) cesarean. In contrast, Cluster 3 showed a markedly different pattern, with only 4.6% (n=2) vaginal births and 95.4% (n=41) cesarean sections.



The average number of emergency consultations in Cluster 2 was the lowest (3.5) compared to Cluster 1 (5) and Cluster 3 (5; P=.62).

Cluster	Control, n (%)	Nonadherent, n (%)	Adherent, n (%)
1	18 (32.7)	12 (35.3)	13 (61.9)
2	15 (27.3)	8 (23.5)	1 (4.8)
3	22 (40)	14 (41.2)	7 (33.3)
Total	55 (100)	34 (100)	21 (100)

[a]Chi-square test; significance set at $P<.05$.

[b]$P=.12$ for the overall comparison across the entire table.

Clustering

In this study, clustering into three groups revealed significant differences in biopsychosocial aspects, which were named by the researchers according to the most striking characteristics of each group (Graph 2). Cluster 1—“experienced, disciplined mothers”—is characterized by multiparous women with lower incomes who had vaginal births, most of whom had more than one comorbidity, a longer history of deceased children, and good lifestyle habits, but who forget to take their medication and consider themselves less happy with their health. Cluster 2—“inexperienced pregnant women with limited involvement in care”—has the highest family income of the three clusters, with a predominance of women in their first pregnancy (nulliparous), with only one comorbidity and no deceased children; despite being the happiest with their health and considering the quality of their diet to be good, most of the patients here ignored what each medication was for, forgot to use their medication, and had the worst lifestyle habits, with higher alcohol consumption during pregnancy and worse quality of sleep. Cluster 3—“conscious multiparous”—is characterized by patients with more than one child, with high rates of cesarean sections, and mostly with only one comorbidity; these are the patients who best understand about the use of their medications and the ones who most remember to take them; although they sleep better than others, their diet is the worst of all clusters.

Discussion

Health Awareness

An app specifically designed for antenatal preparation in high-risk pregnancies has shown significant potential for enhancing health awareness and improving perinatal outcomes. Sakamoto et al [7] regard mHealth as an effective perinatal tool due to its cost-effectiveness and broad availability, as well as its capacity to empower pregnant women to manage their own health, promote healthy lifestyles, and access information anytime, anywhere. In our study, most patients brought their pregnancy-related test results to their antenatal appointments, although approximately 14.3% (n=8) of the control group and 9.1% (n=5) of the app group did not, suggesting gaps in patient education or communication at primary health units. Additionally, a portion of patients was unaware of the purpose of these tests, indicating potential shortcomings in the information provided to them during routine prenatal care.

The question “Do you consider yourself self-aware about your health?” highlighted that a minority of participants (n=7, 12.5%) in the control group and 14.5% (n=8) in the app group lacked a clear understanding of their health conditions. However, most patients consider preventive care to be an important aspect of health (n=54, 96.4% of the control group and n=55, 100% of the app group). DesJarlais [27] showed that, according to the Health Belief Model, women are more likely to seek preventive care if they believe that they are at risk and that the measures will bring more benefits than disadvantages. Many women are unaware of the benefits of antenatal care or have negative attitudes toward it, which may discourage them from seeking it even when it is available. Thus, instructing women on the importance of antenatal care is an important step to reduce health disparities [27], and mHealth proves to be a useful tool to increase women’s confidence and ability to make informed decisions about their care [28].

Health Apps

Studies indicate that women’s health awareness, particularly during pregnancy, can significantly impact the overall health and well-being of both mother and baby, and that mHealth apps play a vital role in this period [29]. Women who have faced a clinical issue during pregnancy tend to increase their focus on health. Rossiter et al [30] observed that pregnant women’s motivation to adopt healthier behaviors was driven by the desire to avoid future health problems and improve overall well-being. The use of mHealth interventions, such as a health app for appointment preparation, consistently improves patients’ self-efficacy, providing tools for self-monitoring and self-care and improving health outcomes [7,29,31,32].

Adherence to an app depends on factors such as perceived usefulness, ease of use, performance, social influence, motivation, trust, privacy and security concerns, technology anxiety, personalization, and support [33-35]. Tailored content, a user-friendly interface, and technical stability improve experience and adherence [36], while demonstrated health benefits further drive adoption [37]. Conversely, technical issues, privacy worries, waning interest, and time constraints are primary barriers to continued engagement [34,36,38]. Addressing these can markedly enhance effectiveness [34].

Health professionals also play an important role by fostering awareness and motivation, providing credibility when endorsing apps [38], and reinforcing perceived usefulness and intent to use [39]. Through open dialogue, physical, and psychosocial support, especially in high-risk pregnancies, they help prevent distorted risk perceptions and ensure patients accept guidance and feedback during antenatal care [40-42]. Ultimately, adopting a person-centered approach through digital health apps such as the Health Assistant app offers promising opportunities to actively involve patients and families in antenatal care, leading to improved health care experiences and outcomes [6].

App Usability: MAUQ

In this study, the Health Assistant app demonstrated good usability among high-risk pregnant women, as indicated by an average MAUQ score of 6.2 from the 23 users who engaged with the app. This result highlights the app’s ease of use and its perceived usefulness for antenatal preparation. Few studies have used the MAUQ for mHealth in pregnant women, and none of them in Brazil. A study conducted in Indonesia with 88 pregnant women to evaluate an app during pregnancy obtained an average MAUQ score of 6.26 in areas with a mobile signal, while in areas without a signal, the average was 6.29, which is similar to our finding [43].

Given that usability significantly impacts the adoption and sustained use of mHealth apps, particularly among populations with varying levels of health literacy, the positive usability scores from our participants suggest that the Health Assistant app effectively meets users’ expectations. Ensuring user-friendly interfaces and intuitive navigation remains essential in maximizing the potential benefits of digital health interventions in antenatal care. According to the study of the development and validation study of the original MAUQ, the higher the score, the greater the usability of the app [20]. Therefore, the average score of 6.2 obtained in this study is consistent with good usability.

Clustering

The cluster analysis conducted in this study identified three distinct groups of high-risk pregnant women, each with specific biopsychosocial characteristics. This classification provided insights into behavioral and clinical patterns that may influence pregnancy outcomes and engagement with digital health interventions, detailed in the following sections.

Cluster 1, referred to as “experienced, disciplined mothers,” included mostly multiparous women with lower income and a history of multiple comorbidities. Although they reported healthier lifestyle habits and demonstrated the highest adherence to the Health Assistant app, they also showed a tendency to forget medication and reported lower satisfaction with their health. These findings align with previous research, suggesting multiparous women are more proactive in managing their complex health needs due to accumulated experiences [7,30].

Cluster 2, “inexperienced pregnant women with limited involvement in care,” was composed primarily of first-time

XSL•FO
RenderX

mothers with higher incomes and fewer comorbidities. Despite reporting high satisfaction with their health and good dietary habits, this group had the poorest adherence to the app, the most frequent forgetfulness in medication use, and the highest rates of alcohol consumption and sleep dissatisfaction. This discrepancy between perceived and actual health behaviors aligns with the Health Belief Model, suggesting lower perceived susceptibility due to lack of previous negative health experiences, leading to reduced engagement in preventive behaviors [27,42,44]. Contrary to findings by Lee et al [45], this study observed lower app adherence among first-time mothers, highlighting a need for targeted education and personalized digital health interventions to enhance awareness of risks and benefits [46].

Cluster 3, identified as "conscious multiparous women," exhibited moderate app adherence, better medication management, and high rates of cesarean deliveries. These women demonstrated a pragmatic and consistent adherence to medical recommendations, reflecting heightened awareness from previous pregnancy experiences [2,47]. Despite their good medication adherence and understanding of treatments, they reported poorer dietary habits, suggesting opportunities for targeted nutritional interventions.

Recognizing these distinct cluster profiles enables the development of tailored interventions to address the unique needs and challenges of each group, ultimately improving maternal-fetal outcomes and optimizing the use of mHealth tools in antenatal care. The main differences among the clusters are related to sociodemographic factors, obstetric history, and patient behavior. A detailed analysis of these aspects is essential for designing personalized strategies in education, adherence, and psychosocial support.

Family Income

During the study period, the minimum wage in Brazil corresponded to approximately 260 dollars [48,49]. Patients with higher incomes and a better understanding of antenatal care may require less intensive interventions. In contrast, those from groups characterized by lower incomes and higher prevalence of comorbidities often need closer monitoring and additional support.

Cluster 2 stood out as all participants reported an income equal to or greater than two minimum wages. Conversely, Cluster 1 showed a significantly higher proportion of patients with lower income (n=14, 32.6% had incomes below two minimum wages). Interestingly, despite previous evidence suggesting that pregnant women from remote areas or lower socioeconomic backgrounds might experience difficulties accessing or effectively using mHealth technologies, our findings indicated the opposite [50]. We observed greater engagement with the app, precisely among participants with lower incomes (Cluster 1). This unexpected finding could be explained by the higher prevalence of comorbidities among these patients, motivating them to seek more active participation in their antenatal care. Additionally, the high proportion of multiparous women in this group (n=37, 86%) might indicate greater health awareness resulting from prior pregnancy experiences, further explaining their increased adherence [51].

Medical History and Medication Adherence

In this study, multiparous women predominated in Clusters 1 and 3, while nulliparous women were the majority in Cluster 2. First-time pregnant women usually experience heightened awareness of bodily changes, possibly due to the novelty and uncertainty associated with pregnancy [52]. In this context, mHealth apps can serve as important tools, offering ongoing support and reassurance regardless of parity. Multiparous women, in contrast, often have better psychosocial adaptation during pregnancy and a greater appreciation for organization and planning based on previous experiences. This previous knowledge might explain their higher engagement with mHealth interventions observed in our results. Specifically, multiparous participants demonstrated greater adherence to the app, likely due to their familiarity with pregnancy-related risks and a proactive approach shaped by prior pregnancies. Thus, in our high-risk pregnancy context, previous experiences seem to strongly influence patients' adherence, highlighting the importance of addressing both the informational needs of first-time mothers and reinforcing engagement strategies tailored for women with prior pregnancies [51].

Previous Losses and Medication Adherence

The group consisting predominantly of first-time mothers with limited involvement in care (Cluster 2) stood out because none of these patients reported previous child losses. These women were characterized by fewer comorbidities (n=20, 83.3%) with only one comorbidity, possibly reflecting better overall health conditions. This may explain their lower adherence to the app, since fewer negative health experiences could lead to a reduced perceived need for additional monitoring and intervention [44]. Conversely, experienced mothers with disciplined engagement (Cluster 1) reported a higher incidence of having lost a child (n=10, 23.3%). This group's socioeconomic profile—with lower income, a higher number of children, and more frequent comorbidities—likely contributed to these experiences. Such adverse life events might have fostered greater health awareness, thus motivating higher adherence to the mHealth intervention observed in this group.

Medication adherence is notably challenging among patients with chronic conditions, particularly in high-risk pregnancies [53]. Our findings demonstrated strong adherence among patients from Cluster 3, who all clearly understood the purpose of each medication prescribed. The fact that these patients were multiparous and had previously undergone cesarean sections further indicates heightened health awareness. This awareness translated into practical adherence behaviors, with the majority of these patients (n=32, 86.5%; P=.03) consistently taking their medications without forgetting. Understanding their medical conditions and the intended benefits of treatments clearly improved medication adherence in this group [6,54].

Self-Awareness and Medication Management

Cluster 2 exhibited the lowest level of awareness regarding medication use, with 20% (n=4) of patients reporting uncertainty about the purpose of each medication. This was unexpected, given that this group was composed mostly of first-time pregnant women with higher income and fewer comorbidities—typically

XSL•FO
RenderX

factors associated with greater engagement in health management. Conversely, Cluster 1 had the highest percentage (n=15, 40.5%) of patients forgetting to take medications. This vulnerability can be explained by the combination of lower income, higher number of children, and increased comorbidities observed in this group, resulting in more complex daily health demands and possibly less family or social support [55,56].

Although the app used in this study did not provide medication reminders, patients who actively used the app generally showed greater health engagement [28]. Apps have been recognized for their potential to facilitate medication adherence by increasing patient awareness and organization [28]. In this study, Cluster 1 patients were most engaged with the app; however, longer follow-up would be needed to determine whether app use directly influenced improved medication adherence over time. Given these observations, both Clusters 1 and 2 might benefit significantly from incorporating targeted medication adherence features into mHealth interventions [57,58].

Lifestyle Habits

Adopting healthy lifestyle habits, such as regular physical activity, balanced nutrition, and adequate sleep, is highly recommended, particularly in high-risk pregnancies [59,60]. In this study, we identified differences in alcohol consumption between clusters. Cluster 2 (inexperienced pregnant women with limited involvement in care) presented the highest prevalence of alcohol use during pregnancy (n=4, 16.7%). This finding was unexpected since women with higher socioeconomic status generally demonstrate fewer risk behaviors during pregnancy [44]. Digital interventions, such as mHealth apps, have been shown to effectively reduce alcohol consumption in pregnant populations [44]. Therefore, this cluster could benefit significantly from increased engagement with such interventions.

Another notable aspect was sleep quality. Half of the patients in Cluster 2 reported inadequate sleep (P<.001). Enhanced app engagement might benefit these women, as mHealth-based interventions have previously demonstrated the ability to improve sleep quality and duration during pregnancy, positively influencing maternal health outcomes [61]. Diet quality perceptions varied among clusters. Interestingly, all patients in Cluster 2 rated their diet quality positively, whereas Cluster 3 was more critical (n=35, 81.4% considered it good; P=.006). It is possible that patients in Cluster 3, who displayed greater awareness and realistic views about medication use, similarly had more accurate self-assessments regarding their dietary habits.

We also observed significant differences between clusters in self-perceived happiness regarding health. Cluster 2 showed the highest proportion of women feeling happy with their health (n=18, 75%), whereas Cluster 1 had the lowest (n=16, 37.2%). This difference may be explained by the higher proportion of multiparous women in Cluster 1, whose additional life stressors and caregiving demands could negatively impact perceived happiness [62]. Additionally, the inherent challenges of high-risk pregnancies might further influence women's emotional state and perceptions of happiness. Despite such challenges, previous research indicates that positive emotional states, such as happiness, can persist during high-risk pregnancies, particularly when reinforced by strong family support and personal resilience.

Clusters, Outcomes, and Health Strategies

Identifying patient clusters allows targeted strategies to prevent adverse outcomes. Our findings revealed notable differences between groups regarding antenatal appointment attendance, route of delivery, and health behaviors.

The number of antenatal appointments varied significantly across clusters. Cluster 2 ("inexperienced pregnant women with limited involvement in care") attended fewer appointments (6.9) compared to Clusters 1 (10.3) and 3 (9.1). This frequency falls short of World Health Organization (WHO) recommendations (minimum 8 visits), highlighting the need for intensified early follow-up and educational interventions, particularly considering their low adherence to the app [56,63]. Conversely, Cluster 1 attended the most appointments, likely due to greater medical complexity and higher app engagement [64]. Although the app did not send reminders, evidence from previous studies supports that increased mHealth use correlates with higher antenatal attendance, suggesting these groups could benefit from enhanced digital interventions [65]. It is noteworthy that, although statistically insignificant, Cluster 2 had fewer emergency department visits (3.5 visits). This can be related to the higher satisfaction with health in Cluster 2, but it can also have to do with higher income, which suggests that these patients, while receiving some care in the private sector, are perhaps keeping less frequent appointments only to retain a link with the public health system for childbirth.

Regarding delivery mode, Cluster 3 had significantly more cesarean sections (n=41, 95.3%) compared to Clusters 1 (n=12, 27.9%) and 2 (n=5, 20.8%; P<.001). This was likely due to the medical complexity of these multiparous patients and previous cesarean histories rather than mere personal preference [66,67]. Reducing unnecessary C-sections remains essential; thus, targeted education through the app could encourage safer delivery alternatives.

Pregnancy itself is a stimulus for lifestyle changes and positive health interventions [60], but cluster-based management strategies implemented by health teams could substantially improve pregnancy outcomes. Cluster 1**,** characterized by multiparity, low income, and high comorbidity, would benefit from interventions focusing on medication adherence, dietary optimization, and family planning guidance. Financial pressures in this group highlight the potential of mHealth tools to support self-management and health education [11]. It would also be interesting to enter information about these needs in the Health Assistant, as this was the group that adhered most to the app [68]. This would be in line with the findings of Wang et al [69], according to which patients expressed the need for apps containing evidence-based, personalized information to support them during pregnancy.

Cluster 2, despite higher socioeconomic status and fewer comorbidities, exhibited poor health behaviors such as alcohol use, inadequate sleep, and limited health awareness. Strategies to enhance app adherence, including personalized information and notifications, could significantly improve self-care and

XSL•FO
RenderX

antenatal attendance. Integrating psychological support and mental health assessments into antenatal care can also address emotional well-being, increase self-awareness and self-care, and reduce risky behaviors [29].

Cluster 3, multiparous health-conscious women, demonstrated moderate app adherence (n=7, 33.3%) but lower self-rated diet quality. Targeted educational campaigns on nutrition, lifestyle, and informed choices regarding delivery methods could enhance patient engagement, improve maternal-fetal outcomes, and reduce unnecessary interventions [59]. Strategies for this group with moderate adherence to the app (n=7, 33.3%) could include educational campaigns to raise awareness about the benefits of the app, provide additional support to encourage its use, and increase attendance at antenatal appointments [70,71].

The cluster analysis presented in this study offers prenatal care teams a practical framework for stratifying pregnant patients according to their biopsychosocial risk profiles. By distinguishing groups with low engagement in antenatal care (Cluster 2) or difficulties in medication adherence (Cluster 1), health care professionals can more effectively identify individuals at heightened risk for disengagement or adverse pregnancy outcomes. Early recognition of these specific risk profiles enables teams to implement targeted, evidence-based interventions—such as personalized education, adherence support, and psychosocial assistance—before complications arise. This cluster-based approach facilitates efficient allocation of resources and proactive management, supporting improved maternal-fetal outcomes [6]. Furthermore, integrating mHealth solutions tailored to each cluster's unique needs can enhance patient engagement and self-management, ultimately strengthening the quality and continuity of antenatal care.

Implications for Future Research: "Clusters in Practice: A Proposal for a Risk Assessment Questionnaire for the First Antenatal Visit"

Based on the questions that most clearly differentiated our clusters, we propose developing a brief screening questionnaire to be administered at the first antenatal visit. This questionnaire would automatically indicate the most likely cluster for each patient, enabling rapid and specific interventions at the outset of prenatal care, thus preventing risks before undesirable behaviors or complications occur. Subsequent steps would involve drafting pilot items covering income, parity, comorbidities, and mHealth use profiles, submitting them to expert review and cognitive interviews with pregnant women for clarity and relevance, conducting a pilot study to assess construct validity (via factor analysis), internal consistency (Cronbach α), and test-retest reliability, and performing a prospective multicenter validation across diverse clinical settings to compare predicted risk scores with actual app engagement, appointment frequency, and maternal-fetal outcomes for sensitivity, specificity, and likelihood ratio estimation. Once validated, an algorithm could be embedded in eHealth records to assign each patient to a cluster and automatically trigger tailored interventions (eg, telemonitoring, reinforced health education, and SMS text message reminders), culminating in a randomized controlled trial contrasting "cluster‐guided" care with usual care using primary end points such as antenatal adherence rates, complication incidence, and health care resource utilization—an approach that, while consistent with established predictive‐health models, will require rigorous clinical validation and user‐acceptance testing to ensure accuracy, usability, and effectiveness before widespread implementation.

Limitations

Though this study has provided us with several insights, it does have some limitations. Many patients were lost during data collection, which is often expected in observational longitudinal studies, but this loss, especially among prospective app users, can make it difficult to assess accurately the effectiveness of the intervention, since part of the target group was not thoroughly followed up. Since the transition from physical to digital records is still in progress, it is not uncommon for patients to resist mHealth adherence at first, and sample reduction in the adherent group in this study seems to have been due to such barriers as low literacy, limited connectivity, low smartphone memory, cultural beliefs, and lack of interest.

The fact that this study was carried out in a public university hospital in southern Brazil may render some generalizations invalid for other regions of the country or for private institutions. The adoption of three clusters yielded less variability in answers and more generalized results. Some sociodemographic factors overlapped among clusters, making it difficult for groups to be clearly distinguished and confusing for outcomes to be analyzed. In addition, the duration of the study, restricted to the period between the first antenatal visit and delivery, may not be sufficient to assess the long-term impacts of app use on maternal-fetal health and the well-being of pregnant women, thus indicating the need for further studies with larger samples and in different socioeconomic contexts.

Conclusions

The use of mobile apps has significant potential to optimize antenatal care and self-awareness for high-risk pregnant women. The usability of the Health Assistant app is in line with the standards expected and observed in other studies. Cluster analysis revealed different profiles of pregnant women, making it possible to identify specific groups that could benefit most from digital interventions and from a personalized approach to organizing their journey and improving pregnancy outcomes. This pioneering study stresses the role of mHealth in high-risk antenatal care and highlights the importance of further exploration of its impact in different settings and populations.

Abstract

Background: Depression is a severe and prevalent mental disorder among youth that requires professional care; however, various barriers hinder access to effective treatments. Chatbots, one of the latest innovations in the research on digital mental health interventions, have shown potential in addressing these barriers. However, most studies on how to design chatbots to treat depression have focused on adult populations or prevention in the general population.

Objective: This study aimed to investigate the problems faced by youth with depression and their adaptive coping strategies, as well as attitudes, expectations, and design preferences for chatbots designed to treat depression.

Methods: We conducted a qualitative study, consisting of a semistructured interview and a concurrent think-aloud session, in which participants interacted with a chatbot prototype with 14 youth with a current or remitted depressive episode.

Results: The participants reported a wide range of problems beyond core depressive symptoms, such as interpersonal challenges, concerns about school and the future, and problems with human therapists. Adaptive coping strategies varied, with most seeking social support or engaging in pleasant activities. Attitudes toward chatbots for depression treatment were predominantly positive, with participants expressing less anxiety about using a chatbot than about seeing a human therapist. Participants showed diverse and partially contradictory design preferences, which included diverse dialogue topics, such as discussing daily life, acute problems, and therapeutic exercises, as well as various preferences for personality, language use, and personalization of the chatbot.

Conclusions: Our study provides a comprehensive foundation for designing chatbots that meet the unique needs and design preferences of youth with depression. These findings can inform the design of engaging and effective chatbots tailored to this vulnerable population.

Introduction

Depression is a prevalent mental disorder in youth with significant personal and socioeconomic consequences that requires professional care [1,2]. Despite the availability of effective treatments, such as cognitive behavioral therapy (CBT) [3], accessing them remains challenging. Even when professional services are free and accessible [4], many youth avoid seeking professional support due to perceived stigma, a preference to solve problems by themselves, and fear of psychotherapeutic settings [5-8]. Interestingly, such attitudinal barriers may be more important reasons for not seeking help than structural barriers, such as limited treatment resources and long waiting periods [8]. Digital mental health interventions (DMHIs) are a promising and effective way to overcome these barriers because they provide anonymous and self-empowered access to effective professional care [9]. However, to leverage the full potential of DMHIs in the treatment of depressive symptoms in youth, 2 major limitations need to be overcome,that is, low adherence [10] and difficulty in establishing a therapeutic

XSL•FO
RenderX

alliance, which is viewed as a crucial factor for effective psychotherapy [11].

Chatbots, software systems that interact with users using natural language [12], have shown the potential to address these limitations. They are well accepted, feasible, and have shown promising effectiveness in strengthening mental health [13-16]. In addition, incorporating chatbots into DMHIs improves user engagement [17] and mental health outcomes [18]. Notably, users seem to develop a therapeutic alliance with chatbots [19-21] partly because of social cues such as empathetic messages and humor [15,22]. Despite these encouraging results, most studies on mental health chatbots, including those targeting depression symptoms, have focused on adult populations [13-16,23]. This is a key shortcoming because the results from adult populations cannot be generalized to youth. Youth face significant developmental changes in their biological, psychological, and social systems [24], and depression symptoms differ from those in adulthood, especially at the onset of puberty [25]. Furthermore, youth interact with smartphones and chatbots differently than adults [26,27], and have expressed that existing DMHIs often fail to address their specific concerns adequately [28].

To address this research gap, recent studies have explored the design of chatbots for youth mental health. Høiland et al [29] involved youth in designing a chatbot for high-school health services aimed at preventing mental disorders. Through focus groups, they identified four key support needs: (1) receiving information about mental health, (2) relating to someone beyond their immediate network, (3) receiving support for self-help, and (4) being referred to mental health services. Similarly, Grové [30] developed a preventive mental health chatbot with high-school students. Participants suggested topics such as school, family, friends, sexuality, and identity as well as resources for adaptive coping strategies, mindfulness, and distractions. They expressed a preference for chatbots with inspiring, charismatic, and fun personalities using emojis, humor, and GIFs. While these 2 studies provide valuable insights, they focused on the prevention rather than the treatment of mental disorders and addressed a broad spectrum of mental health issues rather than specifically targeting depression. Thus, there is a critical need for research on how to design chatbots that focus on specific problems of youth with depressive symptoms to achieve sufficient engagement and optimal treatment outcomes.

Our study aims to address this research gap by investigating the following research questions: (1) What problems do youth with depressive symptoms face? (2) What adaptive coping strategies do they apply? (3) What attitudes and expectations do they have for chatbots designed to treat depression among youth? (4) What are their design preferences?

By addressing these questions, we aim to provide a comprehensive foundation for developing chatbot-based DMHIs tailored to the unique needs and preferences of youth with depression. This foundation will facilitate the development of engaging and effective DMHIs for this vulnerable population.

Methods

Study Design

We conducted a qualitative study to examine how to design a chatbot to treat depression in youth. The study included a questionnaire, a semistructured interview, and a concurrent think-aloud session with a chatbot prototype. We chose interviews because they allowed us to gather rich, detailed data on participants' problems, coping strategies, attitudes and expectations, and chatbot design preferences.

Participants

Participants were eligible if they were between 14 and 17 years of age, owned a smartphone, and met diagnostic criteria for a current or remitted depressive episode. Participants with suicidal ideation or psychotic symptoms were excluded. Participants were recruited through a resident child and adolescent psychiatrist and the University's newsletter between June and August 2021.

The target sample size was calculated based on the goal of data saturation [31], considering age group (14 - 15 and 16 - 17 y), depression status (remitted and acutely depressed), and gender (women and men), assuming homogeneity within each subgroup. Given that data saturation can be achieved at 6 cases per homogeneous group [31], the study aimed to recruit 48 participants. The sample was recruited through convenience sampling but the sampling was constrained by the predetermined recruitment period and available recruitment channels. The final sample consisted of 14 participants (12 women and 2 nonbinary).

Procedure

After participants and caregivers provided informed consent, we assessed their eligibility to participate in the study. Next, enrolled participants answered a questionnaire on sociodemographic information and mental health on a laptop. We conducted semistructured interviews to explore participants' experiences with depression, their adaptive coping strategies, attitudes and expectations toward chatbots for depression, and their design preferences. Finally, the participants interacted with a prototype chatbot using the concurrent think-aloud method.

Material

Eligibility Interview

We conducted a semistructured interview to evaluate participants' eligibility to participate in the study. The interview guide included questions regarding age, smartphone ownership, suicidal ideation, and symptoms of depression, and psychotic disorders. The questions on suicidal ideation and symptoms of depression and psychotic disorders were based on the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*) criteria [32] and Kiddie-Schedule for Affective Disorders and Schizophrenia Present and Lifetime [33]. The complete eligibility interview is presented in Multimedia Appendix 1 .

XSL•FO
RenderX

Questionnaire

Participants completed a questionnaire on demographic characteristics (age, gender, and level of education), history of mental disorders, and previous experience with psychotherapy. We assessed the prevalence of current symptoms of depression using the 8-item Patient Health Questionnaire (PHQ-8) [34] as well as current symptoms of anxiety using the Screen for Child Anxiety Related Disorders (SCARED) [35]. To complement the insights from the semistructured interview on the design preferences, participants answered a questionnaire on potential chatbot capabilities. This questionnaire is based on CBT manuals and literature on the content of DMHIs for depression [36-38] and comprises 13 capabilities that a chatbot to treat depression in youth could implement. For each capability, we asked participants to indicate the extent to which the chatbot should support them on a scale from 1 (“strongly disagree”) to 5 (“strongly agree”). The capabilities are presented in Textbox 1. The participants completed all questionnaires on a laptop using SoSci Survey (SoSci Survey GmbH).

Textbox 1. Items listed in the questionnaire on chatbot capabilities.

The chatbot should support me with…

- how I can become more physically active or do sports.
- how to sleep better.
- how I can change negative or self-critical thinking.
- how I can do more activities that are important to me or that I have enjoyed in the past.
- tracking my mood.
- learning more about my depression.
- improving my social skills.
- reminding me to take my medication.
- connecting with an expert (eg, psychotherapist) if I feel very bad.
- connecting with other people who have similar problems.
- how I can use my breath to make me feel better.
- writing a journal with things that concern me or for which I am grateful for.
- writing about events from my life.

Study Interview

We conducted semistructured interviews to investigate the problems participants faced due to depression, their adaptive coping strategies, their attitudes and expectations toward chatbots for depression, and their chatbot design preferences. Table 1 provides an excerpt of the interview guide. We asked several questions about each topic and prepared subquestions to follow up on specific details or offer suggestions based on the participants’ initial responses.

Table . Excerpt from the interview guide (translated from German).

Topic	Question
Problems	• Think of a period where you felt down. How did it look like?
Adaptive coping strategies	• What have you tried in the past to feel better?
Attitudes and expectations towards therapy chatbots	• Do you know what a chatbot is? • What do you think it would be like for you to use a chatbot that is there to help you with one of the problems you have mentioned? For example, what could be the advantages and disadvantages?
Design preferences for therapy chatbots	• Imagine you are thinking about using one of these chatbots. How should it need to be designed, so that you would download and use it? • How do you imagine an ideal conversation with the chatbot? For example, what topics would you like to discuss or what its personality should be like? • If it was accessible as a mobile app, what should the app look like? • (What) Would you like to personalize? • How often would you like to use such a chatbot (per week)? • How long should every session last?

XSL•FO

Chatbot Prototype: Cady

Cady is the prototype of a chatbot for the treatment of depressive symptoms in youth that we developed for this and subsequent studies. Cady guides participants through a behavioral activation exercise, which is a core component of CBT to treat depression in youth [3]. Behavioral activation aims to encourage patients to engage in pleasant activities to overcome positive reinforcement deficits [39]. The conversation comprised the following sections: (1) introduction; (2) mood check on a scale from 1 (lowest) to 5 (highest) with adaptive empathetic responses; (3) psychoeducation on the relationship between behavior, thoughts, and feelings; (4) finding pleasant activities; (5) planning pleasant activities; (6) advice on how to overcome barriers when performing activities; and (7) feedback and goodbye. The conversation was designed by licensed psychologists based on established CBT manuals for youth [40,41] with a focus on positive, activating, and age-adequate language style. Cady also used emojis in its messages and sent GIFs. Figure 1 represents a screenshot of an example conversation between Cady and a participant. We named the chatbot Cady in accordance with the title of our research project and did not specify its age, gender, or other demographic characteristics to prevent specific demographic characteristics from influencing the results. We developed Cady using the prototyping software, Botsociety [42]. The chatbot was built with a rule-based architecture, where each user input triggers a predetermined response pathway following a decision tree structure. To ensure appropriate responses and maintain therapeutic quality, users primarily interacted with the chatbot by selecting from predefined options presented as buttons. We allowed free-text input in specific situations, for example, to identify and schedule pleasant activities. However, these free-text responses did not alter the chatbot's conversation pathway.

XSL•FO
RenderX

Figure 1. Screenshot of an example conversation between Cady and a participant.

Think-Aloud

We applied the concurrent think-aloud method [43], in which participants are asked to express their thoughts and feelings loudly while interacting with an app. At the beginning of the think-aloud session, the interviewer introduced the chatbot prototype Cady to the participants and explained the think-aloud method. Subsequently, participants interacted with Cady using a laptop. While the participants interacted with the prototype, we recorded the laptop screen and their comments. The interviewer stayed in the room because all participants felt it was easier to share their thoughts and feelings when the interviewer was in the room. The interviewer asked for further explanation if the statements were unclear or nonspecific.

Data Analysis

The interview and think-aloud session were recorded using an audio recorder (Zoom Q2n [Zoom Corporation]) and were

XSL•FO
RenderX

transcribed verbatim. Furthermore, 2 coders analyzed the semistructured interviews and concurrent think-aloud sessions using qualitative content analyses by Mayring and Fenzl [44] and Mayring [45] with the QCAmap software (Fenzl and Mayring) [46]. Similar to Zehetmair et al [47], we chose an inductive coding approach to achieve the most unbiased and thorough description of the data, which we deemed important for the exploratory nature of our study [44,45]. Both coders (Lilli Feline Metelmann and LB) coded the material independently, discussed their coding results, and jointly developed a category system. When disagreements between the coders could not be resolved, a third coder (FOK) was consulted. We chose this process because intercoder comparison is not feasible with inductive category development [44,45]. In an inductive approach, categories are created bottom-up from the material rather than selected before data analysis, as in deductive approaches [44,45]. We report the frequencies of the categories and codes to increase transparency and demonstrate the saliency of the codes in the data. The category system is provided in Multimedia Appendix 2. The questionnaires were analyzed using R (version 4.1.3; R Core Team). For PHQ-8, SCARED, and the potential capabilities questionnaire, we calculated descriptive statistics (mean and SD). For the potential capabilities, we also generated frequency distributions to visualize the response patterns.

Ethical Considerations

The Institutional Review Board of the Medical Faculty of the University of Tübingen approved the study (project ID 595/2021B01). The participants and caregivers provided written informed consent (Multimedia Appendix 3) before screening for eligibility and enrollment. All participant data were deidentified before analysis by removing personal identifiers such as names, addresses, and contact information, and replacing them with unique study codes to ensure participant confidentiality. After the study, participants received a reimbursement of 30€ (equivalent to US $33) for taking part in the study. The study lasted between 1 and 2 hours.

Results

Participant Characteristics

In total, 14 youth between 14 and 17 years old (mean 16.1, SD 1.14 years) participated in the study. Furthermore, 12 participants identified as women and 2 as nonbinary. All participants reported a current or remitted depressive disorder. In addition, 10 participants had a PHQ-8 score of 10 or higher, indicating acute depressive symptoms [48]. Of the total, 12 participants had a SCARED score of 25 or higher, indicating current symptoms of anxiety [49]. Furthermore, 9 participants showed symptoms of both depression and anxiety. Out of 14, 9 (64%) participants were currently receiving psychotherapy, whereas 8 (57%) had received psychotherapy in the past. A comprehensive overview of the participant characteristics is illustrated in Table 2.

XSL•FO

Remitted (>6 mo)	10 (71)
Recurrent (minimum 2 episodes)	5 (36)

[a]PHQ-8: 8-item Patient Health Questionnaire.

[b]SCARED: Screen for Child Anxiety Related Disorders.

Research Question 1: Problems With Depression

All participants (N=14, 100%) experienced problems categorized as depressive symptoms, including lack of motivation and energy, depressed mood, and self-doubt. Furthermore, 2 participants explained their main problems:

> *I just don't have the strength to do anything" and "I'm just tired of everyday life, or of all these everyday activities like brushing my teeth.*

Some participants (9/14, 64%) reported comorbidities, such as panic attacks, anxiety, and excessive alcohol consumption, while 4 participants (28%) reported physical problems, such as tension, headaches, or stomach pain. All 14 participants (100%) also reported interpersonal problems, particularly withdrawal from social relationships, stress caused by parents, and problems with friends. Furthermore, 11 participants (78%) expressed concerns about school or their future. They shared negative experiences at school and experienced pressure to plan their future, which were reflected by statements like:

> *When it comes to school, I have a very, very big fear of the future.*
>
> *Success is a big topic right now, because of the end of school year grades.*

In total, 6 participants (42%) reported experiencing stigma associated with depression. They mentioned that adults stigmatized or trivialized their problems or feared negative reactions when sharing their problems. One participant was concerned that disclosing that they are seeing a psychotherapist would lead to others perceiving them as "sick in the head." Most participants reported encountering difficulties with mental health care. Furthermore, 12 individuals (85%) reported experiencing treatment barriers, including attitudinal and structural barriers. Attitudinal barriers included fear of being judged, self-assessment that problems are not severe enough to deserve support, and negative experiences during psychotherapy (n=9, 64%). Participants reported ineffective techniques, difficulty with disclosing personal information, pressure to perform, trust violations, and condescending treatment from therapists. Structural barriers reported are long waiting lists or being deemed not sufficiently severe by healthcare providers or parents to qualify for professional support.

Research Question 2: Adaptive Coping Strategies

All 14 participants (100%) identified social support as an adaptive coping strategy. The majority received social support from friends, family members, partners, teachers, or people they interacted with online. In total, 13 participants (93%) engaged in activities to distract themselves or to have a positive experience such as spending time outdoors or consuming media. A total of 9 participants (64%) reported receiving professional treatment and 9 (64%) used cognitive strategies, including positive self-talk, self-reflection, and reducing rumination. Furthermore, 6 participants (42%) implemented a daily structure

XSL•FO
RenderX

including forming habits, getting up early, scheduling positive activities, and setting goals. In addition, 7 (50%) prioritized their needs as a coping mechanism, such as intentionally allocating time to self-care or avoiding stressful social situations. Of the total, 3 individuals (21%) engaged in mindfulness practice, such as breathing techniques and meditation, and 2 individuals (14%) sought online information regarding their depressive symptoms, interrelated problems and further information.

Research Question 3: Attitudes and Expectations Toward Chatbots to Treat Depression

Most participants had positive attitudes toward and expectations of chatbots to treat depression. In total, 12 participants (85%) stated that they would be less anxious about using a chatbot than seeing a human therapist. They pointed out that using a chatbot would be a suitable option for discussing sensitive topics that they would not share with others, primarily because they would not fear negative reactions. In addition, texting was considered less intimidating than speaking with a therapist. Furthermore, 11 participants (79%) pointed out the unlimited capacity and flexibility of chatbots:

> *I think it's also an advantage that you can really chat with it at any time, because in therapy you just have one appointment per week. If you feel bad in the evening or at night or something, then you can still text the chatbot.*

In addition, participants indicated that a chatbot is more accessible and requires less effort than seeing a human therapist. A total of 8 participants (57%) expressed confidence in the effectiveness of chatbots for the treatment of depression. They indicated that such a chatbot would be capable of addressing a wide range of issues, and welcomed the idea of having a helpful everyday chatbot. All participants demonstrated keen interest in using a chatbot to treat depression either because they expected it to be effective or because they were curious about using it. One participant stated that a daily usable chatbot could alleviate feelings of loneliness. Several others noted that a chatbot's personal and human-like nature would increase the motivation to use it, particularly compared with other less interactive DMHIs.

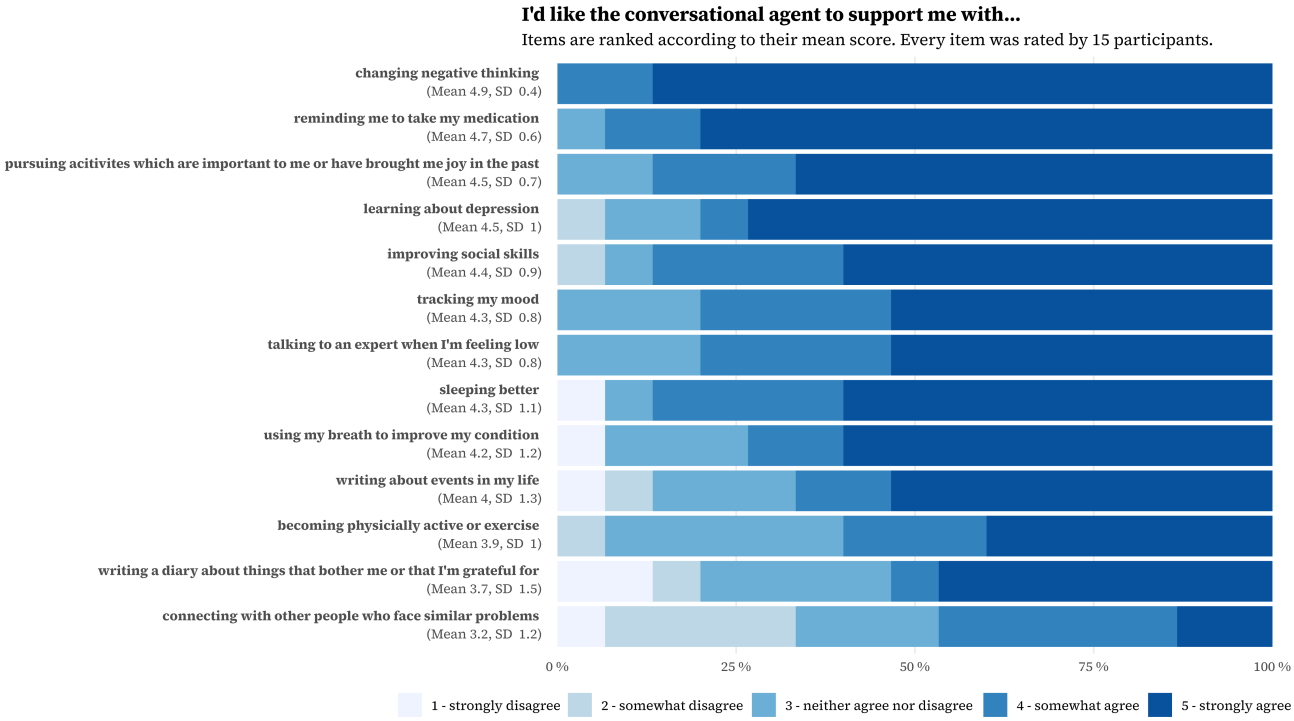
However, participants also reported several concerns regarding the use of chatbots to treat depression. Some participants (n=9, 64%) were skeptical about the chatbot's intelligence and natural language capabilities. They expressed concern that the chatbot would not be able to address individual, diverse, or unusual problems effectively, and feared being disappointed if the chatbot was unable to do so. Participants were particularly worried about inappropriate answers to emotional and intimate topics or inappropriate advice for their problems. Some participants (n=9, 64%) were concerned that a conversation with the chatbot would not feel like a conversation with a human therapist, due to a potential lack of emotional intelligence or overly robotic or analytical responses. However, chatbots that appeared too human were believed to be uncanny. In total, 2 participants (14%) were skeptical about sufficient data security and privacy. Finally, 2 participants (14%) worried that their symptoms of depression, such as little motivation or forgetfulness, would result in low engagement with the chatbot, thereby preventing them from effectively using it. They also pointed out that the lack of social pressure when using a chatbot, compared to seeing a human therapist, could contribute to low engagement, which might not be solvable by the chatbot.

Research Question 4: Chatbot Design Preferences

Category 1: Dialogue Topics and Therapeutic Content

All participants (n=14, 100%) shared preferences regarding dialogue topics that the chatbot should be able to cover. These suggestions include comprehensive assessments of depressive symptoms and interrelated problems, psychoeducation, therapeutic exercises that address specific issues, reminders to address basic needs, support for regulating emotions, tackling intrusive thoughts, and being distracted when needed. Furthermore, they emphasized the importance of discussing their daily lives and, more specifically, sharing current problems and receiving suggestions on how to resolve them. One participant highlighted the importance of the chatbot explicitly asking the user what type of support they require, such as emotional support (ie, listening and validation) or solution-oriented support:

> *Getting advice on how to solve a problem isn't always helpful, even if it's well-intentioned. […] It would be important for the chatbot to ask or understand if you want advice or if you only want to share your feelings.*



Others elaborated on how they imagined talking about daily life and receiving advice:

> *I would just talk about the things that depress me at the time, to which I don't know the answer.*
>
> *I would probably just chat about everyday situations that were unpleasant to me or something like that.*

These preferences were complemented by responses to a questionnaire regarding the chatbot's desired capabilities. Figure 2 presents the full results. The responses indicate the significance of three key components of CBT: (1) cognitive restructuring ("changing negative thinking;" mean 4.9, SD 0.4), (2) behavioral activation ("pursuing activities that are important to me or have brought me joy in the past;" mean 4.5, SD 0.7), and (3) psychoeducation ("learning about depression;" mean 4.5, SD 1). In addition, participants expressed a preference for "improving social skills" (mean 4.4, SD 0.9). On the other hand, therapeutic writing, represented by "writing about events in my life" (mean 4, SD 1.3) and "writing a diary about things that bother me or that I'm grateful for" (mean 3.7, SD 1.5), was rated lower than most items. Finally, "connecting with other people who face similar problems" was ranked the lowest (mean 3.2, SD 1.2).

XSL•FO
RenderX

Figure 2. Results for how much support participants would like for several proposed chatbot capabilities.

Category 2: Personality, Interaction Style, and Social Role

Participants made various suggestions for the chatbot's personality (n=14, 100%), such as understanding, caring, friendly, emphatic, encouraging, humorous, interested, neutral, and nonjudgmental. During the think-aloud sessions, most participants characterized Cady's personality as one of its main strengths. One participant said:

> *I like that you communicate in a friendly way, like an internet friend.*

Furthermore, 2 participants were pleased that Cady was interested and asked them personal questions. For example, 1 participant approved that Cady had asked if she had experienced becoming less active herself:

> *I just think it's good that she is asking if I know something like that or haven't experienced it yet.*

In terms of the interaction style and language used by the chatbot, participants suggested that it should be appropriate for the user's age without complicated terms. This issue was also raised during think-aloud sessions. One participant asked for more age-specific language, such as short sentences:

> *So, this was a therapeutic chat, but if it is supposed to be like a friend, I think it is better if it is writes like people my age, eg using short sentences.*

Another participant perceived the language as too therapeutic:

> *It was relatively authentic, but you also notice that it is not written for my age.*

The human-likeness of the chatbot was also a significant factor, as participants found it important to react to feelings and to understand irony and humor. However, participants also expressed concerns about the chatbot being too human-like, which could lead to irritation or fear. During the think-aloud sessions, 1 participant appreciated that Cady disclosed personal information such as enjoying chats with nice people, which resembled a human-like trait.

Regarding the social role, the participants (n=14, 100%) held divergent views: some desired the chatbot to resemble a friend, whereas others preferred it to assume the role of a therapist or a combination of both. One participant explained their preference for a therapist-like role:

> *I actually think it's better if it were like a therapist [...], because with friends you don't necessarily want talk about everything.*

One participant proposed using situation-specific roles:

> *A therapist if you're doing therapeutic exercises and a friend if you just want to talk.*

Category 3: Personalization

Personalization frequently discussed the importance of personalization (n=13, 92%). Participants reported various aspects that should be personalized, including the chatbot's personality, gender, avatar, message style, dialogue topics, therapeutic content, the mobile app's color theme, notifications, and user profile picture and username. However, the participants had divergent opinions on who should control the personalization of the chatbot. While some suggested that the user should be in control, others believed that the chatbot itself should control personalization. Others, in turn, proposed a mixed approach in which both the user and the chatbot share control. Some participants preferred personalization to occur only once at the beginning, whereas others preferred dynamic personalization, where personalization occurs continuously. In addition to these explicit preferences, personalization also emerged from diverging design preferences. All participants expressed a preference for an appealing user interface, but they

XSL•FO
RenderX

had differing opinions on the specific design elements, with some suggesting a bright and colorful design, whereas others preferred a plain and minimalistic design with black and white colors. Most participants preferred the chatbot as a standalone app, but some preferred integration into a popular instant messaging app such as WhatsApp (Meta). Regarding the interaction modalities, most participants preferred a chatbot over a voice agent. In terms of text input, the participants believed that a mix of predefined answers and free-text input was optimal, as it combines the minimal effort of clicking predefined answers with the flexibility of unrestricted text input. In total, 2 participants (14%) expressed concerns about personalization, stating that personalized content could lead to avoidance behavior, in which users avoid topics that they find difficult or uncomfortable. They also believed that personalization of the chatbot's appearance, such as its gender or avatar, could reduce its seriousness as a tool for treating depression.

Table 3 summarizes key chatbot design recommendations derived from results across all 4 research questions.

Table . Key design recommendations.

Topic	Design recommendation
Assessment	• Incorporate repeated multidimensional assessment, covering depressive symptoms and related problems, to monitor and understand the key issues a user faces. • Ensure assessments are comprehensive yet concise to minimize the effort for users.
Scope and Limitations	• Communicate the chatbot's scope and limitations clearly, for instance, when it cannot properly handle a topic. Redirect users to external resources (eg, helplines and professional interventions) in such cases to ensure users receive appropriate support.
Dialogue content	• Curate a diverse content database covering a wide range of topics that are relevant to youth with depression. • Integrate evidence-based therapeutic techniques alongside user-preferred coping strategies (eg, behavioral activation, cognitive restructuring, and social support). • Enable the chatbot to engage in conversations about users' daily life, including discussions on urgent problems. • Support follow-up discussions on user-reported problems, track progress, and encourage reflection on how successful they carried out the learned techniques.
Personality, social role and language style	• Design a chatbot with an understanding, caring, friendly, empathic, encouraging, humorous, interested, and nonjudgmental personality. • Ensure the chatbot uses age-appropriate language without complicated terminology. • Balance human-likeness (eg, recognizing feelings, irony, humor) with clear boundaries to avoid unrealistic or overly human-like interactions.
Personalization	• Personalize the content selection and presentation. • Personalize the chatbot's persona (eg, personality, social role, gender, avatar, message style). • Explore the impact of persona personalization (eg, switching between formal and casual depending on user feedback, interaction style preferences and situation). • Explore the impact of who controls personalization (the user, the chatbot or both) and when or how often personalization is performed (initial vs ongoing). • Ensure personalization enhances user experience while maintaining the chatbot's therapeutic credibility and seriousness.

Discussion

Primary Findings

This study explored the problems youth face with depression, their adaptive coping strategies, and their attitudes and design preferences for chatbots to treat depression. Our findings indicate that youth experience diverse problems beyond core depressive symptoms, employ a range of coping strategies, hold predominantly positive attitudes toward chatbots for depression, and express diverse, sometimes contradictory, design preferences. In the following section, we discuss the results according to the four research questions guiding this study: (1) the problems youth with depression face, (2) their adaptive coping strategies, (3) their attitudes and expectations toward chatbots to treat depression, and (4) their design preferences for

XSL•FO
RenderX

chatbots to treat depression. As presented in Table 3, our findings across all research questions offer specific guidance for designing chatbots tailored specifically to youth experiencing depression.

Problems of Youth With Depression

First, participants reported various problems with depression beyond the symptoms described in the DSM-5 [50], including mental health and somatic comorbidities, interpersonal issues, and concerns about school and the future. These findings align with previous research showing that youth with depression face an increased risk for anxiety disorders, substance abuse, and physical health issues [51], as well as social withdrawal, lack of friendship [52], diminished academic achievement, school dislike, and pessimism [52]. To address these problems, engaging and effective chatbots should (1) assess both core depressive symptoms and related problems repeatedly to inform therapeutic decisions and strengthen the therapeutic relationship by understanding the users' individual challenges, and (2) curate a diverse content database to address the wide range of problems, aligning with Li et al [53]. Second, participants reported significant barriers to receiving professional treatment, including poor mental health literacy (eg, awareness of symptom severity), attitudinal (eg, perceived stigma), and structural barriers (eg, waiting times). These findings align with research showing that youth struggle to recognize symptoms [54], hesitate to disclose personal information to professionals due to fear of judgement or not being taken seriously [7], and question the effectiveness of professional treatment [7], a concern supported by evidence that 60% of youth with depression do not benefit from psychological treatments [55]. To address these barriers, chatbots should (1) encourage emotional disclosure by providing a nonjudgmental conversational environment, something DMHIs cannot fully achieve due to their static, nonconversational design, and (2) clearly communicate their scope and limitations to set realistic user expectations and direct to external support when needed.

Adaptive Coping Strategies

Participants reported various adaptive coping strategies, including seeking social support, establishing positive activities, using cognitive strategies, and receiving professional treatment. Many also emphasized the importance of focusing on their needs and establishing a daily structure. Most of these strategies fall into the CBT strategies behavioral activation, cognitive restructuring, and problem solving [56], which are effective and first line treatments for depression in youth [57].

The prevalence of CBT-based coping strategies may be due to the previous psychotherapy experience of most participants. Similarly, among youth with nonsuicidal self-injury, those with experience in dialectical behavioral therapy have suggested incorporating it into a DMHI designed for them [58], showing how previous therapy experience influences preferences for DMHIs. The use of CBT-aligned adaptive coping strategies is important, as research shows that youth with depression use adaptive cognitive strategies less frequently than healthy controls [59] and that applying these strategies is associated with fewer depressive symptoms [60]. Chatbots for youth with depression should incorporate these strategies to create engaging and effective content that aligns with users' existing coping strategies and effective therapeutic techniques. For example, the chatbot could facilitate social support by helping users identify supportive individuals and suggesting personalized ways to reach out, such as a video call with a friend who is good at cheering them up or a message to a family member who provides good advice. Chatbots can even draft customizable messages to support users who struggle to reach out.

Attitudes and Expectations Toward Chatbots to Treat Depression

Participants predominantly held positive attitudes toward chatbots to treat depression. Many participants reported feeling less anxious about using a chatbot than seeing a human psychotherapist, especially when discussing sensitive topics. This finding extends research on post-traumatic stress disorder, showing that digital agents lead to greater disclosure of sensitive or stigmatized information [61,62], and supports evidence that youth value the privacy and anonymity offered by DMHIs [63]. Given these findings, chatbots could help users become comfortable with sharing sensitive information and practicing therapeutic conversations, with potential benefits for subsequent sessions with psychotherapists. However, some participants were skeptical about the chatbots' ability to address individual problems and provide appropriate advice on sensitive topics, which is supported by evidence that commercial chatbots for adults with depression often fail to match user inputs, understand messages, or respond appropriately [64]. Although privacy and data security are frequently cited as primary risks of DMHIs for young people [65], few participants raised these concerns. Instead, they viewed chatbots as privacy-enhancing compared with human therapists. Nevertheless, robust privacy and data security remain essential, and it is unclear whether participants were genuinely unconcerned or simply assumed chatbots would have strong protections in place.

Design Preferences

Our study revealed important insights into design preferences for chatbots for youth with depression. First, participants expressed diverse preferences for dialogue topics, with three areas standing out: (1) chatting about daily life, (2) discussing urgent problems and receiving advice, and (3) working through therapy exercises that address specific problems. Interestingly, while youth with nonsuicidal self-injury [58], emotional problems [66], and from the general population [63] included being connected to others facing similar challenges as a key feature of their DMHI, our participants ranked such social connection as their lowest priority, highlighting how design preferences may vary across mental health conditions. In summary, a chatbot to treat depression in youth should reflect these preferences. However, available applications have not implemented chats about daily life, and relied on rule-based approaches for problem-solving [14,15], likely due to insufficient conversational capabilities. Structured therapy techniques, such as behavioral activation or cognitive restructuring, are standard components of DMHIs [38] and chatbots [67]. However, their current implementation remains predominantly static [68], without personalized advice or feedback during therapeutic exercises. Large language models

XSL•FO
RenderX

(LLMs) such as OpenAI's GPT or Anthropic's Claude promise to overcome current limitations of DMHIs and chatbots. LLMs enable chatbots to better address our participants' design preferences, such as natural conversations about daily life and advice on urgent problems. In addition, LLMs can enhance static implementations of therapeutic exercises by offering personalized guidance and feedback. In behavioral activation, LLMs can personalize the explanation of the relationship between behavior and feelings and evaluate the proposed activity plan for feasibility and therapeutic appropriateness. In cognitive restructuring, Sharma et al [69] demonstrated that LLMs can assist users in identifying thinking traps and generating reframed thoughts. Although these enhanced capabilities have the potential to improve understanding and skill development, key challenges remain. LLMs can generate false or harmful messages [70], posing risks to vulnerable users. Future research needs to explore how capitalize on their advanced conversational abilities while ensuring therapeutic quality and safety [71].

Second, our findings show that engaging and effective chatbots for youth with depression need personalization beyond the conversational capabilities of LLMs. Drawing on the framework by Cohen et al [72] for psychotherapy personalization, effective chatbots require personalization in content selection and interaction style. Content selection ensures that chatbots address the diverse problems and dialogue topics our participants reported, aligning with findings from Li et al [53] and Ludlow et al [66]. A personalized interaction style accommodates the preferences for different social roles and language use. While the benefits of personalizing the chatbot persona have been shown [73,74]. LLMs enable the personalization of interaction styles via prompt instructions, reducing the need to craft different responses for each style manually [75]. Despite the clear need for personalization, participants disagreed on who should control it [76], preventing a clear design recommendation. While some preferred user-led personalization, aligning with Kenny et al [63], others favored chatbot-led personalization or a hybrid approach. Given this ambiguity and the lack of empirical evidence [77], future research is needed to guide chatbot personalization.

Limitations

Our study has 2 main limitations. First, our sample size was limited, and the participants were predominantly women. Although depression is more prevalent in women [78-80], the absence of men limits the generalizability of our findings across genders. The gender imbalance resulted from convenience sampling through a single youth psychiatrist. One man was informed about the study but declined to participate. While our study included 2 nonbinary participants, an underrepresented demographic in research, recruiting men would have required targeted efforts beyond our study's constraints. In addition, our sample consisted entirely of participants who had actively sought mental health support, most of whom had previous psychotherapy experience. As a result, perspectives from those who avoid professional help or resist treatment may be underrepresented. Due to these sampling limitations, we likely did not achieve full data saturation. Although qualitative research can reach saturation with as few as twelve interviews [31], our sample composition suggests that some perspectives may have been missed. However, our findings on youth depression and related problems replicated findings from studies with much larger sample sizes [81], indicating that our results are comprehensive. Future studies should recruit a more diverse sample, specifically including men, individuals reluctant to seek professional treatment, and those without previous psychotherapy experience, to validate and extend our findings.

Second, our study captured attitudes, preferences, and hypothetical usage scenarios rather than actual usage behavior. While participants interacted with a prototype during the think-aloud sessions, this brief, controlled interaction may not reflect real-world interactions. The gap between stated preferences and actual behavior is well-documented [82], and our study design does not allow us to determine whether the design preferences of the participants would translate into long-term engagement or effective use. Future research should follow the next steps of an iterative human-centered design process [83,84] with functional prototypes to assess whether the identified design preferences lead to actual user engagement and therapeutic benefits. Despite these limitations, our study provides in-depth findings on the design of chatbots to treat depression in youth, highlighting the value of qualitative research in the iterative development of DMHIs [83,84].

Conclusions and Future Work

Our study provides valuable insights into the problems and coping strategies of youth with depression, and their attitudes, expectations, and design preferences for a chatbot to treat depression in youth. We found complex user needs, predominantly positive attitudes toward chatbots, and various design preferences, including the need for diverse dialogue topics and personalization. Our findings led to concrete design recommendations that lay a crucial foundation for developing engaging and effective chatbots to treat depression in youth.

Despite these contributions, several research directions remain. First, future studies should validate and extend these findings with larger, more diverse samples to ensure broader representation of youth with depression. Second, examining actual usage patterns and long-term engagement with functional chatbot prototypes will help assess the effectiveness of our design recommendations. Third, investigating the responsible integration of LLMs is important, including the development of robust safeguards and evaluating dialogue quality and therapeutic outcomes. Finally, researchers must design and evaluate effective personalization features, particularly regarding whether users, the chatbot or both should control personalization, while balancing implementation efforts and impact. By addressing these research directions, we can further improve chatbots to treat depression in youth and ultimately contribute to more accessible, engaging, and effective mental health support for this vulnerable population.

Acknowledgments

We thank (1) all the participants for their participation in this study, (2) Ulrike Detzner, Reiter, MD for supporting the recruitment, and (3) Lilli Feline Metelmann for her efforts in planning, conducting, and analyzing the study with us. This work was supported by a donation of Cents for help e.V. to SL (project title: “An intelligent therapy chatbot for children suffering from depression and suicidal ideation”). We also acknowledge financial support from the Open Access Publication Fund of the University of Tübingen.

Conflicts of Interest

SL has received public funding, along with other scientists, for on an app-based aftercare intervention for youth and young adults with depression (iCAN study). He has received consultancy fees from companies for advice on study and intervention design in the context of e-mental health. He has also received payments for lectures on e–mental health. None of the other authors declare any conflict of interest.

Abstract

Background: Falls are the leading cause of injury-related death among adults aged 65 and older. The fear of falling can further limit older adults' independence by contributing to activity restriction, social isolation, and physical decline—ironically increasing the risk of mechanical falls. Although home safety assessments have been shown to reduce fall risk by up to 36% and decrease serious injuries such as hip fractures, their adoption remains low. Understanding the barriers to implementing these assessments is critical to improving their uptake and effectiveness.

Objective: This study aimed to (1) identify specific barriers perceived by older adults in implementing home safety assessments and modifications to reduce the risk of mechanical falls, (2) explore the attitudes of health care professionals and other stakeholders toward these assessments, and (3) identify novel design opportunities to guide the development and implementation of more effective home safety assessment techniques and practices to reduce mechanical fall risk.

Methods: This explanatory qualitative study drew on the "inspiration" phase of the human-centered design (HCD) research process. We conducted 35 interviews (28 initial and 7 follow-up) with 28 purposefully sampled participants in the San Francisco Bay Area between February and June 2021. Participants included community-dwelling older adults (n=3), geriatricians (n=4), therapists (n=6), product developers (n=2), older health researchers (n=8), and community program leaders (n=5). Interview notes were analyzed inductively by the research team to extract themes and generate insight statements and design opportunities.

Results: Analysis yielded three key insights: (1) older adults often experience a conflict between maintaining independence and implementing safety modifications. One participant described living with a "repeating mantra in my head throughout the day saying 'above all, don't fall.'" (2) aesthetic and privacy concerns frequently override safety benefits. Participants rejected modifications that made their homes feel "institutional." (3) access to occupational therapy services—already limited in rural areas—was further constrained by the COVID-19 pandemic, with some providers reporting that travel time "took up the majority of their day just assessing one home." These barriers help explain the low adoption of home safety assessments despite strong supporting evidence. The study identified design opportunities to address these challenges, including customizable, user-friendly safety solutions, dignity-preserving approaches to assessment, and technology-enabled remote alternatives.

Conclusions: This study identified specific emotional, aesthetic, logistical, and access-related barriers to the adoption of home safety assessments among older adults. The proposed design solutions offer promising directions to increase uptake, improve user experience, and enhance safety. However, further validation through co-design with a larger and more diverse group of older adults is needed. Future research should pilot test these ideas across varied contexts and evaluate their implementation and impact.

Introduction

A total of 1 out of 3 people aged 65 years and older falls annually, and falls are subsequently the leading cause of injury-related death in this age group [1,2]. Falls result in 2.8 million emergency department visits every year, with 25% of admissions being associated with serious injuries, such as fractures or traumatic brain injury, which can permanently decrease quality of life [3]. Fatal and nonfatal falls cost an estimated US $50 billion in the United States in 2015, which increased up to US $80 billion in 2020, with the bulk of the cost attributed to nonfatal falls and paid for by Medicare [4,5].

Falls and fear of falling in turn threaten older adults' ability to live independently and often lead to self-imposed activity restriction, social isolation, decreased cognitive and physical function, and, paradoxically, an increased risk of serious falls [6,7]. The emotional impact of falling is grave, with studies finding that 80% of older women would prefer death to a bad hip fracture that would lead to nursing home admission [8]. Alternative solutions to receiving 24-hour monitoring and high-level medical care in a nursing home, such as moving into an assisted living community where support is available for activities of daily living, are a last resort for many. The vast majority (90%) of older adults aged 50 years or older prefer to age in place in their current home [9]. However, 85% of these same individuals who desire to remain living at home have not adequately prepared their homes for aging in place through efforts such as removing trip hazards and installing assistive devices (eg, bathroom grab bars) [9]. Finding a wide range of ways to reduce falls can potentially both increase the quality of life for older adults choosing to age independently and also lead to large savings in direct medical costs [10].

The risk of falling and resulting serious injury are associated with many modifiable and nonmodifiable risk factors. Nonmodifiable risk factors include age, cognitive impairment, female sex, and a history of falling [11]. Modifiable risk factors include balance impairment, gait impairment, muscle weakness, medication use, and home environment [11]. Unfortunately, there is no one single risk factor for falls upon which to intervene. Fall risk is multifactorial, and falls tend to occur when impairments exist in multiple domains of an individual's health [12].

There has been extensive research on interventions that can reduce the risk of fall-related injury and mortality in the older adults. For example, home safety assessments performed by an occupational therapist for community-dwelling older adults have been shown to significantly decrease the rate and risk of falling by up to 36%, along with reducing serious fall-related complications, including hip fractures and death [13,14]. Keall et al [15] randomized 842 senior households to an intervention involving a standardized set of home safety modifications including staircase handrails, bathroom grab bars, improved lighting, nonslip mats and rugs, and an educational brochure on home safety, which demonstrated a 26% decrease in fall injuries in the intervention group compared with the control group.

Despite the clear, data-driven benefits of home safety assessments and related home environmental improvements, adoption of these services remains low for a variety of reasons. Some insurance companies that previously covered home safety assessments as a benefit for their members have discontinued this benefit due to low use by older adult policyholders [14,16]. One key reason for the underuse of home safety assessments is that many older adults perceive a visit from a health care provider as a reminder of their inevitable aging and an invasion of their privacy, with some reacting to suggested changes as an encroachment on their personal independence, dignity, and sense of control [17-19] Personalized care approaches that prioritize individual preferences can significantly improve intervention acceptance and perceived autonomy [20]. Furthermore, concerns about loss of independence often outweighs the fear of injury, leading older adults to underuse fall prevention interventions [21].

Older adults' resistance to addressing the physical, social, and emotional changes associated with aging may be exacerbated by their minimal inclusion in decision-making processes, particularly those related to their living spaces [18,22]. Multiple studies suggest that this exclusion increases resistance to home modifications and other aging-related changes, as older adults often feel a loss of control when they are not actively involved in decisions affecting their environment [19,20]. By involving older adults in these decisions, their sense of autonomy and dignity can be maintained, which in turn reduces emotional distress and increases acceptance of necessary changes [21].

Understanding the barriers older adults face in using home safety assessments is critical to addressing modifiable fall risk factors and reducing falls. This study aimed to (1) identify specific barriers perceived by community-dwelling older adults in accessing and implementing home safety assessments and modifications, (2) explore attitudes of health care professionals and additional stakeholders toward home safety assessments, and (3) identify novel design opportunities to guide the development and implementation of more effective home safety assessment techniques and practices.

Methods

Study Design and Setting

This explanatory qualitative research study used human-centered design (HCD) methodology to understand the barriers to home safety assessments and develop opportunities to support fall prevention for community-dwelling older adults [23,24]. The study was performed as a collaboration between Stanford University's Design for Extreme Affordability course within the Hasso Plattner Institute of Design (d.school) and The Better Lab, an academic research laboratory focused on HCD in health care, based in the Department of Surgery at the University of California, San Francisco. Study activities took place between February and June 2021, with interviews conducted both virtually and in person at Stanford Hospital and Clinics.

Research Team Characteristics

The research team consisted of 3 designers from Stanford's d.school, 2 clinical researchers from the University of California,

XSL•FO
RenderX

San Francisco (both practicing geriatricians), and 2 HCD researchers from "The Better Lab." Team members had expertise in geriatric medicine, occupational therapy, design research, and public health. A total of 4 members had prior experience conducting qualitative research with older adults, and all researchers received training in qualitative interviewing techniques to ensure consistency. We acknowledge that our clinical and design backgrounds may have influenced our focus on intervention development. To mitigate bias, our team engaged in regular discussions to examine assumptions and incorporate peer debriefing throughout the study. None of the researchers had prior relationships with study participants.

Participant Selection

We used purposeful sampling to ensure heterogeneity and diverse representation of stakeholder perspectives [25]. Our sampling strategy aimed to include individuals with varied relationships to home safety assessment implementation, including (1) community-dwelling older adults who might benefit from assessments, (2) health care providers who conduct or refer for assessments, (3) family members who support older adults in making home modifications, (4) program administrators who oversee assessment services, (5) product developers working on related technologies such as assistive technology, smart home solutions, or fall prevention tools.

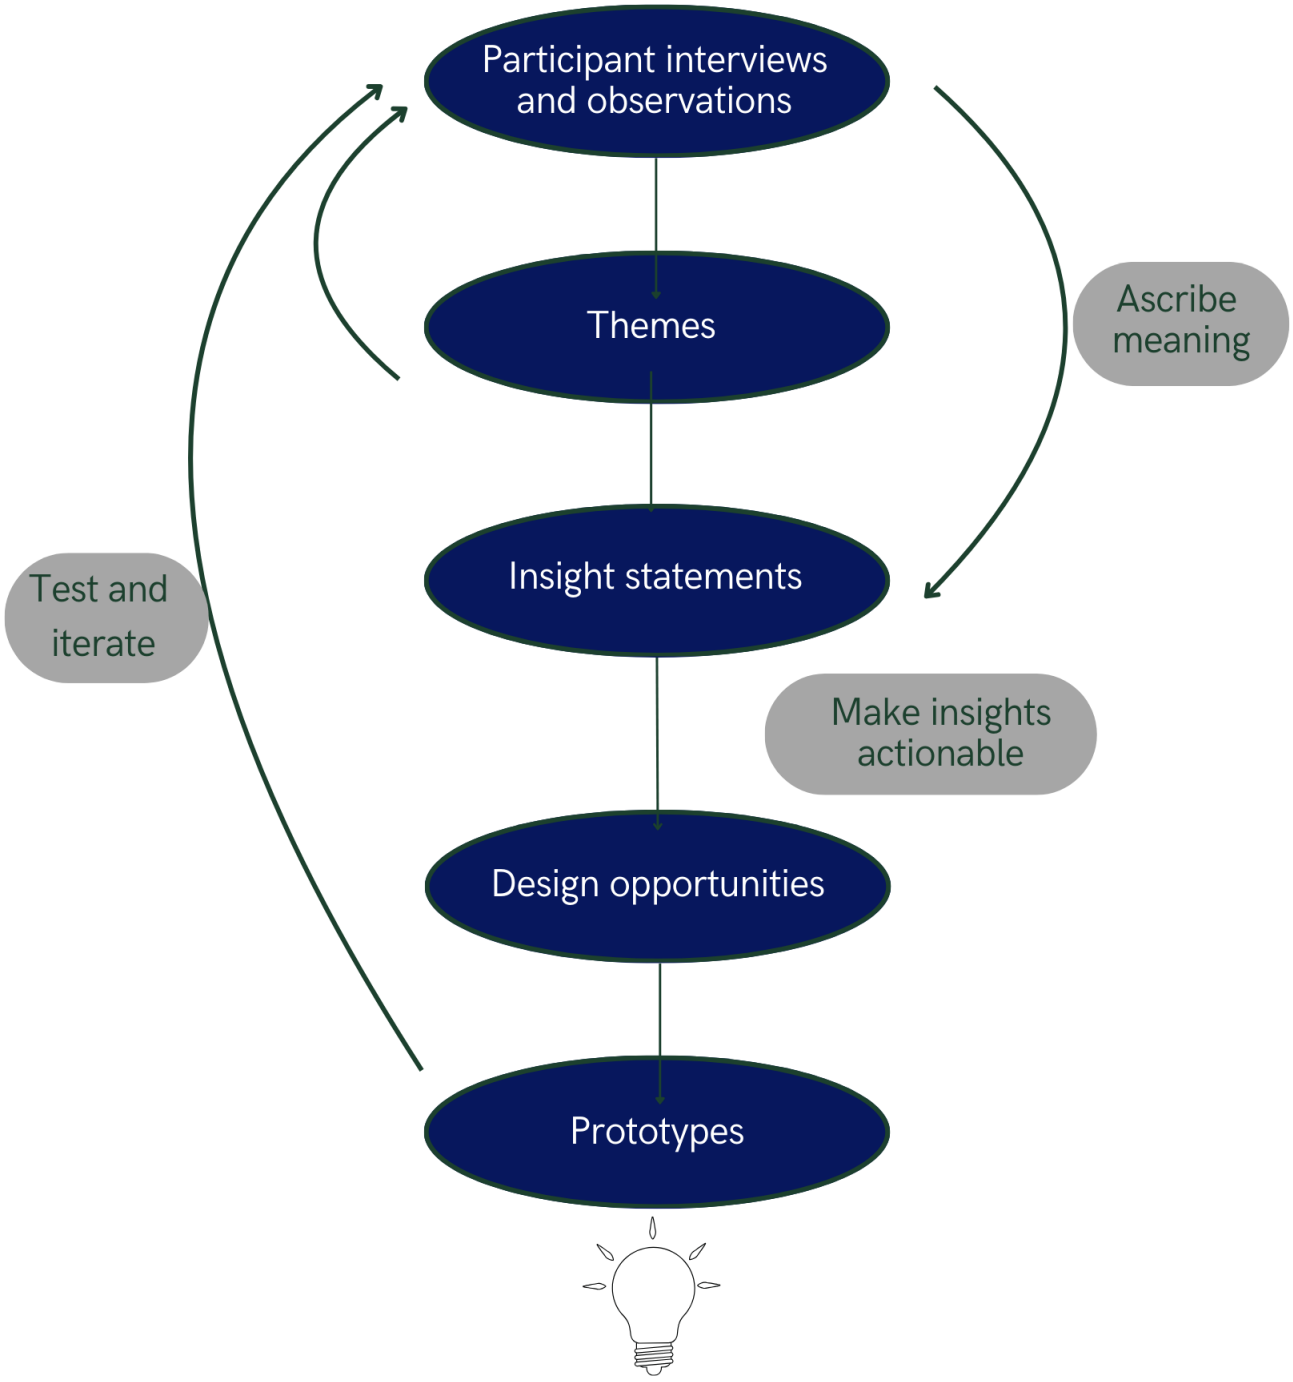
Our selection criteria included age (65+ years for older adults), direct involvement in home safety assessments, and willingness to discuss their experiences. We specifically sought older adults with varying experiences with falls and home modifications, ranging from those who had never had an assessment to those who had implemented modifications. Health care providers were selected to represent different specialties and practice settings.

HCD Process

Over the past decade, the use of HCD in health care has grown substantially. Case studies and qualitative analyses suggest that using HCD approaches may enhance patient engagement and improve service delivery, potentially leading to better health care access and outcomes [26-28]. HCD is problem-solving methodology rooted in engineering, psychology, anthropology, business, and design that brings together designers and stakeholders of an issue to identify challenges and use an iterative process to cocreate solutions [29]. HCD uses ethnographic research methods to identify unmet needs and contextualizes the study challenge within the greater ecosystem to identify impactful and sustainable solutions [24,26-28].

The HCD process consists of three phases: inspiration, ideation, and implementation [30]. The inspiration phase involves identifying unmet needs through interviews and observations with key users and related stakeholders [31]. Qualitative data from these interviews and observations are synthesized to identify themes and inform the creation of insight statements and design opportunities. The ideation phase involves convening users, stakeholders, and designers for group workshops aimed at brainstorming potential solutions and co-designing prototypes of the most desirable, feasible, and viable potential solutions [30,32]. Finally, the implementation phase consists of iterative testing, incorporating user and stakeholder feedback to refine prototypes for pilot testing [30]. This paper describes the inspiration phase of our study in which we explored barriers to home safety assessments and modifications by interviewing older adults, health care professionals, and other key stakeholders.

Inspiration Phase Qualitative Data Collection and Analysis



We recruited all participants using purposeful sampling to ensure heterogeneity and a diverse representation of perspectives in the study cohort, consistent with the HCD methodology [33]. Recruitment criteria involved individuals directly involved with home safety assessments or fall prevention. We obtained qualitative data through interviews with older adult users and other key stakeholders, including clinicians (physical therapists, occupational therapists, geriatricians, and surgeons), family members of older adults, engineers, senior living community administrators, interior designers, and payers. We created a semistructured interview guide to understand factors that contribute to falls, experiences within the health care system following a fall, and the psychological impact of falls.

We interviewed a total of 28 participants for 30 - 60 minute interviews conducted virtually over Zoom (Zoom Communications, Inc) or in person at Stanford Hospitals and Clinics between February and June 2021. In light of COVID-19 restrictions, we conducted interviews both virtually and in-person, and in both settings we ensured participant comfort and openness to create a flexible environment for discussion. Two to three researchers per session conducted the interviews, with 1 lead researcher leading the interview while the other researchers transcribed detailed notes.

Figure 1 illustrates this study's multistep HCD qualitative analysis process, which we followed up to the step of developing design opportunities. We followed a 3-step approach using reflexive thematic analysis [34]. First, 3 team members, who were students with a background in design and working in partnership with a HCD expert, independently conducted an inductive thematic analysis of the interview notes to identify emerging themes and refined them through discussions until consensus was reached [35,36]. Second, the entire research team collaboratively developed and reached consensus on multiple insight statements, capturing relational themes such as tensions, synergies, barriers, and facilitators to health behavior described by participants. Third, all research team members collaborated to translate each insight statement into 1 or more design opportunities through structured discussions, with each opportunity representing actionable concepts or intervention elements that directly address the challenges identified in participant responses [37],[38-39].

Ethical Considerations

This study was determined to be exempt from review by Stanford University's Institutional Review Board (60770). All participants provided verbal informed consent after reviewing study information. Given the sensitive nature of discussions about falls and home modifications, we took particular care to allow participants to skip any uncomfortable topics, provide support resources when appropriate, and to protect confidentiality in our data management. Participation was voluntary, and interviewees received US $20 gift cards as compensation. Interviews were anonymized to protect patient confidentiality. No interviews were audio or video recorded due to the sensitive and confidential nature of these conversations.

Results

Overview

A total of 35 interviews (28 initial and 7 follow-up) were conducted between February and June 2021. Our participant group comprised 28 diverse stakeholders: 3 community-dwelling older adults, 4 geriatricians, 6 therapists (including physical, occupational, and mental health–focused practitioners), 2 product managers, 8 researchers specializing in older health, and 5 leaders of older care programs and communities. Of these, 18 (64%) participants identified as women. Interview lasted between 30 and 60 minutes.

XSL•FO
RenderX

Through inductive analysis of interview data, we identified 3 key insights regarding the interconnected and sometimes opposing perspectives of older adult users, occupational therapists, community living organizations, and geriatricians on fall prevention and home assessments. Below, we present these insights along with proposed design opportunities that emerged from our analysis.

Insight 1

Older adults have a strong desire to maintain active, independent lifestyles that align with a sense of youthfulness, yet alterations to their environments and lifestyles that could enhance their well-being and safety are perceived as undermining independence, vitality, and creating fear around being active.

Older adults may be overwhelmed and disoriented by an increasing loss of control over their health, lifestyle, and relationships. For example, one older adult interviewee described an all-consuming fear of falling following her first fall, such that she hears a repeating mantra in her head throughout the day saying, “above all, don’t fall.” Much like an initial fall, a visit from a health care provider can remind older adults about their inevitable aging, which may contribute to resistance against home assessments. One geriatrician interviewee observed that “patients are reminded of their mortality when an occupational therapist comes to the home to visit.” In addition, multiple stakeholders shared the perspective that during home assessments there is often an extensive list of home modifications that are suggested to make older adults’ homes safer without much consideration of how older adults feel about these changes. For example, one older adult user who had grab bars placed throughout her home reflected that “the way they looked around her home” was a key reason she did not want them installed. The gray color and material of the standard grab bar reminded her of the hospital room, she stayed in for treatment of a former injury, which she wanted to avoid recreating in her home. This suggests that to increase adoption of an effective fall-prevention or safety assessment service, users need to feel motivated and not fearful to make changes to their lifestyle and that engaging users in customizing adaptations to their aesthetic preferences may be a method to improve users’ perception of control.

Much like baby-proofing a home is a sign of natural change in a family unit to protect their well-being, “age-proofing” serves a similar purpose for older adults. As one gerontology expert interviewee noted, “Homes age over time as well, and there’s this idea that a home ages and changes with you.” However, choosing not to “age-proof” their home may be an older adult’s way of rejecting the notion that their lifespan is limited. For example, older adults in our interviews have expressed sentiments such as, “We don’t want to go into a nursing home or senior housing because that’s where old people live.” This fear of aging may lead to a maladaptive way of dealing with the aging process in some individuals, similar to how a fear of falling can paradoxically increase the risk of falls.

Design Opportunity 1

Return a sense of control and autonomy to older adults in the home redesign or adaptation process. A home safety assessment tool can be designed to prioritize customizability and facilitate direct feedback from users. The essential features of this product include:

Active Participation

Engaging older adults as active participants and decision-makers in any home redesign or change so that they can shape their own personal aging experience, which is currently often overlooked.

Customizable Solutions

Providing a customizable system of home modifications that older adults can use to experiment with different materials or patterns (eg, mahogany wood for safety devices such as grab bars) to discern their aesthetic and functional preferences.

Positive Framing

Generating enthusiasm from older adults for home modifications by framing them as enhancing rather than diminishing independence, helping them feel more aligned in their goals of care with occupational therapists and geriatricians.

Growth Mindset Toward Aging

Encouraging a growth mindset to aging that emphasizes openness to adapting in a healthy, safe, and dignified manner while maximizing the opportunities available to older adults for engaging in daily life activities and aging in place.

Insight 2

Older adults are willing to risk their safety, even their lives and health, to protect the familiarity of their homes from the change and invasion of privacy associated with home safety assessments.

Older adults know the layout of their homes intimately; one older adult interviewee described this as follows: “We know our home just as well as you know the layout of your childhood home… and know how to avoid the tiny things even when waking up in the middle of the night.” An academic public health specialist in California who focuses on issues affecting the geriatric population, expressed in an interview that “[Older adults] are reluctant to let a stranger into their homes to change things.” Multiple older adult interviewees expressed that they had already heard from their children and relatives that they need to make their home safer through modifications but had rejected that advice. One older interviewee cited aesthetics as the reason for rejecting suggested changes saying, “My kids have been telling me for months now to clean up my clutter and install a grab bar in my shower, but I just don’t like the way it looks in my home.” However, according to a geriatrician interviewee, when considering accepting support to adapt their homes to support aging in place, “the elderly struggle with dignity.” Home was described by multiple older adult interviewees as representing a personal haven, or area of refuge and constancy away from the influences and preferences of others. Maintaining control over their home may be considered an aspect of living with dignity for the community-dwelling older adults in the current sample.

Both older adult users and clinicians shared in interviews that resistance to changing the home persists even after an older

XSL•FO
RenderX

adult's first fall, suggesting that users' disinterest in making home modifications is not rooted in concern for their health, but rather in the emotions associated with aging, change, and privacy. This idea is supported by the perspective of a fall prevention center leader who stated in their interview that "They [older adults] don't want to change, and this term [home modifications] isn't enough to conquer their fear of change." The design opportunities that we framed from the insights gleaned from interview data, therefore emphasized understanding and addressing older adults' powerful emotions and feelings of fear of change and loss of independence in any solution.

Design Opportunity 2

Reframe how home safety assessments are perceived by users so that older adults can become fully engaged in the broader process of safely aging in place while protecting themselves and preserving their dignity and independence. The home safety modification process can become an engaging opportunity for an older adult to design their personalized "forever" home while also enhancing their safety. The essential features include:

Inspiring a Positive Outlook

Encouraging older adults to embrace the next stage of their life using home safety assessments and modifications.

Connecting With Trusted Professionals

Linking users with local contractors who can install both the necessary fall prevention devices as well as any additional renovations that the older adult would like to enhance their safety while maintaining the comfort of home.

Providing Educational Resources

Offering supplemental educational resources about changes that occur during aging to help users conquer their fear of losing dignity and independence.

Insight 3

Access to home safety assessments would improve older adults' safety yet they are perceived as unsafe or inaccessible, especially during the COVID-19 pandemic. The COVID-19 pandemic illuminated and exacerbated the existing misalignment in supply and demand for occupational therapists and home safety assessments. It also opened opportunities to assess technological approaches to work on the problems of accessibility and acceptability of home safety assessments for older adults. Many community and aging organizations such as Ashby Village in California, have turned to trained volunteers to perform home safety assessments for individuals within their network given the high demand for occupational therapists. During the COVID-19 pandemic, when quarantines and social distancing were established, in-person home safety assessments within these communities were halted. During our interview in 2022, Ashby Village organizers mentioned to us that "we haven't done any home assessments since March 2020 and do not plan on doing any for the foreseeable future." Though they resumed this service postpandemic, in the interim many users who might benefit from a low-cost fall prevention service were left without access. Even though larger health care networks continued to perform in-person visits during the pandemic, we heard from older adult users about their resistance to having a stranger come into their home. "If I can't even feel safe inviting family into my home, why would I invite a complete stranger in?"

Finally, even large health care networks have struggled to reach older adults who live in rural areas. As one interviewee noted, a home safety assessment process for such an individual would consist of "sending an occupational therapist on a 2-hour commute each way to see this person which can take up the majority of their day just assessing one home." This suggests a current unmet need in the home safety assessment space, which likely disproportionately affects rural and underserved populations and will continue to grow as the population ages.

Design Opportunity 3

Increase access to home safety assessment tools using alternative and innovative technologies. Online home safety assessment tools would allow users to benefit from a home safety assessment and a reduced fall risk, even with fewer volunteers and limited in-person visits due to the pandemic. The essential features of such a tool could include:

Online Home Assessments

Developing an online assessment tool which allows users to submit photos of various rooms in their home for review by licensed occupational therapists, which can produce a risk score for each room and identify areas that should be addressed.

Future Adaptability

Implementing computer vision and machine learning, which can examine visual data representations and automate the home safety assessment process over time.

Personalized Recommendations

Combining visual data with user surveys that contain their demographic information and design preferences to generate personalized home modification suggestions, ensuring adaptations accommodate mobility aids (eg, walkers), while remaining functional and aesthetically pleasing to the user.

Further possibilities using a wide range of technological tools and equipments, including smartphone and tablet apps, video games, wearable devices, and future robotic efforts to improve home safety assessments. Their potential impacts on fall prevention efforts are discussed in the "Discussion" section.

Discussion

Principal Findings

This study provides insights into the complex factors affecting the adoption of home safety assessments among older adults and suggests potential directions for improving implementation. Our findings highlight 3 key areas of tension existing between stakeholders in aging in place process, including older adults, clinicians, home assessors, and others: maintaining independence while ensuring safety, preserving home sanctuary while accepting modifications, and balancing assessment access with implementation constraints. Since older adults in the current sample desired to preserve their independence and dignity, they were resistant to implementing recommended changes, especially those related to their home safety, as they wanted to

XSL•FO
RenderX

avoid the negative emotions associated with considering how aging impacts physical and other abilities. The strong emotional responses to home modifications revealed in our study align with previous research showing that older adults often perceive environmental changes as threats to independence [40]. However, our findings extend this understanding by highlighting how aesthetic and personal meaning considerations may override known safety benefits. This suggests that purely educational or risk-focused approaches may be insufficient to drive behavior change.

The COVID-19 pandemic's impact on assessment delivery highlighted both challenges and opportunities in service provision. While disrupting traditional in-person assessments, it accelerated exploration of remote alternatives. However, technological solutions must carefully consider older adults' preferences and potential barriers to adoption.

Technology has become increasingly integrated into the fall prevention research and health care field, especially following the 2008 decision by the Centers for Medicare and Medicaid Services to stop reimbursing costs related to in-hospital falls [41,42]. For example, smartphone and tablet apps have been developed to encourage greater levels of exercise in older adults, which in turn can reduce falls [43]. Similarly, video games such as the Wii Fit have been successfully used to perform mobility-based fall risk assessments in older adults [44]. Wearable sensors have also been increasingly studied, with a systematic review identifying 40 studies and 130 distinct variables examining sensor use in geriatric falls with promising results [45]. Technologically supported interventions may reduce fall risk either by directly minimizing an older adult's physical risk of falling or by improving their confidence to reduce their fear of falling, which is an important predictor of falls. Older adults' adoption of wearable sensors such as fitness trackers could lead to the accumulation of "big data"—a large-scale dataset automatically collected from the sensors themselves, potentially enabling analysis and detection of patterns in fall risk and incidence to be identified more easily—though, this would depend on greater uptake of digital technologies in this population than has yet occurred.

Only a limited number of studies have used technology specific to the home safety assessment process. For example, Du et al [46] used a robotic system operated remotely by occupational therapists to conduct home safety assessments. In addition to providing a video livestream of the home, the system was able to measure distances between objects, detect lighting situations, and communicate with the older adult. Furthermore, ambient camera-based sensors have also been tested for automatic fall detection [47]. However, both solutions face challenges in uptake, given the cost associated with the technological systems and the time needed for installation and for the user to learn the system. Another study collated a protocol to be used for remote home safety assessments through extensive secondary research and interviews with occupational therapists and caregivers [48]. Taken together, these previous studies and our current one highlight the increasing recognition of home safety assessments as a potential area of improvement in fall prevention, and evidence of the value of future investments in user-friendly technological interventions for fall prevention and awareness among older adults.

Limitations

This study has several important limitations. First, while we sought to understand older adults' perspectives, only 3 of our 28 participants were older adults themselves. This occurred primarily due to recruitment challenges related to COVID-19. This limited representation may not capture the full range of older adult views and experiences. Future work should more deeply engage older adults both as study participants and as co-designers of proposed solutions. Second, our proposed design opportunities emerged from researcher analysis rather than cocreation with stakeholders. While grounded in participant insights, these proposals require validation through future participatory design work with end users and stakeholders. Third, all participants were recruited from the San Francisco Bay Area, potentially limiting generalizability to other geographic and cultural contexts. Health care access, technology adoption, and attitudes toward aging may differ substantially in other regions. Finally, our use of interview notes rather than full transcripts may have missed subtle themes or nuances in participant responses. This approach was selected to maintain the confidentiality of participants experiencing a sensitive issue. Future studies would benefit from recorded and transcribed interviews to enable more detailed analysis.

Conclusions

This exploratory study reveals important considerations for improving home safety assessment implementation. Successful interventions likely require careful attention to older adults' emotional needs, aesthetic preferences, and desire for autonomy. While technology-enabled approaches show promise for expanding access, they must be developed in partnership with older adults to ensure acceptability and adoption. Our findings suggest that addressing these factors could potentially lead to more effective interventions and increased adherence to home modifications.

Future research should involve larger, more diverse samples of older adults to validate and refine proposed design opportunities using co-design methods. Prototypes of promising approaches should be pilot tested in varied geographic and cultural contexts. It will be important to then evaluate both implementation outcomes and impacts of pilot-tested interventions on fall prevention.

In addition to research advancements, our findings have practical implications for clinical practice. Training programs for occupational therapists should incorporate strategies to address older adults' emotional and psychological barriers to home modifications. Furthermore, the development of educational materials tailored to older adults' concerns—such as maintaining dignity and control while making safety modifications—could facilitate better engagement with home safety interventions.

Rather than prescribing specific solutions, this work provides a foundation for human-centered approaches to fall prevention that honor older adults' dignity while promoting their safety. By integrating these insights into practice, health care

XSL•FO
RenderX

professionals and designers can create more effective, personalized, and widely adopted fall prevention strategies.

Acknowledgments

This research was funded by the Social Entrepreneurship Lab at Stanford University. The authors would like to thank Stanford University students Summer Hu, Chris J Fisher, and Kesaobaka Modukanele for their support in collecting and analyzing qualitative data for this study. The authors would also like to thank Jessie von Hippel and UCSF medical student Saffanat Sumra for their support in editing this manuscript.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Conflicts of Interest

Abstract

Background: The rapid increase in the number of health apps and their volatility in Austrian pp stores for Android and Apple are signs of a flourishing business sector in the wellness industry.

Objective: In this report, a questionnaire for informed decision-making by users was developed and evaluated using health apps in the categories “Nutrition”, “Exercise”, “Mental Health” and “Symptom Checker”.

Methods: Evaluation criteria were derived from multiple reference documents and weighted in a survey, as well as a focus group meeting. Further, the selected evaluation criteria were tested against selected apps, which were most popular in the above-mentioned categories in fall 2023.

Results: The short questionnaire is to be made publicly available to citizens and covers the categories of the quality of the app provider (regulatory compliance, safety, and quality assurance), the content quality of the app (functionality and evidence-based content), and the user-friendliness of the app. It consists of 6 question items, which appeared to be problematic in the evaluation most often. For ease of use, a short questionnaire with the most critical questions and helpful tips from the evaluation was expanded by the question of importance and with meaningful advice on how to find the right information in an app.

Conclusions: The evaluation based on the comprehensive questionnaire using selected apps confirmed the importance of such a questionnaire since most of the apps lacked basic properties in terms of safety and security.

Introduction

Background

The global as well as national supply of health apps is overwhelming, and more and more people are using health apps. This raises the basic questions of which apps can be considered health apps, and how can the credibility of these apps be better assessed.

Fundamentally, a distinction is made between [1] health and mobile apps. Health apps are applications targeting consumers. They are intended to be used for preventive purposes and help promote or change lifestyle in a health-promoting manner.

On the other hand, medical apps are applications used to support “self-empowerment” (self-determination) and, for example, are supportive in coping with chronic diseases or in rehabilitation [2], which are subject to regulations like the medical device regulations.

The use of evaluation criteria for health apps is important for several reasons, as described below.

Functionality

Evaluation criteria can assess the functionality of health apps to ensure that the intended tasks are effectively fulfilled. This could include monitoring health parameters, reminding users to take medication or providing personalized health recommendations.

Quality assurance

Evaluation criteria help assess the quality of health apps. This is particularly important because the information and functions provided by health apps can have a direct impact on the health

XSL•FO
RenderX

of users. Criteria enable ensuring that the apps provide accurate, reliable, and evidence-based information.

Evidence-based content

Health apps should be based on scientific knowledge to provide accurate and reliable information. Evaluation criteria can verify whether the content presented in the apps is based on current scientific evidence.

Usability and user experience

The usability of health apps is crucial for their effectiveness. Evaluation criteria can assess usability and accessibility to ensure that the apps are easily understandable and accessible. Furthermore, accessibility criteria may be important for allowing the apps to be used by impaired users.

Privacy

Apps may process personal health data, so it is crucial to ensure that only the minimal set of data is acquired ("data minimization") and that data are secured and protected in transit and at rest. Evaluation criteria can consider aspects such as data privacy, encryption, and compliance with regulatory requirements.

Regulatory compliance

Apps, especially health apps may need to comply with certain legal and regulatory requirements. Evaluation criteria can assess whether the apps comply with applicable regulations and standards.

Study Objectives

By applying evaluation criteria, users, health care providers, and regulatory authorities can make more- or better-informed decisions about the selection and use of health apps to ensure that they make a positive contribution to the health and well-being of users. Payors also need clear and transparent criteria to decide on reimbursement aspects.

The objective of this study was to establish evaluation criteria for users to make well-informed decisions in regard to health apps. Health app evaluation frameworks, such as the Mobile App Rating Scale (MARS) [3] and the ENLIGHT Tool [4], provide structured criteria for assessing functionality, usability, and information quality, typically for professional or research use; however, this work focuses on evaluation by laypersons rather than professional organizations, emphasizing user-friendly criteria for informed decision-making.

Methods

Ethical Considerations

Formal ethics approval was not required for this study because no patients or other vulnerable populations were involved. The user survey was completed anonymously by registered participants who volunteered to take part. No identifying information was collected at any stage, and all respondents provided informed consent before proceeding.

Literature Search and Selection of Relevant Documents

The selection of evaluation criteria was conducted as part of a literature search based on the keywords "Bewertungskriterien Apps Gesundheit" (evaluation criteria health apps) and "evaluation criteria health Apps" in English. The search was carried out on the portals Google Scholar and PubMed, and additional literature references from publications were followed up based on the results.

The World Health Organization (WHO) includes "health apps" in the "Classification of Digital Health Interventions v1.0 (DHI)" [5,6]. This primarily categorizes apps according to target groups (eg, for clients or citizens or health care providers) and health system challenges, which then result in system categories for digital health applications.

According to the health system challenges level of health apps, "Lost client data" entails the interventions "1.1.3. Provision of individualized reminder services for clients" and "2.2.1 Longitudinal recording of health status and services of clients", corresponding on a system level to the functions "Client Information System" and "Electronic Health Record". The taxonomy used was based on [7] and the "Guidelines for reporting of health interventions using mobile phones: mobile health evidence reporting and assessment (mERA) checklist" [8].

These two documents generally refer to comprehensive mobile health (mHealth) applications with a strong focus on already manifested diseases.

Partially, reliance was placed on systematic reviews already conducted, such as health technology assessment frameworks for eHealth: a systematic review [9] or framework for supporting reimbursement decisions for digital health applications (mHealth) and its (retrospective) application to selected examples [1].

However, all of these encompass digital health applications, not just health apps. The existing assessment frameworks use different formats (checklists, questionnaires, and tables) and show differences in terms of the spectrum of evaluation domains, additional technology-specific aspects, and target groups. None of the frameworks are fully established or field-tested.

At the European level, there is also the initiative Label2Enable [10]. Label2Enable is an EU-funded project. Its task is to introduce CEN-ISO/TS 82304‐2 and its quality seal for health and wellness apps. The goal is to create a digital single market where high-quality health apps can be extensively used in prevention, health care, and self-care.

The ISO/TS 82304-2:2021(en) "Health software — Part 2 [11]: Health and wellness Apps—Quality and reliability" served as the basis for developing the evaluation criteria.

The following publications also served as the basis for the evaluation criteria:

1. Health apps. Basic paper with special consideration of the aspect of health literacy [12],

XSL•FO
RenderX

2. Opportunities and risks of health apps (CHARISMHA); German: chances and risks of mobile health apps (CHARISMHA) [13],
3. Deutsches Netzwerk Versorgungsforschung e. V. Memorandum - health and medical apps [2],
4. Health apps: How can certification look concretely: Learning from experiences here and elsewhere [14],
5. Digitization and patient safety - HE 2) Checklist for the use of health apps [15],
6. Evaluating, but how? - Criteria for the evaluation and reporting of studies on health and medical apps [16],
7. How good are health apps? What determines quality & risk? What guidance is available? [17],
8. Mobile app rating scale: a new tool for assessing the quality of health mobile apps [18],
9. Methods box health literacy [19],
10. Health apps: significant lever for patient empowerment - potentials, but hardly used so far [20],
11. Professional checklist good health information [21].

Development of Evaluation Criteria

From the above publications, the evaluation criteria mentioned therein were entered into an Microsoft Excel file and assigned to overarching categories. In the next step, the discovered evaluation criteria were harmonized and evaluated. The evaluation criteria with the most matches were included in the list of evaluation criteria and categorized again. The preliminary evaluation criteria were presented and discussed in a focus group, consisting of the project team, health information experts, and public health experts. The evaluation criteria agreed upon in the focus group were prioritized within the focus group meeting and further refined in a quantitative survey of a total of 54 experts with different professions to filter out criteria considered less relevant and to make a final selection. Based on the results of the focus group and the survey, the evaluation criteria were revised and finalized and ended up in a long questionnaire, which is described in the results section.

Evaluation of theQuestionnaire With Selected Apps

The developed questionnaire was evaluated with apps from the following categories: (1) Nutrition, (2) Exercise, (3) Mental Health, and (4) Symptom Checker. These categories were chosen because they cover the main fields of healthy lifestyle. The selection of apps aimed to evaluate the most used apps in Austria in these categories. An attempt to select apps based on existing databases was unsuccessful because the data were at least one year old (eg, Statista [22]) or the databases used a distribution model that was not applicable in this context (eg, data.ai [23]).

For these reasons, an exploratory approach was chosen where 11 individuals from the project team, selected to ensure as much diversity as possible in terms of mobile phones, operating systems, and histories of installed apps, participated. This group consisted of 6 males and 5 females, with 6 participants using the Google Play Store and 5 using the Apple App Store. Each individual searched for the respective keywords in their personal app stores, ensuring a broad variety of search habits and preferences, and recorded the results—15 apps per category—in an Excel spreadsheet. The results were weighted using a pivot table after data cleaning (typos, adding app manufacturers). Then, it was ensured that the top 10 apps in each category were available in both app stores and could be used for evaluation.

The following inclusion and exclusion criteria were additionally considered in the app selection, as listed in Textbox 1:

Textbox 1. Inclusion and exclusion criteria for app selection

Inclusion criteria

- The app must target humans as its audience (excluding apps for pets or similar).
- The app must be available in English or German.
- The app must be available in Austria in the Apple App Store and Google Play Store.

Exclusion criteria

- The app must not require additional hardware (eg, fitness watches, blood glucose meters, etc).
- The app must not be explicitly used for product sales.
- The purpose of the apps must not be to assist with insurance processes (ie, claim management).
- The apps must not require a diagnosis, prescription code, etc.

Each app was assessed by 3 persons [AR, KE, SW] using the long questionnaire (see section results), whereby the persons cross-checked their results within each category of Apps.

Results

Overview

From the comprehensive evaluation criteria, we derived 2 questionnaires (short and long) to enable an informed and self-determined decision regarding the assessment of these apps. All questions in the following tables are to be answered with (yes/no) along with a detailed description. The responses serve as a guidance for the individual decision-making process regarding the app's utility and quality.

Short Questionnaire

The short questionnaire summarizes the questions, which were most often answered with "no" in the evaluation of the long questionnaire and were rated as very important in the focus group and survey mentioned above. Table 1 shows the 6-items

XSL•FO
RenderX

short questionnaire with an explanation of the reason for the importance as well as meaningful advice on how to self-assess the questions quickly.

XSL•FO
RenderX

Table . Short questionnaire with the most relevant questions for informed decision-making for health apps.

Category	Answer	Why is this important?	Meaningful advice
Imprint: Does the App have an imprint indicating the App's manufacturer?	yes or no	• In Austria, there are legal requirements regarding the "Imprint" that must be complied with.	• Often you can find the imprint in the settings or in the Terms and Conditions (Terms and conditions) of the app. • WARNING: Many apps do not have an imprint. This could be an indication that the app is not trustworthy. • An imprint must contain the following information: • Name or company according to the commercial register, • Address, • Contact information (eg, email address or phone number).
Imprint: Is the contact information in the imprint complete?	yes or no		
User account: Do I need to create an account to use the App	yes or no Attention: Both can have advantages and disadvantages!	• If you have to log in to an app, the provider can more easily associate the data directly with you. This is especially true if you need to provide additional personal information (name, address, phone number, etc.) during registration. • If you don't need to create a user account, that can also be an advantage. You can use the app anonymously. • Warning: If you delete an app without a user account or use another device, your data may be lost.	• If you need to create a user account, the manufacturer can store your data and uniquely identify you. • If you need to log in with a password, no one else can use the app under your name. • Hint: Always use a secure password for health apps.
User account: Can you easily delete this account again?	yes or no		• The function to delete the account is often difficult to find. TIP: Check the app's settings. • Additional steps may be required to delete the user account, such as entering the password.
Data Privacy: Is it specified which specific data the App collects? (for example: Name, Location, etc.)	yes or no	• There are legal requirements for data protection in Austria. These requirements must also be complied with in apps.	• You usually find information about data privacy in the privacy policy and/or the Terms and Conditions (AGB). • Sometimes you may not find this information directly in the app but during the registration process. • The privacy policy must specify the categories of data processed (eg, health data). • WARNING: Often, data not related to the app's purpose is processed (eg, GPS data in a flashlight app).

XSL•FO
RenderX

Category	Answer	Why is this important?	Meaningful advice
Data Privacy: Is it indicated whether this data is shared with third parties?	yes or no	• It is best if an app does not share your data with third parties. If data is shared, it must be indicated.	Sharing of Data with Third Parties: • App providers often take the liberty of sharing data with third parties if it is convenient for them. • Tip: Searching for the word "Third parties" will direct you to the relevant section. • If data are shared with third parties, it must be stated to whom the data is transmitted. • Data are often stored outside the EU and are therefore subject to different data protection laws. • If you search for the word "USA," you can find out if your data isarestored in the United States. Different data protection laws Apply there.
Labeling of Advertising: Are paid offers in the App labeled as "Advertisement" or "Ad"?	yes or no	• Advertising must be labeled and clearly recognizable as such.	To access all contents of the app, a paid subscription may be necessary. • Paid subscriptions in apps are often not labeled as advertisements. • Subscription offers can be annoying and are often difficult to dismiss. • Paid subscriptions are often automatically renewed. Warning: Renewal is often agreed upon when subscribing. Always read carefully. • When comparing the costs of different apps, always consider the total annual costs without initial discounts. • Tip: Pay attention to any cancellation deadlines and minimum terms. • Subscriptions can be canceled either directly in the app or on the providers' websites.
App Function: Is the App's function adequately described?	yes or no	• The function of an app is often the decisive reason for using it. Therefore, the app's function should align with your personal goal.	• You can usually read the app's description before downloading. • Warning: Goals and target groups of the app are often not specified. • Pay attention to advertising promises in the description. Promises are often not fully realized. • Tip: Check if the app's function is usable in the country where you reside. For example, apps in the "Nutrition" category may use databases from the USA, which may not be usable in Austria. • Often, a supposedly German-language app also displays content in English.
App Function: Does the description match reality?	yes or no		
	yes or no		

XSL•FO
RenderX

Category	Answer	Why is this important?	Meaningful advice
Information: Is the information contained in the App scientifically supported?		• Health information should meet certain quality criteria. In any case, scientific evidence (sources) should be provided for claims.	• Pay attention to source references for information in the app. • Warning: Often, no sources are provided for health information, recommendations, or claims. This means the information could be fabricated. • Pay attention to the timeliness of health information in apps. Information is often outdated and no longer in line with the state of science (eg, in nutrition apps). • Often sources are provided that don‘t directly match the app‘s function.

App Selection

The selected apps to be tested against the long questionnaire is shown in Table 2. Detailed evaluation is not to be published due to possible violation of commercial law.

Evaluation Results

This chapter summarizes the evaluation results of the long questionnaire against the selected apps (Table 3).

Table . Evaluation results summarized.

Question items	Nutrition	Exercise	Mental health	Symptom checker
Legally required imprint available	• 4 out of 10 apps	• 4 out of 10 apps	• 1 out of 10 apps	• 5 out of 10 apps
Privacy policies that allow for the disclosure of health data to third parties [24]	• All international operating apps	• All international operating apps • Privacy policies are sometimes unclear and contradict the information provided in the app stores by the manufacturers	• All international operating apps • Consent to the terms of use is implicitly obtained for most apps by using the app.	• User consent is mostly requested via checkboxes.
Addressing the sensitivity of health data	• is not explicitly addressed	• is not explicitly addressed	• is not explicitly addressed	• It is recommended that the app does not substitute the doctor
App tracking	• All apps	• All apps	• All apps	• not available
Target group definitions	• Usually not available	• Usually not available	• Not available	• One app only mentions in the disclaimer that it is intended for users in the United States.
Other	• German apps have good privacy policies and refer to scientific sources • For many apps, a newsletter was simultaneously subscribed to without explicit consent	• All apps reserve the right to collect at least pseudonymized user data • Making unsubstantiated claims (“Yoga for Weight Loss”, “Correction of Bow Legs”, “Relieving Menstrual Cramps through Breathing”, ...)	• Two out of 10 apps refer to scientific backgrounds for their implementation • Many of the apps aim to subscribe to a subscription after or during the registration process, which usually ends in a costly annual subscription of 20 - 130 Euros per year (~20$-130 US$ per year) after a certain free trial period. • Since most apps are financed through subscriptions, many do not use advertising placements.	• Some apps allow for the export of data, which can be presented to the doctor as a report in PDF or CSV format or, in very few cases, directly provided to the doctor via a link to the health data. • Many apps are free. Subscriptions usually cost between 7 and 40 EUR per month. • When entering symptoms, some apps provide a wide range of possible causes. This could lead to overdiagnosis and unnecessary interventions.

User Survey

A quantitative survey with 414 participants was conducted to evaluate the value of health app features for achieving different goals from users’ perspectives, aiming for a balanced gender identity, age, and prior experience with health apps. The analysis focused on the relevance of goals such as support for physical activity (fitness), weight management, nutrition, mental health, and the monitoring of physical and mental symptoms. The findings showed that health apps in the “fitness/activity” and “symptom checker” categories were considered most important, while mental health apps were rated as less important. The ratings were influenced by gender, age, and the presence of chronic conditions, and prior experience with health apps also played a role. Women rated health app functions as more important than men, with a focus on supporting physical health

XSL•FO
RenderX

and achieving weight management goals. Men prioritized physical activity support, while younger participants rated the importance of health app features higher than older ones, particularly for fitness-related goals. Individuals with chronic conditions placed more emphasis on functions promoting physical health and were more likely to pay for health apps.

Discussion

Principal Findings

Despite efforts in initiatives like Label2Enable [10], “So far, no unified concept has emerged to provide users with orientation regarding the quality of health apps. Different approaches with varying underlying criteria, often pursued by commercial entities, are being followed (eg, evaluation instruments for users, certifications, quality seals, test reports)” [12]

Our aim with this work has been to provide users with a unified concept for orientation regarding the quality of health apps, knowing well that the comprehensive instruments offered by Health technology assessments are not usable for users. The goal of this work was to create a questionnaire that could be used to evaluate 10 apps each in the areas of nutrition, exercise, mental health, and symptom checkers. The key points were summarized in the short questionnaire and supplemented with helpful tips and a “Meaningful advice” column, enabling users to assess the quality of an app in a short amount of time.

The user survey revealed that data privacy and security considerations played a minor role for most respondents, contrary to the questions outlined in the ”Short Questionnaire .” This could be due, on one hand, to the general perception of loss of control over one’s data, and on the other hand, the impacts of data privacy and security are not directly and immediately discernible to users. Data leaks with potentially negative consequences for individuals may only become known after a considerable period of time, and their effects may unfold gradually.

Additional education and information on “digital self-determination or self-defense” could help address this issue, enabling users to make clear and informed decisions about whether they prefer data-minimizing apps over those whose primary goal is to collect and market metadata. Simple questionnaires, as presented in this work, can raise awareness regarding data privacy and privacy, especially concerning sensitive health data, which may be perceived as critical in connection with initiatives like Elektronische Gesundheitsakte (ELGA) [25] but less so in the context of apps.

Digital health literacy already plays a role in selecting a suitable digital health applications, not only for users but also for therapists and medical professionals. Choosing a suitable, safe, and effective application from the multitude of digital health apps is a significant challenge. Currently, many users (35% in the user survey) select digital health applications based solely on star ratings in app stores, which have limited reliability [26]. In this context, the use of a questionnaire makes sense, especially regarding expected features and their evidence-based justification.

Apps are often downloaded based on advertising on social media, app stores, and recommendations from family and friends. This indicates that a quality-assured app recommended by a doctor could have significant potential for user adoption. Therefore, it is essential that reviews of these apps are quality-assured and reliable. This applies to both health apps and medical apps, which may target vulnerable groups such as people with chronic illnesses. Considerations regarding the German DiGAs [27] were taken into account throughout the project. Still, the outcome of this work is more geared towards private users rather than representatives of the health system. Nonetheless, we are pleased to note that Digitale Gesundheitsanwendungen (DiGAs - in English: digital health applications) have found a place in the preliminary version of the Austrian eHealth Strategy “M1.7 Creation of a unified process for the evaluation of Digital Health Applications and subsequently their introduction into standard care when demonstrably beneficial” [28]. This also applies to statements from the professional assessment of health apps. “The information offered is too extensive for laypeople”—here, too, a standardized evaluation and recommendation by authorities and health care providers would be advantageous.

In general, it can be noted that Austrian app developers adhere more frequently to regulatory requirements than international developers, since they most often met the evaluation criteria, especially in terms of data privacy and imprint. In this context, we would like to appeal to the responsibility of app providers to make a positive contribution to societal challenges A white paper in line with “Good App Development Practice” or regional requirements from pp stores could introduce even quality-assurance restrictions, particularly regarding regulatory frameworks (eg, explicitly demanding a legally compliant imprint) as collected in the results of this work.

Limitations

The selection of apps to be evaluated based on the established and prioritized criteria proved to be more challenging than initially anticipated. This was partly due to the lack of qualified sources for the previously desired criterion of “most commonly used apps in Austria,” requiring us to resort to an exploratory approach. Furthermore, the apps found as a result could not be fully tested and evaluated by all participants, as even during the implementation period, some apps were no longer available in the app stores for specific operating system versions. Nevertheless, a common denominator for joint evaluation had to be found.

In general, we want to emphasize that a framework for evaluating apps was established and applied, aiming to empower users to independently assess and evaluate both current and new apps.

We deliberately refrained from presenting individual apps or manufacturers in a positive or negative light.

Furthermore, we want to emphasize that our study has not been aimed at replacing the traditional instruments of Health Technology Assessment, as the evaluation criteria were created for the purpose mentioned above. However, this evaluation did not involve searching for clinical studies to demonstrate the

effectiveness of the apps, and the apps were not assigned to risk classes according to Medical Device Regulation [29]. As such, for a comprehensive assessment of a health app, fulfilling the requirements of evidence-based medicine, further important domains such as clinical effectiveness, clinical safety, costs, organizational and ethical aspects need to be assessed.

Conclusions

In a rapidly changing landscape such as the app market, it is therefore even more important to have a solid, easy-to-use tool for evaluating health and medical apps at hand. We are aware that this tool may not be sufficient for evaluation by authorities; however, we would like to note that it can provide a good basis for it. We would like to support further research and projects in this direction.

Acknowledgments

The work was commissioned by the Gesundheitsfonds Steiermark, who contributed massively to defining evaluation criteria with their expert network.

Abstract

Background: Technology can be an effective tool for providing health services and disease self-management, especially in diabetes care. Technology tools for disease self-management include health-related applications for computers and smartphones as well as the use of robots. To provide a more effective continuity of care and to better understand and facilitate disease management in middle-aged and older adult patients with diabetes, robots can be used to improve the quality of care and supplement community health resources, such as community pharmacies.

Objective: The aim of this study was to develop a health care robot prototype that can be integrated into current community pharmacies.

Methods: Three user-centered approaches were used: (1) review of the literature on technology use among older adults, 2) reference to the seven key diabetes self-care behaviors by the American Association of Diabetes Educators (AADE), and (3) meeting with health care providers in the community. Field investigations and interviews were conducted at community pharmacies and diabetes health education centers to determine the appearance, interface, content, and function of the robot.

Results: The results show that diabetes health care prototype robots can be established through user-centered design. The following important features were revealed: (1) perceived ease of use is considered a friendly operating interface; therefore, we used less than 3 buttons in an interface; (2) minimization of the interface between blue and yellow, which is unfriendly to older adults; (3) the health education mode was the most preferred mode with sound, image, and video presentation; (4) the most predilected functions are health education resources and health records, and that patient data can be easily collected through health education games and dialogue with robots; and (5) touching the screen is the most preferred operation mode.

Conclusions: An evidence-based health care robot can be developed through user-centered design, an approach in which a model that connects medical needs to people with health conditions can be built, thereby facilitating the sustainable development of technology in the diabetes care field.

Introduction

Diabetes is a significant global health issue, with the number of people affected by the disease continually rising [1]. According to the International Diabetes Federation Diabetes Atlas, the global number of people with diabetes reached 537 million in 2021 and is expected to continue rising, reaching an estimated 783 million by 2045 [2]. The most prevalent form of diabetes is type 2 diabetes, which affects more than 90% of all individuals with diabetes [2]. Uncontrolled diabetes over time can lead to severe complications, including cardiovascular diseases, lower-limb amputation, kidney damage (nephropathy), nerve damage (neuropathy), and blindness (retinopathy) [2,3]. Age is one of the risk factors for type 2 diabetes, with its prevalence and mortality rates rising as individuals get older [4,5]. According to statistics from Taiwan's Ministry of Health and Welfare, the prevalence of diabetes increases significantly from the age of 45 years for both men and women [6]. As the duration of diabetes and patient age increase, patients with diabetes face not only a higher incidence of complications but also challenges related to multiple medications and comorbidities [7]. This underscores the importance of focused

XSL•FO
RenderX

health care management for middle-aged and older adult patients with diabetes.

In recent years, technology has emerged as a crucial tool for disease management, including diabetes [8,9]. The demand for digital health care has surged, evidenced by the introduction of more than 90,000 new health-related apps on platforms like the Apple Store and Google Play in 2020 alone, contributing to a total of over 350,000 health care applications available globally [10]. Among these technological advancements in health applications, health care robots are one of the future trends in health technology [11], driven by the ongoing digitization of health care services.

Community pharmacies play a vital role in providing health care services, offering convenient access to medications and health services that support local health care needs. There are currently more than 7400 health insurance pharmacies across Taiwan [12], and a 2016 survey indicated that over 80% of these pharmacies are open for at least 12 hours, with around 40% operating almost year-round [13]. Compared to hospitals, community pharmacies face less pressure from time constraints and space limitations, positioning them as key players in bridging the gap between individuals and larger medical institutions.

Despite the availability of professional medical information in clinical settings, there remains a challenge in ensuring that patients effectively absorb and apply health education and professional advice once they return to their communities. This gap highlights the need for technological tools that support continuous care, especially for middle-aged and older adults managing diabetes. Integrating robots into community health resources, such as community pharmacies, could enhance the quality of care, improve health management, and advance health promotion within the community. The expertise of pharmacists, coupled with the high accessibility of community pharmacies, makes them an ideal setting for such interventions.

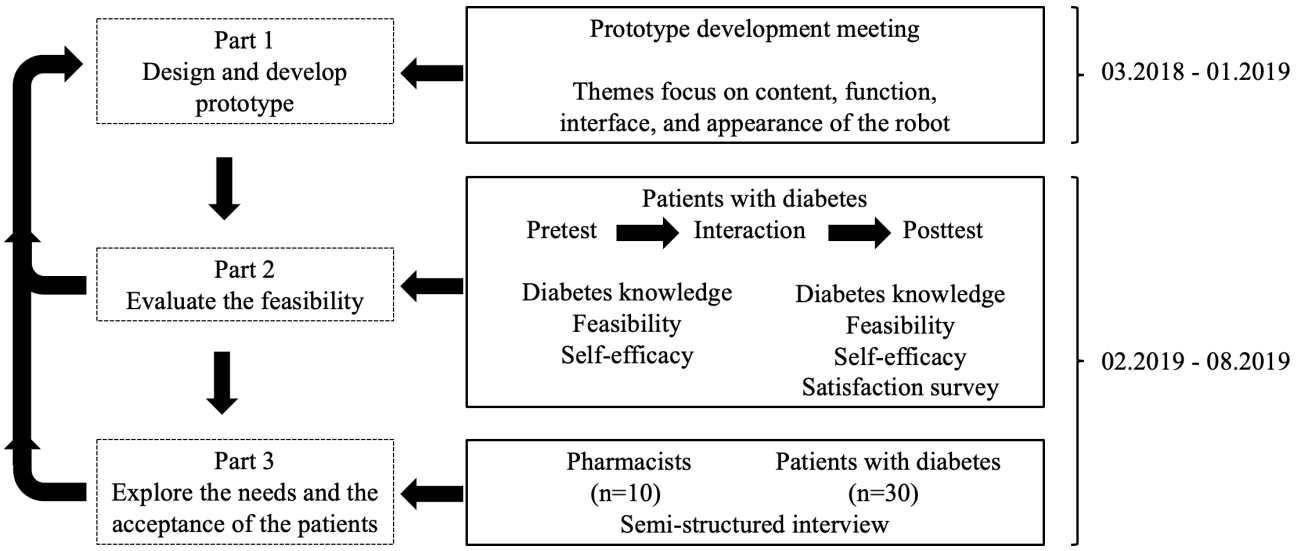
However, current technology development for disease management often excludes medical professionals from the design process and lacks real-world testing [14]. Additionally, there is no clear evidence that technology can effectively integrate with community medical resources or bridge the gap between medical institutions and personal care. Therefore, the aim of this study was to design and develop a prototype of a diabetes care robot that meets the needs of middle-aged and older adult patients with diabetes, aligns with the perspective of community pharmacist care, and can be integrated into the current community pharmacy setting.

Methods

Participants

The design and development of the prototype robot in this study were primarily conducted through literature-based theories and expert team meetings [15]. The development of the prototype robot involved the researcher synthesizing the literature and conducting field visits to pharmacies and health education units. The development goals and direction were then jointly decided during team meetings. The development of the prototype robot began in March 2018. The team included 1 expert in technology, 1 expert in gerontology, 2 physicians, 12 to 15 engineers and research assistants, and 1 researcher. To maintain progress and continuously refine the prototype robot, the team held regular meetings 1 - 2 times per month until a more complete interactive functionality was established to enhance the user experience. Furthermore, to gain a more realistic understanding of the feasibility and initial results of the robot's application in community health care, 30 middle-aged and older adult patients with diabetes, along with 10 community pharmacists, were also included to provide user feedback.

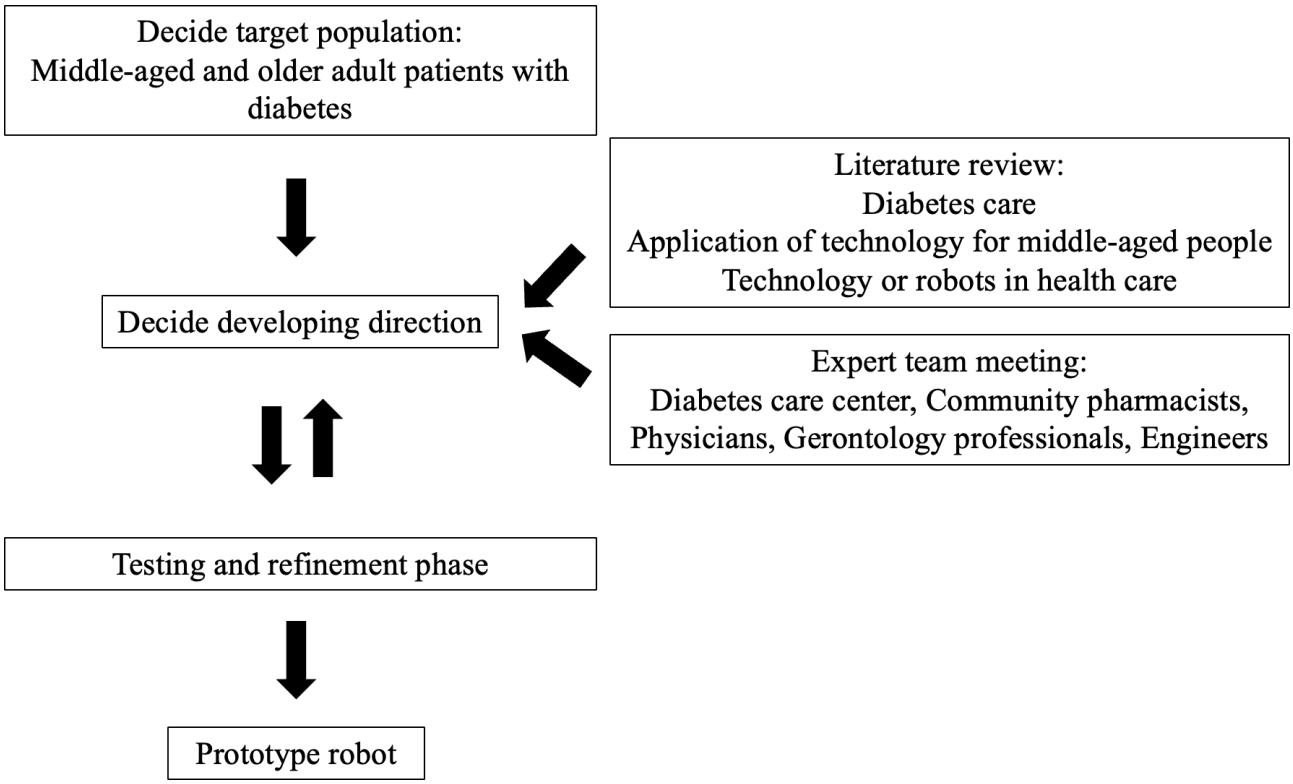
Ethical Considerations



This study was performed in accordance with the relevant guidelines and regulations, including the Declaration of Helsinki and was approved by the Institution Review Board (IRB) of National Cheng Kung University Hospital in Taiwan (No. A-ER-105 - 509). All the participants provided signed informed consent, and all study data were deidentified to protect the identity of participants. Participants did not receive any financial or material compensation for their participation in this study.

Procedures

The research design framework for the prototype robot comprised three steps: using an evidence-based literature review and team meeting to design and develop the robot prototype, evaluating feasibility through collecting pre- and postassessment questionnaires, and exploring needs and acceptance through interviews with the target population, as illustrated in Figure 1.



XSL•FO
RenderX

Figure 1. The research design framework for the prototype robot used in community-based diabetes care.

Although robotics is an emerging technology, there is a lack of understanding about the applications of robotics. To gain a better understanding of user needs, a high-fidelity prototype can be used to provide users with real-world experience and stimulate their needs, thus enabling them to provide more in-depth insights for future development and design [16]. Therefore, the first part of the study was to design and build a prototype community-based diabetes care robot to facilitate user experience, as illustrated in the detailed flowchart shown in Figure 2.

Figure 2. Process showing how to build a prototype community-based diabetes care robot.

The second and third parts were dedicated to testing and evaluating the prototype robot. In the second part, it took 15 - 20 min for the patients with diabetes to interact with the robot. Before and after the interaction, questionnaires including a diabetes knowledge test, self-efficacy for diabetes, and feasibility of use of the robot were administered. In the third section, semistructured qualitative interviews were conducted with middle-aged and older adult patients with diabetes and community pharmacists about their experiences and visions for using the robots. The detailed methods and results of the pre- and postassessment questionnaires, including a diabetes knowledge test, self-efficacy for diabetes, and the feasibility of using the robot in patients with diabetes, as well as the in-depth interviews with both pharmacists and patients with diabetes, were addressed in our previously published study [17]. This prior study demonstrated that robot interaction significantly improved patients' diabetes knowledge and the perceived feasibility of its use in pharmacies. Both patients and

XSL•FO
RenderX

pharmacists gave positive feedback, with patients valuing self-directed learning, comfortable interaction, and vivid engagement, while pharmacists highlighted real-world applicability and new service potential. These findings offer foundational insights that inform the design and objectives of our current research.

Design and Construction of a Prototype Community-Based Diabetes Care Robot

As the goal of this research is to develop a prototype for a community-based diabetes care robot and to gather and understand the perspectives and needs of patients with diabetes and community health care providers, the initial team meetings decided to use an existing robot with foundational functions. This robot was optimized and gradually modified to develop interactive features relevant to diabetes care, aiming for efficiency and smooth user operation. The robot developed in this study uses Zenbo (ASUS), a smart home product from ASUS. The appearance and specifications are shown in Figure 3 and Textbox 1, respectively.

XSL•FO
RenderX

Figure 3. Appearance of the Zenbo robot.

XSL•FO
RenderX

Textbox 1. Zenbo robot specifications and functions; source: ASUS.

Specifications:

- External dimensions: 37 × 37 × 62 cm (length × width × height)
- Weight: 10 kg
- Operating system: Android
- Display screen: 10.1" LCD screen
- Language skills: Chinese
- Functions: Listening, speaking, seeing, emotional expression, playing music and videos, movement, internet connection, and learning

LCD: liquid crystal display

The concept for the prototype robot is primarily derived from research and theory, which must align with the needs of the target population, namely middle-aged and older adult patients with diabetes. Therefore, this study focused on theories and care indicators related to diabetes care [18], collected and organized the design and limitations of technology applications for middle-aged individuals [19,20], and examined the development and application of current technology or robots in health care, as well as the connection between the use of technology and health in middle-aged people and the mode for delivering health services [21], to establish the development objectives [22,23]. Three user-centered approaches were used in the design and construction of a prototype community-based diabetes care robot: (1) a review of the literature on technology use among older adults, (2) reference to the seven key diabetes self-care behaviors by the American Association of Diabetes Educators (AADE), and (3) meetings with health care providers in the community. The literature review search strategy of this study involved collecting studies related to the application of robots in the elderly population [24-27]. Field investigations and interviews were conducted at community pharmacies and diabetes health education centers to determine the design of the robot. Because patients with diabetes go to community pharmacies to take their medications, and in addition to providing pharmaceutical services, community pharmacies can also offer related information on disease care. Therefore, in addition to collecting service experiences from the community pharmacists, the choice of a community pharmacy as the testing site for the prototype is driven by the fact that these pharmacies provide a secure, private, and professionally consultative environment.

The design framework of the community-based diabetes care robot was devised to collect and compile data in four main areas: appearance, interface, content, and function. For appearance, we collected data about the appearance and size of the robot. For interface, data were collected about the color, text size, arrangement, and other screen design. For content, the system was responsible for building the information that needed to be conveyed, with the user's needs as the primary consideration. For function, we collected data about the presentation of the interactive process and information transfer.

Once the direction of development has been established, a prototype robot is initially built that can be used in practice. The development of technology does not only rely on past and proven experience, but also must be tailored to the needs of real users. Therefore, the prototypes need to interact with the users in real life and give them a real experience in accordance with the proposed development directions. It is only after this that users can give practical advice.

Results

Using a literature search and practical experience, this study focused on data collection in four main areas: appearance, interface, content, and function of robot design. The development directions and options for prototype robots are listed in Table 1.

XSL•FO
RenderX

Table . Development directions and options for prototype robots.

	Literature and theory	Interviews and team discussions	Results and design directions
Appearance	• Type: The humanoid type is less well accepted. The doll type, on the other hand, is seen as a toy for children [22]. Prototype robots should avoid being too complex or trendy. However, if the prototype lacks a humanoid feel, it will not be favored by senior citizens [23]. • Application mode: The focus of the robot varies between different appearances. Appearance will affect whether it is presented in a functional or interactive way [28,29].	• Size: The prototype robot must fit into the space of the pharmacy. • Height: It should be at a height at which middle-aged to older adults can sit and see it horizontally.	• It must be confirmed that this model is not complicated and is expected to be well-accepted because it is a non-humanoid model. However, it may be seen as a toy because of the cute non-humanoid appearance. The model does not have hands and feet to operate and therefore operates mainly in a conversational manner. It must be confirmed that the angle and height of the interaction mode (eg, the height of the table or chair on which the robot can be placed) can be adjusted.
Interface	• Colors: Blue and yellow are less recognizable [19]. Yellow and green combinations, and red and purple combinations, are prone to recognition errors [20]. • Operation: Per the Technology and Acceptance Model [30], the interface and operation must be simple because it is used by older adults. The font should be large and clear. The interface should have a maximum of four buttons. All other interfaces have two buttons for simple selection [31].	• The interface should be simple. A single screen does not need much emphasis. Text should be enlarged.	• The color scheme of the interface is highly contrasting to avoid confusion over similar color schemes. The use of blue and yellow colors is reduced and the number of buttons on the interface is 2 - 3. The content is centered, and apart from the main screen, the content is mostly presented as a single theme. The font size ranges from a minimum of 30sp to a maximum of 50sp (sp being the text unit in the Android system).
Content	• Seven key diabetes self-care behaviors by the American Association of Diabetes Educators [18]	• Applications addressing various everyday challenges and health education videos on common diseases in community pharmacies.	• The content of the system is based on the seven diabetes self-care behaviors, with games and interactive dialogues to present a variety of health education methods. To make the content more relevant to the public, common disease symptoms and complications of diabetes are presented.
Function	• Operation: Technology and Acceptance Model [30]. • Health education: Multisensory perception stimulates learning [21], with a core health education focus each time. • Technology applications: The applications of robots in health management can include disease management, monitoring of physiological data, and interactive health education [26,32,33]. The use of technology in diabetes health management focuses on recording and reminding, as well as providing information and entertainment [34-36].	• There are games, friendly greetings, and flexible interaction times.	• The health education mode is presented with sound, images, and video, avoiding a focus on the use of a single sense. The functionality of the current model will be considered and the information on functionality available in the literature will be further researched.

XSL•FO
RenderX

Appearance

Although the robot's appearance was determined based on the available resources, the chosen model features a cute, non-humanoid design to better align with the preferences of older adults and enhance user acceptance. Although the robot's height is a limiting factor, placing the robot on elevated surfaces, such as tables or chairs, can correct height-related issues, making it easier for users to operate.

Interface

As the interface is critical to the overall smoothness of the robot, the presentation of the interactive interface must meet the needs of middle-aged and older adults in terms of the ease of use of technology products and text reading as much as possible. In addition, according to the Technology and Acceptance Model [30], the perceived ease of use should be considered as a whole and should take into account the user-friendliness of the interface so that the user can experience the clearest and easiest process.

In the interface development, to make it easiest for older adults to operate, each screen will display a maximum of two main options, with options clearly framed to reduce the likelihood of users being unsure of their choices. Information and selection buttons will be centrally placed and maximized on the screen to help users quickly focus on key points. The main screen will feature simple text and image displays. To avoid causing difficulties in recognition for older users, the background will be a single color, and the overall interface will use no more than two main color tones. The main screen and option areas will predominantly use a black-on-white color scheme, with high contrast to make text easier to read.

Content

The main content of the development includes the seven key diabetes self-care behaviors according to the AADE standards. The overall main content and functions presented by the prototype robot are detailed in Table 2 and aligned with the seven AADE diabetes care indicators.

The main functions of the system are health education resources and health records. Health education resources are presented through health education quizzes, pamphlets, and videos. The health records section includes health values, discomfort, and nutrition. The concept of this record is to help patients with diabetes manage their records, including basic physiological data such as blood pressure, blood glucose, and blood lipids. The relevant data are entered and the corresponding standard values are provided. The focus of the "Discomfort" program is to understand and record the various conditions in the patients with diabetes and to compare the complications associated with diabetes with the common problems of the family. By reminding and advising patients to be more alert to their health conditions, they can gain a better understanding of their health conditions. The results are recorded for follow-up. All interactions can be fed back to the user in the form of paper or communication software messages.

Table . Functional development and presentation of prototype robots.

Theme	Subtheme	Theme content	Presented at the American Association of Diabetes Educators
Health education resources	Health education test	Questions focus on the seven major areas of diabetes care and common diabetes health problems	Healthy eating, regular exercise, blood glucose monitoring, proper medication use, problem solving, health adaptation, and risk reduction
	Health education leaflet	Share and recommend links to help filter relevant content	Healthy eating, regular exercise, blood glucose monitoring, proper medication use, problem solving, health adaptation, and risk reduction
	Health education videos	Share and recommend links to help filter relevant content	Healthy eating, regular exercise, blood glucose monitoring, proper medication use, problem solving, health adaptation, and risk reduction
Health records	Health values	Alert and record blood pressure, blood glucose and lipids, and provide standard values	Blood glucose monitoring
	Discomfort	Presented in a lifestyle format to remind patients of complications and other problems they may encounter and link them to their disease conditions	Problem solving, health adaptations, and risk reduction
	Nutrition	Ask each other about their dietary status in a simple conversation to help them develop a balanced diet	Healthy eating

Function

To establish the overall function, we should first understand the current mode of application of technology in disease and health management, including the application of health technology for older adults, diabetes management technology tools, and the application of robots in health management, and consider the current operation fluency and feasibility of using robots.

XSL•FO
RenderX

According to the current functional status of the robot, the main functions are primarily simple question-and-answer interactions with pictures and images, so the main functions are presented in a health education manner. A game was used to transfer knowledge on diabetes-related care content, and a thematic health education video was shown as feedback to the patients according to their wrong answers.

The main objective of the development of this prototype robot is to enable patients with diabetes to experience actual interaction with the robot and to understand the possible interaction patterns, in order to understand the experience and perspective of the user. During the development process, the prototype robot is adapted to meet the needs of the community and medical personnel based on the health education needs of the Diabetes Health Centre and the feasible applications of the community pharmacy. In view of the time and cost of development as well as the operation of the technology, the functions were not expanded extensively and were mainly presented in the form of a basic framework. After the patient with diabetes or community health care worker has confirmed the suitability of the directions and content, the functions will be expanded and built. To allow each participant to experience the same features, the most stable and fully developed part (ie, the health education test, a game with the robot, that focuses on diabetes-related knowledge) is used as the main axis for participant interaction. The rest of the developed functions are presented as introductions and simple demonstrations.

Discussion

Principal Findings

This study demonstrated that an evidence-based health care robot can be developed through user-centered design, facilitating the sustainable advancement of technology in the field of diabetes care. The use of technology in patient management can be beneficial to patients. However, the applications of technology that are readily available on the market are not always effective. While the current technology interventions are mostly aimed at behavioral change, they are rarely supported by therapeutic guidelines and theories [35,37], making the development process too subjective or deviating from reality. The core elements of technology development must therefore be user-centered. Thus, based on the technology being developed and designed for diabetes disease self-management, Goyal et al proposed four stages of user-centered development [38]. The first is the so-called development process, which must be evidence-based and analyze possible barriers and problems and must be culturally and environmentally appropriate. In the second stage, the feasibility of the system must be understood. The third stage involves further evaluation of effectiveness. The fourth stage requires more long-term monitoring. At the same time, as the four stages are in a continuous cycle and interact with each other, it is necessary to revise and review them repeatedly to build a technology tool that meets the needs of users [38]. Furthermore, personal health information must also be protected. While this prototype requires login, ongoing efforts should be made to enhance and ensure information security.

Comparison With Prior Work

In previous studies of diabetes care robots, the main focus has been on younger age groups of patients with type 1 diabetes [32,33,39], and less on middle-aged patients with type 2 diabetes. Even in the case of older adult care, the functional applications of robots are mainly companionship-based or focus on social functions for older adults. There should be less involvement in behavioral change, but this is also an important part of health messaging. Therefore, this study uses the seven key diabetes self-care behaviors by the AADE to consider the basics of healthy eating, regular exercise, blood glucose monitoring, and proper medication use as core health-enhancing skills, and to help patients with diabetes better understand their disease and their health. These seven self-care behaviors are interlinked with diabetes disease self-management and not only directly contribute to disease management (eg, reminders and records), but also enhance the overall quality of care for the disease by building up the correct concepts of patients with diabetes. This content is presented as a basic health education leaflet and a health education video to convey information. The health education resources are sourced from relevant health education websites and reference links from major hospitals and institutes, and can be categorized to help patients quickly search and link to relevant functions. In terms of the functions, we should first understand the current mode of application of technology in disease and health management, including the application of health technology for older adults, diabetes management technology tools, and the application of robots in health management, and consider the current operation fluency and feasibility of using robots. The robot itself has basic functions such as playing videos and documents. Based on the current functionality of the robot, the main focus of further development is on the simple interaction with pictures and images. The main function is therefore presented in the form of health education. To make the health education interaction more efficient and interesting, a health education game was used to transfer knowledge about diabetes-related care content, and at the end of one stage of the game, a health education video on the relevant topic was selected and shown as feedback based on the questions that the patient answered incorrectly, to deepen the patient's understanding of the concept.

Past studies have also supported the idea that a multimedia approach to health education can help patients understand the content of health education [40,41]. The health education model is more stimulating, as it delivers information to patients in a variety of ways, such as videos and animations, which in turn produces better health education results. This is one of the main advantages of robots for the implementation of health education [40]. The robot's rich expressions and gestures, as well as its voice-to-voice interactions, are an advantage in teaching [41]. The prototype utilized in this study is a nonhumanoid robot. While humanoid robot interactions are more human-like, their realistic appearance can often induce fear, leading to lower acceptance. In contrast, nonhumanoid robots, though cute, might be perceived more like toys, resembling a game. The advantage lies in a more engaging interaction, but the downside is that they may be seen merely as playthings, potentially overshadowing the educational information they convey.

XSL•FO
RenderX

In the delivery of health services by robots, there is a need for a thorough consideration of the technological side, the professional side, and the patient side. Therefore, in addition to the professional development in the field of technology, the initial development should also identify and create a suitable development direction from the perspective of medical professionals, and build a prototype robot. Later on, the prototype robot can be used to enable patients with diabetes to experience the interaction with the robot, and through this interaction, to gather more in-depth information on patients' thoughts and experiences on the application of technology. In the context of the rapid expansion of technology, it is important to have more detailed information on the user experience so that subsequent developers can have a clearer direction, and at the same time, have the most relevant technological tools for the core users (ie, older adult patients).

Strengths

The main advantage of the robot developed in this study is that the prototype was developed using data from professional team meetings, literature, real-world data, and experience interviews, as well as the participation of people from the relevant professional fields. This comprehensive approach ensured the prototype is robust. In addition, the development of the prototype robot was not a one-off exercise. The aim was to create a prototype that would enable actual interaction with patients with diabetes, not just from the developer's perspective. Each time further progress is made, it will be compared and revised with clinical practitioners to create a more realistic diabetes care robot that can actually interact with patients with diabetes in the real world.

Limitations

The literature reviewed in this study primarily comes from Western countries, which may not fully correspond to the disease characteristics of East Asian populations. Differences in illness, age, and cultural backgrounds may affect users' perspectives. To mitigate this limitation, future studies could be conducted in Western countries to validate the findings and evaluate their applicability in different contexts. In addition, the testing site for this study was a community pharmacy in an urban area, so it does not provide insights into how elderly individuals with different lifestyles or from different regions perceive and use the robot. Consequently, the findings may not be fully applicable to all health care settings. Future research could extend to rural community pharmacies or other community health care settings, including community hospitals, clinics, and chain pharmacies, to test the application of health care robots. Moreover, the size and functionality of the robots used in this study, along with the critical role of the internet in their operation, may limit their capabilities. For example, uninterrupted and smooth conversations rely on a stable network connection. Interruptions or network issues can hinder the robot's performance. Efforts were made to ensure a stable network environment during testing, but future studies should consider testing in various network conditions to better understand the impact of connectivity on robot functionality.

Conclusion

The prototype diabetes care robot was developed using data from the literature, professional team meetings, and practical interviews, with the aim of creating a more evidence-based health care robot that can actually give patients with diabetes a realistic experience for their disease care and enable them to give clearer and more specific feedback for the subsequent development and application of technology in disease care.

Acknowledgments

This work was supported by a grant from the Taiwan Ministry of Science and Technology (MOST 108-2634-F-006 -006-). The Taiwan Ministry of Science and Technology had no role in the design of the study, data collection, data analysis, data interpretation, or writing of the report.

Authors' Contributions

Study concept and design: CJC. Acquisition of data: CJC, LCH. Analysis and interpretation of data: CJC, LCH. Drafting of the manuscript: CJC, LCH. Critical revision of the manuscript for important intellectual content: CJC, LCH, CYC. All authors have read and approved the manuscript.

Abstract

Background: Cardiovascular risk factors such as hypertension often remain undetected and untreated. This was particularly problematic during the COVID-19 pandemic when there were fewer in-person medical consultations.

Objective: This study aimed to determine whether health screening using a telemedicine booth would have an impact on people's medical care during the COVID-19 pandemic.

Methods: Health screening was run using a telemedicine booth (the consult station) that was placed in three different vaccination centers in northern France between July 2021 and September 2021. Participants followed a series of instructions to obtain various measures, including their blood pressure, BMI, and heart rate. If any measures were found to be outside of the normal range, participants were advised to consult a doctor. After 3 months, the participants with abnormal readings were contacted by telephone and were asked a series of standardized questions. The primary outcome was the percentage of respondents who reported that they had consulted a doctor since the health check.

Results: Approximately 6000 people attended the 3 vaccination centers over the study period. Of these, around 2500 used the consult station. A total of 1333 participants (53.3%) were found to have abnormal readings, which mostly concerned their blood pressure, heart rate, or BMI. There were 638 participants who responded to the follow-up call, and 234 of these (37%) reported that they had consulted a doctor since the health check. However, 158 of the 638 respondents (24.8%) reported that they would have consulted a doctor even without the screening.

Conclusions: We succeeded in screening large numbers of people for cardiovascular risk factors during the COVID-19 pandemic by using a telemedicine booth. Although relatively few follow-up call respondents reported that they went on to consult a physician, the screening would nevertheless have raised people's awareness of their cardiovascular risk factors.

Introduction

Cardiovascular disease (CVD) is the leading cause of death worldwide [1]. In France, the disease affects around 7.9% of the population and causes around 140,000 deaths each year, which is only exceeded by deaths caused by cancer [2,3]. The health care costs are substantial, representing around 10% of the country's health care reimbursements [4]. The burden of CVD is likely to increase over the coming years due to an aging population and is thus a major cause for concern [4].

There are several well-known modifiable risk factors for CVD, including obesity, high blood pressure, and physical inactivity [5]. The most significant of these is hypertension because it accounts for the largest number of CVD deaths [5,6]. In France, this affects around 22% of the population, but over a third are unaware that they have the condition because there are usually no symptoms [4,7]. As a result, many people do not benefit from interventions, such as antihypertensive medication, that can effectively lower their blood pressure, thus reducing the risk of CVD [8]. Obesity is another important modifiable risk factor for CVD, which affects 21.6% of the adult population in France [4]. Although effective treatment options are available, such as lifestyle modifications, antiobesity medication, and bariatric surgery, people with obesity typically believe that it is their responsibility to lose weight and so often wait many years before seeking medical help [9-11].

Screening for CVD risk factors is of much importance for public health, as it enables risk factors such as hypertension to be

XSL•FO
RenderX

detected and treated, which can prevent CVD. Most screening takes place during medical consultations with a general practitioner (GP), where blood pressure and weight are regularly monitored. However, some people rarely consult a medical professional. For instance, a study of over 8000 adults in England found that 22.8% (1846/8086) had not consulted a GP over the last year [12]. This means that CVD risk factors may remain undetected and untreated. In addition, the lack of GPs in certain regions is likely to further limit the number of people who are screened [13,14].

Various screening programs have been set up over the years to target people who rarely consult a GP. These programs have often focused on detecting hypertension, also known as the "silent killer," and they have been run in a variety of different settings [15-17]. Some screening programs have involved health checks carried out by nurses, pharmacists, or medical students in settings such as pharmacies, dental surgeries, and community centers [18]. However, these programs may not always be feasible, such as during pandemics when strict social distancing requirements are in place. In addition, they are likely to be limited by funding and staffing resources. As an alternative solution, self-screening facilities have been developed, which have the advantage of lower running costs as well as the potential to be used during pandemics [19]. For instance, health kiosks that assess blood pressure and weight are now available in pharmacies and shopping centers throughout the United States, including more than 6000 health stations developed by the company Higi (Chicago, United States). There is evidence that these have a positive impact. For instance, a study showed that 27.4% (17/62) of users with hypertension achieved blood pressure control within 6 to 12 months [20]. These rates could potentially be improved through patient education and by referring people on to treatment programs, such as the Kaiser Permanente treatment protocol [20,21]. However, health kiosks are not widely available in many countries, including France. Other possibilities for screening include the use of personal digital devices, such as smartphones; however, not all people have these and there are concerns about their accuracy [22].

Recently, a telemedicine booth was developed in France (the consult station, H4D, Paris) that can run a series of health checks in the privacy of a stand-alone booth [23]. The tests can be run by users without any input from a medical professional; there is also the option of using the device for teleconsultations with a physician. The booth can be used to assess blood pressure, BMI, and heart rate, which have all been linked to CVD [5,24]. In addition, other measures can also be obtained that can signal other health conditions, such as oxygen saturation, where low levels could point to anemia or pulmonary diseases, and rapid visual tests, where abnormalities could be a sign of macular degeneration or epiretinal membrane.

In this study, we assessed the feasibility and interest of using the consult station telemedicine booth for self-screening during the COVID-19 pandemic, when there was a particular need for remote medical services. The booths were placed in several vaccination centers throughout northern France at a time when large numbers of people were coming to be vaccinated. Our primary aim was to determine whether screening using the telemedicine booth would have an impact on the medical care of people with CVD risk factors. We also aimed to determine whether people who were not registered with a GP (11% of people in France) [13] had more CVD risk factors and whether they would be more likely to consult a medical professional following the screening.

Methods

Study Design

This study was a prospective, single-arm, multicenter study. All participants provided informed consent before taking part in the study; this concerned all those who had a health check using the consult station. Participants were also sent an information sheet by post or email before the follow-up telephone interview, which included a form to complete and return if they did not agree to their data being used for the study.

Setting

This study was carried out in 3 different vaccination centers between July 1, 2021, and July 1, 2022. The centers were all located in hospitals in northern France.

Participants

Participants were included in the study if they were aged 18 years or older and were affiliated to a social security scheme. Participants were excluded if they could not follow the instructions in the consult station or if they were under guardianship. There was no sample size calculation for this study.

Screening

During the waiting periods at the vaccination centers (before or after vaccination, or at any time for accompanying adults), people were offered a free health check using the consult station, a telemedicine booth developed by H4D (Paris, France). This is a class IIa medical device that can measure people's blood pressure, heart rate, oxygen saturation, BMI, and vision (acuity and central visual field using the Amsler grid) in less than 15 minutes. The health check is run by following a series of instructions on a screen, and it does not require the involvement of medical staff. However, a nurse was present to interpret the results, which were provided on a printed sheet of paper, and participants were advised to see a doctor if there were any readings outside of the normal range. For the purposes of this study, the following readings were considered to be outside the normal range: BMI >30 kg/m^2 (obese: 31 - 40 kg/m^2; severely obese >40 kg/m^2), heart rate >80 beats per minute (bpm) or <50 bpm (high heart rate: 81 - 100 bpm; tachycardia: >100bpm), oxygen saturation <94% (mild: 90 - 93%; hypoxia: <90%), systolic blood pressure <100mmHg or >140mmHg (high: 141 - 180mmHg; very high: >180mmHg), and diastolic blood pressure <70 mmHg or >90 mmHg (high: 91 - 100mmHg; very high: >100mmHg). The Amsler grid results were marked as abnormal if the participants saw the grid to be distorted (eg, wavy lines) when focusing on the central dot. We took the contact details (eg, telephone and email) of the participants who had screening results outside the normal range, with their permission. These participants were then contacted 3 months later to evaluate the impact of the screening.

XSL•FO
RenderX

Follow-Up

Three months after the health check, the participants were contacted by telephone and were asked to respond to a series of questions. These covered their demographic details (sex and history of smoking), their medical history before the health check (hypertension, cardiac arrhythmia, pulmonary disease, diabetes, or sleep apnea; whether they took medication), their reason for coming to the vaccination center (to be vaccinated, accompanying someone, or member of staff), whether they were registered with a GP, and how often they saw a medical professional. Participants were also asked whether they had consulted a doctor since the health check, and if so, whether this was with their GP. They were also asked whether the doctor had confirmed the cardiovascular risk factors and initiated regular follow-up appointments to monitor these. They were also asked whether they would have consulted a doctor without the health check (yes or no). Additional questions covered whether they had seen or planned to see a medical specialist, or whether they had been told that this was not necessary. Participants were also asked whether they had been to see a dietician. If they were smokers, they were also asked whether they had stopped smoking or taken steps to do so. Participants were also asked whether their health check had been before or after vaccination (or during vaccination for those accompanying others).

Outcome Measures

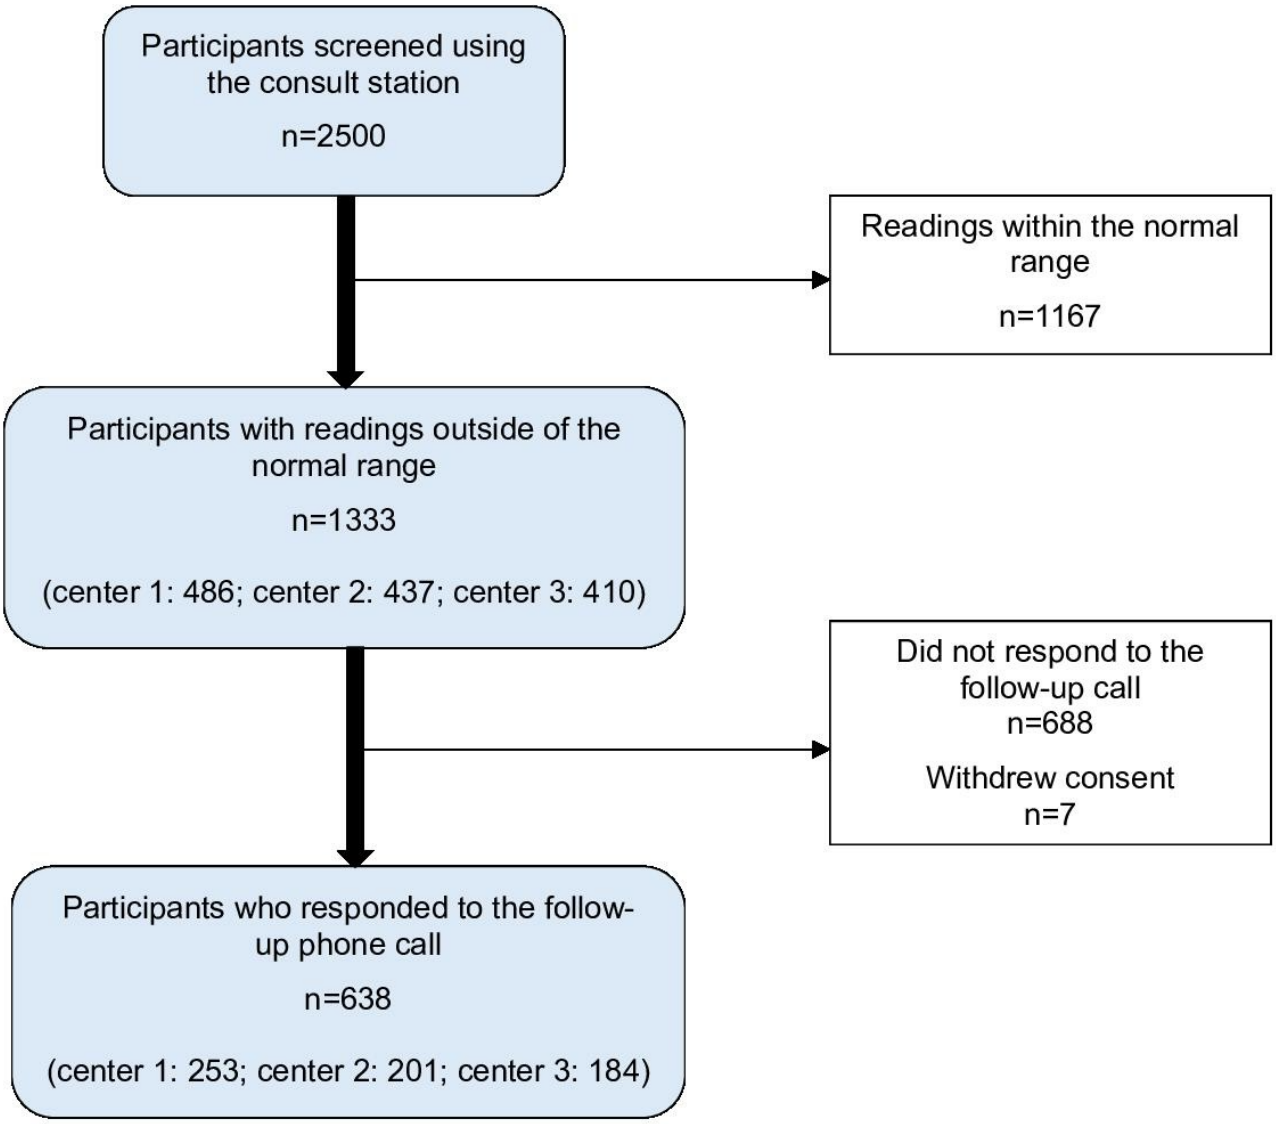
The primary outcome was the percentage of participants with abnormal screening results who then consulted a doctor (GP or specialist). The secondary outcome was the percentage of participants not registered with a GP who then consulted a doctor (GP or specialist) following abnormal screening results. An additional secondary outcome was the difference in cardiovascular risk factors between participants who were registered with a GP and those who were not registered with a GP.

Data Analysis

The program R (R Foundation for Statistical Computing) was used for the statistical analyses. The qualitative variables were summarized using frequencies and percentages; quantitative variables were summarized using the means and standard deviations, or medians, inter-quartile ranges (IQR), and ranges. Statistical analyses were run according to the type of data (eg, χ^2 or Fisher exact tests for categorical data) using a significance level of 0.05. We also ran univariate and multivariate analyses to identify factors that could predict whether the participants would consult a doctor following screening.

Ethical Considerations

The study was approved by the ELSAN Institutional Review Board (#2022-03-Dr DECAMBRON-01; approved on March 21, 2022) and is registered on the Health Data Hub (number: F20220309155706. All participants provided informed consent.



Results

Participants

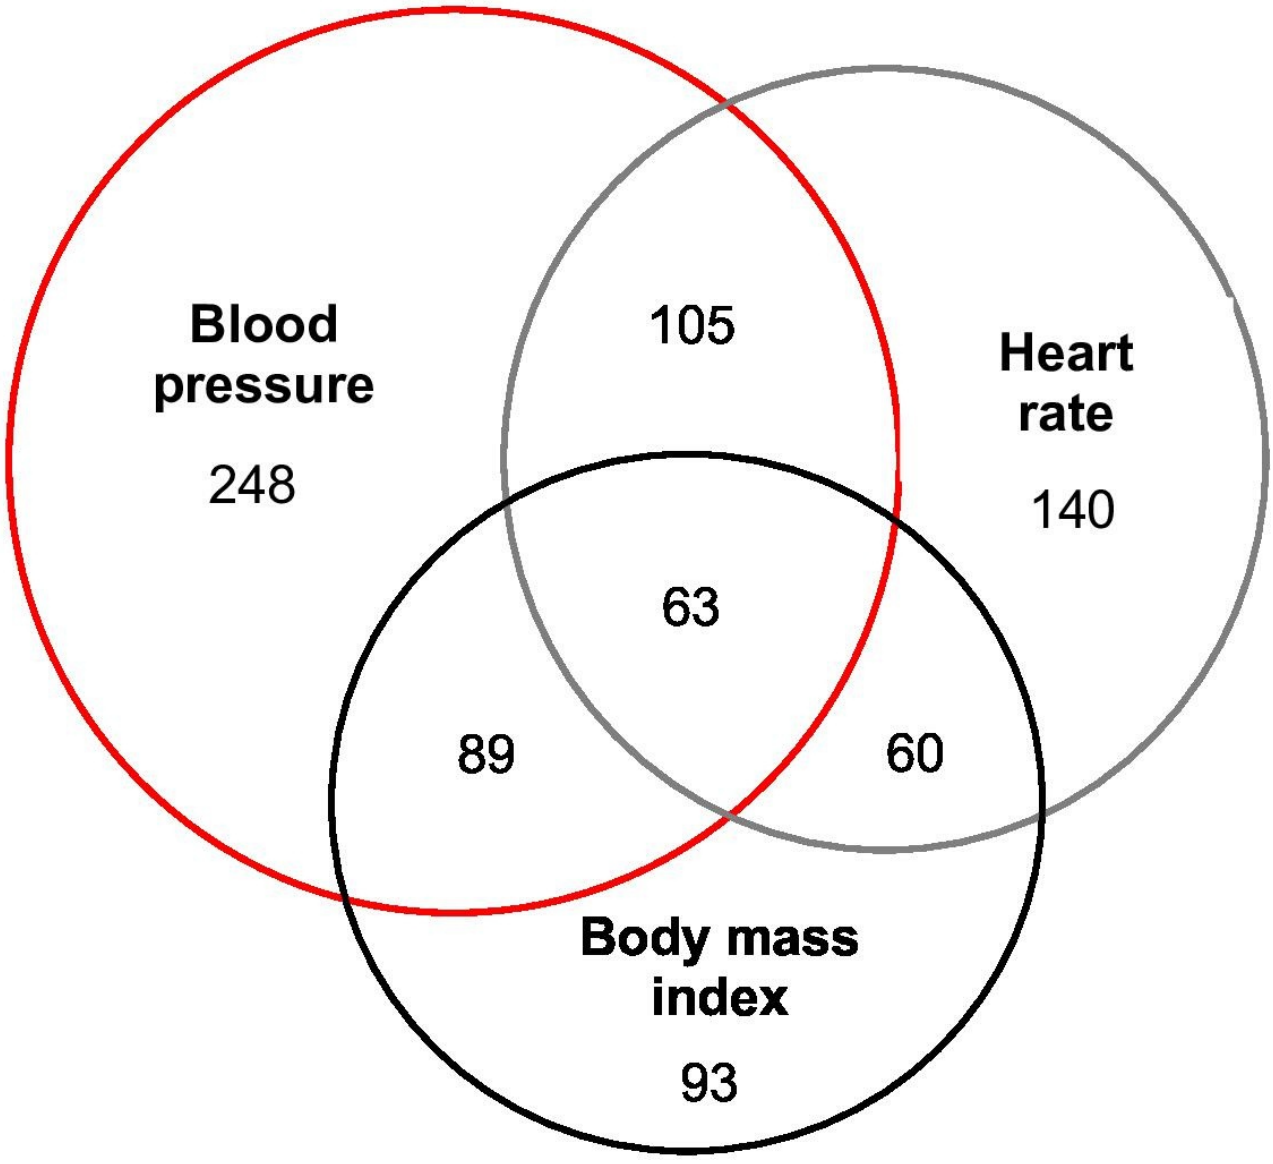
Approximately 6000 people attended the three vaccination centers between July 2021 and September 2021 and were given the opportunity to take part in the study. There were around 2500 people who had a health check using the consult station (2500/6000; 41.7%). In total, 1333 participants (53.3%; 1333/2500) were found to have readings outside the normal range and so were advised to consult a doctor (center 1: N=486; center 2: N=437; center 3: N=410). These participants (N=1333) all provided their contact details, but 7 withdrew their consent and only 638 (47.9%) responded to the follow-up telephone call (center 1: N=253; center 2: N=201; center 3: N=184; see Figure 1).

XSL•FO
RenderX

Figure 1. Flow chart of the study participants.

Screening Results

Results sheets were available for just 1087 of the participants who used the consult station (1087/2500; 43.5%; all at center 1 and center 2). These data were analyzed, and it was found that over a quarter had heart rate, BMI, and blood pressure outside of the normal range (Table 1). The overlap between these abnormal readings is shown as a Venn diagram (Figure 2).



XSL•FO
RenderX

Table . Consult station screening results based on the available results sheets (total: 1087).

Variable	Statistical values	Number of readings outside normal range, n/N (%)[a]
Body mass index (kg/m^2), median (IQR) range	26 (23 - 30) 14 - 53	305/1025 (29.8)
Heart rate (beats per minute), median (IQR) range	75 (67-84) 21-132	368/985 (37.4)
Oxygen saturation (%), mean (SD) range	97.5 (1.6) 75 - 99	13/986 (1.3)
Systolic blood pressure (mmHg), median (IQR) range	126 (114 - 138) 84 - 225	283/1016 (27.9)
Diastolic blood pressure (mmHg), median (IQR) range	80 (73 - 89) 42 - 136	416/1016 (40.9)
Amsler grid (central visual field)	—[b]	105/1016 (10.3)

[a]The total number of available readings is lower than the actual number of participants who completed each measure. This is because results sheets were not available for all study participants (eg, none were available from center 3); in addition, certain measures were not obtained for all participants.
[b]—: not applicable.

Figure 2. Venn diagram showing the overlap between abnormal readings for body mass index, blood pressure, and heart rate. Note that the abnormal readings for blood pressure include both abnormal diastolic blood pressure and abnormal systolic blood pressure. Participants who had abnormal readings for both of these were counted once.

RenderX

Primary Outcome Measure

Of the 638 participants who responded to the follow-up telephone call, 234 (36.7%) reported that they had consulted a doctor (GP or specialist) since the health check (center 1: 70/253, 27.7% participants; center 2: 53/201, 26.4% participants; center 3: 111/184, 60.3% participants). However, 24.8% of the participants (158/638) reported that they would have consulted a doctor anyway even without the health check (Table 2).

[a]GP: general practitioner.

[b]Note that some patients may have had more than one concomitant disease.

[c]The percentage is not shown as the number includes participants who are counted more than once because they take more than one drug.

[d]The percentage only includes participants who saw a GP.

[e]The percentage only includes participants who saw a GP and had the risk factors confirmed.

Chi-square tests were run to identify potential factors that might predict whether participants consulted a doctor following the health check. The factors that had a *P* value above .2 were the participants' sex (*P*=.16), their reason for coming to the vaccination center *(P*<.0001), whether they smoked *(P*=.03), whether they were registered with a GP *(P*=.19), and whether they had a history of certain diseases (hypertension, cardiac arrhythmia, pulmonary disease, diabetes, and sleep apnea*; P*<.0001). A multivariate analysis was then run, which included these factors. The results showed that the reason for coming to the vaccination center and a history of certain diseases were statistically significant at the *P*<.05 level *(P*<.001 for both factors). The pattern of results indicated that participants were more likely to see a doctor following the health check if they had come to the center to be vaccinated or if they had a history of certain diseases.

Secondary Outcome Measures: Differences Between Participants Registered With a General Practitioner and Those Not Registered With a General Practitioner

There were 18 participants (18/638; 2.8%) who reported that they were not registered with a GP. Five of these (27.8%) consulted a doctor following the health check. Due to the lack of data, we did not carry out further analyses.

Additional Analyses

Additional analyses were run to determine whether there were significant differences between the 3 vaccination centers in terms of the follow-up call results (Table 3). We found that there was a significant difference between the centers in terms of the proportion of participants who were registered with a GP *(P*=.04). Specifically, fewer were registered with a GP at center 2 (94.5%) than at center 3 (98.4%) and center 1 (98.4%). This can be attributed to the relative lack of GPs in this region (101 per 100,000 individuals compared with 129 and 159 per 100,000 population for the other 2 regions) [25]. We also found a significant difference concerning the proportion of participants who consulted a GP following the health check *(P*<.001). This was higher at center 2 (45%) than at the 2 other centers (20.9% and 19.2%). Similarly, a higher proportion of participants at center 2 (34.3%) consulted a medical specialist than at the 2 other centers (17.7% and 20.7%*; P*<.0001). These results indicate that the screening led more participants at center 2 to consult a doctor. However, a higher proportion of participants at this center reported that they would have seen a doctor anyway (50.3% vs 14.5% and 12.0%*; P*<.0001). Of note, the participants at the different centers did not differ significantly in terms of how often they usually saw a doctor *(P*=.82).

Discussion

Principal Findings

In this study, large numbers of people were screened for CVD risk factors during the COVID-19 pandemic using the consult station telemedicine booth. According to the available results sheets, over half had readings outside the normal range, which were mostly for blood pressure (diastolic: 41%; systolic: 28%), heart rate (37%), and BMI (30%). Even though relatively few people reported that they consulted a doctor because of their results (around 12% of the follow-up call respondents), the screening would nevertheless have raised people's awareness of their risk factors and may have led to beneficial lifestyle changes.

Our study showed that the telemedicine booth was generally well-accepted by the French public, with around 42% of visitors to the vaccination centers choosing to use the device. Although the booth's enclosed environment may have led to fears of infection during the pandemic, we found that this did not prevent almost half of the visitors from using the consult station and benefiting from the free health check. We speculate that even more people would use the device at other times when there is less fear of infection. Indeed, the privacy provided by the booth is likely to encourage more people to use the device as this could improve user experience.

This high level of acceptance supports the use of telemedicine booths for CVD screening not only during pandemics but also at other times. They could potentially be used to screen large numbers of people, and they have the advantage of low running costs. They would be of particular benefit to regions that lack medical professionals, the so-called "medical deserts" of France, to improve screening services in these regions [13]; the booths could also potentially be used to provide teleconsultations with medical professionals in these regions. The telemedicine booths should ideally be placed in carefully selected locations to target groups of people who are known to have a higher risk of CVD, such as older adults. This has already been done in the United States, where blood pressure checks have been run in Black-owned barbershops to target Black American men who have a high prevalence of hypertension [26].

One of the strengths of our study is that we evaluated the impact of the screening by examining whether people with abnormal results went on to consult a physician. This is an important consideration, as it has been pointed out that people with hypertension may not always seek medical treatment [27]. In our study, only around 12% of the respondents reported that they consulted a doctor because of the screening. This raises the question as to why this was the case, especially as the participants had been explicitly advised to see a doctor. One possibility relates to the fact that the study took place during the COVID-19 pandemic, and so participants may have avoided medical consultations when there was a risk of infection as well as an overwhelmed health system. Another possibility is that some participants may already have been aware of their condition and so they may already have consulted a doctor about it. It is also possible that some participants did not fully understand the dangers of their abnormal readings or the fact that effective treatment options are available from their GP; this consideration is important, as it could potentially be remedied by providing educational material.

Although relatively few participants with abnormal readings consulted a doctor, improvements may nevertheless have occurred. Specifically, it is possible that the participants may have adopted lifestyle changes to improve their health. For instance, they may have searched the internet for advice on how to lose weight or lower their blood pressure. In support of this, a previous study found that many people with obesity prefer to find out about weight management from the internet, friends, and smartphone apps rather than from their health care provider [28].

Our statistical analyses revealed 2 factors that could predict whether participants with abnormal readings would consult a doctor. The first was having a history of certain diseases, such as diabetes. This could be attributed to the fact that patients with these diseases often have regular follow-up appointments with a GP. In addition, they may also be more aware of their need for medical care. The second factor was coming to the center to be vaccinated (as opposed to accompanying someone or for work); this may be because these participants were generally inclined to seek medical care (eg, vaccination) and so they would be more likely to consult a doctor following the screening.

One of the aims of our study was to examine differences between participants who were registered with a GP and those who were not. In France, it has been reported that a substantial proportion of the population (11%) does not have a GP [13]. However, we only identified 18 participants (2.8%) who were

XSL•FO
RenderX

not registered with a GP, and so we did not carry out statistical analyses. This low number may be because the people who came to the vaccination centers were generally inclined to seek medical care, including vaccination, and so would also be more likely to register with a GP. We noted that most of the participants who were not registered with a GP were at center 2, which can be attributed to the relative lack of GPs in this region (101 per 100,000 population for the center 2 as opposed to 129 and 159 per 100,000 population for the 2 other centers) [25]. However, this did not appear to affect the postscreening medical consultations, as the participants at this center were also more likely to see a physician following the health check. This latter finding may relate to the fact that over half of the participants at center 2 reported seeing a GP at least once a month, unlike at the other 2 centers; these participants may therefore have been more likely to consult a physician following the health check simply because they were already frequent health care users.

The limitations of this study include the lack of a control group and missing data (no screening results for over half of the participants). In addition, we were unable to link the follow-up results to the initial screening data (except for 55 participants). In addition, it is possible that certain screening measures (eg, blood pressure) may have been affected by the vaccination (eg, prevaccination anxiety or postvaccination side effects) [29]. The results might also have been affected by bias in terms of the study participants, as those who took part were at a vaccination center and so were presumably inclined to seek medical care. Finally, we did not assess whether the screening had an impact on risk factor control over the long term.

In the future, it would be helpful to run further studies to identify the most effective locations for screening, with the aim of targeting people who rarely consult a GP. In addition, it would be helpful to develop educational pamphlets or videos that explain CVD risk factors and the treatment options that are available, as this could potentially increase the number of people who seek medical care. Additional screening measures could also be introduced to detect other diseases, such as the ankle-brachial index, which can indicate whether someone has peripheral artery disease, a prevalent but currently under-diagnosed condition [30]. It would also be beneficial to introduce mHealth systems, such as mobile phone-based lifestyle interventions, for patients who are found to have CVD risk factors. These has previously been shown to effectively lower the risk of atherosclerotic CVD and increase peak oxygen consumption and so could potentially greatly increase the health benefits following screening [31,32].

As a final note, there are current plans for the consult station to be used for screening in regions of France where there is a high prevalence of hypertension and a lack of medical services. Our medical group has also started sending mobile health buses to medically underserved towns in the Hauts de France region, which aim to promote healthy lifestyles and prevent disease through patient education.

Conclusions

By placing the consult station in vaccination centers during the COVID-19 pandemic, it was possible to screen large numbers of people for CVD risk factors. Our results support the use of telemedicine booths for health screening, particularly in regions that lack medical professionals. In the future, it would be helpful to develop educational material to ensure that users understand the significance of any abnormal results and the treatment options that are available.

Acknowledgments

Abstract

Background: The widespread prevalence of cancer across the globe demands cutting-edge solutions for its treatment. Current cancer therapies, notably chemotherapy, pose challenges due to their side effects. The early detection and management of the side effects are vital but complex. This study introduces a mobile health app designed to bridge the communication gaps between patients with cancer and health care providers. Hence, it allows patients to report symptoms immediately and also enables proactive symptom management by health care providers.

Objective: This study has 2 objectives: first, to design a cancer-focused mobile health app that integrates educational content and real-time symptom reporting for chemotherapy patients. Second, to validate and evaluate the app quality using the Mobile App Rating Scale (MARS). The app seeks to foster health care communication, reduce hospital readmissions, and optimize symptom management, contributing to a more impactful patient experience.

Methods: This mixed-methods study details the development and validation of mobile health applications. The app was designed by a multidisciplinary team, including nurses, medical professionals, pharmaceutical chemists, computer engineers, and software developers, using agile methodologies. For validation, the app was assessed by 13 evaluators, including clinical professionals (nurses and physicians) and engineers. The evaluation included technical performance analysis using Google tools and quality assessment using the MARS, which measures engagement, functionality, aesthetics, and information quality.

Results: Performance metrics highlighted areas for improvement, with loading times showing delays in displaying content. Meanwhile, the response time of the app was moderate, and visual stability remained excellent. The app achieved an overall MARS score of 3.75 (SD 0.42), indicating consistent quality, with functionality scoring the highest (4.35; SD 0.52) and engagement the lowest (3.31; SD 0.61). The reliability of the MARS was confirmed (interclass correlation coefficient: 0.84; 95% CI: 0.72 - 0.92). Evaluators unanimously praised the app's potential benefits for patients and clinical professionals while identifying areas for improvement such as customization, onboarding guidance, and navigation.

Conclusions: The CONTIGO app showed strengths in functionality, usability, and information quality, supported by robust security measures. However, areas such as user interactivity and engagement require improvement. Future refinements will integrate insights from patients with cancer to address user-specific needs and enhance the oncology care experience.

Introduction

According to the World Health Organization (WHO), cancer is one of the leading causes of mortality worldwide. In 2020, approximately 19 million people were diagnosed, and 9.3 million people die each year [1,2]. In the particular context of Chile, a comparable pattern was noted; in the same year, 54,000 cases of cancer were diagnosed, with 28,000 fatalities attributed to the disease annually. Additionally, cancer is the leading cause of disease burden and is responsible for 13% of disability-adjusted life years (DALYs) [3-6].

Continuing medical advances and the current therapeutic approach to cancer are multimodal and incorporate various strategies to maximize treatment efficacy. This comprehensive approach encompasses modalities such as radiotherapy, surgery, immunotherapy, and chemotherapy, the latter considered the gold standard [7-11]. Additionally, the application of an interdisciplinary approach includes palliative care to reduce suffering and improve the overall quality of life of patients and their families. This multidimensional strategy seeks to address the disease and provide comprehensive support, considering the patient's physical, spiritual, and psychosocial dimensions throughout the disease [12-14].

In this sense, it is essential for health care professionals to monitor and accompany patients and continues to be a challenge for health care professionals, requiring collaborative efforts between clinical staff, patients, and their families. The WHO promotes ensuring quality in care processes and incorporating patient-reported outcome measures (PROMs) and patient-reported experience measures (PREMs) [15] with tools that allow for the timely identification of these symptoms to contribute positively to patient well-being and service delivery by clinical staff [16].

Significant growth in health care technologies may favor this process. According to projections by the Center for Technology and Communication, approximately 7.49 billion people worldwide will be using mobile devices by 2025 [17] and Android users currently have access to 3.55 million apps [18], of which 1 million are aimed at influencing people's health, fitness, nutrition, and well-being [19].

Mobile applications in health, known as mHealth apps, have proven helpful and significant benefits for patients and health care professionals. These apps assist patients in adopting healthier lifestyles, enhancing self-care, and improving the quality of services, with a substantial focus on educational services and sensibilization programs [20-22]. This information is crucial for promptly notifying health professionals so that they can make informed decisions and effectively manage patients' adverse effects [23-27].

In line with these advancements, Wasserman et al [28] conducted a study to evaluate the quality and usefulness of 17 digital mHealth applications designed for adults with cancer. The study focused on assessing apps with tailored digital features and measured their performance using standardized tools, including the Mobile App Rating Scale (MARS) and a checklist of user-desired features derived from the literature. These features included functionalities such as symptom tracking, treatment management, and communication tools, highlighting the potential role of mHealth apps in supporting comprehensive cancer care and addressing unmet needs in symptom management and patient engagement.

We developed the CONTIGO app, designed specifically for the Chilean context and to operate within the UC-Christus network [29]. Its primary aim is to help patients adopt healthier lifestyles, improve their self-care, and positively impact their quality of life and that of their families. In addition, the app aims to facilitate communication between health care professionals and patients to reduce hospital readmissions and unnecessary emergency room visits while optimizing symptom management.

This study presents the results of designing a mHealth application for patients with cancer that integrates educational content with the functionality of immediate notification of unpleasant symptoms associated with chemotherapy administration to the treating physician and nurse. Additionally, it shows the results of validation and quality assessment of the mobile application "CONTIGO" by using the MARS, which allows mHealth developers to maximize the application's benefits to significantly impact the patient [22,30-36].

Methods

Study Type

This study employed a mixed methods approach. This methodology is presented in two sections: (1) design a mobile application, and (2) validation and quality assessment.

Ethical Considerations

The research protocol for designing a health mobile application for patients with cancer was reviewed and approved by the Scientific Ethics Committee CEC Med-UC (09/2023) ID 230808005. All participants provided informed consent before submitting their responses. Participation was voluntary, and participants were informed of their right to withdraw at any time without consequence. The study did not include any vulnerable populations and was conducted in accordance with established ethical standards for human subjects research. Data were collected anonymously through a Google Form, and no personally identifiable information was recorded. As a result, all data are fully anonymized and cannot be linked to individual participants. Researchers did not have access to responses while participants completed the evaluation, ensuring both privacy and impartiality. No financial or material compensation was offered for participation. Anonymized data may be made available upon request

XSL•FO
RenderX

mHealth App Design

To develop "CONTIGO," a multidisciplinary team consisting of nurses, pharmaceutical chemists, medics, computer engineers, and developers was formed. Previous research was considered, and principles of agile methodologies were adopted, such as software development, responsiveness to change, an iterative process with the client, and the assessment of individuals and interactions in the process. As a result, 5 stages for the development of the application were established.

Phase 1: Information Analysis

To construct the educational content, we conducted focus groups involving 1 PhD student in health science, a nurse with a master's degree, 3 nurses with oncology experience, and 2 oncologists. These professionals identified a critical gap in patient education: newly diagnosed oncology patients often forget or lack access to the educational information provided during consultations. This application was developed as a response to this need, ensuring that patients have a reliable and accessible source of information to revisit at their convenience. The research team adhered to the recommendations outlined in the Guide of Elaboration and Application of Focus Groups (G-DEP-005) [37] and followed an iterative process to obtain a theoretical framework for each section of the application. The framework was presented using text, images, and personalized videos. The application's initial focus prioritized the needs and preferences of health care professionals because the tool was designed to support their educational role with patients. The requirements were collected through a detailed request form completed by a trained clinical team member, who classified them by priority. This approach ensured the application's alignment with clinical standards while laying the groundwork for future integration of patient-specific preferences.

Phase 2: Design

We considered a previously created interface [38], which had been evaluated in earlier studies using patient focus groups. Feedback from these studies informed the decision to adopt and optimize this interface for the current application. Adjustments were made to the graphical interface, focusing on scenario optimization and comprehensive software restructuring. These modifications aimed to ensure an attractive, user-friendly, and efficient interface for the application's target users.

Architectural development prioritized asynchronous services to enhance system flexibility and scalability, ensuring the application could adapt to future updates and user demands.

Phase 3: Development

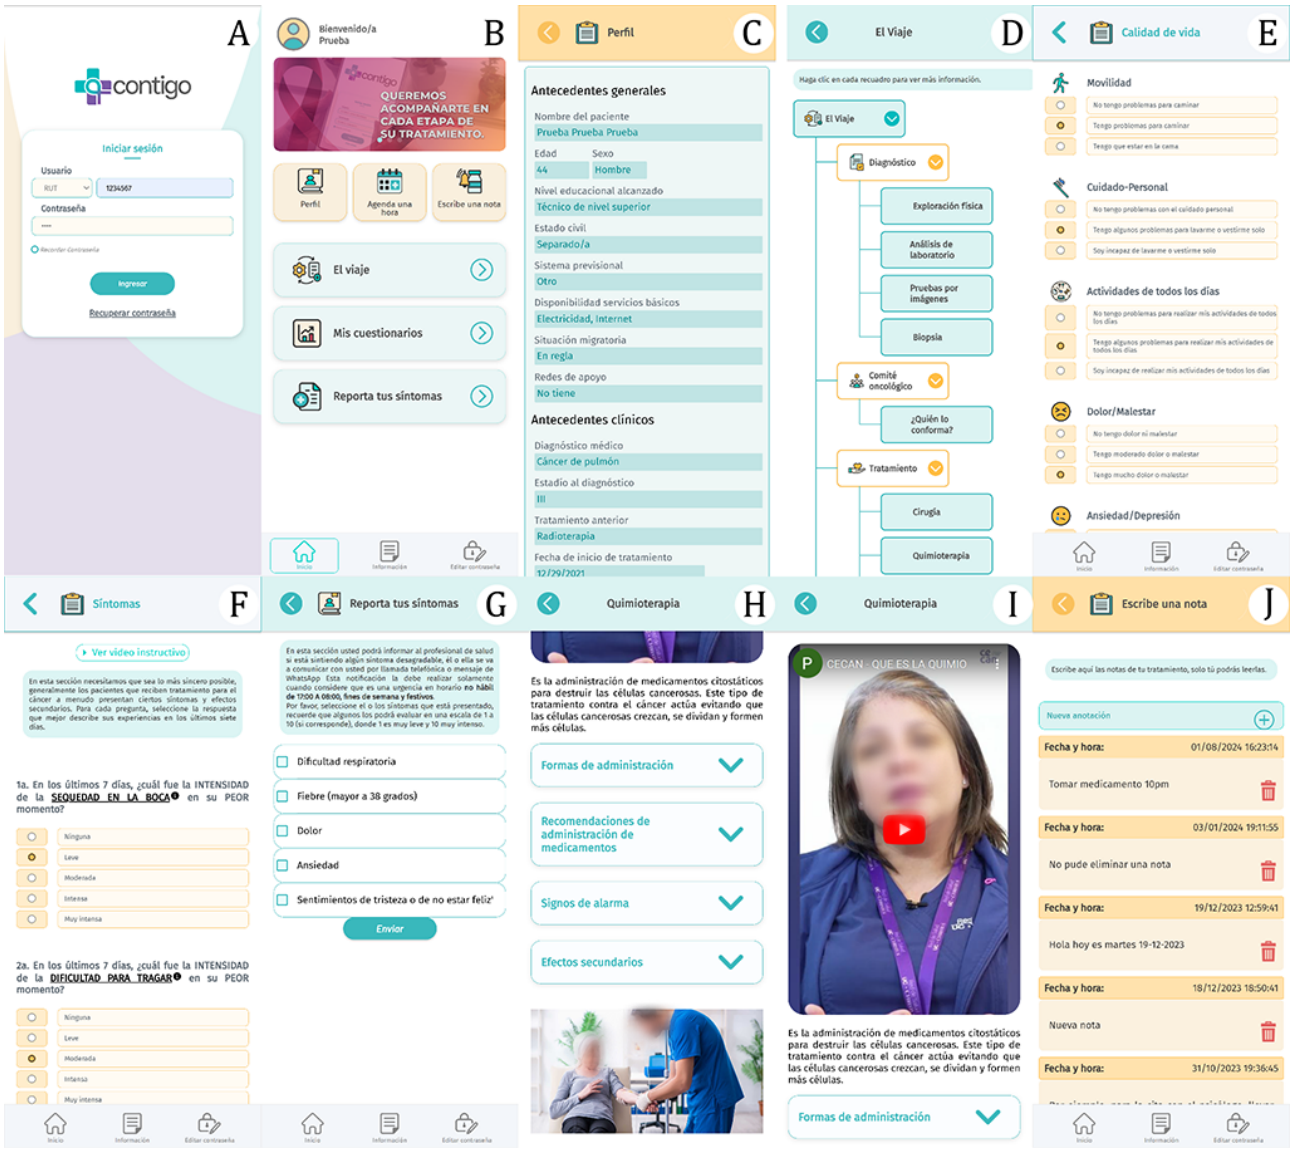
In this phase, decisions were made regarding implementation and coding, scenario adjustment, and software restructuring. Docker containers were used to simplify deployment and optimize application management and distribution. Security measures, such as management through Cloudflare, were integrated to prevent potential distributed denial-of-service (DDoS) attacks. Data encryption techniques were also applied to ensure information security. An open-source, high-performance PostgreSQL relational database management system was defined. A backup program was established every 3 hours using incremental backup copies to ensure data integrity and availability.

Phase 4: Functional Testing

This phase focused on verifying the system's robustness through emulation and simulation tests, followed by the implementation of the application on real devices. The teams were divided into 2 groups: one consisting of engineers and developers and the other consisting of a clinical team. This division aimed to enhance mobile device applications' quality, stability, and user experience.

Phase 5: Deployment

The engineering team officially delivered the "CONTIGO" mobile application to proceed with the final validation process and quality evaluation. Figure 1 presents the final version of the application and its sections, which include a variety of features designed to support patients and clinical professionals.



The application allows patients to record chemotherapy-related symptoms, enabling clinical teams to make data-driven decisions and manage side effects more effectively. Furthermore, the app offers features such as patient profile management, appointment scheduling, and access to educational materials presented through text, images, and videos.

The educational videos included in the app cover a variety of topics designed to improve patients' understanding of their treatment and care. These topics include laboratory tests, imaging tests, oncology committee decisions, treatment options, chemotherapy, radiotherapy, immunotherapy, palliative care, what is cancer, what is chemotherapy, what is a catheter with a reservoir, what is a continuous infusion pump, what are side effects, and what are the warning signs. The videos aim to provide patients with clear and concise explanations of medical procedures and key concepts to empower them in managing their care.

Additionally, the app includes digital questionnaires for reporting physical and psychological symptoms, as well as assessing quality of life. To enhance patient-clinician communication, the app integrates an instant messaging system, facilitating real-time interaction with the clinical team.

Validation and Quality Assessment

In this study, the validation strategy reported in TGUM-GISSIC groups was applied and adapted to the current Chilean context in Chile. Technical attributes that determine the quality of an application, such as performance, graphical interface structure, usability, robustness, and information security, were identified [39]. Recommendations followed from the assessment and accreditation of health-related mobile applications [20]. The literature search began by identifying a validated questionnaire, and among the identified instruments, the MARS scale was selected.

The performance and robustness of the application were evaluated using Lighthouse [40,41], a widely used, open-source Google-developed tool for assessing web and mobile app quality. Lighthouse provides metrics across several categories, such as performance, accessibility, best practices, and search engine optimization (SEO), which are essential for understanding the application's functionality and user experience.

Lighthouse simulates a page load in a controlled environment, emulating device and network conditions to capture performance data and generate metrics for performance. These insights highlight areas needing improvement, ultimately helping developers enhance the user experience.

Its metrics include:

- First contentful paint (FCP): Measures the time it takes for the first visible content, such as text or images, to appear on the screen after the page starts loading. It provides an early indication to users that the page is loading and responsive, enhancing perceived performance. Optimal values are under 1.8 seconds, moderate values range between 1.8 and 3.0 seconds, and values above 3.0 seconds indicate a need for improvement.
- Largest contentful paint (LCP): Represents the time taken for the largest visible content, like a banner image or block of text, to fully render in the viewport. It reflects how quickly the main content becomes available, which is critical for user engagement. Optimal values are under 2.5

XSL•FO
RenderX

seconds, moderate values range between 2.5 and 4.0 seconds, and values above 4.0 seconds require improvement.
- Speed index: It evaluates how quickly content is visually displayed during the loading process by calculating the average time for visible portions of the page to appear. This metric gives a holistic view of the loading experience, beyond individual milestones. Optimal values are under 3.4 seconds, moderate values range between 3.4 and 5.8 seconds, and values above 5.8 seconds indicate poor performance.
- Total blocking time (TBT): Measures the total duration when long tasks (exceeding 50 ms) block the main thread, preventing the app or website from responding to user inputs. This metric directly impacts the perceived interactivity of the app during its loading phase. A lower TBT score indicates smoother transitions and better responsiveness. TBT scores were categorized based on established benchmarks: scores under 200 milliseconds were considered optimal, scores between 200 and 600 milliseconds as moderate, and scores above 600 milliseconds as requiring improvement.
- Cumulative layout shift (CLS): Assesses the visual stability of a page by measuring unexpected layout shifts caused by late-loading elements like images or ads. A low CLS score ensures a smooth and stable user experience, avoiding accidental clicks or frustrating movements of content. Optimal CLS values are under 0.1, while scores between 0.1 and 0.25 indicate moderate stability. Values above 0.25 reflect significant layout instability, which can negatively impact user experience.

The MARS scale was adapted and validated in Spanish to evaluate other attributes of "CONTIGO" critically and systematically [30-32]. This scale consists of 23 items, offering a reliable, flexible, multidimensional, Likert-type tool, with scores ranging from 1 (worst) to 5 (best). It comprises 3 sections. The first one evaluates unbiased quality, consisting of 4 dimensions (engagement, functionality, aesthetics, and quality of information). The second one assesses subjective quality, and the last one evaluates with 6 questions designed the perceived impact of the application on the users and their behavior change.

Application Evaluation

For the evaluation process of the "CONTIGO" mobile application, eligibility criteria were established for potential evaluators. This aims to ensure that evaluators possess the necessary expertise to provide meaningful feedback on the application's functionalities and effectiveness in supporting patients. The evaluators were selected from convenience samples that included nurses with master's degrees or specialization in oncology, computer engineers with prior experience in mobile application development, and professionals working in various oncology settings who have at least 3 years of practical experience. The sample included professionals from institutions directly involved in the app's development as well as external institutions. This approach ensured a diversity of perspectives during the evaluation process.

Evaluators who were directly involved in the development of the "CONTIGO" mobile application were excluded.

The unit of analysis for this research comprises the responses collected through the application of the MARS, provided by clinical oncology experts and computer engineers who evaluated the quality of the mobile application designed for patients with cancer.

The guidelines from the CHERRIE Checklist were followed for the survey application in Google Form [42].

Procedure for MARS Questionnaire Evaluation

Professionals meeting the criteria were invited to participate in the evaluation. During the evaluation period, which spanned approximately 1 month, each evaluator had independent access to the application to explore its features and functionalities at their convenience.

To ensure consistent understanding of the evaluation criteria, each evaluator received an initial training session with a researcher. During this session, researchers explained the elements of the MARS tool using official explanatory slides from the tool's authors. After this, evaluators independently used the app and completed the MARS rating questionnaire anonymously through a Google Form in Spanish. Informed consent was obtained before submission.

To further support the evaluators, researchers were available to answer questions or clarify doubts during the evaluation period. However, researchers could not access the responses while evaluators completed the questionnaire, ensuring the anonymity and impartiality of the process.

Data Analysis

The free-text comments provided by evaluators were analyzed using thematic analysis, following Braun and Clarke's [43] approach. This method allowed us to systematically identify recurring patterns and key themes from the qualitative feedback.

To enhance the reliability of the analysis, 2 independent researchers reviewed the comments and performed an open coding process. The initial codes were then discussed and refined through a consensus-based approach to consolidate the final themes. The analysis focused on 3 main areas: design and usability, content and features, and user onboarding.

No qualitative analysis software was used; instead, a manual coding process was conducted to ensure a direct focus on the key user experience concerns highlighted by the evaluators.

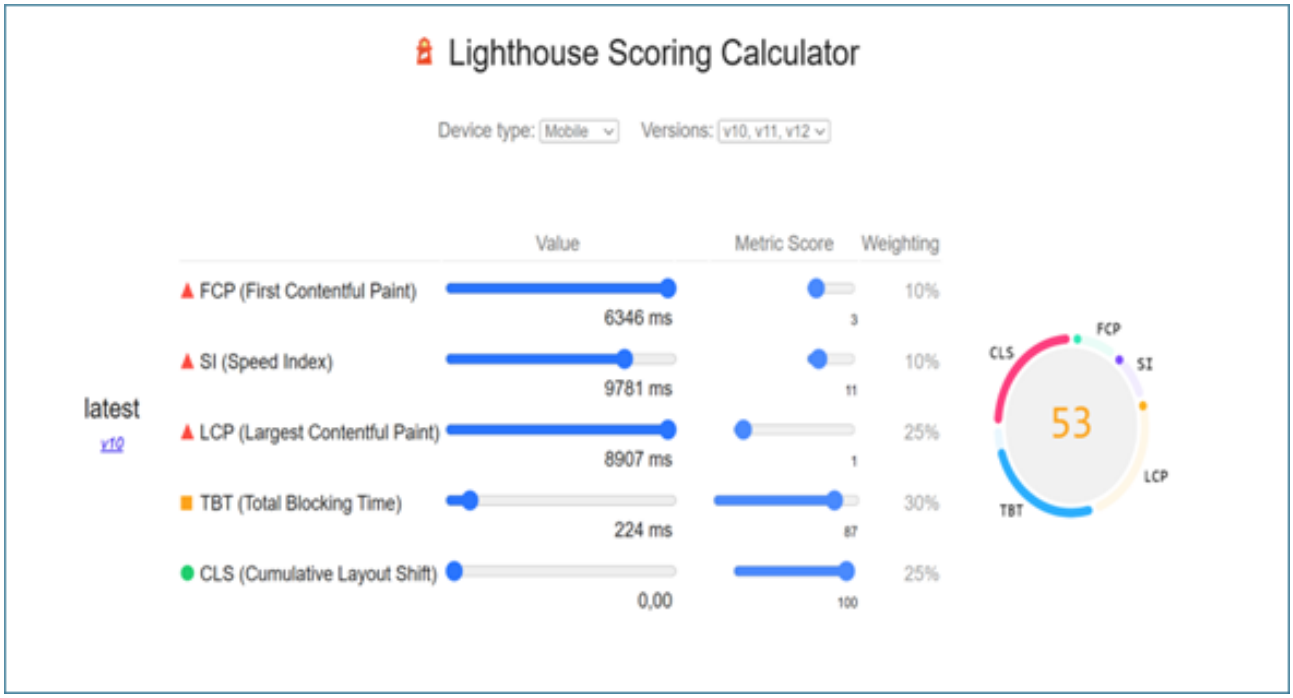
Results

App Development

During the early stages of app development, focus groups with health care professionals identified a key challenge: newly diagnosed oncology patients often forget or lack access to the educational information provided during consultations. This finding reinforced the need for a digital tool that allows patients to revisit educational materials at their convenience. As a result, the app was designed to integrate structured educational content

XSL•FO
RenderX

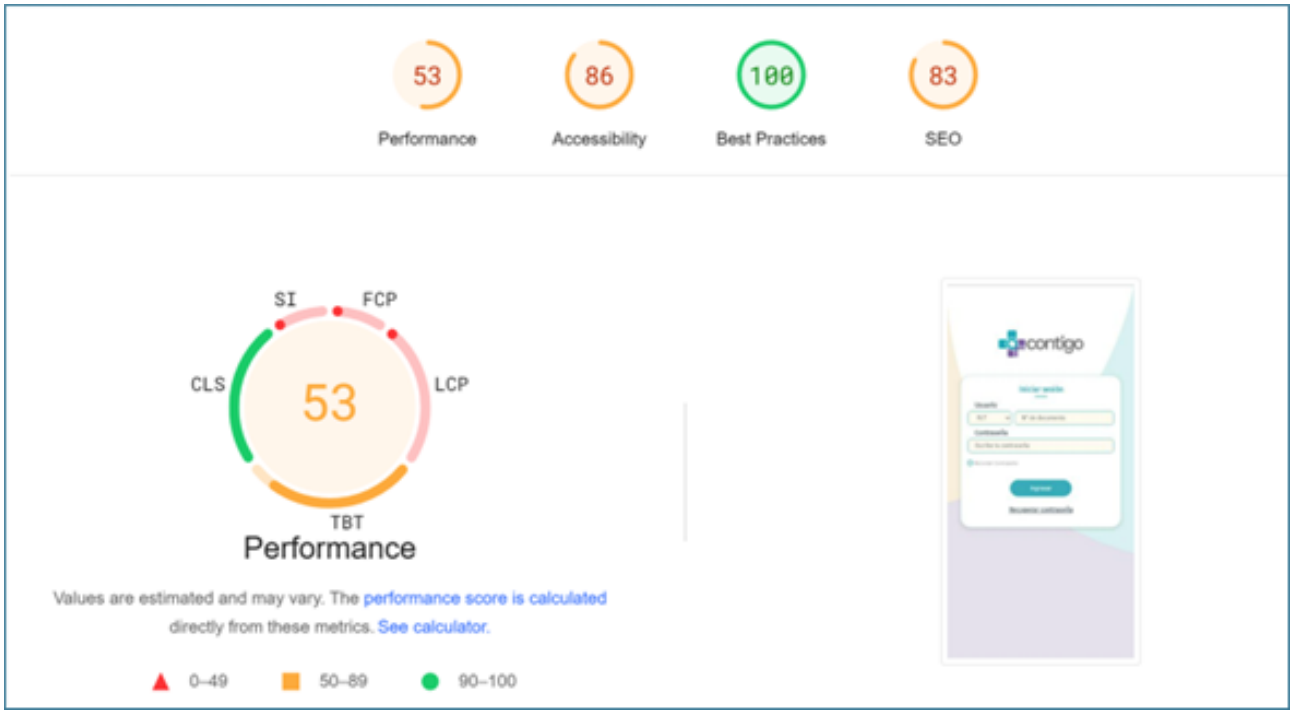
through text, images, and videos, ensuring accessibility and continuous support for patients.



Performance and Robustness

The performance evaluation highlights areas requiring improvement, with an FCP of 6.3 seconds and an LCP of 8.9 seconds, indicating significant delays in rendering the initial and largest visible content. The Speed Index (SI) of 9.8 seconds reflects slow visual load times, impacting the perceived user experience. Despite these results, the TBT of 224 milliseconds falls within the moderate range, suggesting acceptable interactivity during loading. Visual stability, measured by CLS, scored 0, ensuring a smooth and stable interface (Figure 2).

In addition to these detailed performance metrics, the app was evaluated more broadly across categories such as Accessibility, Best Practices, and SEO (Figure 3). Accessibility scored 86, reflecting good compliance with accessibility standards. Best Practices achieved a perfect score of 100, indicating full adherence to technical and security guidelines, while SEO scored 83, highlighting solid SEO with some room for improvement. Figure 3 provides a general overview of the app's technical quality, complementing the specific performance insights presented in Figure 2.



It is important to note that the data presented in Figures 2 and 3 were obtained using automated testing tools, specifically the Lighthouse tool (Chrome Web Store). These evaluations were conducted to simulate realistic usage conditions and assess the app's technical performance, including speed, visual stability, and compliance with industry standards.

Figure 3. Performance and robustness CONTIGO mobile application.

Security

The security certificate was issued by a trusted entity, "R3." This certificate indicates the validity of both server and client authentication in secure communication. A series of hexadecimal characters evidence the certificate's integrity, its fingerprint. With this certificate, the server identity can be identified when the user uses the mobile application, thereby thwarting phishing attempts and guaranteeing those users connect to the correct server.

Mobile App Rating Scale (MARS)

The MARS, which consists of 3 sections and 4 dimensions, was used to evaluate other technical aspects of quality, including content, usability, functionality, operability, accessibility, and reliability.

In total, 13 experts assessed the CONTIGO app: 6 were clinical staff, including nurses and doctors, and 7 were informatics engineers. In terms of educational level, 23.1% held a PhD, 15.4% were specialists, 30.85% had a master's degree, and 30.8% only had an undergraduate degree. The mean age of the experts was 41 years, providing a balanced representation of professionals across different stages of their careers.

The overall quality of the app, evaluated as the mean MARS score, was 3.75 out of 5 (SD 0.42) (Table 1). Next, we proceeded to assess each of the 4 dimensions of the MARS. The mean score for objective quality was 3.82 (SD 0.42), whereas subjective quality was lower at 3.38 (SD 0.72), with a higher variation as expected. The objective quality comprises 4 dimensions. Functionality had the highest score at 4.35 (SD 0.52), followed by information at 3.87 (SD 0.45), aesthetics at 3.85 (SD 0.59), and engagement with an average score of 3.31 (SD 0.61). Lastly, the app's impact on habits of life received a score of 3.96 (SD 0.55).

To see if engineers and clinicians had different opinions about the app, we analyzed the statistics for each group individually. We did not find significant differences in the scores given by these 2 groups of evaluators (Figure 4).

RenderX

Table . Mobile application rating scale of CONTIGO.

	Mean	SD	IQR
Objective quality	3.82	0.42	0.48
Engagement	3.31	0.61	0.60
Entertainment	3.08	0.83	1.00
Interest	3.46	1.08	1.00
Customization	2.85	1.23	1.00
Interactivity	3.23	0.70	0.00
Target group	3.92	0.47	0.00
Functionality	4.35	0.52	0.75
Performance	4.69	0.61	0.00
Ease of use	4.23	0.58	1.00
Navigation	4.08	0.92	1.00
Gestural design	4.38	0.62	1.00
Aesthetics	3.85	0.59	0.67
Layout	3.77	0.89	1.00
Graphics	3.77	0.70	1.00
Visual appeal: How good does the app look?	4.00	0.68	0.00
Information	3.87	0.45	0.57
Accuracy of the app description	3.38	1.27	1.00
Goals	3.36	1.23	1.50
Quality of information	4.08	0.47	0.00
Quantity of information	4.00	0.55	0.00
Visual information	4.08	0.73	1.00
Credibility	4.08	0.83	2.00
Evidence base	4.00	0.00	0.00
Subjective quality	3.38	0.72	1.00
Would you recommend this app?	3.85	1.17	2.00
How many times do you think you would use this app?	3.54	0.75	1.00
Would you pay for this app?	2.38	1.21	2.00
What is your overall star rating of the app?	3.77	0.80	1.00
Habits of life	3.96	0.55	0.33
Awareness	4.15	0.77	1.00
Knowledge	4.38	0.74	1.00
Attitudes	3.69	0.72	1.00
Intention to change	3.92	0.83	0.00
Seek of help	3.77	0.70	0.00
Behavior change	3.85	0.53	0.00

XSL•FO

Figure 4. Boxplot comparing clinicians versus engineers.

Consequently, with the above, the MARS demonstrated good reliability among evaluators with an interclass correlation coefficient (0.84; 95% CI 0.72 - 0.92)). The total score demonstrated high internal consistency (Cronbach α=.86). Although the MARS has been previously validated, reporting these metrics ensures that the evaluators in this study demonstrated consistent scoring. The Pearson correlation revealed a moderate but significant correlation between the MARS star rating item (#23), r(13)=0.657, *P*<.01.

Upon completing each questionnaire, experts were allowed to voluntarily provide comments about the app. Unanimously, they agreed that the application's design would be highly beneficial for both patients and clinical professionals, particularly in aiding in the early detection of symptoms.

The free-text comments were formally recorded and analyzed using thematic analysis to identify key areas for improvement. A total of 12 comments were collected, and 3 main themes emerged:

- Design and usability: Suggestions included enhancing font readability, improving navigation, and ensuring consistency in icon usage across different sections. For instance, one evaluator noted: "The font size is too small in some sections, making it difficult to read. Consistent font sizes for text would improve usability."
- Content and features: Evaluators recommended adding more detailed symptom tracking options and tailoring educational content to different user needs. A clinical evaluator suggested: "The app could include fields for tracking specific chemotherapy cycles and whether the treatment is curative or palliative."
- User onboarding: Some participants highlighted the need for better guidance for first-time users, such as an introductory tutorial. One comment stated: "Adding a quick tutorial for new users would help them navigate the app more effectively."

Discussion

Principal Findings and Comparison With Previous Works

This article describes the development and initial evaluation of a mobile application designed to support oncology patients undergoing chemotherapy and assesses its quality. The findings emphasize the importance of interdisciplinary collaboration and iterative design processes in health care app development. These processes ensure that the app's content is robust, its usability is optimized, and it aligns with clinical and educational standards [37].

Therefore, the results provide a detailed insight into the performance and overall quality of the application. While the app demonstrated strengths in areas such as accessibility (86) and adherence to best practices (100), it also highlighted areas for improvement in performance metrics, including FCP (6.3 s) and LCP (8.9 s), which exceeded optimal thresholds. The TBT scored within the moderate range (224 ms), reflecting acceptable interactivity, and the CLS scored 0, ensuring excellent visual stability. Overall, the application adheres to crucial quality standards [20,39,40] but underscores the need for further optimizations to enhance perceived user performance and loading times. These findings emphasize the importance of iterative testing and refinement during app development.

XSL•FO
RenderX

One important usage of MARS is to evaluate which areas of the app require more work to provide the final user with a better experience. In that line, we reviewed the score of each item and looked for the reasons behind that score, taking into account comments given about the app.

Of the app's 4 subjective dimensions, engagement received the lowest overall score, indicating significant room for improvement. This was largely due to limited customizability (2.85), as the app lacks options for important capabilities such as color and font size customization, which are particularly useful for users with reduced vision or color blindness, as well as direct access to functionality through favorite shortcuts.

Additionally, the entertainment subdimension scored 3.08, reflecting the app's reliance on informative videos as its main source of entertainment and the absence of gamification elements or other engaging digital features. However, the interest subdimension scored slightly higher at 3.46, suggesting that the app maintained a moderate level of engagement among evaluators despite these shortcomings. Concerning the functionality, the app showed the highest score. Evaluators appreciated its good performance (4.69), gestural design (4.38), ease of use (4.23), and ease of navigation (4.08). The aesthetics of the app (3.85) were evaluated moderately high; some users noticed that there were some inconsistencies in the layout, graphics, and fonts.

The app performed well in the Information dimension (3.87), especially in items such as the quality of information (4.08), visual information (4.08), credibility (4.08), quantity of information (4.00), and evidence base (4.00). Its performance in terms of the accuracy of the app description (3.38) and its goals (3.36), on the other hand, was much lower. The app was not available on the app store; the description provided in the Google form questionnaire given to the evaluators was taken into account for the assessment. While some users were highly positive, stating they would recommend the app to everyone and rating it as one of the best they have used, others were more reserved or critical.

The subjective quality of the application varied among users based on their recommendations. Even though the app received a good score in terms of how likely evaluators would recommend the app (3.38), at the same time it received a much lower score in terms of how likely evaluators would pay for the app (2.38).

The results also showed that the evaluators consider that app would likely have a good impact on the habits of life (3.96). The evaluators provide a critical foundation for understanding the app's strengths and areas for improvement [20,30,31]. This study highlights the value of involving health care professionals in the early stages of app evaluation, as their expertise ensures alignment with clinical standards and educational goals. Additionally, it is crucial to involve patients to capture the unique needs and preferences of the app's end-users.

To address this limitation, 2 ongoing clinical trials will directly involve patients with cancer [44,45]. These trials will evaluate the app using the uMARS tool, which focuses on patient-centered aspects such as usability, engagement, and impact on quality of life. By integrating patient feedback, these trials aim to refine the app further, ensuring it meets the specific needs of its target population.

Despite this limitation, the study contributes to the field of health apps by demonstrating the importance of phased evaluation approaches. These ensure that health apps are rigorously tested for technical and clinical standards before involving end-users, creating a strong foundation for iterative improvement.

Conclusions

This study provides an initial evaluation of the CONTIGO app, a tool designed to support oncology patients undergoing chemotherapy by addressing key aspects of symptom tracking, education, and patient-clinician communication.

The findings demonstrate that the app meets critical standards for functionality, usability, and information quality, supported by robust security measures and exceptional visual stability. However, performance evaluations revealed areas requiring improvement, particularly in loading times and user interactivity, emphasizing the need for further technical optimizations to enhance the user experience.

The evaluation also highlighted opportunities to improve user engagement and aesthetic consistency through features like gamification and personalization, which could significantly enhance the app's adoption and impact.

A significant limitation of this study was the lack of patient involvement in the evaluation phase. This decision prioritized input from health care professionals to ensure alignment with clinical and educational standards. Ongoing clinical trials involving patients with cancer are addressing this limitation by capturing patient-specific feedback on usability and impact using the uMARS tool.

This study contributes to the growing field of mHealth by underscoring the importance of phased evaluations that integrate iterative testing and stakeholder feedback. Future work will focus on refining the app based on patient insights, ensuring it effectively meets its target population's needs and improves the oncology care experience.

Limitations and Future Directions

The primary limitation of this study was the exclusion of patients with cancer during the initial evaluation phase. This decision was based on the need to ensure the app met clinical and educational standards before involving end-users. Health care professionals were selected as evaluators due to their expertise in oncology care and their ability to provide detailed feedback on the app's content and usability.

Efforts were made to recruit patients for this phase through oncology clinics and patient support groups. However, challenges such as scheduling conflicts, the burden of ongoing treatments, and limited interest in participating in a non-clinical evaluation restricted patient involvement. Additionally, it was not possible to recruit patients who were not already participating in other clinical trials, as this could have introduced confounding variables to this study.

XSL•FO
RenderX

To address this limitation, 2 clinical trials are currently underway, incorporating the uMARS tool to assess the app's usability and quality from the patient perspective. These trials will provide a comprehensive understanding of the app's impact and inform future refinements.

By prioritizing health care professionals in the early phases, we ensured a solid foundation for the application's content and usability, which will now be validated and refined based on direct input from patients.

Acknowledgments

This work was funded by the ANID FONDAP (152220002), Center for the Cancer Prevention and Control (CECAN), and Convocatoria número 22 del Sistema General de Regalías (SGR) y Ministerio de Ciencia, Tecnología e Innovación de Colombia (MINCIENCIAS).

The researchers extend their gratitude to the entire engineering team at the Technological Institute for Health and Wellness Innovation, which was consistently willing to address challenges—particularly Engineer Katherine Figueroa. They also wish to acknowledge the nurses and pharmacists who, in various capacities, contributed to the development of the application: Lillian Macaya, Patricia Pérez, and Antonio Gonzalez.

Abstract

Background: Treatment-resistant schizophrenia (TRS) is a severe form of schizophrenia associated with low adherence to treatment and poor outcomes. Mobile health (mHealth) interventions may be effective in preventing relapses, increasing treatment adherence, and managing some of the symptoms of schizophrenia. Mobile therapeutic attention for treatment-resistant schizophrenia (m-RESIST) is an innovative mHealth developed specifically for TRS.

Objective: We aim to evaluate the effects of m-RESIST on the clinical and functional outcomes and on the perceived quality of life in people with TRS.

Methods: A feasibility study without a control group was performed to test the m-RESIST solution on patients with TRS. Participants were recruited from Spain, Israel, and Hungary. This study's population (N=31) followed 3 months of intervention. The m-RESIST was configured by an app, a wearable, and a web-based platform. The severity of symptoms was evaluated by using the Positive and Negative Syndrome Scale (PANSS) and the Clinical Global Impression-Schizophrenia (CGI-SCH) scale. Functionality was assessed by the Global Assessment of Functioning and perceived quality of life was evaluated by the EuroQol visual analogue scale (EQ-VAS).

XSL•FO
RenderX

Results: Significant reductions were found in symptoms from pretrial to posttrial on the PANSS total (mean difference −7.2, 95% CI −11.1 to −3.4; *P*=.001), the PANSS positive (mean difference −1.36, 95% CI −2.6 to −0.1; *P*=.04), the PANSS negative (mean difference −2.1, 95% CI −3.1 to −1.1; *P*<.001), and the PANSS general symptoms (mean difference −3.8, 95% CI −6.8 to −0.8; *P*=.02). In almost one-fifth of the participants (6/31), the overall score for the PANSS decreased by more than 20%, which may be considered a clinically significant change. On the CGI-SCH scale, the sum of total severity of illness decreased significantly (*P*=.03). A decrease in the sum of positive and negative symptoms of the CGI-SCH score was also found (*P*=.04 and *P*=.03, respectively). The sum of depressive or cognitive symptoms did not change. The functionality of participants increased significantly on the Global Assessment of Functioning (*P*≤.001). The perceived quality of life on the EQ-VAS also improved (mean difference 6.7, 95% CI 0.5 to 12.9; *P*=.04).

Conclusions: To our best knowledge, this was the first study to address the efficacy of the mHealth app m-RESIST on the symptoms and functional capacity and on the quality of life for people with TRS. Our preliminary findings showed that implementing the m-RESIST solution decreased the symptoms and severity of disease, and improved the functionality and perceived quality of life among those with TRS. The change of symptoms on the PANSS total may be clinically significant. Modern technologies such as mHealth interventions may be useful in treating symptoms and functionality even in TRS, which is a major clinical challenge, with usually poor outcomes. These results should be corroborated by performing a controlled trial.

digital health; mHealth; m-RESIST; application; treatment-resistant schizophrenia; psychosis; feasibility study; mobile phone; mobile health; mobile therapeutic attention for treatment-resistant schizophrenia

Introduction

Background

Schizophrenia is a severe mental disorder and has a prevalence of 1% of the population worldwide [1]. A meta-analysis showed that only 13.5% of the patients were in recovery, which included clinical remission and good social functioning outcome [2]. Despite the common use of antipsychotic drugs, 30% - 50% of patients with schizophrenia still obtained a low benefit from conventional treatments [3,4]. This inadequate response to pharmacological treatment is known as treatment-resistant schizophrenia (TRS). TRS implicates an important burden at three levels, as follows: (1) clinical (negative attitude to medication, drug abuse, and nutritional or physical health problems); (2) economic (hospitalizations and polytherapy); and (3) humanistic (depression and social isolation) [5]. As a result, dealing with TRS involves a high emotional burden for patients and their caregivers, affecting their quality of life. The current health care and social support systems are unable to provide adequate and effective solutions to these patients.

Results from earlier studies on psychosis [6-8] supported that information and communication technology (ICT) tools in the treatment of patients with TRS would be useful. Smartphone ownership among people with schizophrenia is also relatively high and increasing [9-11]. Patients seemed capable of using mobile phones to monitor their symptoms, participate in therapeutic interventions, and increase physical exercise [12]. Previous feasibility studies have shown that interventions based on mobile health (mHealth) could promote the empowerment of patients with schizophrenia [9,13]. Some mHealth interventions may also be effective for increasing treatment adherence and decreasing relapses [13,14].

Several digital solutions also specifically for schizophrenia exist [15,16]. Apps such as FOCUS [6,17-19], SMARTapp [20], MACS [21], weCope [22], My Journey 3 [23,24], and App4Independence [25] offer disease management strategies in general. Others are more focused on symptom monitoring, namely Crosscheck [26], Actissist [27], ClinTouch [28], ExPRESS [29], Ginger.io [30], ReMindCare [31], and MindFrame [32]. Other mobile apps are supported in cognitive behavioral therapy (SlowMo) [33]; TechCareApp [34]; movisensXS [35]; PRIME [36], or work as an agenda (MONEO) [37], or target specific domains such as social skills (MASS) [38], sleep (ExpiWell) [39], medication adherence (MedActive) [40], or delivers positive psychology content (+ Connect) [41]. Digitally delivered psychological therapies, the use of social media, virtual reality, and chatbots are also digital solutions that may have a role in the treatment of those with schizophrenia [42,43]. Digital phenotyping and machine learning, virtual reality interventions, and language models, with ChatGPT, as a well-known example, have developed in recent years [42,43].

A systematic review and meta-analysis by Vitger et al [44] examined digital shared decision-making interventions in mental health care, analyzing 16 randomized controlled trials (RCTs), of which only 3 evaluated apps. The findings suggest that digital shared decision-making tools may positively impact patient activation, decisional conflict, working alliance, and symptom severity. Specific digital interventions include a tablet app for patients with schizophrenia, designed to assess and record satisfaction with life and treatment domains, facilitating discussions between patients and nurses [45]. Another tablet app addresses concerns raised by patients with psychosis, providing methods for clinicians and patients to collaboratively explore and manage issues [46]. Additionally, the smartphone app “Power Up” aims to promote patient activation among children and adolescents facing mental health challenges [47].

XSL•FO
RenderX

Patient-reported outcomes collect data directly from patients. These data are used in clinical practice, helping decision-making. A systematic mapping review analyzed the characteristics and outcomes of mHealth interventions in psychosis based on 29 publications reporting on 23 studies [48]. Objective measures included data passively obtained from phone usage or embedded sensors. Subjective measurement instruments include either observer-rated or self-report questionnaires that can be written or administered digitally, whether regarding their health status or experience using the mHealth intervention [48]. Outcomes were grouped into 8 categories, namely severity of psychosis-related symptoms, functioning, well-being, medication adherence, adverse events, user experience, technical, and all other outcomes reported [48].

Real-time and in-context patient-generated symptom data, obtained through remote-monitoring platform technology, have the potential to timely warn clinicians about the need for intervention, improve treatment decisions by providing a clearer picture of changing patterns of symptoms, and support scheduling of health care contacts based on need [42].

Systematic comparison of apps with other digital interventions may help us to better understand their roles in mental health care. The main use of smartphone data (active and passive) is tracking mood and lifestyle in people with major depression, bipolar disorder, and psychosis. They also have future potential in machine learning toward individualized risk prediction and delivery of targeted “just in time” intervention. Key issues are a lack of validation across studies and establishing trust around data usage. Priority actions include data standards for interoperability and validation, and industry-academic partnerships around access [42].

Digitally delivered psychological therapies are used in the self-management of symptoms of depression and anxiety. They have the potential for precision interventions and preventive treatments. Lack of engagement, saturated consumer marketplace, and claims outpacing clinical evidence are major issues. Establishing an evidence base for use in people with diagnosed mental disorders is warranted [42].

Population level monitoring of mood and anxiety is possible with the help of social media. The future potential of social media lies on its potential for real time monitoring of mental health state and for access to peer support. Key issues are sampling bias, access to data from social media companies, and also privacy. Priority actions are industry-academic partnerships and privacy standards [42].

The main use of virtual reality is exposure therapies, and it may have higher engagement and potentially higher efficacy than apps. Increased accessibility, low-cost headsets, and expanded clinical targets are important [42]. Chatbots have future potential to increase access to care but they have limited range of appropriate response. Establishing evidence base for use in people with diagnosed mental disorders is needed [42].

The 5 principles of the Collaborative Care Model are evidence-based care, measurement-based treatment to target, population health management, accountable care, and team-based care [49]. Practices with integrated mental health clinicians can maximize the impact of digital mental health tools by integrating digital information and interventions into the course of clinical care. This allows for the practice of hybrid care, a combination of synchronous and asynchronous health care, which can enable increased access to care. Hybrid care can address the known challenge of low retention in digital health tools, given that a digital navigator or clinician can promote engagement, guide the patient to relevant content, and, depending on the tool, use data from the patient’s use in further guiding face-to-face care [49].

The findings from the pilot study suggest that smartphone apps may become a useful tool for psychiatric rehabilitation, addressing both psychiatric and co-occurring medical problems. Individualizing functions to each patient and facilitating connection with a certified peer specialist may be an important feature of useful apps [50].

Apps can be successfully integrated into real-world care [43]. These models of care involve both synchronous (eg, a therapy visit) and asynchronous telehealth (ie, app use between visits) and can provide therapeutic synergy between in-person and remote care [51]. The ReMindCare app for early psychosis has been integrated into clinics since 2018, and implementation models for integrating apps in youth services for schizophrenia, and coordinated specialty, have already been developed [31,52-54]. While the actual dissemination of these models is impossible to ascertain, they can already support the use of apps to improve vocational training, educational opportunities, medication adherence, cognitive training, symptom tracking, psychoeducation, and more. Apps for schizophrenia have also led to the development of human support roles as part of mental health services to facilitate their implementation in clinical practice, such as the FOCUS mHealth support specialist [55] and the mindLAMP digital navigator [53].

A renewed focus on privacy and data protection is essential for the success of mental health apps, as users must trust these apps for widespread adoption. Many health-related apps collect sensitive data, including demographic, medical, and lifestyle information, sometimes even unrelated to the app’s intended purpose [42,43,56,57]. Despite the importance of privacy, a significant portion of mental health apps (31% - 49%) lack a privacy policy, and collected data can be shared with third parties or used for advertising [42,43,56,57]. Vulnerable populations, such as individuals with schizophrenia, require additional research protections to ensure their privacy and security [43].

A cross-cultural psychological assessment focuses on understanding how a client’s cultural background influences their behavior, emotional state, and psychological needs. A recent review of 2248 studies found that only 57 specifically targeted migrants, refugees, or cultural minorities [58]. Of these, half used digital health technologies developed for the general population without cultural adaptations, while the other half tailored the interventions to meet the specific needs of these populations [58]. However, only a small number of studies involved a high level of participation from these groups in the development and testing of the digital tools [58].

XSL•FO
RenderX

Despite rapid progress, there is room for improvement. Presently, there are fewer than 10 apps whose design was specifically tailored to people with schizophrenia and that are accessible for immediate public download on the Apple or Android (Open Handset Alliance [led by Google]) marketplaces. Moreover, many of these 10 apps appear neglected by developers after their launch, with an average time since the last update of 1121 days [43,59]. The number of studies on the efficacy of mHealth apps on the symptoms and functional capacity, and on the quality of life in schizophrenia and related psychotic disorders is limited according to recent systematic reviews [15,56,60,61].

The systematic review by Miralles et al [56] found 3 studies evaluating efficacy of mHealth solutions in schizophrenia spectrum and in other psychotic disorders. Two of the three papers found decrease in symptoms measured by the Positive and Negative Syndrome Scale (PANSS) [6,27]. The third one reported no significant change in the symptoms on the PANSS, or no positive changes in functioning and in quality of life [36].
.

Additionally, a cross-sectional study on WeChat use and endorsement of WeChat-based mHealth among people living with schizophrenia (N=400) in China was carried out. Compared to nonusers, WeChat use was associated with improved health outcomes, including lower psychiatric symptoms, lower depression, higher functioning, better recovery, and higher quality of life [62].

A recent study of patients with a diagnosis of schizophrenia, randomized to receive either SlowMo, a blended digital therapy targeting reasoning, or usual care, found no significant difference between groups on the primary outcomes related to paranoia at 24 weeks (the primary end - point) [33].

The Mobile Therapeutic Attention for Treatment-Resistant Schizophrenia Project

The project of mobile therapeutic attention for treatment-resistant schizophrenia (m-RESIST), funded by the Horizon 2020 Programme of the European Union, designed and developed a mobile therapeutic attention for TRS. This digital solution consisted of a new and innovative mHealth solution based on novel technology and offering highly modular and flexible functioning. This solution was developed specifically for patients with TRS and their caregivers based on their needs [63-65].

The positive acceptance of the m-RESIST solution was related to its usefulness in meeting user needs, its capacity to empower them, and its possibility of maintaining human contact [63].

The only mHealth study performed in those with TRS indicated that the m-RESIST solution is feasible and is an acceptable, satisfactory, and potentially useful tool for a population with TRS [65].

Aims

In this study, our aim was to evaluate the effects of the m-RESIST solution on the clinical and functional outcomes and the perceived quality of life for those with TRS. To our best knowledge, there are no previous studies which have addressed these issues.

Methods

Study Design and Setting

This was a prospective, 3-month long, multicenter follow-up study without a control group that was carried out with patients with a diagnosis of TRS between March and November 2017. Blinding was not considered due to the absence of a comparator group. No sample size calculation was done.

In this study, the intervention involved patients and their caregivers, and the main actors involved in the deployment of the m-RESIST solution were psychiatrists, psychologists, and case managers. The key aim of the m-RESIST solution was to engage patients with TRS, together with their caregivers, in therapeutic processes, and empower them to enable their self-management.

Participants were recruited from 3 clinical sites: Sant Pau Hospital, Semmelweis University, Sheba Medical Center, and Gertner Institute of Epidemiology and Health Policy Research. These sites provided full-spectrum mental health services to adult people from their catchment area and have extensive experience in participating in large-scale clinical trials in patients with schizophrenia.

Patients underwent a 3-month long modular intervention designed for patients with TRS. The intervention was based on the recognition of early warning signs of psychosis to improve positive symptoms, treatment adherence, and a healthy lifestyle.

The m-RESIST Solution

The intervention was supported by 3 mHealth tools: a wearable (smartwatch), a mobile app, and a web-based platform, which are presented in the figure of the protocol article. Data for usage was captured automatically by the m-RESIST software [64].

The functionality of the smartphone was based on the m-RESIST app. Through this app, patients had access to educational content about TRS condition and related issues; could track their early warning signs symptoms and biological variables (eg, sleep and steps counter); could ask for help with questionnaires or the “alarm button”; receive and practice helpful CBT-based coping strategies and exchange messages with their caregiver or health care provider [64].

The wearable was a smartwatch that collected data from patients and sent it wirelessly to the smartphone. Sensor data was recorded through automatic passive upload. The variables collected were the level of activity, heart rate, sleeping pattern, and steps counter [64].

The web-based platform was the tool that the health care providers (case manager, psychiatrist, and psychologist) used to collect assessment data, to monitor patients’ state and review data collected by sensors, to communicate by texting with patients, caregivers, and other professionals, and to consult recommendations (based on guidelines and experts’ opinion) [64]. Mental health care professionals helped patients with TRS in using the intervention [64]. The m-RESIST intervention was

XSL•FO
RenderX

provided in 5 languages: Spanish, Catalan, Hungarian, Hebrew, and English.

The trial was registered in Clinical Trials (NCT03064776), and the study protocol was published earlier [64].

Staff or Participant Training Protocols

Three user guides were prepared to ensure that all m-RESIST users (patients, caregivers, and clinicians) will be able to understand and follow the instructions of the devices or system used in home or health care facilities. The dashboard user guide explained quickly and simply the applications and functionalities that clinicians can perform when logging in. The mobile application installation guide was addressed to clinicians in case they need to install the m-RESIST solution in patients' devices. This guide details the steps to download the m-RESIST application and install it on the smartphone and the smartwatch. The mobile application user guide was addressed to patients, caregivers, and clinicians and described the functionalities of the m-RESIST app working together with the smartwatch, once the app was installed on the Android smartphone provided. This user guide also specifies briefly the operations and the use of the smartwatch given to the patient at the beginning of this study. Finally, a short instruction sheet was designed. This sheet contained the main steps to charge smartphone and smartwatch devices and the main considerations to take into account to ensure devices were connected and worked properly.

In case of the PANSS, raters at each site had to perform a training to ensure liability between sites.

Language Adaptation Process

To ensure the language adaptation process, the clinical research team from each site was responsible for adapting the m-RESIST solution from English to Spanish, Catalan, Hungarian, and Hebrew.

Technical Support Procedures

To solve and improve the issues of the m-RESIST solution during the pilots, incidences were collected by the clinicians and communicated by email to the technical team. Thus, they could fix them.

Ethical Considerations

This study protocol received approval from the ethics committees of the 3 participating institutions: Hospital Santa Creu i Sant Committee (IIBSP-RES-2016 - 51), Egészségügyi Tudományos Tanács Tukeb, Semmelweis Ethical Committee (54920-4/2016/EKU), and Sheba Medical Center Ethical Committee (3472 - 16 SMC). Participants were fully informed of the purpose and procedures of this study, and signed informed consent forms were obtained before any study-related activities were performed. The database generated by this study did not contain any identification of the participants but kept only a numerical code in a separate list; thus, the patients' identities were protected. The information collected in this study was always treated as grouped data and never as individual or personal data, thereby maintaining anonymity and confidentiality. No compensation was provided to the participants.

Study Participants

Patients with TRS were recruited for this study. The eligibility criteria were (1) patients aged 18 - 45 years with a diagnosis of schizophrenia according to *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* criteria; (2) duration of disease less than 15 years to meet the criteria for TRS [66,67]; (3) familiarity with ICT tools; and (4) physical capability to use them; and presence of a caregiver. Exclusion criteria were (1) remission according to the Remission of Schizophrenia Working Group [68]; (2) presence of delusions mainly related to their therapists or with new technologies; (3) presence of vision, hearing, or motor impairment, interfering with operating a smartphone; (4) presence of a caregiver or informal carer who is not used to ICT tools or has physical incapability to use them; and (5) presence of intellectual developmental disability. The caregivers were also recruited as part of the m-RESIST project.

A total of 81 patients with TRS, with their caregivers, were selected for invitation to participate by researchers. Almost half of them (n=39) were willing to enroll, and nearly 80% (n=31) of those started this study and followed the whole 3 months of intervention. The dropout rate was 18% (n=8).

Measures in This Study

All the outcomes of this study's protocol are shown in Table 1.

XSL•FO
RenderX

Table . Schedule of study protocol periods and assessments.

	Recruitment	Preintervention	Intervention						Follow-up
Activity or assessment		V0	V1	V2	V3	V4	V5	V6	V7

GAF[c]		✓							✓
EQ-VAS[d]		✓							✓

[a]PANSS: Positive and Negative Syndrome Scale.

[b]CGI-SCH: Clinical Global Impression Schizophrenia.

[c]GAF: Global Assessment of Functioning.

[d]EQ-VAS: EuroQol visual analogue scale.

In this study, the severity of symptoms was assessed using the PANSS and the Clinical Global Impression-Schizophrenia (CGI-SCH) scale [69,70].

- The PANSS was used to assess positive and negative symptoms of schizophrenia. This scale consists of 30 items rated from 1 to 7 according to increasing levels of psychopathology, where: 1=absent, 7=extreme. Four scores are obtained: positive, negative, general symptoms, and total. The PANSS was completed on 2 occasions, at the start (VO) and the end (V7) of the intervention.
- The CGI-SCH scale measures global clinical impression and consists of 5 different ratings (positive, negative, depressive, cognitive, and global) that are rated from 1 to 7, where: 1=normal, 7=among the most extremely ill patients. the CGI-SCH scale was evaluated in all protocol visits (V0-V7).

Functional and Perceived Quality of Life Outcomes

Functionality was assessed by using the Global Assessment of Functioning (GAF) scale [71] and perceived quality of life by the EuroQol visual analogue scale (EQ-VAS) [72].

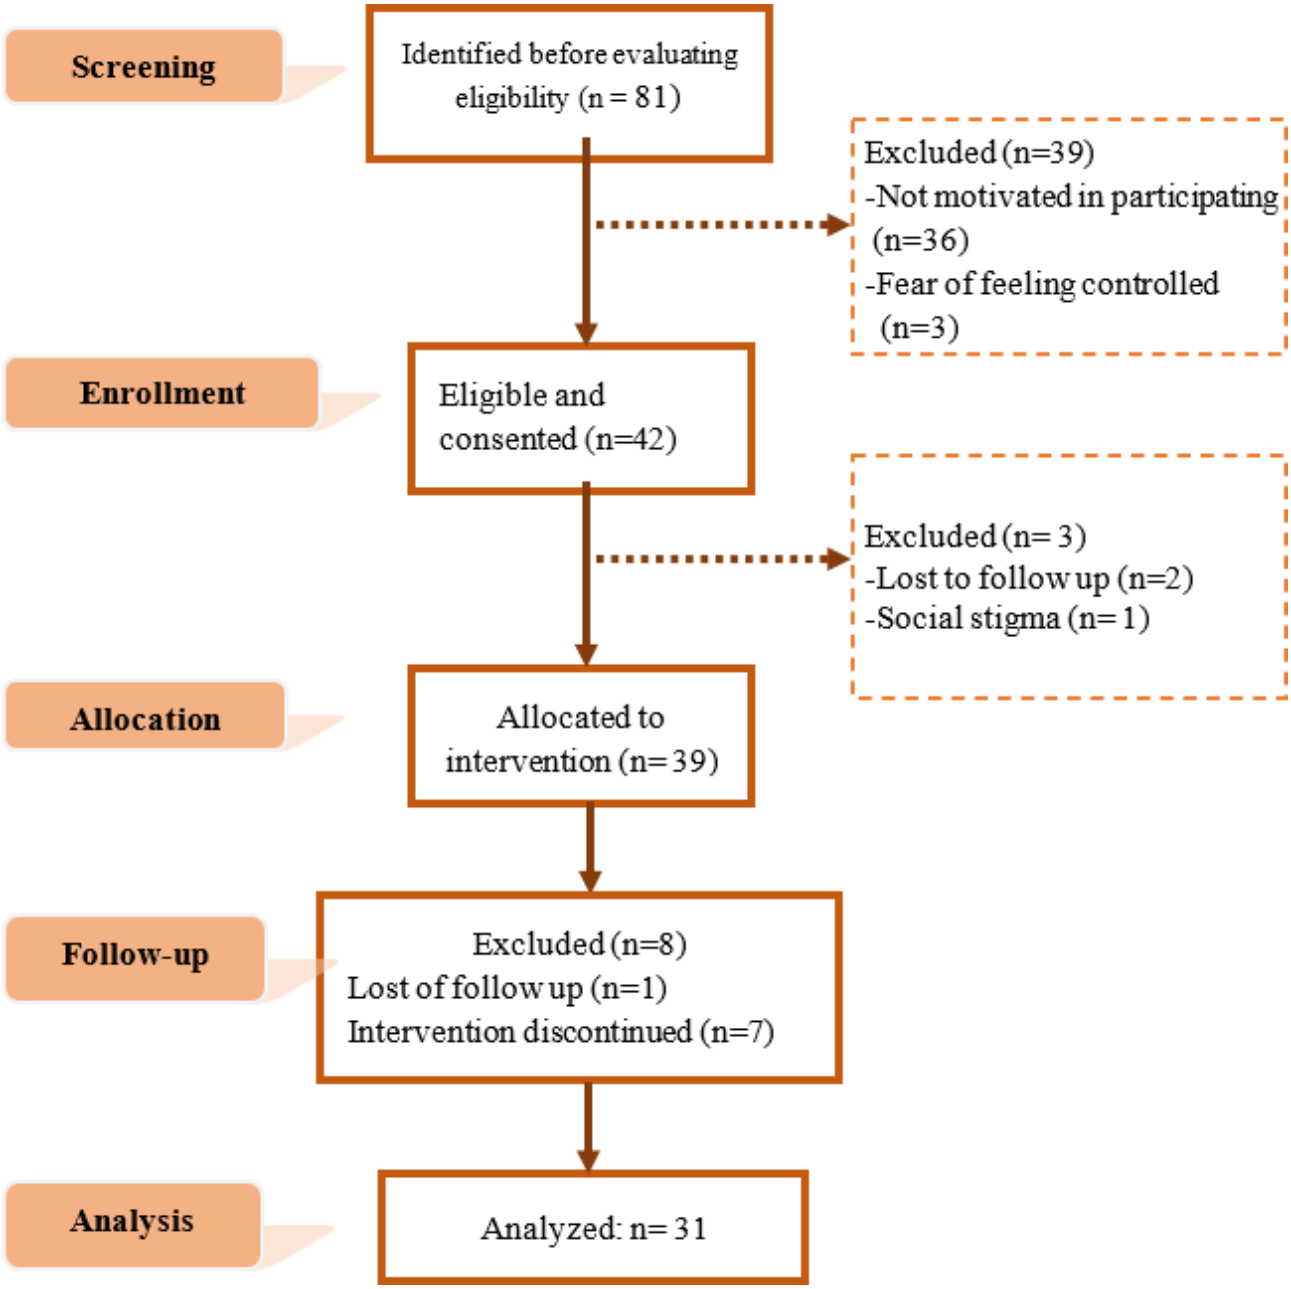
- The GAF scale ranges from 1 (maximum level of disease) to 100 (the healthiest). It was performed on 2 occasions, at VO and at V7.
- The EQ-VAS is scored on a 20 cm visual analogue scale with end points labeled “the best health you can imagine” and “the worst health you can imagine.” It was administered on 2 occasions, at V0 and V7.

Adverse Events

Clinician asked for adverse events at each pilot visit, and they were reported. Safety measures were collected throughout this study. The presence of serious and nonserious adverse events, defined as any clinical change or illness reported during this study, was monitored in every clinical visit. The adverse events observed when carrying out this study, either by the clinician or by the patient themselves and regardless of the causality relationship ascribed, were recorded in the clinical records and on the patient`s dashboard.

Statistical Analysis

The sociodemographic characteristics of the participants with TRS were presented using frequency distributions for categorical variables and mean with SD for age. The outcomes in baseline



XSL•FO
RenderX

and follow-up were presented using mean with SD for PANSS scores and EQ-5D, and medians with IQR for CGI-SCH and GAF scores. The change from the baseline to the follow-up was analyzed using the paired *t* test (PANSS scores and EQ-5D) or the Wilcoxon test (CGI-SCH and GAF scores). Statistical analyses were performed using the SPSS Statistics (version 29.0; IBM Corp).

Results

The study participation flowchart based on the CONSORT (Consolidated Standards of Reporting Trials) 2010 statement recommendations [73] is presented in Figure 1.

Figure 1. m-RESIST study participation flowchart. m-RESIST: mobile therapeutic attention for treatment-resistant schizophrenia.

Background Variables

The sociodemographic characteristics of this study's population (n=31) are presented in Table 2. No statistically significant differences in sociodemographic characteristics were found at baseline between the participants in the 3 sites. The percentage of men and women was almost equal (n=16, 51.6% and n=15, 48.4%, respectively). Most participants were singles (n=25, 80.6%) and lived with parents or relatives (n=23, 74.2%). Almost half of the study population had a full-time or a half-time job (n=15, 48.4%). The most common education level was primary studies (n=15, 48.4%). Almost two of the third lives with parents or relatives (n=20, 64.5%). Nearly all study participants had a caregiver (n=28, 90.3%; Table 2). Those patients without a caregiver had support in their immediate environment.

Nearly all participants were currently on 1 or 2 antipsychotics (30/31, 96%), and clozapine was the most used drug (11/31, 35.5%). Olanzapine, clozapine, and risperidone were previously

XSL•FO
RenderX

the 3 most frequently taken antipsychotics (13/31, 41.9%; 9/31, 29%; and 9/31, 29%, respectively).

Table . The sociodemographic variables of this study's population.

	Values
Age, mean (SD)	33.9 (7.6)

[a]Missing n=1.

Clinical Outcomes

Significant reductions were found in symptoms from pretrial to posttrial on the PANSS total (mean 73.7, SD 14.8 versus mean 66.5, SD 12.8; mean difference −7.2, 95% CI −11.1 to −3.4; *P*=.001), PANSS positive (mean 15.2, SD 2.8 versus 13.8, SD 3.2; mean difference −1.36, 95% CI −2.6 to −0.1; *P*=.04), PANSS negative (mean 21.2, SD 4.9 versus 19.1, SD 4.3; mean difference −2.1, 95% CI −3.1 to −1.1; *P*<.001), and PANSS general symptoms (mean 37.3, SD 9.3 versus 33.6, SD 8.4; mean difference 3.8, 95% CI −6.8 to −0.8; *P*=.02) (Table 3).

In almost one-fifth of the participants (6/31), the overall score for the PANSS decreased by more than 20%.

The sum of global severity of illness also decreased significantly on the CGI-SCH scale (median 4, IQR 3-4 vs median 3, IQR 3-4; median difference 0, IQR −1 to 0; *P*=.03). A decrease in the sum of positive (median 3, IQR 2.75-4 vs median 3, IQR 2-3.25; median difference 0, IQR −1 to 0; *P*=.04) and negative (median 4, IQR 3-4 vs median 3, IQR 3-4; median difference 0, IQR −1 to 0; *P*=.03) symptoms was also found. The sum of depressive or cognitive symptoms did not change (Table 3).

XSL•FO

Table . Change of symptoms between baseline and follow-up.

		Baseline	Follow-up	Difference	*P* value
PANSS[a,b]					
	Total score	73.7 (14.8)	66.5 (12.8)	−7.2 (−11.1 to −3.4)	.001
	Positive symptoms score	15.2 (2.8)	13.8 (3.2)	−1.36 (−2.6 to −0.1)	.04
	Negative symptoms score	21.2 (4.9)	19.1 (4.3)	−2.1 (−3.1 to −1.1)	<.001
	Generalized symptoms score	37.3 (9.3)	33.6 (8.4)	−3.8 (−6.8 to −0.8)	.02
CGI-SCH[c,d]					
	Sum of positive symptoms	3 (2.75 to 4)	3 (2 to 3.25)	0 (−1 to 0)	.03
	Sum of negative symptoms	4 (3 to 4)	3 (3 to 4)	0 (−1 to 0)	.03
	Sum of depressive symptoms	3 (2 to 3.25)	3 (2 to 3)	0 (−1 to 0.5)	.22
	Sum of cognitive symptoms	3 (2.75 to 4)	3 (2 to 3)	0 (−1 to 0)	.23
	Sum of global severity	4 (3 to 4)	3 (3 to 4)	0 (−1 to 0)	.03
GAF[d,e]		55 (45 to 55)	60 (50 to 65)	5 (0 to 10)	<.001
EQ-VAS[b,f]		66.1 (18)	72.8 (16.5)	6.7 (0.5 to 12.9)	.04

[a]PANSS: Positive and Negative Syndrome Scale.

[b]Mean (SD) for the baseline and follow-up, and mean (95% CI) with paired samples *t*-test for the difference.

[c]CGI-SCH: Clinical Global Impression-Schizophrenia.

[d]Median (IQR) for the baseline and follow-up, and median (IQR) with Wilcoxon test for the difference.

[e]GAF: Global Assessment of Functioning.

[f]EQ-VAS: EuroQol visual analogue scale.

Functional and Perceived Quality of Life Outcomes

The functionality of participants increased significantly from pretrial to posttrial on the GAF scale (median 55, IQR 45-55 vs median 60, IQR 50-65; median difference 5, IQR 0-10; *P*<.001), but it was not considered clinically significant due to participants remaining in the same interval (moderate symptoms).

The perceived quality of life evaluated by the EQ-VAS also improved (mean 66.1, SD 18 vs mean 72.8, SD 16.5; difference 6.7, 95% CI 0.5-12.9; *P*=.04) (Table 3).

Adverse Events

The symptoms of TRS got worse in 1 participant before the intervention and in 2 participants during it, which was considered not to be related to the m-RESIST solution.

Discussion

Principal Results

To our best knowledge, this was the first study collecting data on the symptoms, psychosocial functioning, and quality of life for people with TRS by using the mHealth platform (m-RESIST solution). Our novel preliminary findings showed that the total, positive, negative, and general symptoms according to the PANSS were significantly decreased after intervention compared with the starting point. In almost one-fifth of the participants (6/31), the overall score for the PANSS decreased by more than 20%, which may be considered a clinically significant change [74].

According to Suzuki et al [75], the partial response of clinical trials in schizophrenia could be defined ≥10% to <20% decrease on the PANSS. In our study, the change in positive score was 8.9%. Interestingly, the change in the negative score was 10.2%, which may mean a partial response according to Suzuki`s definition. The decrease in the generalized symptoms scores and the total score was 10.2% versus 9.8%. Therefore, the mean differences of 1 - 2 points on the positive and negative subscale scores may be indicatively clinically meaningful to a small extent at the most. Nevertheless, one should be careful in interpretations regarding the significance of the results. The clinical implications of PANSS scores may not always be clear [76].

The sum of global severity, and the sum of positive and negative symptoms on the CGI-SCH scale were lower at the end of the study compared to the starting point, but the sum of depressive or cognitive symptoms did not change. The functionality measured by the GAF scale was also significantly better at the

XSL•FO
RenderX

end of this study as compared to its level at the beginning. The perceived quality of life also increased during this study.

Comparisons With Prior Work

The finding of a significant decrease in all PANSS scores and global severity, positive and negative symptoms on the CGI-SCH scale at the study end compared to the starting point is partly in line with former data, as previous studies have shown efficacy of mobile interventions for schizophrenia [6,15,27,36,43,56,61,62]. To the best of our knowledge, this is the first study to show the efficacy of an mHealth platform (m-RESIST solution) in TRS.

A study by Ben-Zeev et al [6] demonstrated the feasibility, acceptability, and efficacy of a smartphone intervention for schizophrenia, followed by those with schizophrenia or schizoaffective disorder (N=33) for 1 month without a control group. Its results showed a significant decrease in the total, positive, and general scores but not in the negative score in the PANSS. A noncontrolled study by Kidd et al [25] with patients with primary psychosis (N=38) reported a decrease in certain items of the Brief Symptom Inventory (eg, psychotism, paranoid ideation, and depression) when followed for 1 month.

Bucci et al [27] carried out an RCT among those with early psychosis (N=36). The results showed a decrease in the total, negative, and general scores of the PANSS after a follow-up of 12 weeks.

WeChat is the most widely and extensively used mobile social networking app in China. A cross-sectional study on WeChat use and endorsement of WeChat-based mHealth among people living with schizophrenia (n=400) in China was carried out. Compared to nonusers in this study's population, WeChat use was associated with improved health outcomes, including lower psychiatric symptoms (the Brief Psychiatric Rating Scale), lower depression (the Patient Health Questionnaire-9), higher functioning (GAF), better recovery (the Recovery Assessment Scale), and higher quality of life (the first 2 general questions from the World Health Organization Quality of Life Brief Scale) [62].

However, another RCT with participants with recent-onset schizophrenia spectrum disorders (N=43) showed no changes in their positive or negative score of the PANSS or their functioning measured by the Role Functioning Scale. The quality of life measured by the interview-based Quality of Life Scale Abbreviated did not improve [36]. A recent study with patients with a diagnosis of schizophrenia (N=361), randomized to receive either SlowMo, a blended digital therapy targeting reasoning, or usual care, found also no significant difference between groups on the primary outcomes related to paranoia (the Green et al [77] Paranoid Thoughts Scale) at the primary end point at 24 weeks [33].

Decrease in Symptoms

It should be taken into account that the decrease in symptoms in patients with TRS, characterized by the persistent presence of symptoms, would not be expected in such a short term. Following the considerations of this study by Ben-Zeev et al [6], the improvement in the PANSS scores obtained in this study of the m-RESIST solution should be evaluated prudently. In the case of patients with schizophrenia, in the framework of a study, a placebo effect of the offered intervention has been observed. One factor that would influence the improvement of symptoms would be all the care received for participating in a study. It could be considered that participation in a structured intervention program would promote a state of security, such that it would improve aspects such as the symptoms of the disorder itself [78,79].

However, the overall score for the PANSS decreased by more than 20% in almost one-fifth of the participants which may be considered a clinically significant change [74]. Furthermore, the negative symptoms on the PANSS decreased during a rather short period of 3 months. It may imply that somehow the m-RESIST solution may manage to activate patients.

Perceived Quality of Life and Functioning

The perceived quality of life and functioning improved in our study, which is partly in line with the earlier studies, as a study by Schlosser et al [36] did not find positive effects on functioning and quality of life. Instead, the findings of Yu et al [62] showed improvement both in functioning and quality of life. Our findings on the improvement of quality of life may need to be treated with caution as the findings of the EQ-5D-5L scale have shown weak correlations with the objective measures among patients with schizophrenia [80].

Study Timeline

The data collection period was in 2017. Although progress has been made, there is still room for improvement in mHealth apps for people with schizophrenia, with fewer than 10 apps specifically designed for this population available for public download [43,59]. The m-RESIST solution is a new, innovative mHealth tool developed for patients with TRS and their caregivers, offering modular and flexible functions. This study aimed to evaluate the effects of m-RESIST on clinical outcomes, functional outcomes, and perceived quality of life in individuals with TRS. To the best of our knowledge no previous studies have addressed these specific issues.

For the above reasons, our research results provide significant new information on the use of mobile applications in the treatment of TRS.

Strengths

This study has several strengths. To our best knowledge, this was the first study collecting data on the symptoms, functioning, and perceived quality of life among patients with TRS by an mHealth intervention. This was also a multicenter study covering different cultural environments. The m-RESIST solution is an innovative mHealth solution based on novel technology, offering highly modular and flexible functioning and planned intervention. It has been developed specifically for patients with TRS [63-65]. The outcomes of this study will also help to perform a cost-effectiveness RCT in the future.

Limitations

Some limitations of this study need to be discussed. First, there was no control group, so it is not possible to determine whether the clinical improvements were related to the use of the

XSL•FO
RenderX

m-RESIST solution. Second, this study's design is a limitation, as, due to the small sample size and the short length of the intervention and follow-up period, the differences found in outcomes should be treated with caution. Therefore, the generalization and maintenance of the results are uncertain. Third, the so-called Hawthorne effect may also have implications for the generalizability of results because the behavior of research participants is influenced by observation and measurement. In general, results in experimental settings may be more positive compared to routine clinical applications [78,79].

The moderately high mean baseline score for the PANSS (73.7) demonstrates that our patients with TRS have quite severe psychotic symptoms. Even so, they responded to intervention markedly.

Potential Selection Bias Regarding Digital Literacy

Digital literacy can be defined as the varying ability of both children and adults to use digital technologies and understand their risks. Patients who do not know how to use digital health tools, do not see the importance of those tools, or cannot access them in their preferred language, ultimately will not use them [81]. This may cause potential selection bias because, for the reasons above, those people may not participate in the studies [81].

Technical Implementation Challenges

The digital divide remains a barrier, with people with schizophrenia eager and able to obtain smartphones and learn new skills, but resources and training are often not provided. Expanding train-the-trainer and literacy programs such as the Digital Health Navigator initiative, which was specially designed to support people with psychosis, offers 1 tangible next step [42,43,53] However, a lagging infrastructure and skill base have limited the application of digital solutions in mental health care [82]. Additionally, evidence is needed on the effectiveness and appropriateness of digital health tools for patients who are marginalized and may lack access to digital health interventions [83].

The digital divide remains a barrier, with people with schizophrenia eager and able to obtain smartphones and learn new skills, but resources and training are often not provided [51]. Expanding train-the-trainer and literacy programs such as the Digital Health Navigator initiative, which was specially designed to support people with psychosis, offers 1 tangible next step [53,84].

Cost Implications for Real-World Implementation

Despite modest effect sizes, the relatively low cost and high scalability of most of the interventions tested support their public health relevance [85]. A recent review on this topic found only 37 relevant studies published in middle- and lower-income countries between 2016 and 2020, with the majority reporting feasibility and accessibility outcomes instead of efficacy, cost-effectiveness, or implementation [86]. However, the costs of implications for real-world implementation may be a concern, and that is why it has been asked if mHealth tools can decrease hospital stays and encourage patients to use mobile apps in favor of reducing costs [61]. Digital health tools still hold a unique potential to extend access to care in middle- and lower-income countries, where there is less investment or infrastructure around mental health [86]. Smartphone use is common and rapidly expanding in those countries, and thus represents a promising tool to reduce the mental health gap [42].

Conclusions

Our preliminary findings showed that implementing the m-RESIST solution may decrease the symptoms and severity of illness and improve the functionality and perceived quality of life among people with TRS. The change of symptoms on the PANSS scores may be indicatively clinically meaningful to a small extent at the most. Nevertheless, one should be careful in interpretations regarding the significance of the results.

Implementing the m-RESIST solution may be a promising tool to improve the treatment even in TRS, and to offer a new tool for its present treatment options, already in the near future. If successful, this would be a very important step forward as TRS is a major clinical challenge, with usually poor outcomes. Before being implemented in daily practice, these results should be corroborated by performing controlled clinical trials with people with TRS, comparing treatment as usual with the m-RESIST solution.

Acknowledgments

This work has been supported by the Horizon 2020 Framework Programme of the European Union (grant 643552) and partly funded by the CERCA (Centres de Recerca de Catalunya) Programme/Generalitat de Catalunya. We thank all the patients who participated in this study for their essential contribution to our field of research. We are also thankful to Ona Corporation (IIBSP-AMA2016-99). We are grateful to all the members of the mobile therapeutic attention for treatment-resistant schizophrenia (m-RESIST) project, who are also the authors of this paper under the name of the m-RESIST Group.

The m-RESIST Group is composed of the following members: Francisco Alcalde, Caritat Almazán, Anna Alonso-Solís, Jesús Berdún, István Bitter, Walter Baccinelli, Maria Bulgheroni, Caro Mendivelso, Asaf Caspi, Tanguy Coenen, Xavier Constant, Iluminada Corripio, Enrico d'Amico, Ilaria De Vita, Marisol Escobar, Kinga Farkas, Kata Fazekas, Shenja van der Graaf, Eva Grasa, Margarita Hospedales, Elena Huerta-Ramos, Matti Isohanni, Erika Jääskeläinen, Charlotte Jewel, Teija Juola, Timo Jämsä, Rachelle Kaye, Panagiotis Kokkinakis, Hannu J Koponen, Silvia Marcó, Gregoris Mentzas, Jouko Miettunen, Jani Moilanen, Susana Ochoa, Ilias Papas, Fotis Paraskevopoulos, Elisabeth Reixach, Katya Rubinstein, Elena Rubio-Abadal,Garifalia Sebú, Annika Seppälä, Jussi Seppälä, Valentina Simonetti, Matthias Stevens, Anna Triantafillou, Zsolt Szabolcs Unoka, Judith Usall, Vincenzo Vella, and David Vermeir.

Abstract

Background: A neck-specific exercise program has shown sustained clinically important changes in pain and disability for approximately 50% of individuals with chronic whiplash-associated disorders (WAD). However, there is limited information about factors related to treatment response.

Objective: The aim of this study is to identify factors related to changes in disability, neck pain, and physical function after a neck-specific exercise program delivered in 2 different ways for individuals with persistent WAD grade II or III, and to investigate whether any factors could predict those with clinically improved versus not improved disability, pain, and physical function.

Methods: This was a planned secondary analysis of a multicenter prospective randomized controlled trial. Participants (n=140) with persistent (between 6 mo and 5 y from injury) WAD grade II or III were randomized into a 12-week, internet-based neck-specific exercise program (NSEIT) with 4 physiotherapy visits or the same exercise program supervised by a physiotherapist (NSE) twice per week for 12 weeks. Multivariate data analyses and orthogonal partial least squares (OPLS) models were used to investigate change in psychological and physiological factors (independent factors) related to change in the dependent factors: neck-related disability measured with the Neck Disability Index (NDI), neck pain intensity measured with a visual analogue scale, and physical function measured with the Patient-Specific Functional Scale (PSFS). Outcomes were measured at baseline and at 3-month and 15-month follow-up. OPLS discriminant analysis was used to investigate differences between the two groups (NSEIT and NSE) by studying the change scores of the dependent and independent factors. OPLS discriminant analysis was also used to investigate whether background variables and baseline measurements of the independent factors could predict clinically significant improvement in the dependent factors NDI, neck pain, and PSFS.

Results: There were no significant differences between the groups. In both NSEIT and NSE, improvements in the following independent factors were related to improvements in NDI, pain, and PSFS at 3-month and 15-month follow-up: anxiety, depression, cognitive failures, pain catastrophizing, self-efficacy, fear avoidance beliefs, cervical range of motion, headache, and symptom satisfaction (R^2=0.31 - 0.37; Q^2=0.25 - 0.30; cross-validated ANOVA P<.001). No significant OPLS models could be built to distinguish clinically improved versus nonimproved patients as assessed by NDI, neck pain, or PSFS.

Conclusions: Improvements in both psychological and physiological factors were related to improvements in disability, neck pain, and physical function after 12 weeks of NSEIT or NSE. The results indicate that these factors are interrelated and can be improved both with NSEIT and NSE. Known risk factors for poor outcomes of neck disability in WAD, such as low self-efficacy, fear avoidance beliefs, depressive symptoms, and catastrophizing, were improved, and we need to examine other factors not included in this study that can identify those who are not improved after NSEIT or NSE.

Introduction

Whiplash-associated disorders (WAD) are indirect trauma to the neck, commonly related to a car crash [1], and approximately half of those injured develop chronic disability and pain [1,2]. Chronic WAD will have extensive consequences for the individual living with persistent pain, leading to a burden for the individual and high costs for society [3,4]. Depression, low levels of life satisfaction, and posttraumatic stress have been observed 5 years after whiplash injury [5]. Costs increase as many individuals with chronic WAD are consumers of multiple health services and experience reduced work ability [4,6]. Although the evidence is moderate at best, exercise and patient education are recommended treatments in chronic WAD [7].

Approximately 50% of the included participants in a neck-specific exercise program, conducted by 2 of the authors in this study (GP and AP), with chronic WAD grades II (neck pain and musculoskeletal findings during a physical examination) and III (as grade II but with additional neurological findings) had a sustained clinically important change in pain and disability [8,9]. Despite these promising results, about half of the participants were not clinically improved, demonstrating that chronic moderate-to-severe WAD is difficult to treat successfully. Consequently, there is a need to identify factors related to improvement in disability and pain in order to optimize treatment, discriminating them from factors that may contribute to sustained problems.

An earlier study found that depression, low self-efficacy, and higher disability were associated with a larger pain area in women with chronic WAD [10]. In another study, self-efficacy mediated the association between pain intensity and pain-related disability, and kinesiophobia mediated the association between self-efficacy and pain catastrophizing in acute and subacute WAD [11], which can lead to chronic disability. However, that study did not investigate factors related to improvements after rehabilitation. In studies where interventions included acceptance and commitment therapy or cognitive behavioral therapy, psychological factors had a mediating or predictive effect on pain and/or disability outcome for individuals with chronic WAD [12,13]. Another study found that participation in a neck-specific exercise program was the only significant factor associated with neck pain reduction at 12-month follow-up [14], and neck muscle endurance and perceived work ability were mediators for a reduction in pain [15] in chronic WAD. The treatment of chronic nonmalignant pain is influenced by biological, psychological, and sociological factors [16]. Numerous studies have found factors such as anxiety, catastrophizing, and severe pain to be related to poor treatment outcomes after acute whiplash injury [17].

However, to our knowledge, there is very limited information about factors related to treatment response in chronic WAD, or about the optimization of a neck-specific exercises program delivered via the internet. Internet-based exercise interventions with fewer visits to physiotherapists can increase availability, shorten waiting times, and reduce costs. Internet-based treatment may also strengthen the patient's own resources for greater autonomy and their ability to conduct long-term self-care [18]. Factors associated with improvements in an internet-based neck-specific exercise program (NSEIT) may differ compared to a neck-specific exercise program supervised by a physiotherapist (NSE) and need to be investigated. Moreover, the ability to predict those who will not recover after NSEIT and NSE is highly relevant to improving treatment in chronic WAD.

The aims of the study were (1) to investigate factors related to change in neck pain and disability after NSEIT or the same exercise program supervised by a physiotherapist (NSE) for individuals with chronic WAD grade II or III and (2) to investigate whether other factors could predict those with clinically improved versus not improved pain and disability after 3 months of NSEIT or NSE.

Methods

Overview

The recruitment of participants and the exercise interventions were reported earlier [9] and are briefly described below. This was a planned secondary analysis, based on a multicenter, prospective randomized controlled study [9]. Data were collected from April 6, 2017, until September 15, 2020, and the main outcome data have been published [9]. The participants were recruited from 10 county councils in Sweden.

Participants

Individuals with chronic (between 6 mo and 5 y from injury) WAD grades II–III [19] with neck symptoms within the first week after a whiplash injury in a 4-wheeled motor vehicle crash were eligible for inclusion. Symptoms emanating from the neck were verified through the participant's medical history and a physical clinical examination. For additional inclusion and exclusion criteria, see Textbox 1.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion

- Average neck pain last week ≥20 mm on a 0-100 mm visual analogue scale
- Neck disability ≥20%
- Age 18 - 63 years
- Daily access to a computer, tablet, or smartphone and the internet
- Sufficient time and motivation to follow the treatment program

Exclusion

- Signs of head injury
- Serious physical pathology
- Surgery on the cervical column
- Generalized or more dominant pain elsewhere in the body
- Previous fractures or dislocation of the cervical column
- Other illness or injury that may prevent full participation in the study and/or for which exercises are contraindicated
- Previous severe neck problems that resulted in sick leave for more than 1 month in the year before the current whiplash injury
- Lack of knowledge of the Swedish language
- Diagnosed severe mental illness
- Current alcohol and/or drug abuse

Reasons for the exclusion criteria were as follows: (1) the programs could lead to increased illness or potentially negatively influence other important treatments, (2) another illness or disease made it impossible to perform the programs and/or follow them for three months, (3) the exercises were contraindicated, and (4) participants were unable to understand the information and/or the exercises.

Ethical Considerations

The study was approved by the regional ethical review board (approval numbers 2016/135 - 31, 2016/526 - 32, and 2017/45 - 32). The study was registered in ClinicalTrials.gov (NCT03022812, initial release 12/20/2016) and the study protocol was published prior to data collection [19]. The original written and informed consent allowed for this secondary analysis without requiring additional consent, and no new data were collected for this study. Deidentification was used to prevent the identification of individuals. The key code is securely stored according to the regulations of the ethics committee and the Swedish Authority for Privacy Protection. The results are presented at the group level, ensuring no connection to individual participants. Participants were not compensated for their involvement in the study, except for traveling cost compensation in accordance with national ethical regulations.

Recruitment

Information about the study was provided via health care personnel and advertising. Interested participants completed a short survey on the Linköping University website. The patient's medical history was compiled and a physical examination was carried out before inclusion. Once the study criteria had been met, the participants were included after giving written and oral informed consent. The test leaders were blinded to group allocation. The participants were blinded to group allocation when baseline data were collected [19].

Randomization

Participants (n=140) were randomized into 2 groups (n=70 in each group) using a computerized block randomization list stratified by sex. After randomization, the treating physiotherapist was contacted by the research team and called the patient to the first appointment.

Before the start of the study, all treating physiotherapists received oral and written information and a day of practical training from the project leaders. A detailed description of the NSEIT and NSE exercise program has been published [9].

NSEIT Group

In the NSEIT group, the participants underwent a 12-week exercise program with 4 visits to the physiotherapist (at weeks 1, 2, 3, and 7) to be introduced to the exercises, to progress the exercises, and for follow-up to ensure correct performance. The patient had access to the internet-based program on a website. The program included photos and videos of the exercises, information about the musculoskeletal anatomy of the neck and about neurophysiological and neurobiological pain, and strategies for dealing with neck pain relapse. The exercises were initially targeted to activate the deep neck muscles and increase postural control, continuing with an individually tailored progression of neck muscle endurance exercises [9,19]. At the end of the treatment period, the participants were encouraged to continue doing the exercises 2-3 times per week and to include neck-specific exercises (for additional details, see [9]).

XSL•FO
RenderX

NSE Group

In the NSE group, participants received the same information and exercises as the NSEIT group, but in visits to the physiotherapy clinic twice per week (a maximum of 24 sessions) [9,19].

Patient and Public Involvement

Patients were involved in developing the questionnaires before recruitment to the study started. The questionnaires were tested by 3 patients to ensure the inclusion of relevant questions and readability. Patient satisfaction with the exercises, information, tests, and intervention (NSEIT or NSE) were measured postintervention.

Adverse events could be reported to the project leaders directly by participants, the test leaders, or the treating physiotherapists (for details, see [9]).

Predictor Variables and Outcome Measures Used in Multivariate Modeling

Measurements were collected via questionnaires at baseline and at 3-month and 15-month follow-ups. The following variables were used in the multivariate modeling.

Background Variables

The following variables were only collected at baseline: age (years), sex (male/female), smoking (yes/no), level of education, pain duration (months since injury), WAD grade II and III according to the Quebec Task Force classification [20], and expectations of the intervention on a 0 to 10 scale (with higher scores indicating stronger belief that the treatment would help) [21].

Dependent Factors

The Neck Disability Index (NDI*)* measures self-perceived disability in everyday life because of neck pain, including 10 items of neck-related disability, which are summed and transformed into a percentage (0%=no disability; 100%=highest score for disability) [22].

Current neck pain was measured on a visual analogue scale (VAS) from 0 - 100 mm, where 0=no pain and 100=worst imaginable pain intensity [23].

The Patient-Specific Functional Scale (PSFS*)* measured level of physical function, graded from 0 (unable to do the activity) to 10 (functional level equal to preinjury status), regarding self-perceived physical activity, leisure time, and work [24].

Independent Factors

Measures of factors considered as potentially related to change in pain and disability were selected based on a review of the literature and the clinical experience of 2 specialist physiotherapists with over 15 years of experience managing patients following a whiplash injury:

- Self-reported pain medication use (“Do you take pain medication?” Yes/no).
- Symptom satisfaction was measured on a 7-point scale from 1=happy about symptoms to 7=unhappy about symptoms [25].
- Exercise level rating of daily activities and sports (from 1=inactivity to 4=high activity level) [26].
- Dizziness at rest and while in motion and unsteadiness and headache intensity were measured on VAS scales from 0 mm=no dizziness/unsteadiness or headache to 100 mm=extreme dizziness/unsteadiness or headache [23,27].
- The Post-Traumatic Stress Disorder Checklist (the specific trauma version, PCL-S) measures posttraumatic stress reactions and consists of 4 subscales (re-experience, avoidance, negative alterations in cognition and mood, and hyperarousal), with a total score ranging from 0=no stress reaction to 80=extreme stress [28].
- Fear Avoidance Beliefs Questionnaire measures the individual’s fear of pain and consequent avoidance of physical activity because of their fear. It consists of 2 subscales (Physical Activity subscale [4 items] and Work subscale [7 items]), with a total score ranging from 0 to 66, where higher scores indicate higher fear avoidance beliefs [29].
- The Hospital Anxiety and Depression Scale gives an anxiety score (from 0=no anxiety to 21=maximal anxiety) and a depression score (from 0=absent depression to 21=maximal depression) [30].
- The Pain Catastrophizing Scale measures the extent of catastrophizing according to the 3 subscales (rumination, magnification, and helplessness), with a total score range of 0 - 52, with higher scores indicating higher pain catastrophizing [31].
- The Self-Efficacy Scale measures self-perceived performance of 20 everyday functional tasks in spite of pain, with total scores ranging from 0 to 200, where higher scores indicate higher perceived self-efficacy [32].
- The Cognitive Failures Questionnaire measures behavioral problems associated with attentiveness and memory in everyday life, with the total score ranging from 0 to 100, where a higher score indicates a greater frequency of cognitive failures [33].
- The EuroQol quality-of-life instrument version with 5 dimensions and 3 response levels (EQ-5D-3L) and EuroQol health-related quality of life measure using a VAS (EQ-VAS) measure health-related quality of life. EQ-5D-3L scores range from −0.624 to 1 and EQ-VAS scores range from 0 to 100 mm, with higher values indicating better health-related quality of life [34].

The following physiological measures were collected by the test leader at baseline and 3-month and 15-month follow-up:

- Dynamic hand strength was measured in kilograms using the Jamar dynamometer [35].
- Ventral and dorsal neck muscle endurance (NME*)* was registered in seconds [36].
- Active range of cervical motion in sagittal, lateral, and frontal planes was recorded in degrees using the cervical range-of-motion device [37].
- The Cranio-Cervical Flexion test was used to measure the action of the deep cervical flexor muscles, registered in mm Hg [38].
- Balance test: standing on one leg with eyes closed was measured in seconds [27].

Statistical and Multivariate Data Analysis

Multivariate data analysis was used to investigate the relationships between the variables using SIMCA software (v.18.0.0.372; Sartorius Stedim Data Analytics AB). For this, orthogonal partial least squares (OPLS) and OPLS discriminant analysis (OPLS-DA) were used. In general terms, these methods are linear regression methods that model the association between predictors (X) and response (Y) variables. They do this by summarizing the information in the original variables into a few virtual variables (components) that are selected to maximize the covariance between the X and Y variables. This allows the identification of the association between many X and Y variables simultaneously. The methods also separate variation in predictors that are either predictive for the response variables or not (orthogonal). This minimizes the issue of collinearity seen with classical regression models.

First, the differences between patients randomized to either NSEIT or the same exercises and information at a physiotherapy clinic (NSE) [9] were investigated by studying the changes (change scores) of variables between the 3 time points (baseline to 3 mo, baseline to 15 mo, and 3 mo to 15 mo) using OPLS-DA. Both the dependent factors disability (NDI), neck pain (VAS), and physical function (PSFS) and the independent factors (defined above) were included as X variables to investigate which of the variables may explain differences between NSE and NSEIT.

Second, OPLS models were used to investigate the relationship between changes for the dependent and independent factors at the 3 time points (baseline to 3 mo, baseline to 15 mo, and 3 mo to 15 mo). Y variables were set to the change scores for the dependent factors NDI, neck pain, and PSFS (using the average of the 3 PSFS components physical activity, leisure time, and work). X variables included all independent factors and all background variables detailed previously. A positive change score indicates improvement (eg, a higher change score in neck pain indicates less pain) and a negative change score indicates deterioration. To identify which of the X variables (independent factors) were most important for the changes in the Y variables (dependent factors; NDI, neck pain, and PSFS), those independent factors in a first model that had a variable influence on projection value of at least 1.0 and a variable influence on projection value greater than the standard error were included in a second OPLS model with one predictive and one orthogonal component.

Third, multivariate models using OPLS-DA were used to investigate whether background variables and baseline measurements of any of the independent factors could predict clinically significant improvement in the dependent factors NDI, neck pain, and PSFS. Individuals with clinically improved NDI, neck pain, and PSFS (value change NDI ≥7, neck pain ≥50% improvement, PSFS ≥2-point improvement) [22,23,39] were compared to individuals with no improvement or deteriorated values on these outcome measures.

All multivariate models were assessed using the fit of the data to the model (R^2) and the predictability of the model fit on new data (Q^2); the significance of group separation was assessed using cross-validated analysis of variance (CV-ANOVA) [40]. The maximum value for each (R^2 and Q^2) is 1.0 and symbolizes a perfect model. The loadings (weights representing the variables) were used for interpretation of the association between the X (independent factors) and Y (dependent factors) variables.

Sample size and power calculations were calculated based on the primary outcome measure (NDI) in the previous randomized controlled study [8]. To detect a between-group noninferiority margin of 7% with 1-sided α=.025 and β=.8, a total of 47 participants were needed in each group. To account for dropouts, 70 participants were included in each of the 2 groups (140 in total) [9]. Compliance with the exercise program (NSEIT, NSE) was defined as at least 50% self-reported completion of the exercises.

Results

Overview

Baseline characteristics of the participants are shown in Table 1. In the NSEIT group, of the initial 70 participants, 63 (90%) and 56 (80%) participants completed the 3-month and 15-month questionnaires, respectively. In the NSE group, of the initial 70 participants, 64 (91%) and 58 (83%) completed the 3-month and 15-month questionnaires, respectively (Figure 1).

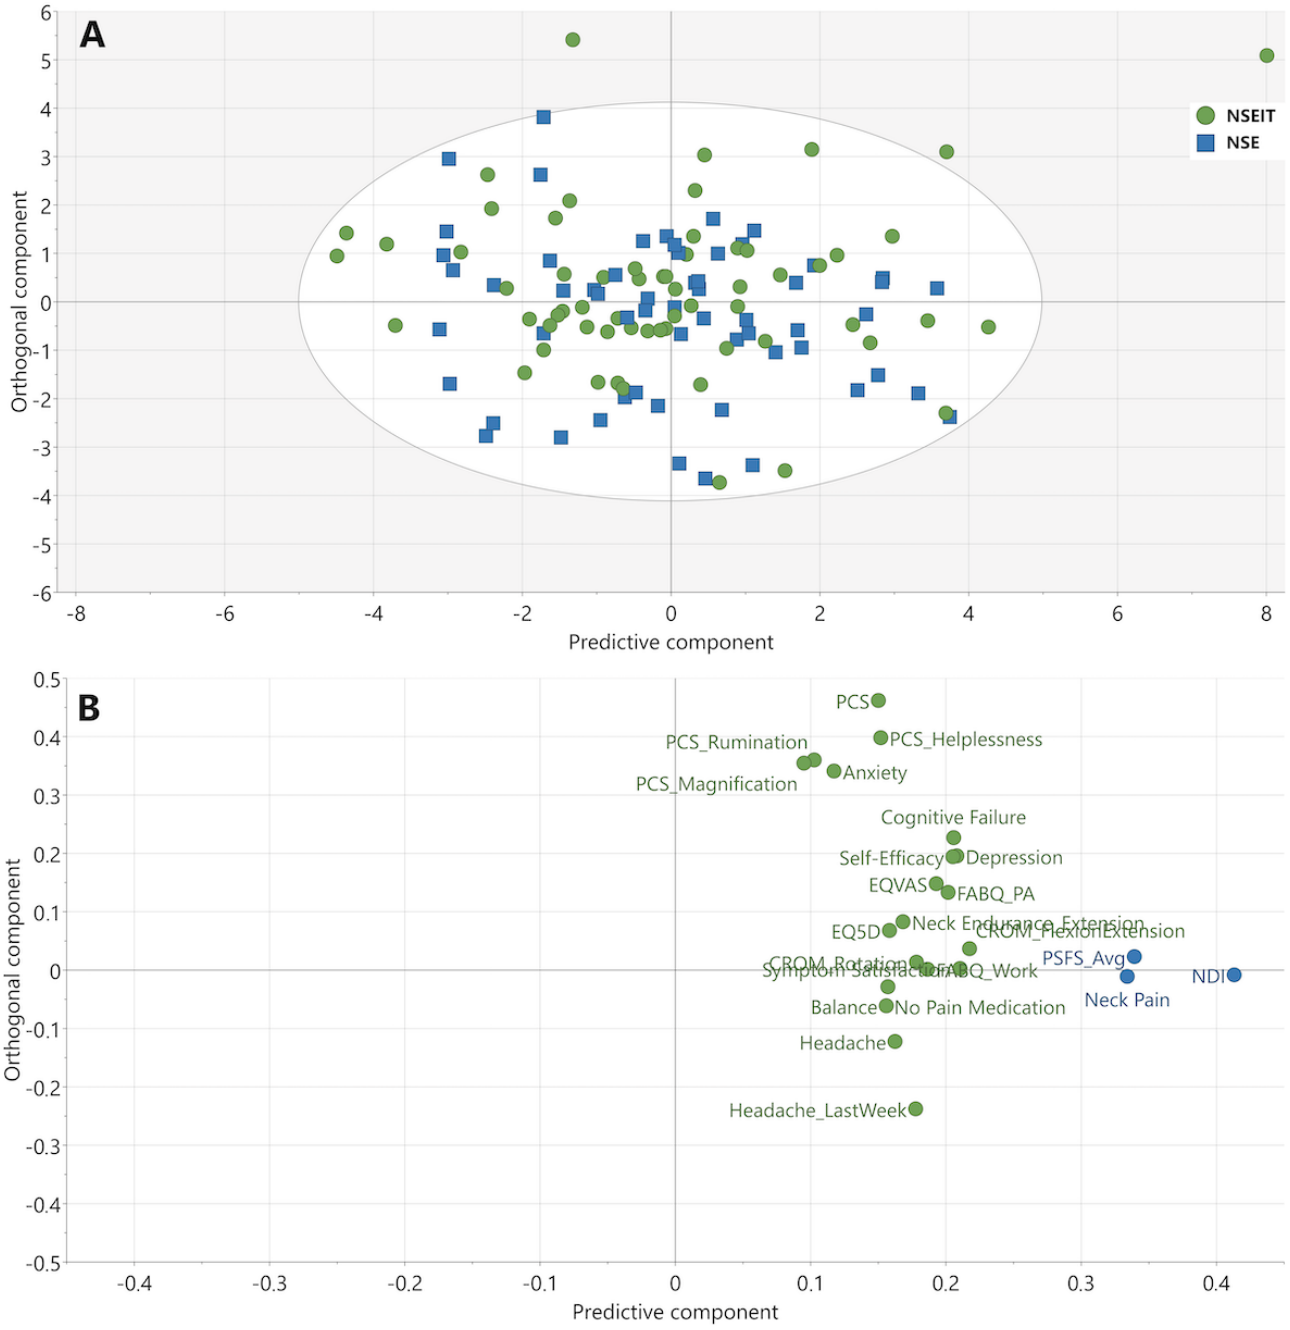
During the 12-week intervention period, the participants' self-reported compliance with the exercise program was higher in the NSE group (59/64, 92%) than in the NSEIT group (46/63, 73%; *P*=.006). No adverse events were reported.

Between-Group Differences

No significant OPLS-DA models could be built to separate patients receiving NSEIT from those receiving NSE (baseline to 3 mo: R^2=0.22, Q^2=–0.12; baseline to 15 mo: R^2=0.22, Q^2=0.01; 3 mo to 15 mo: R^2=0.17, Q^2=–0.10; all models CV-ANOVA *P*>.99). There were also no differences between the NSEIT and NSE groups regarding independent factors associated with improvements in the dependent factors NDI, neck pain, and PSFS (Figures S1-S3 in Multimedia Appendix 1).

Factors Related to Improvements in Disability, Neck Pain, and Physical Function



No background factors were found to be associated with improvements in NDI, neck pain, or PSFS in any of the multivariate models.

Improvement From Baseline to 3-Month Follow-Up

At 3 months compared to baseline, 20 independent factors were identified as associated with improvements in NDI, neck pain, or PSFS (R^2=0.31, Q^2=0.25, CV-ANOVA *P*<.001; Figure 2).

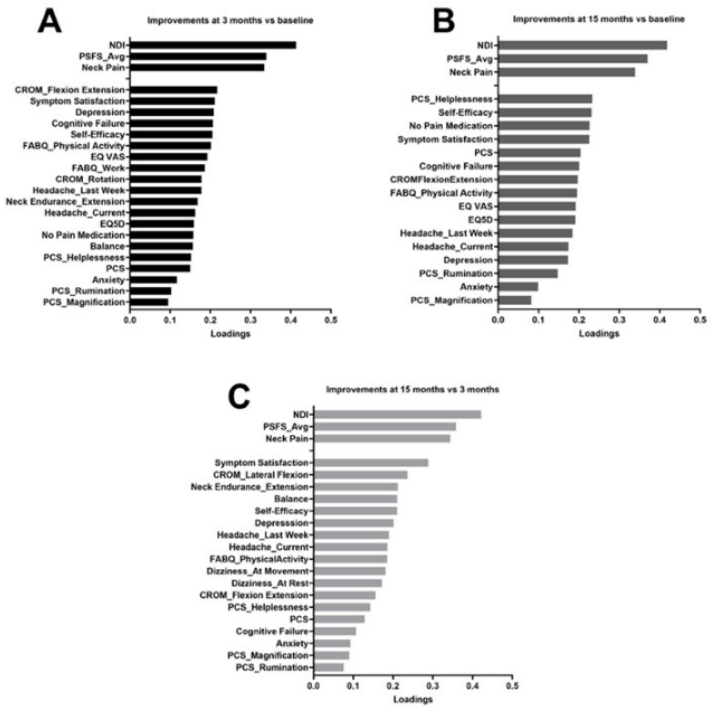
Improvement From 3-Month to 15-Month Follow-Up

At 15 months compared to 3 months, 18 independent factors were identified to be associated with improvements in NDI, neck pain, and PSFS (R^2=0.34, Q^2=0.28, CV-ANOVA P<.001; Figure 4).

XSL•FO
RenderX

Figure 4. OPLS model depicting changes in independent factors from 3 months to 15 months. (A) Score plot of participating patients. The color corresponds to grouping in either NSE (blue squares) or NSEIT (green circles). There were no differences between the NSEIT and NSE groups. (B) Loading plot of analyzed variables, showing the contribution of each independent factor to the OPLS component underlying the participant separation in the score plot (A). The x-axis depicts the most important predictive component for separating participants based on improvements in the primary outcomes NDI, neck pain, and PSFS (blue circles; R^2=0.34, Q^2=0.28, cross-validated ANOVA P<.001). CROM: cervical range of motion; EQ5D: EuroQol health-related quality-of-life scale; EQ-VAS: EuroQol visual analogue scale; FABQ: Fear Avoidance Beliefs Questionnaire; NDI: Neck Disability Index; NSE: neck-specific exercise program supervised by a physiotherapist; NSEIT: internet-based neck-specific exercise program; OPLS: orthogonal partial least squares; PCS: Pain Catastrophizing Scale; PSFS_Avg: Patient-Specific Functional Scale average (the average of the 3 PSFS components physical activity, leisure time, and work).



Variable Loadings for the 3 Models

The contribution of each variable (loadings) to the predictive component (x-axis) for the 3 models (Figures 1-3) is visualized in Figure 5. Thirteen of the 23 identified independent factors were common for all 3 models and included both psychological and physiological factors. The most important factors, as determined by a higher loading, that were related to improvements in NDI, neck pain, and PSFS were as follows: anxiety and depression, cognitive failure, pain catastrophizing, self-efficacy, fear avoidance beliefs, cervical range of motion, headache last week, current headache, and symptom satisfaction. Factors only found in 1 or 2 models were fear avoidance beliefs subscale work, balance (standing on one leg), cervical motion (lateral flexion and rotation), neck muscle endurance (extension), taking no pain medication, dizziness at rest and at movement, and health-related quality of life (Figure 5).

XSL•FO
RenderX

Figure 5. Loadings (contribution of each independent factor) obtained through OPLS after selecting outcome measures with variable influence on projection greater than 1.0. The three models (A-C) show the association between independent factors for improvements in NDI, neck pain, and PSFS at different time points. (A) Improvements between baseline and 3-month follow-up. (B) Improvements between baseline and 15-month follow-up. (C) Improvements between 3-month and 15-month follow-up. A higher value for the loadings indicates it is more important in the models. CROM: cervical range of motion; EQ5D: EuroQol health-related quality-of-life scale; EQ-VAS: EuroQol visual analogue scale; FABQ: Fear Avoidance Beliefs Questionnaire; NDI: Neck Disability Index; NSE: neck-specific exercise program supervised by a physiotherapist; NSEIT: internet-based neck-specific exercise program; OPLS: orthogonal partial least squares; PCS: Pain Catastrophizing Scale; PSFS_Avg: Patient-Specific Functional Scale average (the average of the 3 PSFS components physical activity, leisure time, and work).

The 5 most important independent factors related to changes in NDI, neck pain, and PSFS between baseline and 3-month follow-up were improvement in cervical range of motion (flexion/extension), symptom satisfaction, depression, cognitive failure, and self-efficacy (Figure 5A).

The 5 most important independent factors related to changes in NDI, neck pain, and PSFS between baseline and 15-month follow-up were improvement in pain catastrophizing (helplessness), self-efficacy, taking no pain medication, symptom satisfaction, and pain catastrophizing (total score; Figure 5B).

The 5 most important independent factors related to changes in NDI, neck pain, and PSFS between 3-month and 15-month follow-up were improvement in symptom satisfaction, cervical range of motion (lateral flexion), NME (extension), balance, and self-efficacy (Figure 5C).

Baseline Factors Determining Clinically Improved Versus Nonimproved Patients in Disability, Neck Pain, and Physical Function

Using OPLS-DA modeling, no significant models could be built to separate those patients whose NDI, neck pain, or PSFS was clinically improved from those with no improvement or showing deterioration based on background variables and baseline measurements of any of the independent factors (Figures S4-S9 in Multimedia Appendix 1).

Discussion

Principal Findings

This secondary analysis of a prospective randomized study investigated factors related to change in neck pain and disability (including functional ability) after a NSEIT or NSE exercise program for individuals with chronic WAD grade II or III.

The multivariate OPLS-DA models showed no significant differences between NSEIT and NSE. Thus, factors related to changes in pain and disability were the same in both groups, independent of how the exercise program was delivered. On the other hand, the multivariate OPLS models of improvements in neck pain and disability between the 3 time points (baseline to 3 mo, baseline to 15 mo, and 3 mo to 15 mo) indicated a number of related factors in both NSEIT and NSE. In total, 23 factors were identified and 13 of them featured in all 3 time points. However, neither the baseline factors nor changes in the independent factors could predict which patients were improved versus nonimproved in pain and disability.

Improvements in psychological and physiological factors were associated with an improvement in disability, pain, and physical function in both groups (NSEIT and NSE). It seems reasonable to assume that the effect may be related to the neck-specific exercise intervention itself, regardless of whether it was internet-based or physiotherapist-supervised, because the neck-specific exercise and information program were identical in NSEIT and NSE. The 4 face-to-face visits in NSEIT included

XSL•FO
RenderX

examination, an introduction to performing the exercises, progression of exercises, and follow-up. A possible explanation is that 4 visits to the physiotherapist combined with the internet-based program enabled these patients to feel confident and skilled enough to perform the exercises to the same extent as participants in the NSE group, who had many more visits to the physiotherapist.

In our study, participants in both groups described having increased knowledge regarding WAD, a stronger neck, and fewer symptoms [41]. Moreover, no significant differences were seen between NSEIT and NSE for primary or secondary outcomes [9,42].

The interpretation of the multivariate OPLS models was based on the weights (loadings) reflecting the relationship between dependent factors (NDI, neck pain, PSFS) and independent factors. Thus, independent factors with higher loadings were more closely related to improvements in NDI, neck pain, and PSFS compared to outcomes with lower loadings in the same model (Figure 5). Improvements in self-efficacy and symptom satisfaction were prominent in all 3 models (baseline to 3 mo, baseline to 15 mo, and 3 mo to 15 mo). Neck-specific exercises have been shown to improve neck-related function [42] and, in combination with the patient education in our NSEIT/NSE program, the exercises may lead to an enhanced ability to perform everyday functional activities, as the improvements in NDI and PSFS indicate [9].

Comparison to Prior Work

Psychological factors such as low self-efficacy, fear avoidance beliefs, depressive symptoms, and catastrophizing have earlier been shown to be predictors of a poor outcome of neck disability in chronic WAD [43-47], but they are also shown to be improved after 3 months of neck-specific exercise [48]. One of the most important factors to improve self-efficacy is personal mastery experiences, that is, the ability to successfully perform a task [49]. When individuals in the NSEIT and NSE groups could perform activities with less pain, their self-efficacy and symptom satisfaction increased. A painful stimulus, such as neck pain, can trigger catastrophic thinking, fear-avoidance beliefs, and avoidance behaviors, resulting in more pain and depression and leading to chronic disability as described by Vlaeyen and Linton [50] in their fear-avoidance model. Our neck-specific exercise program included information on whiplash injury, outlining why pain can persist even after potential injuries to muscles or ligaments have healed, and highlighting the importance of exercising the neck muscles. The exercises should not exacerbate neck pain but should be progressed over time, leading to the activity level recommended by the World Health Organization, as described in detail previously [9].

Physical activities and exercises are highly effective for improving symptoms of depression [51]. This may explain the association between improvements in NDI and PSFS (physical function) and depressive symptoms in this study. A speculative explanation is that the effect of our neck-specific exercise program is related to mutually positive associations. Physical function and self-efficacy increased—while pain, fear avoidance, and depression decreased—as a result of the exercise program. Anxiety and pain catastrophizing were included in the 3 models but had a lower influence on the dependent factors (neck pain and disability). Improvement in cognitive failures was also related to an improvement in pain and disability in all 3 models. Previous studies have shown that cognitive failures and attention problems are common and disabling when living with pain [52], a finding that is not limited to subjective reports, as these patients also fail in standardized cognitive tests [53]. However, another study found the relationship between chronic pain and cognitive tests in whiplash inconclusive [54]. Coexisting brain injury due to the whiplash trauma may be another reason for cognitive failures independent of pain [53], although individuals with brain injury were excluded in this study. Our results indicate that improvement in pain and disability after NSEIT or NSE was to some extent related to improvement in anxiety, pain catastrophizing, and cognitive failures. A causal relationship cannot be established in this study, but the findings may be of importance for improved rehabilitation in chronic WAD.

Background variables and baseline values of the independent factors in our study could not separate individuals with clinical improvement versus nonimprovement in disability, neck pain, and physical function. Moreover, no background variables were found to be associated with improvements in NDI, neck pain, or PSFS. A possible reason is that we failed to include the most relevant factors in the analyses despite the inclusion of many variables in the OPLS and OPLS-DA models. However, we included background variables and independent factors that were previously reported in the literature to be important in predicting and relating to disability and pain in WAD and chronic pain [10,11,14,43,44,46,47,55-57]. Nonetheless, there are conflicting results in earlier studies regarding the importance of some of the background variables and baseline values of the independent factors to pain intensity in chronic pain [55]. In chronic WAD, female gender, older age, and WAD grade III were related to nonrecovery in one study [56], while another study found that pain-related catastrophizing explained the variance in disability in patients with chronic WAD [44]. In contrast, we have previously found that no background variables were predictive of pain reduction in chronic WAD at 1-year follow-up [14]. However, higher baseline NDI score, absence of dizziness, and higher patient expectations, but not psychological factors, were associated with disability reduction [14]. We have also previously found that neck muscle endurance and perceived work ability were mediators for reduction in pain [15] in chronic WAD, and we identified a lack of improvement in ventral NME as a factor for ongoing dizziness in WAD after an exercise intervention [57]. The participants in this study had higher neck muscle endurance at baseline [42] compared to earlier results [58] and they improved more at the 3-month follow-up [42,58]. Higher neck muscle endurance may reduce disability and pain, which in turn can influence other factors and may explain the discrepancy between our results and other studies [12,44,56].

We recently reported that between 47% and 74% of participants with chronic WAD grade II and III demonstrated sustained improvement in disability, pain, and physical function after 3 months of NSEIT or NSE [9], but we failed to identify factors

XSL•FO
RenderX

associated with responders and nonresponders. Differences in analysis methods may explain the discrepancy between the present results and other studies [12,44,56]. An interesting result in this study was that neither psychological factors such as low self-efficacy, depression, and fear avoidance, nor background characteristics such as older age, low disability level, or WAD grade III, could predict nonresponders. Further studies should include factors related to possible tissue damage or altered function in chronic WAD, but one problem is that there is still a lack of reliable and effective diagnostic tools.

The results indicate that we need to go further to be able to improve our understanding of chronic WAD and to optimize treatment. Biomedical and/or psychosocial factors not investigated in this study are likely to be important for identifying nonresponders to NSEIT and NSE in chronic WAD.

Strengths and Limitations

This is the first study investigating factors related to pain and disability after an internet-based exercise program for chronic WAD grade II and III patients and, to our knowledge, factors related to the outcome of PSFS have not previously been reported for chronic WAD.

The strengths of multivariate OPLS analysis are the ability to include many variables and observations and the fact that several response variables (dependent factors) can be modeled together. OPLS can also cope with multicollinearity and missing values, which is a major advantage compared with traditional regression models. OPLS models use latent variables to model the data; these latent variables, which are linear combinations of the original variables, reduce the dimensions and minimize the issue of multicollinearity. Furthermore, OPLS separates the predictive variation (related to the response variable) from the orthogonal variation (unrelated to the response variable), thus focusing on the most relevant information, which simplifies the model and improves interpretability [59-61]. Moreover, the benefits of using multivariate statistics in this analysis are that variables can be scaled and centered on the mean, implying that each variable will have the same potential to affect the model, and that a patient or cluster of patients can be related to a variable profile rather than a single variable.

There are several limitations in this study. First, in the OPLS analyses, all 3 models (baseline to 3 mo, baseline to 15 mo, and 3 mo to 15 mo) showed relatively low explained variance, with the highest explanation level for the baseline to 15-month follow-up (R^2=0.37, Q^2=0.30). The goodness of fit of a model varies depending on the type of data and the specific application. For example, spectroscopic calibration models require values close to 1.0. However, while high R^2 and Q^2 values are desirable, they must be interpreted in the context of the specific application and data type [62]. Lower values indicate a less robust fit and predictive ability but might be acceptable, for example, in OPLS models that include self-reported psychological symptoms. Second, the results of this study are only generalizable to those individuals who fulfill the study criteria and are motivated to participate in exercise, but not to all individuals with WAD. Moreover, long-term effects can be influenced by various factors. For example, consistently measuring outcomes over time can introduce bias and affect the reliability of the results due to changes in the patient's life situation. Additionally, dropouts commonly increase over time. Third, only individuals who understood the Swedish language were included, and the age range was limited to 18 - 63 years. Thus, this study excluded minorities from a different background who did not understand Swedish and the results cannot be generalized to those aged under 18 or over 63 years.

Conclusions

After 3 months of NSEIT or NSE, improvements in neck pain and disability were related to improvements in 23 other physical and psychological factors. However, the findings should be interpreted with caution, as the results showed relatively low explained variance. No recommendations can be given for which individuals will benefit from NSEIT or NSE, due to the study's inability to distinguish between clinically improved and nonimproved participants regarding neck pain and disability. Further research is warranted to improve our understanding of those who are improved or not improved after 3 months of NSE or NSEIT.

Acknowledgments

We would like to thank all the participants with whiplash-associated disorders, the primary care physiotherapists, the test leader, and the research staff. The funder had no role in the study design, data collection and analyses, decision to publish, or preparation of the manuscript. The study was funded by Vinnova (grant number 2018- - 02244), the Swedish Research Council (grant number 2018- - 02476), the Centre for Clinical Research Sörmland at Uppsala University Sweden (grant numbers 736751, 854531, and 930399), the Regional Research Council Mid-Sweden (grant numbers 641551, 838701, and 939243), the Medical Research Council of Southeast Sweden (grant numbers 844451 and 939838) and Östergötland County Council (grant numbers 676261 and 847691).

Data Availability

The datasets generated during this study are available from the corresponding author on reasonable request and after ethical approval.

Authors' Contributions

GP and AP designed, formulated, and created the study. GP, AP, and SL analyzed and interpreted the data. GP, AP, and SL wrote the manuscript. GP, AP, and SL reviewed and approved the final manuscript. GP and AP were responsible for the management and coordination of the research study. GP and AP are responsible for the presentation of the published work.

Conflicts of Interest

None declared.

Abstract

Background: Dementia is a widespread syndrome that currently affects more than 55 million people worldwide. Digital screening instruments are one way to increase diagnosis rates. Developing an app for older adults presents several challenges, both technical and social. In order to make the app user-friendly, feedback from potential future end users is crucial during this development process.

Objective: This study aimed to establish a user-centered design process for the development of digiDEM-SCREEN, a user-friendly app to support early identification of persons with slight symptoms of dementia.

Methods: This research used qualitative and quantitative methods and involved 3 key stakeholder groups: the digiDEM research team, the software development team, and the target user group (older adults ≥65 years with and without cognitive impairments). The development of the screening app was based on an already existing and scientifically analyzed screening test (Self-Administered Tasks Uncovering Risk of Neurodegeneration; SATURN). An initial prototype was developed based on the recommendations for mobile health apps and the teams' experiences. The prototype was tested in several iterations by various end users and continuously improved. The app's usability was evaluated using the System Usability Scale (SUS), and verbal feedback by the end users was obtained using the think-aloud method.

Results: The translation process during test development took linguistic and cultural aspects into account. The texts were also adapted to the German-speaking context. Additional instructions were developed and supplemented. The test was administered using different randomization options to minimize learning effects. digiDEM-SCREEN was developed as a tablet and smartphone app. In the first focus group discussion, the developers identified and corrected the most significant criticism in the next version. Based on the iterative improvement process, only minor issues needed to be addressed after the final focus group discussion. The SUS score increased with each version (score of 72.5 for V1 vs 82.4 for V2), while the verbal feedback from end users also improved.

Conclusions: The development of digiDEM-SCREEN serves as an excellent example of the importance of involving experts and potential end users in the design and development process of health apps. Close collaboration with end users leads to products that not only meet current standards but also address the actual needs and expectations of users. This is also a crucial step toward promoting broader adoption of such digital tools. This research highlights the significance of a user-centered design approach, allowing content, text, and design to be optimally tailored to the needs of the target audience. From these findings, it can be concluded that future projects in the field of health apps would also benefit from a similar approach.

Introduction

Dementia is a widespread syndrome that currently affects over 55 million people worldwide, with annually almost 10 million new cases. The diagnosis of and treatment for people with dementia are going to be among the biggest challenges for health care systems worldwide [1]. A study by Eichler et al [2] found that 60% of people living with dementia in Germany had no formal diagnosis. Another problem lies in the long diagnostic periods. In the Bavarian Dementia Survey (BayDem) study, Wolff et al [3] found that the median time between the first perceived symptoms and diagnosis in Bavaria was 16 months. As Barth et al [4] were able to show, rural areas are also particularly affected here due to a high difficulty in accessing the facilities needed to diagnose and treat patients with dementia.

Screening instruments are one way of improving the diagnosis rate. A study with 146 participants has shown that diagnoses could be increased by almost 50% through upstream cognitive screening [2]. Internet-based screening tools offer the additional advantage that they can be used at a low threshold, regardless of time and place [5]. Digital technologies and the internet are already playing an increasingly central role in the everyday lives of older people. The proportion of people with internet access is growing across all age groups. In recent years, the number of German senior citizens (79 - 84 years) who regularly use the internet has more than doubled (18.8% in 2011 vs 39.4% in 2017). There is also an increased interest in health websites among older people [6]. In the 2021 report published by the German Federal Office for Information Security, it was stated that around 163,000 different health apps existed [7]. However, there is a lack of high-quality dementia apps. As analyzed in an earlier study, for only 6 of 20 identified dementia apps, scientific evaluation studies have been published. In none of those studies, the effectiveness of the respective screening app could be proven. Among the published app evaluations, screening apps received the worst overall quality rating. In summary, the analysis showed that the existing apps at this time did not provide reliable information and results [8].

Thus, in the digiDEM Bayern project (Digital Dementia Registry Bavaria), we have not only focused on the establishment of a digital registry for persons with mild cognitive impairment and mild to moderate dementia [9,10], but also on the development, scientific evaluation, and sustained provisioning of innovative eHealth tools and digital apps [11,12]. The goal of our current project, in this context, was to establish a user-centered design process for the development of digiDEM-SCREEN, a user-friendly app to support the early identification of persons with slight symptoms of dementia. The objective of this publication is to illustrate the iterative and agile user-centered development process consisting of 8 phases to move from a conceptual idea to an early prototype and a final prototypical implementation with continual involvement and feedback process from stakeholders and intended future users.

Methods

Overview

In order to achieve the goal of a user-friendly screening app for people with slight dementia symptoms, a user-centered iterative development approach comprising the following steps was chosen:

1. A systematic literature research of scientifically evaluated digital and nondigital dementia screening tests.
2. An early prototype (V1) development based on the guidelines for graphic design and textual formulation criteria for people with cognitive impairments. Graphical requirements include an easy-to-understand layout, standardized navigation elements, and a clear division of instructions into several steps [13]. In addition, textual guidelines such as short and concise sentences, logically structured sections with headings and an active approach to the user should be observed [14]. Furthermore, the expertise of 3 clinicians from different disciplines with long-term experience in dementia research and 2 professors of medical informatics with expertise in developing mobile health apps, supported by their teams was incorporated into the development.
3. Conduction of an initial evaluation of the early prototype (V1) based on a focus group discussion (FGD) with potential end users (older adults ≥65 years with and without subjective cognitive impairments) [15]. The group discussion was recorded and transcribed afterward. The results were then categorized and analyzed based on a previously published qualitative content analysis [16]. The following categories were extracted: general linguistic adaptations, task-related linguistic adaptations, menu navigation, general navigation, and specific design changes to individual components.

1. Incorporating the FGD feedback and results into the specification for the prototypical implementation of digiDEM-SCREEN (V2).
2. The second evaluation with a new group of potential users (older adults ≥65 years with and without subjective cognitive impairments) was based on the think-aloud method, where participants speak their thoughts and wishes aloud during the test and are observed by a researcher who also takes notes [17].
3. Incorporating the user feedback and think-aloud evaluation results into the enhanced specification for the subsequent digiDEM-SCREEN development step (V3).
4. Conduction of an additional focus group evaluation of the improved beta version of the app (V3) with people with migration background (nonnative German speakers).
5. Development and deployment of the first ready-to-use digiDEM-SCREEN version (V4).

Recruitment of the facilities for participation (steps 4, 5, and 7) was based upon the network of research partners in the project

XSL•FO
RenderX

digiDEM. The older adults from the facilities were informed about participation options in former group meetings (informed consent). After consenting, participants were invited to take part in the respective focus groups.

In steps 3 and 5, the System Usability Scale (SUS) has been calculated for the respective prototype versions by applying the German version of the standardized SUS questionnaire [18]. The scale can take values between 0 and 100; the higher the value, the higher the user-friendliness is categorized [19]. In addition, also in step 7, a self-assessment was used to determine technology use, interest, and expertise, each on a 5-point Likert scale (1 - 'Does not apply at all'; 5 - 'Applies completely'). The participants gave their subjective assessment and considered if they could use the app on their own (on a scale of 1 to 10) of the app and the specific components [20]. Furthermore, the participants were asked to name the most considerable problems associated with the app and if they wanted to change something.

Thus, our user-centered software design and development process included qualitative and quantitative evaluation methods at 3 different stages of the development process.

Ethical Considerations

This study was approved by the Ethics Committee of the Medical Faculty of the Friedrich-Alexander Universität Erlangen-Nürnberg (application number: 20-253_1-B; August 14, 2023). Written consent was obtained prior to the user testing and focus group discussion. All participants data were pseudonymized. The list of reidentifying data was stored separately from the analyzed data, and only authorized individuals have access to them. No one was paid to test the app.

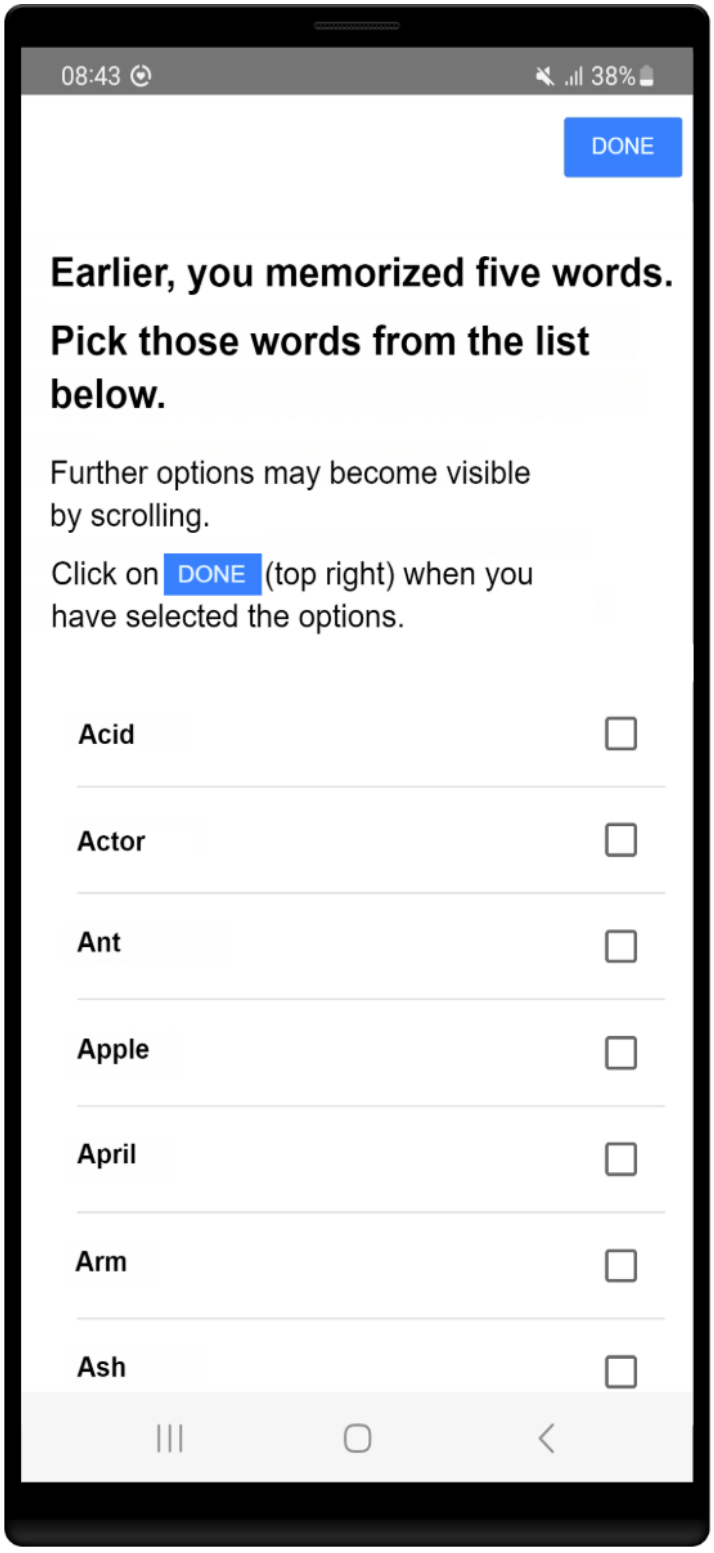
Results

Steps 1 and 2: Development of the First Prototype (V1)

Prior to developing the screening test, we conducted systematic literature research. The search terms are shown in Multimedia Appendix 1. Criteria for the decision on a suitable screening tool were the scientifically examined psychometric properties (sensitivity and specificity), the availability of being a free to use app (not paid), and the technical feasibility of a tablet/smartphone. The main source of information was the systematic reviews of Chan et al [21] as well as the specific studies of the screening tools [22,23]. The decision on the Self-Administered Tasks Uncovering Risk of Neurodegeneration (SATURN) was based upon a group discussion about the aforementioned criteria as well as the (methodological) quality of the screening tools and the underlying scientific studies in general.

The SATURN [24] proved to be a test with particular promising diagnostic values (sensitivity: 0.92; specificity: 0.88 in dementia cases vs controls) [21]. The test is usable via a tablet. Administration time is about 10 minutes, which can be especially beneficial for older adults as shorter tests might induce less fatigue and therefore be more suitable for repeat administration compared with lengthier instruments [25]. Thus, the SATURN provides the foundation for the development and validation of a German adaption of the test usable as an app via smartphone and tablet.

To date, there is no German version of the SATURN test. The translation of the English version of the SATURN into German was carried out independently by 2 research assistants from the digiDEM Bayern project (MZ and ND) using the translate-retranslate method. Apart from some general adaptations, such as the correct assignment of the users' residence, linguistic aspects were also taken into account, and the texts were adapted to the German-speaking context. In some translations, the number of letters in the word increased noticeably (eg, farm - Bauernhof). A shorter related word (field - Feld) was then used in these places. Additional instructions were developed. The test adaptations aimed to ensure that both the implementation and the evaluation could be carried out entirely by the user or the system alone. At the start of the original SATURN test, the participant was asked to read aloud the task (close your eyes) and perform it [24]. Without a handler to check the action, there could be no subsequent evaluation (What phrase did you first read from this tablet?). Therefore, the researcher chose an alternative task (tap on the yellow circle) that also involved reading and performing an action.



The final screening test consists of tasks from 6 different cognitive domains: Comprehension, Visuospatial, Orientation, Memory, Calculation, and Executive Function. Points are awarded for each task, which adds up to a maximum score of 30. The tasks must be completed without the help of other people. Participants may use their visual aids to complete the tasks; all other aids (eg, paper and pencil) are not permitted. A detailed description and illustrations of the individual test tasks can be found in Multimedia Appendix 1.

Another innovation is that the authors are developing the app as a tablet and a smartphone version. Due to the smaller display sizes, new components like the word selection task shown in Figure 1 had to be created. The researcher also developed some new logic to prevent larger adjustments, for example, that the user is only allowed to undo the last connection at the last task (tap on the circle with a blue background; Figure 2).

The following table (Table 1) shows the baseline characteristics of the participants in the usability analysis. This is followed by a description of the details of the individual events.

Study sample characteristics	FGD[a] 1 (Prototype V1)	Usability test (Prototype V2)	FGD 2 (Prototype V3)
Study population	13	21	7
Age (years), mean (range)	75.8 (66-84)	70.2 (65-80)	60.8 (53-69)
Sex, n (%)			
Male	1 (7.7)	8 (38.1)	0 (0.0)
Female	12 (92.3)	13 (61.9)	7 (100.0)
Education, n (%)			
Low	4 (30.8)	0 (0.0)	1 (14.3)
Medium	5 (38.4)	10 (47.6)	1 (14.3)
High	4 (30.8)	11 (52.4)	5 (71.4)
Self-perceived cognitive impairment, n (%)	5 (38.4)	5 (23.8)	0 (0.0)
Nonnative German speaker, n (%)	0 (0.0)	2 (9.5)	7 (100.0)
SUS[b] (0 - 100), mean (SD)	72.5 (1.6)	82.4 (16.1)	—[c]
App rating (1-10), mean (SD)	7.3 (2.1)	8.7 (1.5)	8.7 (1.2)
Independent app use (1-10), mean (SD)	7.5 (2.9)	8.95 (1.3)	8.5 (1.0)

[a]FGD: focus group discussion.

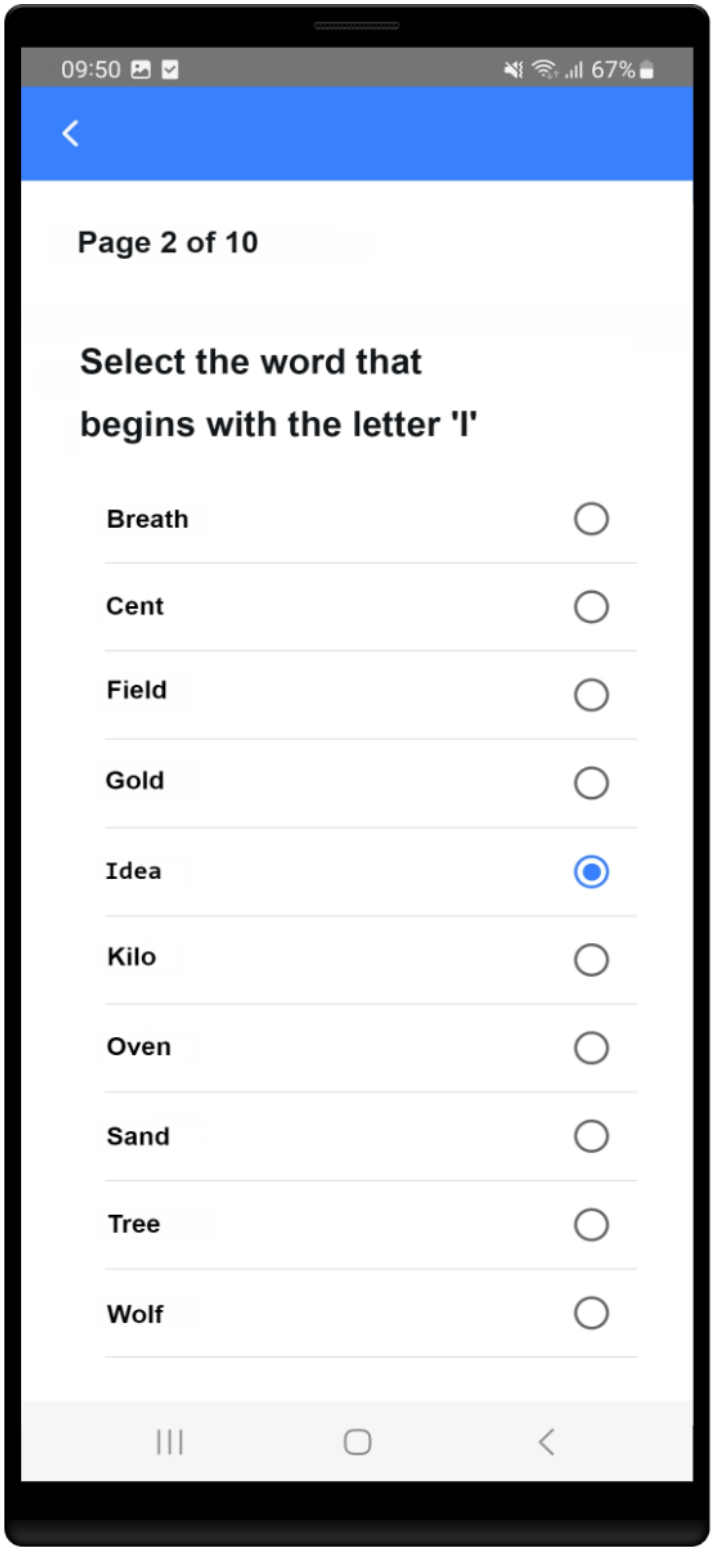
[b]SUS: System Usability Scale.

[c]Not applicable.

In both the first 2 focus groups, the SUS score was slightly lower in people with subjective cognitive impairment (FGD1: healthy older adults=74.4; people with subjective cognitive impairment=69.5; FGD2: healthy older adults=83.5; people with subjective cognitive impairment=82).

The SUS score decreased with advanced age (FDG1: ≥80 years old=63.8, 79 - 70 years old=73.9, ≤70 years old=85.0; FDG2:≥80 years old=75.0, 79 - 70 years old=77.5, ≤70 years old=85.0). People with a medium-level education had the best scores on the SUS (FDG1=85.0; FDG2=83.3), followed by people with a high-level education (FDG1=73.8; FDG2=83.0) and people with a low-level education (FDG1=55.6).

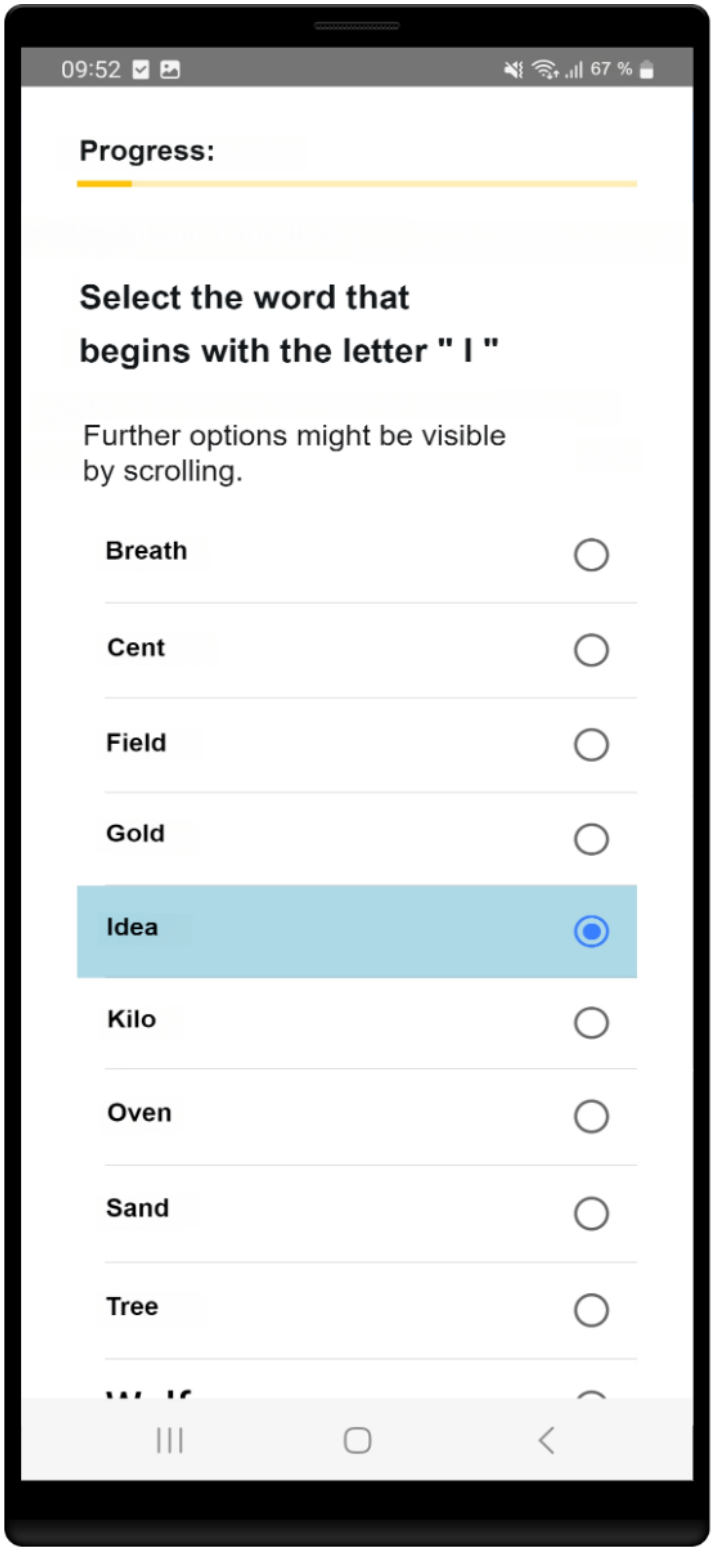
Steps 3 and 4: Focus Group Discussion V1



The first FGD took place as part of a memory training group. A memory training group is a frequent meeting of older adults, in which those adults perform different memory training exercises under the supervision of a group leader. Frequent excursions are also part of this service. The service is offered by a nonprofit organization (German: Wohlfahrtsverband) and is led by a research associate in the project digiDEM. The group consisted of a total of 13 participants. Their baseline characteristics are shown in Table 1. On average, they used modern technologies frequently (3.39) and showed an average interest in technological innovations (3.00). Their self-assessment of their competence in using modern technology was moderate (2.39), but the fear of failure played only a moderately important role (2.69).

Due to the large number of participants, 3 small groups were formed for the test. Participants were able to extensively test the app prototype and contact a research assistant with any questions. The individual components of the prototype achieved a subjective app rating of 7.3 (out of 10) points and an SUS score of 72.5. Participants also generally felt able (7.5 out of 10) to use the app independently without outside help. Subsequent group discussion of the results took place again in a large group.

The 2 most significant areas of improvement were observed in all the 3 small groups. Many participants recognized the letter I as T due to the inverted commas (‘I’) and had problems answering this task correctly. Participants also did not always recognize the selected word, as only the radio button on the right-hand side of the prototype showed their selection. The app prototype (V1) is shown in Figure 3. Participants therefore specifically requested that the entire line be colored when a selection was made. The 2 adjustments are shown in Figure 4.



XSL•FO
RenderX

Figure 3. Illustration of the prototype (**V1**).

XSL•FO
RenderX

Figure 4. Final visualization (**V4**).

In addition, minor inconsistencies were noticed in this test, such as the fact that sometimes “Next” and sometimes “Done” were used to move on to the next task. The participants also wanted the selected images to be marked more clearly and the contrast and color intensity to be adjusted so that the colors could be recognized more clearly. One participant commented that she liked the “simple design” and that it did not distract from the actual content. Another participant mentioned that the instructions were too complex (“They were good instructions that you could actually understand. But I really had to read very carefully”). Therefore, the descriptive text has been simplified. Feedback on the user-friendliness of the FGD was predominantly positive. One participant particularly liked the fact that she could use the app without having much prior knowledge. The general consensus was that the app was easier to use on a tablet than on a smartphone due to the larger screen size. However, the smartphone version was also rated as usable by participants. These points mentioned were discussed with

XSL•FO
RenderX

the developers and incorporated into the second prototype accordingly.

Steps 5 and 6: Think-Aloud Usability Evaluation (V2)

A total of 21 older adults, who were randomly selected from participants in a dementia prevention event for older adults (≥65 years), participated in this usability test. Their baseline characteristics are shown in Table 1. They most frequently use modern technology (4) and are interested in technical innovations (3.62). They rated their competence in modern technology as average (3.33), while the fear of failure did not play a significant role (2.48).

The quantitative key figures collected increased compared with the first version. This prototype achieved a subjective app rating of 8.7 (out of 10) points and an SUS score of 82.4. The participants' assessment of using the app independently, without external help, also increased significantly (8.95 out of 10).

Based on the researchers' observations and the participants' statements minor adjustments and precisions, such as allowing €67 and €67.00 as the correct answer in the calculating task, were made. Some users also commented negatively about the last task's descriptive text. Due to the length and complexity of the content, the question was often not solved or only solved with a hint from the research assistant. Based on this feedback, the language of the text was revised again.

Step 7: Focus Group Discussion With Nonnative Speaker (V3)

The last user test took place under the aspect of accessible language and comprehensibility. To this end, an FGD was conducted with people with a migration background. Seven older adults took part in this FGD. Their baseline characteristics are shown in Table 1. They came from 4 different countries (Iraq, Kuwait, Sri Lanka, and Syria) and were all nonnative German speakers. They most frequently use modern technology (3.86) and are interested in technical innovations (3.57). They rated their competence in modern technology as average (3.14), while fear of failure played a minor role (2.58).

The quantitative indicators collected were similar to those of the German-speaking users. This prototype achieved a subjective app rating of 8.7 (out of 10) points. These participants also rated the success of using the app independently, without external help, at 8.5 (out of 10). Unfortunately, no SUS score could be obtained from this group due to the language barrier.

Two relevant changes emerged from the group discussion. First, a note on scrolling (Figure 4) was added in the appropriate places, and second, the language was adapted. A total of 5 of the 7 participants answered one of the initial questions (Select the fruit from the list.) incorrectly. The participants confused 2 words "Kirsche (cherry)" and "Kirche (church)," which are very similar in German. As this error does not indicate a possible cognitive decline, the word "Kirche (church)" was changed to "Kapelle (chapel)."

Step 8: Development and Deployment of the First Ready-to-Use digiDEM-SCREEN Version (V4)

In this step, the digiDEM-SCREEN test was finalized as a screening app for recording the current cognitive status of users. A validation study is currently underway. The test will be administered to patients in outpatient memory clinics and its sensitivity and specificity will be evaluated in the context of existing diagnoses and other nondigital cognitive tests. As part of the validation, cut-off values for categorizing current cognitive ability will also be determined as part of the validation. Depending on the test result, the user is given a short recommendation and options for action. If the result is above the threshold value calculated in the validation study, the screening does not indicate memory impairment. It is recommended that the test be repeated at regular intervals to monitor changes in memory performance. If the final result is below the threshold, further neuropsychological assessment in a memory outpatient clinic is recommended.

A study is currently underway to determine the sensitivity and specificity of the developed screening test (V4) and its correlation with the Montreal Cognitive Assessment [26]. For increased transparency, the research group has registered the project in the German Clinical Trials Register (DRKS) (registration number: DRKS00033764). After validation, the test will be available free of charge to anyone interested. Different randomization options have been used to minimize the learning effect. There are 5 versions of the test, which differ in the order of the numbers to be memorized. In addition, the position of each answer option is randomized for each test session. There are also plans to offer the screening test in different languages in the future. The possibility of multilingualism has already been taken into account in the programming of the app. This will be easy to implement once further translations have been validated.

Discussion

Principal Findings

There is a lack of evidence in the field of freely accessible apps for people with dementia, especially screening apps. A study published in 2023 showed that there are not any scientific studies to prove the effectiveness of any of the German-speaking screening apps [8].

A user-friendly app should have 3 main characteristics: typography appropriate for the target group (eg, recognizable icons), intuitive operation, such as fewer clicks to the desired action, and simplicity (eg, simple navigation) [27]. Three key stakeholder groups were involved in developing the digiDEM-SCREEN app: the digiDEM research team, the software development team, and the target user group (older adults ≥65 years with and without subjective cognitive impairments). Developing an app for older adults presents several challenges, both technical and social. Older adults may have less technology experience and difficulty understanding complex user interfaces [28]. Many older adults also have age-related limitations, such as visual or hearing impairments [29]. Cognitive abilities can decline with age, making complex

XSL•FO
RenderX

apps more difficult to use. The app should be tailored to the cognitive needs of older users, for example, by providing clear instructions and simple interactions. Considering these challenges when developing an app for older adults can help to create a user-friendly and accessible application that improves the lives of older people and promotes their independence [27]. In order to make the app as user-friendly as possible, feedback from potential future end users is essential. A critical examination of the study population shows that the participant structure is dominated by women in terms of gender. This could lead to a distortion of the results, as the findings may not be transferable to the entire target group. However, an empirical comparison of the usability of a mail app between male and female users showed that there are no statistically significant differences in the performance criteria of efficiency, effectiveness, and satisfaction between the 2 groups [30]. Another study examined whether there were systematic differences between women and men in the evaluation of the user experience of 3 websites and showed that there were no significant differences between the genders. Personal attitudes and preferences have a greater influence on the results [31].

The activities summarized under the term “patient and public involvement” enable patients to be actively involved in the planning and development of new products. International associations such as Alzheimer Europe as well as scientists are very interested in encouraging the active involvement of people with dementia in research for brainstorming and counseling [32].

Digital health apps often struggle with low adherence. One possible reason for this is users’ personal frustration with the content of the intervention, the way it is presented, and the nonintuitive handling [33]. The selected user-centered design could sustainably increase adherence. Users have unique knowledge, perspectives, and experiences that can influence a product’s quality, appropriateness, and user-friendliness. User testing is an essential part of the iterative development process and contributes to increasing the quality and success of the app [34]. Prototypes make it possible to recognize potential problems or weaknesses in user interaction or design at an early stage. By discovering these problems at an early stage, expensive changes or new developments in later phases of development can be avoided [35]. Thus, using the prototype design in the first workshop provided the team with a cost-effective way to get feedback and evaluate the idea. In the user tests, the tablet prototype of the app performed better than the smartphone version. The participants mainly criticized the smaller font and display size, which made it somewhat difficult to enter answers in some places. Despite these criticisms, the smartphone version was still rated as user-friendly. Smartphones are the most common mobile devices. A study by Weber et al [36] from 2020 found that an average of 41.4% of 71.6-year-old participants used their own smartphone. Due to the high availability of smartphones among seniors, the research team decided to stick with both versions. The mobile app also works offline, so no internet connection is necessary. Those decisions made it possible to reach a larger number of potential users. During the test phases, the participants did not use their devices, which they were familiar with in everyday life, but devices provided by the research team. For example, the display size, operating system (or at least the version), and individual settings may differ from their device. It is expected that user-friendliness will be even higher when users utilize their own smartphone or tablet.

The workshop participants were positive about the experience and gave constructive comments on the app. In addition, the SUS score also increased with each iteration of the app version. Bangor et al [37] described that products with a SUS score of 90 points and above were rated as exceptional, products with a SUS score of 80 points were rated as good, and products with a SUS score of 70 points were rated as acceptable. Anything below 70 points had usability issues that were a cause for concern. That means all SUS assessments are above the average and at least rated as acceptable. The prototype V1 gained a SUS score of 72.5 from the participants of the FGD. The rating of the second app version was notably better (SUS score: 82.4) and, therefore, rated as good. Due to some comprehension difficulties, unfortunately, no SUS score could be raised in the second FGD. Whenever questionnaires are used directly with people with dementia, the questions should be short and understandable (no technical terms), and double negatives should be avoided [27].

The results of the user evaluations showed that a user-friendly screening test for people with subjective cognitive impairments could be developed for the German-speaking population.

The main focus of the focus groups was on minimizing potential sources of error. Nevertheless, there is still a residual risk that the test cannot be carried out properly. If the first 3 simple test tasks are not answered correctly, an end screen appears with the message that the test cannot be carried out due to technical or language barriers. In this case, the user is advised to visit a specialized clinician. In the general instructions before the start of the test, participants are also informed that for example visual aids should be used.

Strengths

Different potential end users were included in the development process of the digital screening test as an app in order to improve usability and avoid technical or linguistic barriers. Moreover, additional languages and other extensions like a dementia prevention module can be added to the app.

Limitations

There was no random sampling of participants. Furthermore, although the SUS scale is the most frequently used scale to assess the user-friendliness of IT applications, it also has its weaknesses. The results of a systematic review show that some studies found that the double-negative questions from the SUS are challenging to understand for people with dementia [27]. With this knowledge in mind, we used simple language and no double negatives for the remaining questions we phrased. In the first FGD, the researchers had to explain individual questions to the group, and no SUS score could be collected in the last FGD. Most of the participants needed help understanding the questions. They were, therefore, unable to give reliable answers.

XSL•FO
RenderX

Conclusions

The development of digiDEM-SCREEN serves as an excellent example of the importance of involving experts and potential end users in the design and development process of health apps. From the initial stages of the project, experts were engaged in the content and design realization, providing a solid foundation for further development. The intensive testing phase, in which various end users tried out the app prototype in several iterations, clearly demonstrated the value of early and continuous feedback for improving the final product. This research highlights the significance of a user-centered design approach, allowing content, text, and design to be optimally tailored to the needs of the target audience. From these findings, it can be concluded that future projects in the field of health apps would also benefit from a similar approach. Research teams and app developers should integrate user-centered design practices into their development processes to ensure that the applications they create are not only functional but also user-friendly and appealing to the target audience. Such an approach could significantly enhance the acceptance and effectiveness of health apps, thereby making a valuable contribution to digital health care. A close collaboration with end users leads to products that not only meet current standards but also address the actual needs and expectations of users. This is a crucial step toward improving health technology and promoting broader adoption of such digital tools.

Acknowledgments

The present work was performed by MZ in partial fulfillment of the requirements for the degree “Dr. rer. biol. hum.” at the Faculty of Medicine of the Friedrich-Alexander-Universität Erlangen-Nürnberg. The project is funded by the Bavarian State Ministry of Health, Care and Prevention (funding code: G42d-G8300-2017/1606-83).

Authors' Contributions

MZ, ND, RP, PH, PKR, and HUP contributed to the conceptualization of the study. MZ and ND conducted the investigation, while MZ, ND, and HUP developed the methodology. Project administration was managed by RP, PH, EG, PKR, and HUP. The app programming was carried out by FH, JH, KK, and RP. Supervision was provided by MZ, ND, PKR, and HUP. MZ was responsible for writing the original draft, and MZ, NDI, EG, KK, and HUP contributed to the review and editing of the manuscript.

Conflicts of Interest

RP is a partner in Lenox UG, a company focused on applying scientific findings in digital health applications. Lenox UG holds shares in HealthStudyClub GmbH. This company is responsible for developing the app presented in the paper. RP received consultancy fees, reimbursements for conference attendance, and travel expenses in connection with the topics of mobile health and e-mental health. KK is also a shareholder in HealthStudyClub GmbH and has joined the company as chief technical developer. FH and JH work as freelancers for HealthStudyClub GmbH.

Abstract

Background: Muscle fatigue, characterized by reduced force generation during repetitive contractions, impacts older adults doing daily activities and athletes during sports activities. While various sensors detect muscle fatigue via muscle activity, biochemical markers, and kinematic parameters, a real-time wearable solution with high usability remains limited. Plantar pressure monitoring detects muscle fatigue through foot loading changes, seamlessly integrating into footwear to improve the usability and compliance for home-based monitoring.

Objective: This study aimed to investigate the effects of muscle fatigue on plantar pressure measurements using a self-developed wearable plantar pressure system.

Methods: Twelve healthy participants completed a 5-minute calf muscle fatigue protocol. The plantar pressures and surface electromyography (sEMG) activity of the gastrocnemius muscles were recorded before and after exercise. The plantar pressures at 6 regions and the median frequency (MDF) of sEMG were analyzed to quantify fatigue.

Results: The self-developed foot pressure system showed a significant decrease in plantar pressure peak values at the heel of the left (P=.003) and right feet (P=.001) and at the lateral toe of the left (P=.001) and right feet (P=.026). A significant increase was observed at the metatarsal head of both the left foot (P=.001) and the right foot (P=.017). The MDF of sEMG signals significantly decreased in the left (P=.001) and right gastrocnemius (P<.001).

Conclusions: Plantar pressure changes and sEMG signals effectively detect gastrocnemius muscle fatigue using the proposed wearable system, supporting the development of a wearable solution for detecting muscle fatigue suitable for home-use.

(JMIR Hum Factors 2025;12:e65578) doi:10.2196/65578

KEYWORDS

muscle fatigue; plantar pressure sensors; wearable devices; home-based monitoring

Introduction

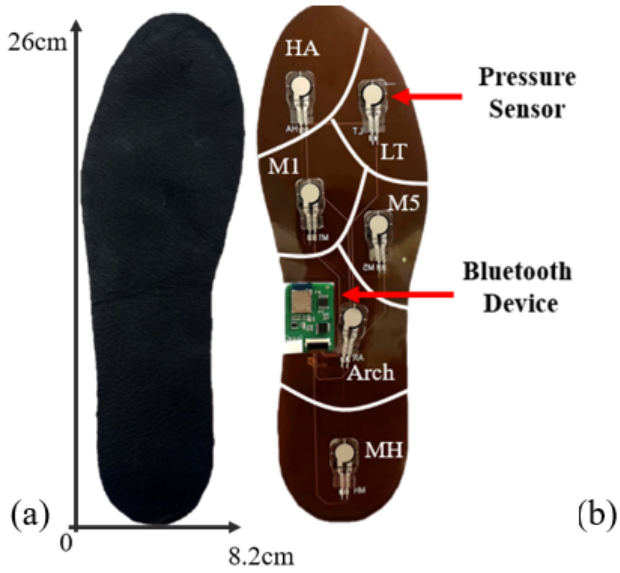
Muscle fatigue, characterized by the reduced ability to generate adequate force during repetitive contractions [1], affects performance across different groups and activities including daily activities of older adults as well as athletes during sports. Muscle fatigue disrupts the neuromuscular system and affects different aspects such as muscle strength, force production, and movement patterns, resulting in stiffness of the muscles and joints, impaired motor control, and poor balance [2], thereby increasing the risk of injuries. For instance, in badminton players, muscle fatigue impairs neuromuscular coordination, by reducing input from the foot sole receptors, and muscle force production, leading to weaker responses and decreased reaching distance performance [3]. Running-induced fatigue reduces lower limb muscle activity, decreases shock absorption capacity, and alters plantar pressure distribution [4], thus increasing the risk of running-related injuries such as stress fractures in the foot [5]. Mello et al highlighted how fatigue delays the gastrocnemius muscle's activation by 1 second relative to the center of pressure, thus impairing balance [6]. Furthermore, Morrison et al found that muscle fatigue in older adults (aged 60 - 79 years) significantly increased reaction times, postural sway, and fall risk compared to younger individuals (aged 30 - 59 years) [7].

Muscle fatigue can be detected through various methods, including blood lactate concentration [8], electromyography (EMG) [9], mechanomyography (MMG) [10], near-infrared spectroscopy (NIRS) [11], and kinematic parameters using inertial measurement units (IMUs) [12]. While the lactate concentration provides an estimation of global fatigue, it cannot monitor fatigue in real-time [8]. MMG, NIRS, and IMUs can be used in wearable forms; however, the use of NIRS and MMG has challenges owing to issues such as time lags, the use of

XSL•FO
RenderX

MMG has susceptibility to motion artifacts [13], and the use of IMUs needs further research regarding the relationship between kinematic parameters and muscle fatigue [14]. Surface electromyography (sEMG) is a widely used wearable method for real-time monitoring of local muscle fatigue by measuring myoelectric activity [15]. Fatigue reduces muscle fiber conduction velocity, shifting the sEMG power spectrum to lower frequencies (eg, decreased median frequency) and increasing signal amplitude. sEMG captures these changes and quantifies muscle fatigue using time-domain or spectral parameters [8]. However, the use of sEMG in a home setting is difficult, owing to the challenges of correctly attaching the electrodes and regularly wearing the device without assistance [16].

Adherence is a critical factor for effective daily monitoring, as meaningful and continuous data are required for accurate analysis [17]. Wearable devices integrated with mobile apps present promising healthcare solutions for home-based monitoring. The integration of hardware sensors and software mobile apps enables continuous and unobtrusive monitoring, thereby providing real-time data analysis that can support timely interventions [18]. A suitable alternative wearable approach for muscle fatigue monitoring is the use of plantar pressure sensors, which can be seamlessly integrated into a shoe's insole for daily comfortable wear. Wearable plantar pressure sensors in the foot insole are widely used for the detection of diabetic foot ulcers [19], gait analysis, and the measurement of the ground reaction force [20] and the center of pressure [6]. Muscle fatigue impacts body mechanics and alters foot loading patterns, measurable through plantar pressure at different foot regions. Considerable research has explored changes in plantar pressure following various physical activities linked to lower limb muscle fatigue, such as badminton [21], walking [22], and long-distance walking [23].



Despite the aforementioned advancements, wearable foot plantar systems for detecting muscle fatigue in everyday physical activities have yet to be designed. In this study, the effect of calf muscle fatigue in healthy participants was investigated using a self-developed wearable plantar pressure system that was suitable for daily use. The results can provide a muscle fatigue detection method for developing a wearable plantar pressure monitoring system

Methods

The Digital Foot Pressure System

A self-developed digital foot pressure system was utilized in this study. Figure 1 shows the wearable plantar devices for both the left and right feet as well as the measurements of the devices. Each device, designed to be worn comfortably with shoes, is equipped with 6 pressure sensors (A301 Flexiforce, Tekscan Inc.). The system also has a nRF52840 microprocessor (Nordic Semiconductor) used for the analog-to-digital converter measurement of foot plantar pressure, a wireless Bluetooth 5.0 module for data transmission, and a lithium-ion battery for power supply. The system operates with a sampling rate of 100 Hz, ensuring high-resolution data capture. The data from the 6 pressure sensors in both the left and right devices can be transmitted wirelessly in real time via Bluetooth to a custom-developed Android mobile app. This app facilitates real-time data display, analysis, and cloud storage, as shown in Figure 2. The pressure sensors are strategically arranged on the foot insole to cover 4 main plantar anatomical areas: the toes, metatarsals, arch, and heel. This general layout enables accurate measurement of natural gait; the layouts of the toes and metatarsals are further divided into 2 parts to capture plantar pressures along the mediolateral axis during walking [24].

Figure 1. Wearable plantar pressure device in an insole format. (**A**) Foot insole with 6 regions of pressure measurements: hallux (HA), lesser toe (LT), first metatarsal (M1), fifth metatarsal (M5), arch, and medial heel (MH); (**B**) Coordinates of the 6 pressure sensors on the insole.

Ethical Considerations

The research was approved by the Ethics Review Board of the Chung Yuan Christian University for Human Subjects Research (No. 8800-4-07-002). The participants were informed of the requirements and procedures of the entire experiment, and written consent was obtained before testing.

Subjects

A briefing session was conducted to familiarize the participants with the fatigue protocol and the walking test to be used in the research. Twelve healthy participants from the Chung Yuan Christian University, Taiwan, were recruited for the research. The mean (SD) age of the participants was 23.7 (2.6) years, and their mean (SD) weight was 62.4 (6.3) kg. The dominant limb of each participant was determined by identifying which foot would step out first once they started walking. The exclusion criteria included participants with plantar fasciitis or flatfoot and those who could not run independently for 5 minutes. Given that these foot disorders were excluded, experiments for minimizing variability could be performed. Then, suitable foot insole sizes were given to the participants.

Experimental Procedures

The experimental procedures were divided into 4 main steps. First, baseline tests were performed to measure the EMG of muscle activity and foot plantar pressure in both the legs. During the baseline test, the sEMG activities of the participants' gastrocnemius and rectus femoris muscles in the right and left legs were recorded using sEMG electrodes (T709, Comepa, France) and a data acquisition instrument (MP36, Biopac Inc., USA). The skin of each participant was cleaned with alcohol before the electrodes were attached. The sEMG muscle activities were recorded at a sampling rate of 2000 Hz. The plantar pressures at 6 locations in the left and right legs were measured simultaneously with sEMG. The plantar pressures were recorded using the wearable foot plantar device that was developed specifically for this study. Then, timed up-and-go and 10-meter walk tests were conducted; the participants were asked to rise from a standard chair, walk for 10 meters at their most comfortable speed, turn around, walk back. and sit down again [25].

After the baseline test, each participant was instructed to perform a fatigue exercise. All the participants were asked to place a weight-bearing apparatus on each leg and perform forefoot running for 5 minutes. The weight-bearing apparatus was 1/20th of a participant's weight [26]. sEMG data were collected from the gastrocnemius and rectus femoris muscles to capture the electrical activity associated with muscle contractions, and the wearable foot plantar pressure device was used to monitor changes in pressure distribution under the feet. This dual approach allowed the fatigue levels in both the muscles to be evaluated and quantified. After the exercise, the rating of perceived exertion (RPE) scale was used to assess and document each participant's perceived level of fatigue. Postfatigue measurements were recorded immediately after the fatigue protocol, while the participants performed timed up-and-go and 10-meter walk tests, and sEMG and foot plantar pressure measurements for both legs were collected.

EMG Muscle Fatigue Analysis

Three consecutive sEMG signals from the gastrocnemius and rectus femoris muscles were averaged for prefatigue and postfatigue analyses. The sEMG envelope was calculated from the raw sEMG signal through a 20 - 500–Hz finite impulse response bandpass filter. The signal was then processed via fast Fourier transformation to calculate the power spectrum median frequency (MDF) of the sEMG. A shift in the MDF to a lower frequency during exercise is considered localized muscle fatigue [27]. This method allowed researchers to determine whether muscle fatigue was induced in the gastrocnemius muscles, thereby increasing confidence in these data's correlation with foot plantar pressure data. The MDF is the frequency at which the EMG power spectrum is transmitted, and it is given by

XSL•FO
RenderX

(1)∑j=1MDF Pj=∑j=MDFM Pj=12∑j=1M pj,

where Pj is the power spectrum of the EMG at frequency bin *j*. The MDF splits the power spectrum of the EMG into two equal-amplitude regions.

The RPE Scale Analysis

The RPE scale was utilized to assess each participant's self-reported fatigue level. This subjective measurement tool is widely employed in the fields of physical activity, exercise, and sports to evaluate an individual's perceived effort and fatigue during physical tasks [28]. Participants rate their exertion based on sensations such as increased heart rate, breathing rate, muscle fatigue, and overall physical strain. The Borg RPE Scale, ranging from 6 to 20, is one of the most commonly used versions, with higher scores indicating greater levels of exertion [29].

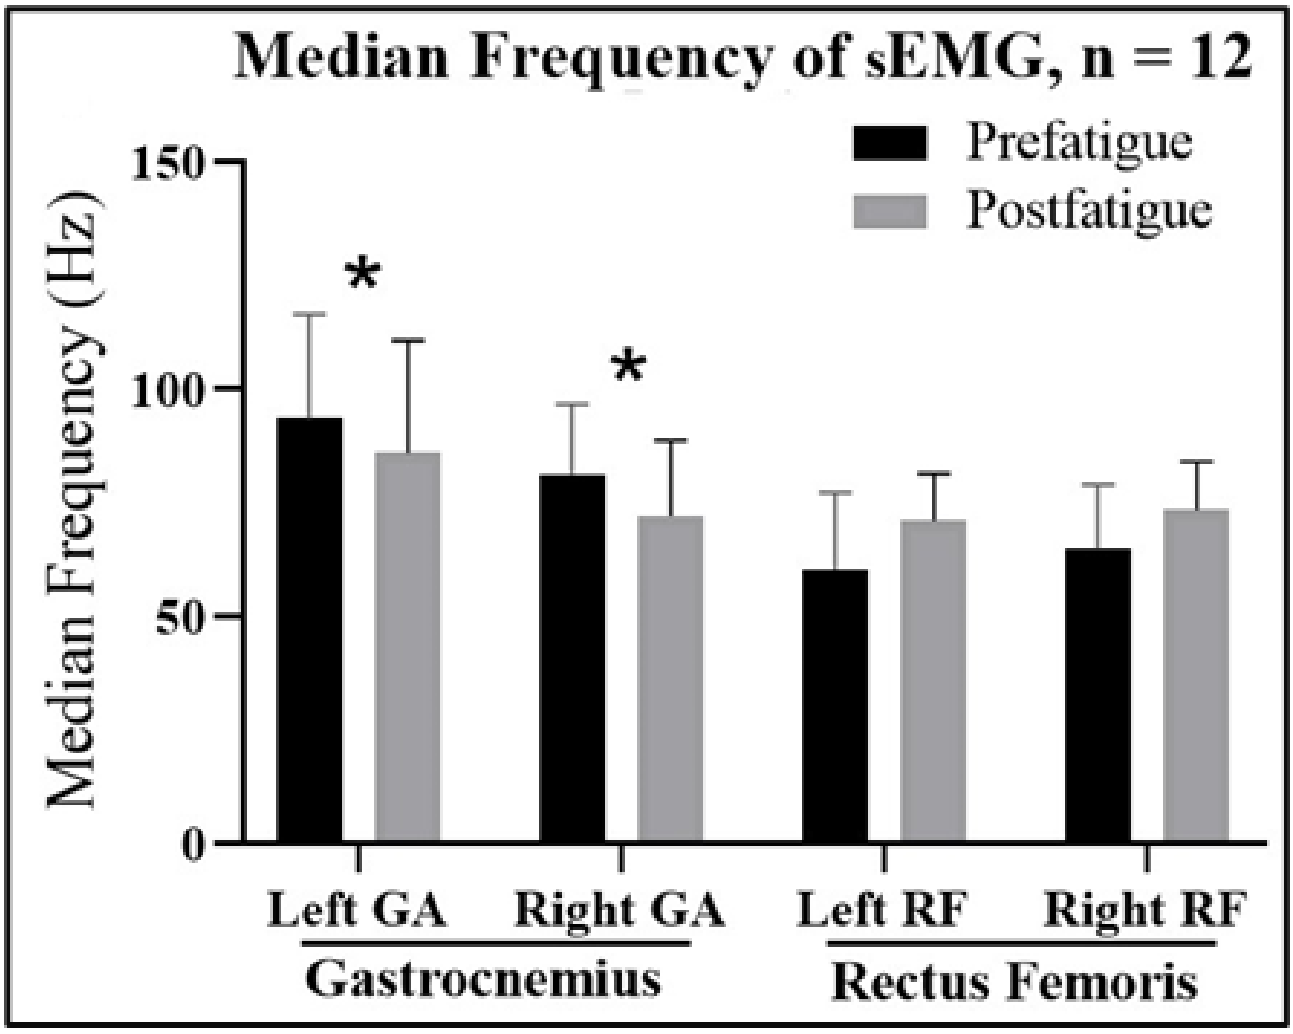
Foot Plantar Pressure Analysis

Foot plantar pressure data, obtained using the developed digital foot plantar system and the commercial system, were simultaneously collected with the EMG data. The 6 plantar pressures in the left and right feet obtained in this research represent 6 anatomical areas of the foot: hallux (HA), lesser toe (LT), first metatarsal (M1), fifth metatarsal (M5), arch, and medial heel (MH). The peak pressures (Pa) in these 6 anatomical areas were analyzed and calculated from the raw plantar pressure data via MATLAB version R2022a (Mathworks Inc.). The measurements for the three consecutive prefatigue and postfatigue tests were averaged and compared. On the basis of the preliminary results, changes in the mean peak pressure of the 6 anatomical areas before and after the fatigue protocol were determined.

Statistical Analysis

In this study, the MDFs of the sEMG signals and the mean peak plantar pressures in each anatomical area for each participant before and after the fatigue protocol are presented as the means (standard errors). A paired *t* test with repeated measures was used to compare the MDFs of sEMG signals from the gastrocnemius and rectus femoris muscles before and after fatigue exercise. Then, a paired *t* test with repeated measures was used to detect significant differences in the 6 anatomical areas (ie, HA, LT, M1, M5, arch, and MH) before and after muscle fatigue exercise for the wearable plantar pressure system. All the statistical tests were performed with the significance level of $P<.05$.

Results



The data for muscle fatigue, RPE, and mean plantar pressure were collected and analyzed using a paired *t* test.

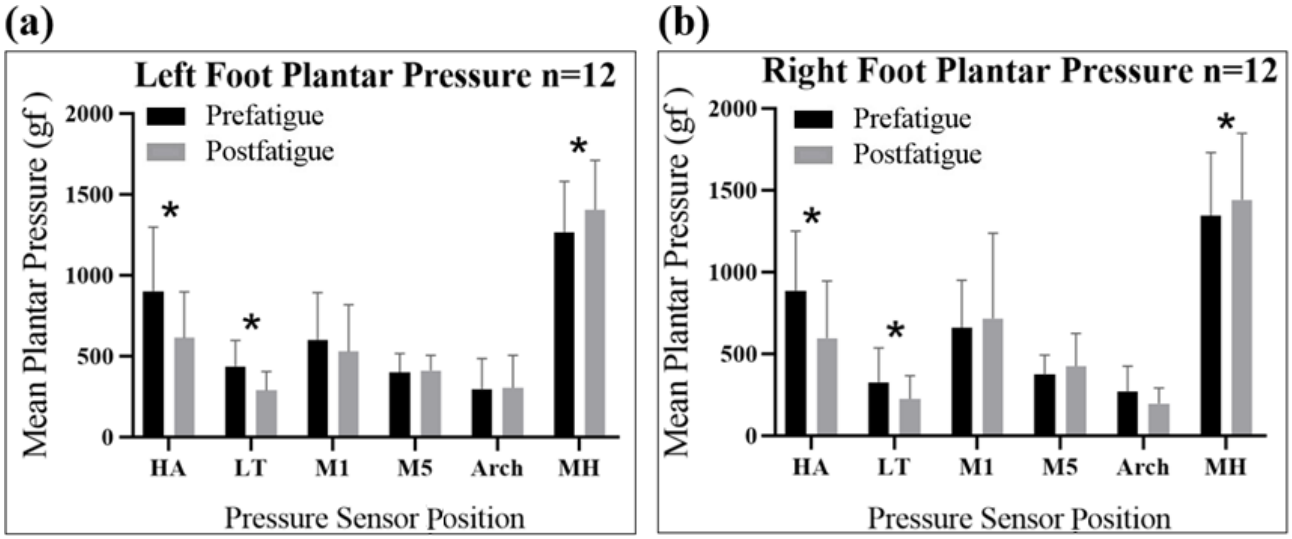
MDFs of sEMG in Detecting Muscle Fatigue

The MDFs of the sEMG data of the gastrocnemius and rectus femoris muscles are presented in Figure 3. The MDFs (SD) of the sEMG data of the left and right gastrocnemius muscles significantly decreased from 93.6 (22.8) Hz to 86.1 (24.6) Hz in the left foot and from 81.3 (15.5) Hz to 72.1 (16.6) Hz in the right foot after exercise for muscle fatigue ($P=.001$ and $P<.001$, respectively). However, the MDF of the sEMG before and after muscle fatigue exercise did not significantly differ between the left and right rectus femoris muscles.

XSL•FO
RenderX

Figure 3. Medium frequency of the sEMG for the gastrocnemius (GA) and rectus femoris (RF) muscles in the left and right legs before the fatigue exercise (prefatigue) and after the fatigue exercise (postfatigue). sEMG data of the left and right gastrocnemius muscles significantly decreased after the exercise for muscle fatigue (*P*=.001 and *P*<.001, respectively).

The RPE Scale in the Muscle Fatigue Protocol



The RPE scale was used in the experiment to assess the muscle fatigue levels of the 12 participants. All the participants reported that the level of fatigue in the gastrocnemius muscle was greater than that in the rectus femoris. The analysis of the average RPE scores revealed that the mean fatigue level for the gastrocnemius muscle was 14.3 (SD 1.3), whereas the mean fatigue level for the rectus femoris was 7.0 (SD 1.3). The significant difference in fatigue levels (P <.001) between the two muscles aligns with the analysis of MDF in the sEMG data. These findings confirmed that the gastrocnemius muscle experienced greater fatigue than the rectus femoris did during the experiment.

Foot Plantar Pressure in Detecting Muscle Fatigue

The data for the left and right feet (Figure 4A and B, respectively) were obtained using a developed digital plantar pressure measurement system. Figure 4 shows the changes in plantar pressure before and after fatigue. The changes were noticeable in terms of the plantar pressure at the HA, LT, and MH on both feet after gastrocnemius muscle fatigue. The pressure values at other locations also changed, but they were not statistically significant.

Figure 4. Mean peak plantar pressure before the fatigue exercise (prefatigue) and after the fatigue exercise (postfatigue) by sensor positions: hallux (HA), lesser toe (LT), first metatarsal (M1), fifth metatarsal (M5), arch, and medial heel (MH) in the (**A**) left foot: a statistically significant decrease in the mean plantar pressure peak values was observed in the HA (*P*=.003) and LT (*P*=.001), while the MH showed a statistically significant increase (*P*=.001) after the fatigue exercise; and (**B**) right foot: a statistically significant decrease in the mean plantar pressure peak values was observed in the HA (*P*=.001) and LT (*P*=.026). A significant increase was noted in the MH position after fatigue (*P*=.017).

The mean plantar pressure values were measured using the self-developed foot pressure system. A significant decrease was observed in the mean plantar pressure peak values in the HA of the left foot (*P*=.003) and right foot (*P*=.001) and in the LT of the left foot (*P*=.001) and right foot (*P*=.026). A significant increase was observed in the mean plantar pressure peak value in the MH position after fatigue in both the left and right feet (*P*=.001 and *P*=.017, respectively). The mean plantar pressure peak value in the right HA decreased by 32.6%, from 883.2 (366.8) gf to 595.1 (349.2) gf, and that in the left HA decreased by 31.9%, from 900.7 (396.2) gf to 612.8 (284.0) gf. The mean plantar pressure peak value in the right LT decreased by 31.1%, from 325.8 (210.6) gf to 223.7 (141.4) gf, and that in the left LT decreased by 33.9%, from 435.6 (162.0) gf to 287.8 (115.8) gf. The mean plantar pressure peak value in the right MH increased by 7.2%, from 1343.4 (385.7) gf to 1440.3 (406.8) gf, and that in the left MH increased by 11.0%, from 1265.5 (313.0) gf to 1404.9 (304.4) gf. The changes in the mean peak pressure in the M1, M5, and arch positions were not significant. However, the M1 and arch positions showed a change in the mean peak pressure in both the left and right feet. In contrast, we observed an increase in the mean peak pressure in the M5 position in the left and right feet of 12.5 (24.5) gf and 52.0 (79) gf, respectively. The details of the changes in the mean peak plantar pressures before and after fatigue exercise by sensor position via the wearable plantar pressure system are shown in Multimedia Appendix 1.

Discussion

Principal Findings and Comparison With Previous Works

The results of this study demonstrated that muscle fatigue in the gastrocnemius significantly affects the plantar pressure in the HA, LT, and MH regions in both the legs. In particular, the mean peak plantar pressure in the HA and LT regions significantly decreased and that in the MH regions significantly increased after 5 minutes of muscle fatigue exercise in the gastrocnemius compared with the value before the fatigue exercise. This finding was determined using the self-developed wearable foot plantar pressure system proposed in this research. Muscle fatigue exercise in this study induced muscle fatigue solely in the calf area, which corresponded with a significant decrease in the MDF of the sEMG of the gastrocnemius muscle but not in the MDF of the sEMG of the rectus femoris. As presented, sEMG is highly muscle-specific and effective for detecting localized muscle fatigue; it is not useful to detect muscle fatigue in deeper muscles like the tibialis posterior in the calf area [5]. Pressure sensors offer an alternative by measuring the fatigue in muscles through shifts in loading patterns, providing a broader and more accessible assessment.

The findings of this study align with existing literature, showing that muscle fatigue in the lower limb induces a significant decrease in the mean pressure in the HA area and a shift in plantar pressure from the forefoot to the hindfoot [21,23,30,31]. This could be due to individuals starting to adapt their plantar pressure pattern from the forefoot to the hindfoot to avoid overuse of the forefoot [23]. The literature also revealed a significant decrease in the first metatarsal region. Similar findings were observed in this study, but the results in the first and fifth metatarsals and arch regions were not statistically significant. This discrepancy could stem from differences in fatigue protocols, as more intensive activities, such as 30-minute runs, lead to greater pronation and increased medial midfoot loading, whereas walking shows no such midfoot differences [32-35]. Additionally, subject variability, including anatomical factors such as arch height and leg-length differences, may contribute to variance in medial midfoot pressure [30,36]. For instance, flat feet increase loading on the medial longitudinal arch, while high arches shift the load to the lateral edge [37].

In this study, a shift in loading from the forefoot region including the HA and LT to the hindfoot including the MH after 5 minutes of fatigue exercise results in gastrocnemius muscle

XSL•FO
RenderX

fatigue. This finding could serve as an indicator for real-time monitoring of lower limb muscle fatigue, aiding in the prevention of injuries or falls in older adults and athletes. When a healthy person participates in sports such as badminton or running, muscle fatigue of the lower limb may be expected. These fatigued muscles can result in compromised reaction times, joint stability, and dynamic balance, thereby reducing impact absorption, which heightens the risk of injuries [21,38]. Athletes and coaches should monitor for fatigue alerts and ensure timely rest to recover muscle strength, preventing performance issues and injuries [39]. For older populations, particularly those at high risk of falls, such as patients with sarcopenia [40] or stroke [41], this system enables continuous home-based monitoring of plantar pressure patterns. A shift in plantar loading from the forefoot to the hindfoot could trigger alerts for rest to individuals or caretakers, minimizing fall risks associated with muscle fatigue.

Usability is a key factor in the adoption of digital health technologies such as the proposed wearable plantar pressure system [42]. Compared to sEMG, MMG, NIRS, or IMU wearable devices, its shoe-based form offers a user-centered design for daily wear, eliminating the need for users to remember and attach it correctly, thereby enhancing acceptance and compliance in home settings. A previous study highlighted the importance of face-to-face interactions with physicians in increasing their trust in digital health technologies [43]. Clinical or expert recommendations play a critical role in encouraging patients to adopt the device. The system's ability to support effective remote patient management allows both users and experts to review and monitor past performance or clinical conditions, thus fostering engagement [44]. These features, combined with its user-friendly design and portability, enhance the system's feasibility and scalability for home-based applications, promoting widespread adoption.

Limitations

This study has some limitations. First, direct evidence for the development of muscle fatigue in the gastrocnemius could not be provided by this study, given that muscle force was not directly measured. Instead, the MDF of the sEMG signal, which shifted to a low frequency, was used as an indicator of muscle fatigue; this approach is a common research method for measuring muscle fatigue [45-47]. The decrease in MDF was likely caused by changes in the properties of the muscle fibers, such as decreased conduction velocity and increased muscle fiber recruitment [48]. The MDF of the sEMG measurement might also be affected by factors other than fatigue, such as the muscle fiber type [49] and motor unit firing rate [50]. However, this limitation was compensated by the RPE scale questionnaire. Second, the effects of fatigue were measured only in the rectus femoris and calf gastrocnemius muscles; the effect of upper leg fatigue on plantar pressure was ruled out. sEMG measurements of other calf muscles, such as the tibialis anterior, can provide insights into a particular calf muscle's interaction with plantar pressure. The short test duration and limited wearing time (10 - 20 min) in this study may not accurately represent real-life scenarios, necessitating extended testing to better simulate prolonged activities. In addition, wearable devices must adapt to various environments and wearing conditions, as factors such as daily wear and tear, temperature, humidity, flooring, and uneven terrain can impact sensor performance.

Conclusions

The results of this study demonstrated a significant decrease in the mean plantar peak pressure in the HA and LT and an increase in the mean plantar peak pressure in the MH as an indicator of the onset of muscle fatigue in the gastrocnemius. This work is an exciting proof-of-concept outcome showing that muscle fatigue in the gastrocnemius can be detected via a wearable plantar pressure system. These findings can be used to further develop a wearable lower limb muscle fatigue monitoring system for minimizing injury risk in sports or during the daily activities of older adults.

Acknowledgments

The author would like to thank the participants for their time and willingness to take part in this study. This work was supported by the Taiwan National Science and Technology Council (Grant No. 110-2222-E-033-006-MY3).

Abstract

Background: Targets of bullying are at high risk of negative socioemotional outcomes. Bullying programming in rural schools is important as bullying is more prevalent in those schools compared to urban schools. Comprehensive, school-wide bullying programs require resources that create significant barriers to implementation for rural schools. Because technology-based programs can reduce implementation barriers, the development of a technology-based program increases access to bullying prevention in rural settings.

Objective: We aimed to conduct usability testing of a bystander bullying intervention (STAC-T). We assessed usability and acceptability of the STAC-T application and differences in usability between school personnel and students. We were also interested in qualitative feedback about usability, program features, and feasibility.

Methods: A sample of 21 participants (n=10, 48% school personnel; n=11, 52% students) recruited from 2 rural middle schools in 2 states completed usability testing and a qualitative interview. We used descriptive statistics and 2-tailed independent-sample *t* tests to assess usability and program satisfaction. We used consensual qualitative research as a framework to extract themes about usefulness, relevance, needs, barriers, and feedback for intervention development.

Results: Usability testing indicated that the application was easy to use, acceptable, and feasible. School personnel (mean score 96.0, SD 3.9) and students (mean score 88.6, SD 9.5) rated the application well above the standard cutoff score for above-average usability (68.0). School personnel (mean score 6.10, SD 0.32) and students (mean score 6.09, SD 0.30) gave the application high user-friendliness ratings (0-7 scale; 7 indicates highest user-friendliness). All 10 school personnel stated they would recommend the program to others, and 90% (9/10) rated the program with 4 or 5 stars. Among students, 91% (10/11) stated they would recommend the program to others, and 100% (11/11) rated the program with 4 or 5 stars. There were no statistically significant differences in ratings between school personnel and students. Qualitative data revealed school personnel and students found the application useful, relevant, and appropriate while providing feedback about the importance of text narration and the need for teacher and parent training to accompany the student program. The data showed that school personnel and students found a tracker to report different types of bullying witnessed and strategies used to intervene by students a useful addition to STAC-T. School personnel reported perceiving the program to be practical and very likely to be adopted by schools, with time, cost, and accessibility being potential barriers. Overall, findings suggest that the STAC-T application has the potential to increase access to bullying prevention for students in rural communities.

Conclusions: The results demonstrate high usability and acceptability of STAC-T and provide support for implementing a full-scale randomized controlled trial to test the efficacy of the application.

Introduction

Background

National statistics indicate that bullying is a national public health issue in the United States, with 19.2% of students aged 12 to 18 years reporting being bullied at school in the past year [1]. Bullying peaks in middle school, with 26.5% of sixth-grade students reporting being a target of school bullying, followed by 26.3% of seventh graders and 25.1% of eighth graders. Among students who report being bullied, 21.6% report being bullied online. Findings from a meta-analysis examining consequences of bullying have indicated that students who are targets of bullying report a wide range of negative mental health outcomes, including symptoms of anxiety, posttraumatic stress, depressive symptoms, nonsuicidal self-injury, suicidal ideation, and suicide attempts [2]. Similarly, being a target of cyberbullying is associated with internalizing symptoms, suicidal ideation [3-5], and alexithymia and psychotic experiences [6]. Thus, it is imperative to develop effective interventions for middle school students that are accessible and easy to implement to reduce bullying and the associated negative consequences.

Youth in Rural Schools

Students attending school in rural communities are at high risk of experiencing both school bullying and cyberbullying [7-9]. According to US national statistics, the highest rates of bullying among rural youth in the past decade were reported in 2019, with 27.7% or rural students reporting being bullied compared to 22.4% of students in urban areas [10]. Although rates of bullying peaked in 2019 for both rural and urban students, the most recent US national statistics indicate that the prevalence of school bullying victimization continues to be higher among students in rural areas (23.8%) than among students in urban areas (19%) [1]. Furthermore, among targets of bullying, students attending rural schools are also more likely to report being bullied online (23%) compared to students attending urban schools (19.5%). Rural students also report a higher rate of being bullied with repetition (18.8%) compared to urban students (14.4%). Among middle school students attending schools in rural communities, bullying victimization is associated with poor school relationships, negative school experiences [11], and depression and anxiety [11,12]. These data suggest the importance of developing school-based bullying prevention programs specifically for students in rural communities.

School-Based Bullying Interventions

Comprehensive, school-wide interventions are effective in reducing bullying and the associated negative mental health outcomes [13]. Furthermore, bystander training (eg, teaching students who witness bullying to intervene in bullying situations) is an important intervention component [13]. Although up to 80% of students report witnessing bullying [14], only 20% intervene [15]. Because students report that they do not know how to intervene when they witness bullying [16], bystander training is a promising approach to bullying prevention. However, few comprehensive school-based programs incorporate bystander training. In addition, comprehensive, school-wide bullying prevention programs are expensive, complex, and time intensive and require extensive training [17]. Because these interventions require substantial resources, many schools face implementation barriers. Schools in rural communities may also face economic disparities, creating further implementation challenges [18], including a lower tax base, increased training costs due to bringing in expert trainers, frequent staff turnover, school closures, staff overload, and lack of program advocates in bullying prevention [19]. Challenges related to logistical problems, training requirements, and limited funding can negatively impact program adoption and sustainability [19].

Shifting to a Technology-Based Bullying Intervention

Technology-based interventions have the potential to improve access to programming and decrease implementation barriers experienced in rural communities [19]. Although some rural areas have higher rates of poor internet connectivity, eligible schools in rural communities can receive discounts for internet and broadband services [20]. Federal grants to build broadband infrastructure in rural areas are also available [21]. In addition, research conducted with key middle school personnel (ie, administrators, teachers, and school counselors) in rural communities indicates both a strong interest in technology-based bullying prevention programs and positive implementation conditions (eg, administrative support and technology readiness) [22]. Thus, most students in rural communities have access to the necessary infrastructure to support technology-based programs, and key personnel in rural middle schools indicate that schools are interested and ready for technology-based bullying interventions.

Although there is strong interest and need for online bullying prevention programming, very few US bullying prevention programs include a technology component. Programs that do offer it as an adjunct to in-person delivery [13]; often rely on simple texting, not multimedia interfaces; and they do not train student bystanders to intervene. For example, the Build Respect, Stop Bullying program for middle schools uses an online platform [23] but is part of a large program with staff or family components without bystander training. Other available technology programs include (1) an SMS text messaging program pairing youth with a “text buddy” [24]; (2) apps that encourage students to report cyberbullying, block websites attracting cyberbullying, and notify parents and school personnel of cyberbullying; and (3) online social media campaigns and educational resources (eg, videos, testimonies, and quizzes) [18,25,26]. Although there are programs that incorporate technology into bullying prevention and intervention, none appear to offer a route to a technology-based, interactive bystander training for middle school students.

XSL•FO
RenderX

The STAC Intervention

STAC [27] is a brief, stand-alone bystander intervention that includes didactic and experiential training followed by 2 booster sessions. The 75-minute didactic training includes education about bullying and cyberbullying, the consequences of bullying, and bystander roles and a description of the four STAC strategies: (1) "Stealing the show"—using humor or distraction to interrupt the bullying situation removing the attention away from the target, (2) "Turning it over"—informing an adult about the bullying and asking for help, (3) "Accompanying others"—befriending or providing support to the targeted student, and (4) "Coaching compassion"—gently confronting the perpetrator to increase empathy for the target. The experiential training comprises a series of role-plays during which students practice using the STAC strategies through bullying scenarios. The STAC training is followed by two 15-minute booster sessions to reinforce learning. The STAC intervention is effective in reducing bullying [28,29] as well as mental health risks for bystanders [30-34]. STAC has also been adapted to be culturally appropriate for middle school students in rural communities [35-37]. Research on the adapted STAC intervention demonstrates both bullying reduction [35,38] and improved mental health [35,39] among students trained in the program.

The Technology-Based STAC Intervention

The technology-based STAC intervention (STAC-T) is an online application developed to shift intervention delivery from in-person implementation to a technology-based format, thereby increasing accessibility and reducing barriers to intervention implementation. STAC-T is designed to be easily disseminated to large groups of students, who can access the intervention from a computer, tablet, or smartphone. In addition, the 40-minute STAC-T application is designed to be modular, increasing implementation flexibility. The initial training is followed by one 15-minute booster session designed to reinforce skill acquisition through virtual role-plays. The program is interactive, including knowledge checks, personalized feedback, and the selection of avatars to respond to bullying scenarios. Initial development included the design and testing of a STAC-T prototype. The design of STAC-T was developed based on the content of the in-person STAC intervention for rural middle schools as well as feedback from an expert advisory board and key middle school personnel in rural communities. In addition, students attending rural middle schools participated in 3 iterative focus groups, providing feedback on program usefulness, content, and functionality [40]. Once developed, the STAC-T prototype was evaluated through usability testing, which provided feedback from end users on program functioning [41]. The results from usability testing with key personnel and students from 2 rural middle schools indicated that the STAC-T prototype was easy to use, acceptable, and feasible, supporting the full-scale development of the STAC-T application [40].

This Study

Bullying is a significant public health concern for students attending rural schools [7-9]. Comprehensive bullying intervention programs that incorporate bystander interventions are the standard for practice [13]; however, they place a high demand on schools for implementation [17] and can contribute to disparities in rural schools [19-22]. STAC-T has the potential to reduce barriers and increase access to bullying prevention for middle school students in rural settings [40]. Therefore, the purpose of this study was to evaluate the usability and acceptability of the full-scale STAC-T application to determine readiness for a large, multisite randomized controlled trial to evaluate the efficacy of the STAC-T application for middle school students in rural communities. Usability testing is an important step in the process of intervention development as it predicts the likelihood of program adoption [42]. To achieve this aim, we implemented usability testing with key stakeholders (ie, school personnel and students) at 2 middle schools in rural communities in 2 states (N=21) using a mixed methods design. This study had the following objectives: (1) to assess usability and acceptability of the STAC-T application and (2) to assess differences in usability between school personnel and students.

Methods

Participants

Participants were key school personnel (ie, administrators, teachers, and school counselors; 10/21, 48%) and students (11/21, 52%) recruited from 2 middle schools in rural, low-income communities in the Northwestern and Southern regions of the United States. Between 5 and 10 usability testers are needed to identify most usability issues [43]. The schools were selected based on previous and ongoing research partnerships. The 2 schools were Title 1 schools, with 95% and 99% of the student population at the 2 schools eligible for reduced or free lunch. Among school personnel, the ages ranged from 26 to 55 years (mean 43.4, SD 9.8 years), and most (9/10, 90%) were female. School personnel self-reported ethnicity or racial background as White (5/10, 50%), Hispanic or Latino (3/10, 30%), and Black or African American (2/10, 20%). Among students, ages ranged from 11 to 15 years (mean 12.8, SD 1.3 years), with 36% (4/11) in grade 6, a total of 18% (2/11) in grade 7, and 45% (5/11) in grade 8. Students self-reported gender as female (6/11, 55%) and male (5/11, 45%). Students self-reported ethnicity or racial background as White (4/11, 36%), Black or African American (4/11, 36%), and Hispanic or Latino (3/11, 27%).

Development of the STAC-T Application

The translation from the STAC in-person intervention to STAC-T was guided by persuasive system design, a theoretical guide for translating clinical aims to health-related technology frameworks [44-46]. The STAC-T application was developed using Agile programming, a collaborative and incremental programming methodology [44-46]. The application was functional on all web browsers that support HTML5 and was built on a full-stack web application using HTML and JavaScript as the main interface. React.js was used as the front-end framework. The look and feel of the program were designed using Adobe Illustrator and Photoshop and developed using HTML elements plus SVG, PNG, JPG, WAV, MP4, and GIF images, audio, and video graphics. The system is accessible on desktop computers and iOS and Android tablets and smartphones. All design and programming elements were

XSL•FO
RenderX

aligned, and stakeholders' inputs were incorporated throughout the multistage development. Programmers produced the STAC-T application; alpha and beta tested it in-house for stability and code errors; tested it for usability; and revised it following an iterative, Agile production process.

In previous studies, as well as the in the iterative interviews and focus group conducted in this study, participants indicated that increasing program interactivity, adding more color, and including more realistic images such as avatars were important to increase engagement [40] and promote behavior change [47]. Therefore, design elements such as space (bright colors and visual space), components (realistic characters and familiar objects), and mechanics (actions reported by students that occur in rural middle schools) were established for the program features. In addition, STAC strategy practice was designed to require students to select an avatar, view bullying scenarios and select actions to operationalize the STAC strategy, view the avatar enacting the selected action, and receive feedback on its effectiveness. An artist hand illustrated and styled 6 avatars. The avatars had light-, medium-, and dark-colored hair in different styles as well as light, medium, and dark skin tones for students to choose from to best represent themselves and stimulate engagement. To reward learning and bolster adherence, "badges" (visual reward icons; eg, "Show Stealing Badge") were included as intermittent awards to encourage user engagement (Figure 1).

The STAC-T application content comprises three modules: (1) What is Bullying?—users are presented with background information on bullying, including bullying definitions (ie, physical, verbal, and relationship bullying as well as cyberbullying), bullying facts and statistics, characteristics of students who bully, and negative consequences of bullying; (2) What are Bystanders?—users are taught what a bystander is and how bystanders affect bullying outcomes (this module explains the 4 bystander roles: *assistants*, those who intentionally help the bully; *reinforcers*, those who are not directly involved in hurting another student but encourage the bully by standing around, laughing, or watching quietly; *outsiders*, those who do not take sides while witnessing bullying; and *defenders*, those who do something to stop the bullying situation or help the target in some way); and (3) STAC Strategies—users are introduced to the 4 STAC strategies, which are "Stealing the show," "Turning it over," "Accompanying others," and "Coaching compassion" (this module also includes STAC strategy practice using avatars selected by the user). The booster session includes additional practice with bullying scenarios and STAC strategy use.

Iterative interviews (15/21, 71% of the participants; 7/15, 47% female and 8/15, 53% male; 6/15, 40% White; 6/15, 40% Black or African American; 3/15, 20% Hispanic or Latino) and 2 rounds of iterative focus groups (20/21, 95%; 11/20, 55% female and 9/20, 45% male; 6/20, 30% White; 9/20, 45% Black or African American; 3/20, 15% Hispanic or Latino; 2/20, 10% other) conducted with middle school students attending schools in rural communities in 2 states informed program development before usability testing. Students participating in the interviews provided feedback on design aspects of the program, including color scheme, narration, and cartoons. Students were given a sample slide in 5 color schemes, 3 narrator voice samples, and 3 cartoon-style character depictions. Students were asked to rank a series of questions about each program aspect and then rank their preferences. Feedback and ranked choices were used to select color schemes, the narrator, and the program artist. Iterative focus groups were then conducted to gather feedback from students related to content and stylistic aspects of the program. Overall, the program was well received; students reported that the content was helpful and they liked the look and feel of the teacher who appears throughout the training. Students in the first round of focus groups provided specific feedback to incorporate more cyberbullying scenarios (eg, having bullies use their phones to record their peers without their knowledge), make the appearance of the characters more realistic (eg, changing clothing, adding eyes to all the characters, and changing hairstyles), and improve the function of the program to make navigation more user-friendly. Students also expressed disliking a particular activity, which was removed from the program. Students' feedback was incorporated into the program before conducting the second round of focus groups. The students in the second round of focus groups provided additional feedback about how to make the appearance of the characters more realistic (eg, adding emotion to the characters), as well as adding background images to make the scenarios look more like what they are used to seeing at school and school-related activities, such as sporting events (eg, adding teachers, lockers, wall hangings, and bulletin boards). They also provided specific feedback about how to make student behaviors more realistic (eg, having the target look sad instead of crying and changing the type of bullying from physical to verbal in front of adults). Input from the focus groups informed the development of the final STAC-T application used in this study.

Figure 1. Samples from the technology-based STAC application.

Procedures

Participant recruitment and usability testing occurred in 2024. The researchers provided the liaisons (eg, school counselor and principal) from each school with an email script describing the purpose and procedures of the study. Inclusion criteria for school personnel consisted of being employed as a principal, teacher, or school counselor at the partnering school; speaking English or Spanish; consenting to participate; and having a desire to make a positive difference in the school climate. For students, inclusion criteria consisted of being enrolled in the partnering school, speaking English or Spanish, having parental consent and student assent, and having a desire to make a positive difference in the school climate. To assess desire to make a positive difference, school liaisons were provided with rubrics developed by the research team to identify key school personnel and students who exhibited the following characteristics assessed by the rubric: caring for students; having a desire to be a positive influence on the school climate; being approachable to students; caring about addressing the problem of bullying; and having leadership qualities in the case of school personnel or leadership, maturity, responsibility, caring toward others, influence, and a desire to be a positive influence on their peers in the case of students. For each item, school personnel and students were assessed on a 3-point scale, which included the ratings of *yes*, *somewhat*, or *no* for each item described previously. School personnel and students who scored *yes* or *somewhat* on all inclusion criteria were eligible to participate. Exclusion criteria for the study for both school personnel and students included having participated in a previous STAC study, speaking a language other than English or Spanish, and not providing consent or assent to participate.

The school liaison used the inclusion and exclusion criteria and the rubric to identify and contact key school personnel and students and then used the script to invite them to participate in the study.

Similarly to our previous usability research [40], we conducted the usability testing and interviews remotely. Research supports remote usability testing as a viable approach to gather high-quality user experience feedback [48,49]. To mitigate technology-related problems, before the testing session, a team member worked with the school liaison to ensure that they could open and operate the program using the school's computers and firewall. When problems occurred during the testing session, participants switched to a different device or, in one case, rescheduled the testing session.

During the usability testing, participants were asked to review the entire STAC-T application, including the booster session. Participants were asked to talk aloud while completing the tasks, identifying problems and the solutions attempted. The researchers and users were on videoconference and shared their screens. The researchers could see what the participants were doing, and they were able to communicate with each other in real time. The researchers observed the users as they worked through the tasks and asked questions to gather more data. After completing the STAC-T application, participants were asked to complete a brief usability survey followed by a semistructured interview and then a demographic questionnaire. All participants were asked to provide information about their perceptions of (1) program utility, (2) relevance and appropriateness of program content, (3) ways in which they would improve the program, and (4) using a bullying and strategy use tracker after the training. School personnel were also asked about (1) their thoughts on implementation feasibility, (2) the likelihood of school program adoption, (3) their thoughts on companion trainings for teachers and parents, and (4) barriers to program use. All individual interviews lasted 1 hour and were video recorded.

XSL•FO
RenderX

Measures

Demographics

Participants self-reported their age, ethnicity or race, and gender. Students also reported their grade level.

Program Usability

Usability was assessed using the System Usability Scale (SUS) [50]. The SUS is a widely used 10-item validated tool that measures the usability and acceptability of technology-based programs. Responses are measured on a 5-point Likert scale ranging from 1 (*strongly disagree*) to 5 (*strongly agree*). To calculate the SUS score, responses are converted as follows: (1) for odd-numbered items, 1 is subtracted from the response; (2) for even-numbered items, 5 is subtracted from the response; (3) the converted responses are added; and (4) the total is multiplied by 2.5. The final SUS score ranges from 0 to 100. An SUS score of ≥68 is considered above average [51].

Program User-Friendliness

One item selected from previous usability research [40] was used to assess the user-friendliness of the program. Participants were asked to rate the user-friendliness through the following question—"Overall, I would rate the user-friendliness of this program as:"—using a 7-point scale ranging from 0 (*worst imaginable*) to 7 (*best imaginable*).

Program Satisfaction

In total, 2 items selected from previous usability research [40] were used to assess program satisfaction. Participants were asked the following question—"Would you tell your friends/colleagues to use the program?"—with *yes*, *no*, and *don't know* as response choices. Participants were also asked how many stars they would give the program (1 star being the lowest and 5 stars being the highest).

Interview Questions

Following usability testing sessions, participants were asked a series of open-ended questions about the utility and relevance of the application prototype, as well as ways to improve the application, likelihood of program use, and potential implementation barriers. School personnel and students were asked the following: (1) "Please talk about your perception of how useful this program could be to helping to address the problem of bullying at school," (2) "Please share your thoughts on whether you think the content of this program is relevant and appropriate for students at your school and your community," and (3) "Can you talk about ways that you would improve the program?" Students were also asked the following: "If your school asked you to continue using the tracker, would it be useful?" School personnel were also asked the following: (1) "What are your thoughts on how practical or workable you think it would be to use this program at your school?" (2) "What do you believe is the likelihood that your school would use this intervention?" (3) "Do you think an online, brief teacher training and parent training module would be a helpful addition to this program?" (4) "What, if anything, would keep you from using this program?" (5) "How would you envision using the tracker, if at all, after completing the training modules and the two boosters?"

Data Analysis

Quantitative Analysis

Quantitative data from the questionnaires were analyzed using SPSS (version 29.0; IBM Corp). Before conducting statistical analyses, we examined the data for missing data points. We found no missing data. The data were also examined for outliers, defined as >3.3 SDs above the mean [52]. We found no outliers. To ensure that continuous data met statistical assumptions for parametric statistical tests, we assessed acceptable normality by using established guidelines for examining skew and kurtosis [53]. All continuous variables were within the acceptable range for skew and kurtosis. Descriptive statistics were used and are presented separately for school personnel and students. We examined differences between school personnel and students using 2-tailed independent-sample *t* tests for continuous variables and chi-square analyses for categorical variables. All statistical assumptions were met for the *t* tests and chi-square analyses. We controlled for type I error using the Bonferroni correction. On the basis of the calculated Bonferroni correction, all analyses were considered significant at $P<.004$.

Qualitative Analysis

Qualitative data from open-ended questions were analyzed separately for school personnel and students. In total, 3 team members, 2 of whom conducted the usability tests, transcribed the data verbatim. We used consensual qualitative research as a framework for data analysis. We used thematic analysis [54,55] to identify, analyze, organize, describe, and report themes found within the qualitative data. A faculty member with expertise in qualitative data analysis, along with 2 graduate students, 1 PhD student and 1 masters of art in counseling student, with previous experience in qualitative data analysis, analyzed the data. The faculty member led the data analysis team. The team met 2 times via Zoom (Zoom Video Communications). During their first meeting, the faculty member discussed the analysis protocol with the 2 students, as well as expectations and biases that they needed to be aware of as they analyzed the data. Each team member analyzed the transcripts for the school personnel and students separately to arrive at initial themes for each open-ended question from the interview protocol. Next, the team met one more time via Zoom and conducted additional email communication over a 4-week period to arrive at a consensus on themes and frequency categories supported by participant quotations. During their meetings, the team members shared their themes for each question and discussed agreement or disagreement about themes. The analysts relied on participant quotes to resolve disagreements. Once the team members reached a consensus, an external auditor reviewed the interview transcripts and themes for the school personnel and students. The auditor agreed with the team's findings. Interview data were deidentified to ensure anonymity, and quotes were identified by participant type (ie, school personnel or students).

Ethical Considerations

This study was registered with ClinicalTrials.gov (NCT05572398). All research procedures were approved (101-SB21-205) by Boise State University's institutional review

XSL•FO
RenderX

board. Researchers obtained informed consent from school personnel and parental consent and student assent in the case of students. For students, school liaisons met briefly with potential participants identified through the inclusion criteria to explain the project, and interested students were sent home with a letter describing the project as well as an informed consent form for the parent or guardian to sign. English and Spanish translations were provided in schools with a large Hispanic student population. Parents were also emailed the information and consent form. Parents could choose to sign the consent form via pen and paper or electronically. If they did not provide consent electronically, students were asked to return the signed consent form to the school liaison. Parents were provided with the study principal investigator's contact information and were encouraged to contact her if they had any questions or concerns. Students who returned the signed consent form were then provided with an opportunity to assent immediately before the interview, focus group, or usability testing session. In addition, several steps were taken to protect confidentiality: participants were informed that they were free to refrain from answering any questions, all data were identified only by a personal identifier number, and all research team members completed required training in protection of human research participants. School personnel received a US $50 Amazon gift card as an incentive for participation in the usability testing and individual interview. There were no incentives for student participants.

Results

Quantitative Analysis

Program Usability

Usability scores on the SUS are presented in Table 1. Overall, scores for both school personnel and students suggested a very high level of usability, functionality, and acceptability. As shown in Table 1, there were no differences in the scores on any of the individual items or the SUS total score between school personnel and students, with both participant groups scoring the STAC-T application at a very high level of usability.

Table 1. Means and SDs of the System Usability Scale scores from school personnel and students[a].

	School personnel (n=10), mean (SD)	Students (n=11), mean (SD)	*t* test (*df*)	*P* value
"I think that I would like to use the program frequently."	4.60 (0.52)	4.18 (0.60)	–1.70 (19)	.11
"I found the program to be more complex than it needed to be."	1.20 (0.42)	1.64 (0.92)	1.37 (19)	.19
"I thought the program was easy to use."	4.90 (0.32)	4.91 (0.30)	0.07 (19)	.95
"I think that I would need the support of a technical person to be able to use this program."	1.10 (0.32)	1.36 (0.67)	1.13 (19)	.27
"I found the various functions in the program were well put together with each other."	4.40 (1.27)	4.55 (0.69)	0.33 (19)	.74
"I thought there was too much inconsistency in this program."	1.00 (0.00)	1.55 (1.04)	1.66 (19)	.11
"I imagine that most people would learn to use this program very quickly."	4.90 (0.32)	4.55 (0.82)	–1.28 (19)	.22
"I found the program very awkward to use."	1.00 (0.00)	1.18 (0.40)	1.42 (19)	.17
"I felt very sure that I could use the program correctly."	4.90 (0.32)	4.55 (0.69)	–1.49 (19)	.15
"I needed to learn a lot of things before I could get going with this program."	1.00 (0.00)	1.55 (0.93)	1.84 (19)	.08
System Usability Scale total score	96.00 (3.94)	88.64 (9.51)	–2.27 (19)	.04

[a]Responses were scored on a 5-point Likert scale ranging from 1 (*strongly disagree*) to 5 (*strongly agree*).

Program User Friendliness

School personnel and students rated the program highly on user-friendliness. Among school personnel, scores on user-friendliness ranged from 6.00 to 7.00 (mean 6.10, SD 0.32). Among students, scores on user-friendliness ranged from 6.00 to 7.00 (mean 6.09, SD 0.30). There were no differences in scores between school personnel and students on user-friendliness (t_{19}=–0.07; *P*=.95).

Program Satisfaction

Program satisfaction ratings are presented in Table 2. Overall ratings suggested that school personnel and students were satisfied with the program. There were no differences in scores between school personnel and students on program recommendation (χ^2_1=1.0; *P*=.33) or star ratings (χ^2_1=2.8; *P*=.25).

XSL•FO

Table 2. Program satisfaction results for school personnel and students.

	School personnel (n=10), n (%)	Students (n=11), n (%)
Would recommend the program		
Yes	10 (100)	10 (91)
No	0 (0)	0 (0)
Unsure	0 (0)	1 (9)
Star rating		
1 star	0 (0)	0 (0)
2 stars	0 (0)	0 (0)
3 stars	1 (10)	0 (0)
4 stars	5 (50)	3 (27)
5 stars	4 (40)	8 (73)

Qualitative Analysis

Overview

Qualitative feedback for the STAC-T application supported the quantitative findings and was very positive overall, with both school personnel and students sharing the perception that the STAC-T application is useful, relevant, and appropriate, as well as providing feedback on ways to improve the program. In addition, school personnel shared positive thoughts about program practicality and adoption, including interest in a teacher and parent training, and discussed barriers to program adoption. Both school personnel and students talked about the benefits of tracking students' reports of different types of bullying and strategies they used to intervene both as part of the program and as a stand-alone feature to be used after the training. The results are presented in the following sections organized by the following themes: (1) usefulness, (2) relevance and appropriateness, (3) program improvement, (4) program tracker, (5) practicality and adoption, (6) teacher and parent training, and (7) barriers.

Usefulness

All school personnel (10/10, 100%) and students (11/11, 100%) indicated that the program was useful and increased students' knowledge to intervene in bullying situations. For example, a school personnel member shared the following:

> *...the program that you guys are creating, will definitely inform the students what they need to look for, how they can become an active positive person.*

A student also stated the following:

> *I think it'll be helpful by telling other kids that it's not right to bully other kids because you don't know how they feel, and you don't know what they go through.*

In terms of increasing knowledge, a school personnel member indicated the following:

> *I like how it has all the different ways for the students to see how you can step in you know...that there's things they can do.*

Another one added the following:

> *...it gives students the tools that they might feel like they lack in general when bullying happens.*

A student stated the following:

> *It can teach ways on how to and when bullying is happening, how do we handle it, and make it stop quicker.*

Another student added the following:

> *...if people are making fun of a person about how they look or the way they eat, and they post a video on social media, I can like easily screenshot, show it to the principal, my teachers, to get these people to stop and like get them to stop the bullying.*

Relevance and Appropriateness

All school personnel (10/10, 100%) and students (11/11, 100%) reported that the program content was relevant and relatable and taught students empathy and prosocial attitudes. For example, one school personnel member shared the following:

> *I think the content was really relevant. It's things that you actually see at school or that you hear about or that we, that get actually reported.*

Another school personnel member added the following:

> *Oh yeah, absolutely. I think that they [students] can relate to cafeteria situations, getting on the bus and you know posting things especially you know on social media or on Instagram or TikTok or whatever.*

A student shared the following:

> *I think that is really, really relevant and I think that a lot of the situations that were used in this app as examples can be used. They can be real life situations.*

In terms of empathy and prosocial attitudes, a school personnel member said the following:

> *I think this program would help...teach more empathy cause when students have more empathy, they're less likely to exhibit those bullying behaviors.*

A student indicated the following:

XSL•FO
RenderX

It basically says that bullying is not okay and if you do see it here are a few ways on how to stop it.

Program Improvement

Both school personnel (9/10, 90%) and students (6/11, 55%) offered feedback on how to improve the program and talked about the importance of having the program be fully narrated. School personnel talked about ways to improve student engagement and user experience. For example, a school personnel member stated the following:

...making it so that all of the pop-ups and scenes are narrated.

A student also said the following:

Once you add that narrative it is going to be good because most middle schoolers they aren't going to want to read it.

In terms of improving engagement and user experience, a school personnel member said the following:

Just there was one [activity] where you had to click the arrows to move on and I feel like just making it a little bit more simple.

Another school personnel member added the following:

Slowing down the captions on the cartoons because to allow kids to see the picture to get a frame of mind of what's going on and then read the words.

Program Tracker

All the school personnel (10/10, 100%) and students (11/11, 100%) indicated that they would find using a bullying and strategy use tracker useful if their school asked them to continue to use it. When asked about how they would envision using the tracker, school personnel indicated that they would use it for data collection for programmatic feedback and prevention as well as ongoing teaching and student support. For example, when asked about the usefulness of the tracker, a school personnel member stated the following:

Yeah, you know, I think that would be good.

Another one added the following:

You can bring that data up and say, you know, you know, we're, we're seeing this type of bullying going on.

A student said the following:

Oh, yeah. Because it would let more people know that bullying has been going on and stuff.

Practicality and Adoption

All the school personnel (10/10, 100%) agreed that the program would be practical and workable, and almost all school personnel (9/10, 90%) stated that they would be likely to use the program at their school. For example, one school personnel member said the following:

...our students would definitely get on and be able to, you know, go through that program without any problems at all.

Another school personnel member stated the following:

Practical. I think that it addresses the needs of our students in their day-to-day interactions.

In terms of likelihood of use, one school personnel member stated the following:

I think it would be highly likely.

Another school personnel member added the following:

This will be helpful and they [schools] will use it because it wouldn't take too much time away from the academics, academic goals that we have.

Teacher and Parent Training Modules

All school personnel (10/10, 100%) reported that a brief online teacher and parent training would be useful, and almost all (9/10, 90%) stated that it would provide a common language and a means for future collaboration. For example, one school personnel member shared the following:

It's teaching the parents and the teachers what that looks like, you know, conversation or tools to help our kids.

Another school personnel member added the following:

Yes. Yes, so that you have this so that we're all working together as a team. And using that common language.

Barriers

When asked about barriers to using the program, most school personnel members (7/10, 70%) reiterated that they would use the program, but many of them (8/10, 80%) discussed barriers. For example, one school personnel member stated the following:

I can't think of one negative reason or one reason I wouldn't want to use it.

However, other school personnel identified potential barriers, with one member stating the following:

Not being accessible on the devices that the kids have available.

Another school personnel member said the following:

Time. But I don't see that as a factor for us because we could fit it into our advisory class.

A third school personnel member added the following:

Only thing I can think of is funding.

Discussion

Principal Findings

The purpose of this study was to examine the usability of the STAC-T application, a technology-based bystander bullying intervention designed specifically for middle schools in rural communities. We were interested in feedback from middle school personnel as they are in the position of making decisions related to adopting and implementing bullying interventions and from students as end users. The primary aim of this study was to test the usability of the STAC-T application and assess

XSL•FO
RenderX

program utility, user-friendliness, and relevance as well as feasibility and ways to improve the program. Overall, both the quantitative survey results and qualitative interview findings indicate that participants perceived the STAC-T application to be useful, user-friendly, and appropriate for students at their schools and reported high levels of satisfaction with the program. The findings of this study indicate that the STAC-T application is relevant and feasible for implementation in middle schools in rural communities. The quantitative and qualitative findings are consistent with our previous usability testing research [40].

The findings of this study provide support for the usability of the STAC-T application. Both school personnel (mean 96.0, SD 3.9) and student (mean 88.6, SD 9.5) scores on the SUS demonstrated a very high level of usability, exceeding the standard cutoff score of 68 [51]. Both school personnel and students also rated the user-friendliness of the STAC-T application as very high, with all participants rating the program at ≥6 on a scale ranging from 0 to 7. We found no differences between school personnel and students on SUS scores or user-friendliness ratings, suggesting that both groups of users found the STAC-T application to be highly usable. The qualitative data supported these results, with both school personnel and students indicating that they perceived the program to be useful as well as relevant and appropriate for middle school students in rural communities. Furthermore, both school personnel and students reported high levels of satisfaction with the program, with 100% (10/10) of school personnel and 91% (10/11) of students indicating that they would recommend the program to others. Furthermore, most participants (20/21, 95%) gave the program 4 or 5 stars on a scale ranging from 1 to 5 stars. These findings are particularly important as usability and acceptability are associated with both program adoption and implementation [42].

In terms of practicality and adoption of the intervention, school personnel believed that their school would be likely to use the STAC-T application and identified cost, time, and access as potential barriers. Our results are aligned with those of previous studies that indicate that school administrators in rural communities feel favorably about adopting and implementing online programs to address the problem of bullying [20]. In addition, our findings are similar to those of previous studies that identify cost [7,20], time [56], and access to technology [57] as notable barriers to online programming implementation in schools located in rural areas.

School personnel and students reported positive perceptions of the STAC-T program, as well as feedback for program improvement. The results of the qualitative analyses showed that both school personnel and students thought that the STAC-T content was relevant and relatable and increased students' knowledge of how to intervene in bullying situations. School personnel also stated that the program taught students empathy and prosocial attitudes. Furthermore, school personnel stated that the program was practical and workable and would be used at their school and that teacher and parent trainings would be useful additions to STAC-T to provide a common language among stakeholders. These findings suggest a need for bystander bullying intervention programs in rural schools that teach students how to intervene when they witness bullying behaviors through conducting role-plays to practice strategies across different bullying scenarios. In terms of program improvement, both school personnel and students highlighted the importance of having the entire program narrated to students. School personnel also talked about ways to improve user engagement by simplifying and slowing down a few program activities. Both students and school personnel also saw value in the posttraining tracker. Including these program modifications is likely to increase user engagement [40], which, in turn, can influence positive behavior change [47], potentially increasing the efficacy of STAC-T.

Limitations

This study supports the usability, relevance, and feasibility of the STAC-T prototype. However, certain limitations must be noted. Participants were recruited from 2 schools in rural, low-income areas from 2 states, one in the Northwestern region and one in the Southern region of the United States. Although participants were recruited from 2 different states to increase generalizability, school personnel and students from different regions of the country may have a different perspective. Future research including a broader geographic sample would increase generalizability. Furthermore, most of the school personnel participants in this study were female, further limiting the generalizability of the study. In addition, because of the small sample size, we were unable to explore differences in demographic factors, limiting information that could guide improvements to the STAC-T application. Finally, it is also possible that social desirability influenced participants as they were aware that the goal of the study was to translate the in-person STAC intervention to a technology-based format.

Implications

This study has important implications for the development and implementation of STAC-T in middle schools in rural communities. First, participants provided very high usability ratings for the STAC-T application, with qualitative data supporting the usability, utility, and relevance of the program. The findings also provided valuable information about the program itself, including the need for program narration and the utility of a type of bullying and strategy tracker that could be used after the training. School personnel also provided feedback about the importance of both teacher and parent modules to foster collaboration. These modules could be developed and offered to schools as companion modules for STAC-T. School personnel could provide teachers with the STAC-T teacher training during professional development time at school and provide parents with a link to the parent training via email. Training teachers, parents, and students could provide a common language and increase buy-in from all stakeholders [58,59]. In addition, participants indicated that program implementation is feasible as long as the program is cost-effective, brief, and students can access it on their school devices. Translating STAC from an in-person modality to an online platform can help decrease barriers to implementation, increasing implementation feasibility for rural schools by decreasing program costs and reducing the demand on schools by decreasing the need for staff training, in-class time, and

XSL•FO
RenderX

expert support. Overall, the findings of this study provide valuable feedback and a strong scientific premise for moving forward with a large, multisite randomized controlled trial to examine the efficacy of the STAC-T application.

Conclusions

Bullying is a significant public health concern for students in rural middle schools. Training students to intervene and developing programming that increases access are important factors in addressing this problem. The findings of this study demonstrate the usability, relevance, and feasibility of the STAC-T application. The preliminary data from this study support conducting a large, multisite randomized controlled trial to assess the efficacy of the STAC-T application for middle school students in rural communities. Technology-based bullying interventions, and STAC-T in particular, could be an instrumental approach to decreasing educational and mental health disparities in rural schools and helping address the problem of bullying.

Abstract

Background: Telemedicine has emerged rapidly as a novel and secure tool to deliver medical information and prescriptions. A secure, connected health care app (WiStim) has been developed in order to facilitate dialogue between patients and the medical team during an ovarian stimulation cycle for medically assisted reproduction (MAR).

Objective: This study aimed to evaluate the patients' and midwives' levels of satisfaction with the connected mobile app.

Methods: We conducted a prospective, observational, single-center study at Lille University Hospital, France. From May 1 to July 31, 2021, all women undergoing ovarian stimulation started to receive their treatment advice through the mobile app. A total of 184 women were included and they filled out the 30-item Usefulness Satisfaction and Ease-of-Use (USE) questionnaire, which examines the users' opinions in 4 dimensions: usefulness, ease of use, ease of learning, and satisfaction. The women also answered a series of closed and open questions. The 5 midwives in our assisted reproductive technology center filled out the French version of the 10-item System Usability Scale (SUS) when the app was implemented and then after 3 and 6 months of use. We also performed semistructured interviews with the midwives.

Results: Overall, 183 women using the app completed the questionnaire. None refused to use the app, and 1 withdrew from the study. The mean scores for the four USE dimensions were all significantly greater than 4, that is, the middle of the response scale. The women liked the app's ease of use, the access to tutorial videos, and the reminders about appointments and treatments. In particular, the women liked to be able to (re)read the information; this reassured them, might have reduced the number of missed appointments and treatments, and made them more independent during the day, especially when they were working. Some of the women regretted the loss of direct contact with the midwife. The mean SUS score was 76 (SD 13.54) at the start of the study, 75 (SD 17.16) after 3 months, and 84 (11.21) after 6 months. According to the adjective rating scale, these scores corresponded to good usability for the app. After the requisite training and a familiarization period, the midwives reported that using the app saved them 2 hours a day. The mobile app enabled better transmission of information and thus probably helped to decrease treatment errors.

Conclusions: The WiStim connected mobile app is one of the first reliable, secure apps in the field of MAR. The app reassured the patients during the ovarian stimulation. Women and the medical team considered that the app was easy and intuitive to use. Given the growth in demand for MAR programs and the medical team's workload, the time savings provided by the app constitute a nonnegligible advantage.

Introduction

In 2018, the European Society of Human Reproduction and Embryology's 22nd report on medically assisted reproduction (MAR) in Europe highlighted a continuous increase in the number of treatment cycles and the broad range of techniques used [1].

Every day, around the world, thousands of women undergo hormone assays and ultrasound scans of the pelvis as part of their MAR program. These burdensome, complex procedures can generate stress and anxiety for the women and their partners [2-4]. The women consulting in MAR departments are young, active, and, in many cases, occupied by work and family activities. Furthermore, health care professionals have to deal with a growing administrative burden and increasing demand for MAR while still providing high-quality patient care and support.

A large number of "eHealth" smartphone apps are being developed [5-8]. WiStim is a secure mobile app created in 2016 to facilitate communication between MAR patients and medical teams. The app provides access to a variety of documents and media (eg, test results and tutorials on self-injection) and gives daily advice on treatment during the ovarian stimulation phase. The objectives are (1) secure communication with patients, (2) better traceability, (3) a lower frequency of treatment errors caused by poor understanding, and (4) time savings for the care team. At present, the patient has to pay a subscription fee; however, some hospitals are considering whether to subsidize or cover this fee.

During each in vitro fertilization, frozen embryo transfer, or intrauterine insemination cycle, the midwife calls the women daily in order to adjust the treatment, check on adherence, and answer any questions. These calls are time-consuming and can be replaced with a connected app.

The primary objective of the current study was to evaluate levels of satisfaction with the connected app, according to both the patients and health care professionals. The secondary objectives were to identify potential difficulties in the use of the app and to study any app-associated changes in the health care professionals' practices and work organization.

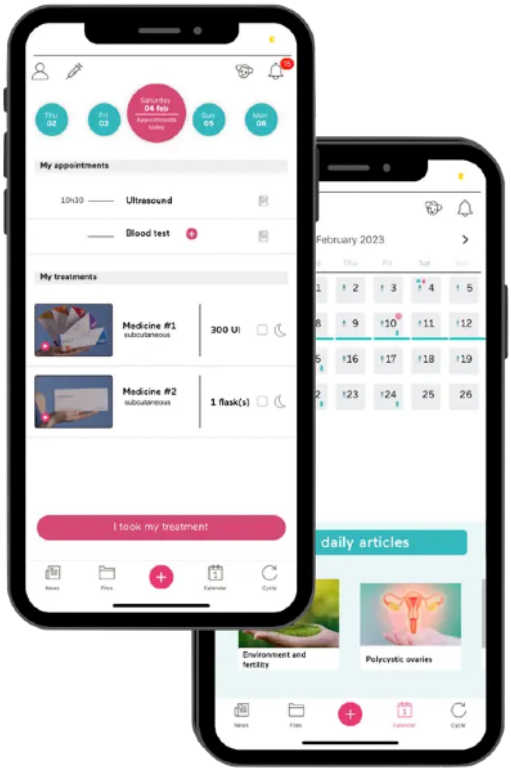
Methods

Overview

We conducted a prospective, observational, single-center study in the MAR department at Lille University Hospital (Lille, France) from May 1 to July 31, 2021.

Ethical Considerations

In line with the French legislation on human and social science surveys of routine clinical practice using anonymized personal data [9], approval by an independent ethics committee was neither required nor sought.



Connected Mobile App

The WiStim platform includes a mobile app for the patient (Figure 1) and a web-based management module for the medical team. The mobile app gives the patient access to advice on treatment, including the dose, the administration route, and any changes in the regimen. Tutorials on self-injections are also available. Every evening, the patient receives a reminder about her treatment and the date of her next appointment. The medical team sends information about the treatment and the next appointment through a secure web server (accredited by the French Ministry of Health) and is informed in real time about the woman's treatment.

The app requires a monthly subscription. However, Lille University Hospital has chosen to pay this cost on the patient's behalf during an initial test year.

XSL•FO

Figure 1. The mobile app for the patient.

Patients

During a consultation, the gynecologist explained the app's principles to the patient and gave the latter an information sheet explaining how to download, install, and use the app. The patient then installed the app on her mobile phone and created an account. Once the stimulation phase had started, the patient received treatment advice through the app.

At the end of the MAR procedure, the women filled out a questionnaire (Multimedia Appendix 1). The questionnaire's closed questions concerned the type of MAR and the impact of using the app. The patient was able to write a comment for each closed question. Several open questions probed the woman's opinion of the app and the app's strengths and weaknesses. Next, the woman filled out the 30-item Usefulness Satisfaction and Ease-of-Use (USE) questionnaire, which measures the user's feelings in four dimensions: usefulness, ease of use, ease of learning, and satisfaction (Multimedia Appendix 2) [10,11]. The participants were not paid for their participation in the study.

Midwives

The five midwives in our MAR center filled out the French version of the System Usability Scale (SUS) when the app was implemented and then after 3 and 6 months of use [12]. The SUS (Multimedia Appendix 3) is a standardized, 10-item questionnaire for assessing the level of satisfaction with a technology's usability. For each of the 10 items, the midwives were invited to rate their level of agreement on a 5-point Likert scale ranging from "strongly disagree" to "strongly agree." We also performed semistructured interviews with the midwives 6 months after the implementation of the app in order to evaluate their opinion of the connected app, identify any changes in their work organization, and assess the app's acceptability (as defined in the unified theory of acceptance and use of technology [UTAUT]) [13]. The interviews were audio-recorded and transcribed.

Statistical Analyses

Statistical analyses were performed using Jamovi software (Jonathon Love, Damian Dropmann, and Ravi Selker, version 2.2.5, 2021), and thematic analyses of qualitative data were performed using QualCoder 3.0 (C Curtain). Data on the women's characteristics were used to describe the sample and perform subgroup analyses. The women's answers to the closed questions were analyzed using descriptive statistics, and the comments were analyzed qualitatively in order to highlight recurrent themes. Emerging themes in the qualitative analyses were not quantified; the goal was to understand the variety of the user's points of view. The data on the USE items and dimensions were analyzed with descriptive and inferential statistics. The threshold for statistical significance was set to $P<.05$. The results of the various questionnaires were compared in order to identify similarities and differences between the answers.

The SUS satisfaction score ranges from 1 to 100. Perceived satisfaction and usability are considered to be good when a score of 75 or more is obtained. To qualify the level of satisfaction, the mean SUS score was assessed against Aaron et al [14] grade scale and adjective rating scale. Semantic units (ie, sets of words representing the same idea) were extracted from the interviews with the midwives. An ergonomist attributed each semantic unit to one of the following themes: the opinion of the app, changes in practice, and dimensions of UTAUT acceptability (facilitating conditions, effort expectancy, social influence, and performance

XSL•FO
RenderX

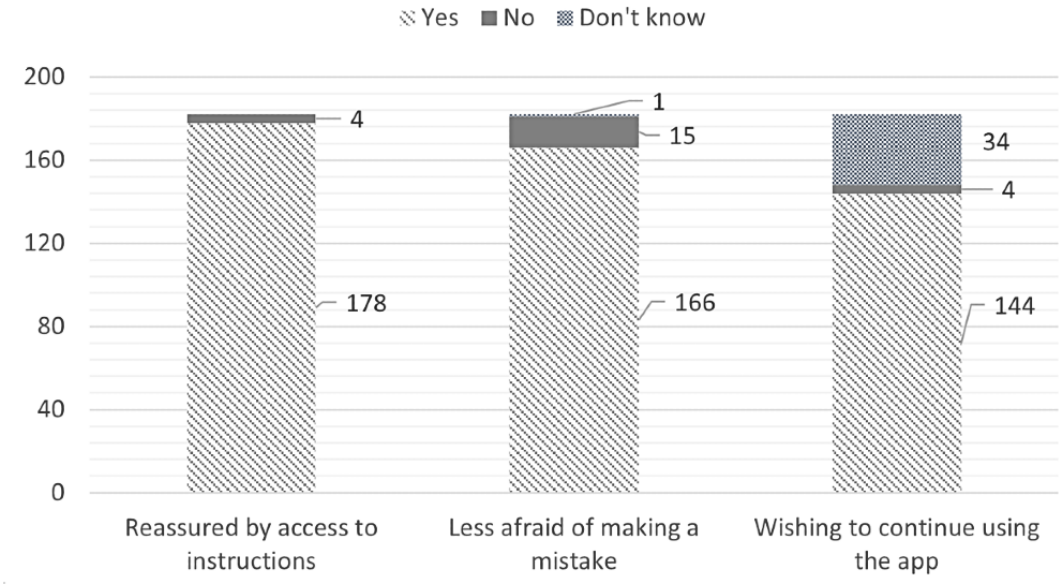
expectancy). Within each theme, several subthemes were developed to represent the semantic units' diversity.

Results

Patients

Overview

During the recruitment period, 250 paper questionnaires were randomly distributed, and 184 patients responded (intrauterine insemination: 12%, in vitro fertilization: 73%, egg donation: 2%, frozen-thawed embryo transfer: 9%, fertility preservation: 4%). A total of 91 respondents had already been followed up by phone before the implementation of the app, 90 were monitored with the connected app alone, and 3 did not answer this item in the questionnaire. One woman discontinued use of the app prematurely, preferring direct contact with a midwife, and 2 women failed to complete the USE questionnaire.



The mean scores for the four USE dimensions were all significantly greater than 4, that is, the middle of the response scale (usefulness, n=5.66, t_{180}=13.4, P<.001; ease of learning, n=6.25, t_{178}=18, P<.001; ease of use, n=5.96, t_{180}=16, P<.001; satisfaction, n=5.90, t_{177}=15.4, P<.001). The scores did not appear to be influenced by whether or not the women had been followed up by phone before the use of the app.

This good level of perceived usability was corroborated by our analysis of the women's comments and answers to the open questions. In all, 172 women described what they liked about the app. The app was seen as being easy to use in a guided, stepwise manner ("simple to use," "intuitive," and "clear"). Another reason for liking the app was its match with the women's needs and activities. The women mentioned the gain in efficiency linked to the app's centralization of information on treatment, follow-up, and appointments.

A total of 178 (97.8%) of the 182 respondents considered that the ability to access advice through the app was reassuring (Figure 2). The participants, having initially been followed up by phone, stated that they felt surer about the advice with the app because the instructions had to be rapidly written down during the phone call; with the app, the advice was available round the clock. The women also liked the additional information (eg, how to perform an injection) and the automatic reminders about appointments and treatments. A total of 166 (91.7%) of the 181 respondents considered that with the app, they were less stressed about making a treatment mistake. The participants liked the independence that the app provided; they no longer had to wait for the phone call from the midwife; previously, the call could come at any time in the afternoon.

Overall, 34 women did not reply to the question about wanting to continue to use the connected mobile app or not. 97.3% of the respondents said that they would be annoyed if they had to stop using the app (Figure 2). The 4 participants, who said they would feel relieved if they had to stop using the app, had all initially been followed up by phone and preferred direct communication with the medical team.

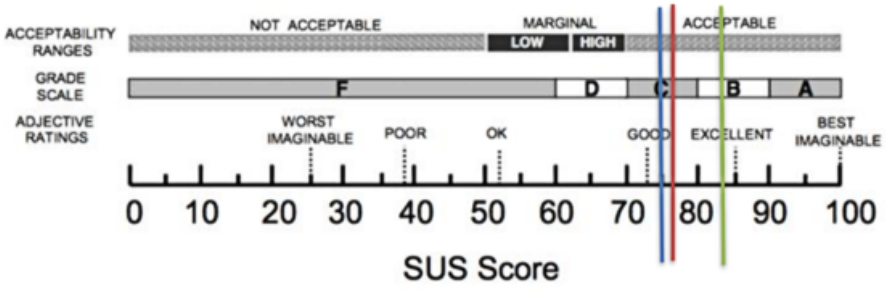
Figure 2. Answers to the following closed questions: "Does access to advice in the mobile app reassure you?" "Have you felt less stressed since you starting using the mobile app?" "Would you like to continue using the mobile app?".

Some weaknesses were mentioned: appointment errors, the lack of tutorials about some older models of self-injector pens, and late treatment reminders (ie, given after the scheduled time). Certain women expressed the need for direct interaction with the team of midwives via a chat function; the MAR department had decided not to offer this function because the women had already been given an email address for any questions.

A total of 53 (58.2%) of the 91 women who had initially been followed up by phone did not perceive any change in how they managed their treatment since the implementation of the app. In contrast, 38 (41.7%) women stated that the app modified the management of their treatment; they highlighted the lower mental burden, the easy, permanent access to information, the reassuring nature of the treatment reminders and app reminders,

XSL•FO
RenderX

and the fact their day no longer had to be organized around the call from the midwife.



Midwives

The five midwives working in the MAR department at the time of the study filled out the SUS and were interviewed. The mean age was 43.6, and the midwives had been working in the department for an average of 6 years. The mean SUS score was 76 at the start of the study (n=4 respondents), 75 after 3 months (n=5), and 84 after 6 months (n=4; Figure 3). According to Aaron et al [14] adjective rating scale, these scores corresponded to good usability for the app.

A total of 207 semantic units were extracted from the semistructured interviews and analyzed. Even though the midwives stated that they needed some time to learn how to use the app and that the use of the app reduced the level of human contact with the women, they were generally very satisfied. The midwives found the interface pleasant to use and considered that the app was useful for the women and for the nurses who visited the women at home on a routine basis; the app modernized the midwives' practices.

During the interviews with the midwives, 3 of the 4 UTAUT dimensions emerged: facilitating conditions, effort expectancy, and performance expectancy. The social influence dimension did not emerge.

Figure 3. The mean System Usability Scale (SUS) score at the start of the study (76, SD 13.54) and after 3 months (75, SD 17.16) and 6 months (84, SD 11.21).

Facilitating Conditions

The midwives said that for the installation of the app, some IT equipment (computers) had been purchased and that they had attended training sessions on the use of the app. The midwives emphasized the good availability and responsiveness of the WiStim team when questions arose.

Effort Expectancy

The midwives viewed the app as a rather simple-to-use tool once they had been trained in its use. The app's different functions enable them to consult the patients' data, communicate with them, plan their appointments, and monitor their adherence to treatment.

Given that the app had not been integrated into the hospital information system at the time of the study, the midwives could not enter appointments into the hospital information system's diary from the app or vice versa; hence, to make appointments, they had to work on two IT tools in parallel. Even though the app had a simple-to-use interface, the fact that it was a web-based tool meant that the transitions were sometimes slow. Hence, data sometimes had to be entered twice: once on paper and then on the app.

Performance Expectancy

Use of the app was associated with a fall in the number of daily calls from midwives to patients. Nevertheless, the midwives continued to phone the women when the medical team had decided to stop the treatment or when the women had not ticked the boxes for adherence to treatment. This enabled them to optimize the dialogue by phone. Certain women continued to call or email the midwives regardless, to check that they had correctly understood the treatment procedures and advice specified by the app or to change an appointment. The midwives replied to these questions by email or by phone. The frequency of these requests tended to fall over time, as the midwives and the patients became more familiar with the app.

In order to ensure that the women were using the app correctly, the midwives helped some of them (especially those who did not understand or speak French sufficiently well) to install the app and explained how to use it. Furthermore, the advice stored in the app can be presented in several languages.

The decrease in the number of phone calls freed up an average of 2 hours per day, which enabled the midwives to perform other tasks (consultations, patient education sessions, etc).

Discussion

Principal Findings

On an annual basis, our center performs around 1400 oocyte retrieval procedures, 900 frozen embryo transfers, and 700 intrauterine inseminations. This corresponds to 30 to 50 women per day seen for ultrasound scans and hormone assays, and the volume of activity is increasing. Until now in France, MAR has only been available to heterosexual couples on medical indication. The law on bioethics, to be promulgated in 2021, extends MAR to female couples and single women. Activity in MAR centers has therefore risen sharply. Use of the connected mobile app was associated with a considerable decrease in the number of phone calls during the day. This resulted in significant time savings for the medical team, who were therefore able to perform other tasks. The women received their treatment advice in a secure manner, which had not been the case previously. The women felt reassured and less stressed about making treatment mistakes.

XSL•FO
RenderX

We did not question the partners, but in the open-ended questions, some of them said that they were reassured to be able to read the treatment instructions and felt more involved in the care compared with the phone call.

At present, it is difficult to quantify the extent of treatment errors during an ovarian stimulation program. Till date, no study has been published in the literature on this subject. Nevertheless, along with the treatment reminders, the fact that the woman's prescription is given in writing in the app and can be accessed at any time (and in several languages, if required) probably helped to reduce forgetfulness and treatment administration errors. This traceability is essential for secure communication between patients and professionals. Barrière et al [15] conducted an observational, real-life, longitudinal study involving 488 patients from 28 infertility centers in France to evaluate patient–infertility care provider relationships and communication in Assisted Reproductive Technology centers and investigate whether the quality of the care provided had an impact on patient adherence to treatment and monitoring protocols. They showed that even when patient-physician relationships appear to be satisfactory, patient miscomprehension and noncompliance during infertility treatment may be underestimated, and improvements in communication are also required.

Several studies [16,17] and reviews of the literature [18-20] have shown that stress is a major risk factor for impaired quality of life and a poor experience of infertility treatment. It also exposes patients to the risk of abandoning assisted reproduction procedures, thereby reducing their chances of pregnancy. It is therefore conceivable that mobile apps can reassure patients undergoing infertility treatments and consequently reduce the stress inherent in these procedures, as suggested in a recent review [21]. Further studies using standardized questionnaires and comparing the anxiety levels of the app users with those of nonusers could answer this hypothesis. The risk of dropping out of infertility management procedures could also be compared between these two groups.

Over the last decade, huge progress has been made in information and communication technology. "eHealth" and smart (connected) devices have brought together services that facilitate communication with the patient and thus improve the overall quality of care (teleconsultations, electronic health records, smart eHealth apps, etc) [22]. Telemedicine enables medical data to be shared with the patient or between health care professionals. Many connected health apps have been developed – notably in the fields of radiology and cardiology [23]. A recent study showed that connected health technologies can facilitate access to cancer care and improve the patient's psychological well-being and quality of life [24]. Recently, connected apps have been developed for use in gynecology and obstetrics [25]. There are probably other connected apps in the world in the field of fertility, but to date and to our knowledge, there are very few publications on this subject. Boivin et al [26] were interested in the development of a mobile app (MediEmo) to provide support during medically assisted reproduction. MediEmo is an app combining patient medication diary management and ease of integration into clinic systems with emotional support and data capture. They showed that 98% of patients expressed willingness to use the app, and almost 80% did so. Thus, the development of smartphone apps can contribute to fertility care and should be encouraged.

The profile of women in MAR programs is particularly suitable for this type of development: they are young and active and they all use a smartphone.

The protection of the patients' personal data is a crucial aspect in the development of connected health technologies [27,28]. WiStim complies with the European Union's General Data Protection Regulation, and the app's host is accredited by the French Ministry of Health.

One limitation is that the app is currently fee-based, although various funding options are being considered. In the present case, our hospital paid for the subscription to the app, and so it was cost-free for the users. However, the hospital's finance department is currently carrying out a medical-economic survey to assess the profitability of financing the app in relation to the time saved by the midwives. In fact, the midwife who used to call patients back can now do consultations instead.

Another limitation is the relatively small number of questionnaires analyzed and the fact that this was a single-center study. These are preliminary results, and they pave the way for further investigations in a larger population. Indeed, a multicenter study, with more questionnaires and over a longer period would be desirable to confirm these data.

Moreover, the questionnaires were distributed as soon as the app was installed in the department, so a learning curve was necessary for both patients and professionals. Overall satisfaction is probably higher now that the tool is better understood. Till now, all our patients have used the app.

Conclusion

Our results showed that the use of the connected health care app reassured women during the ovarian stimulation phase of a MAR program. Both the women and the medical team considered that the app was easy and intuitive to use. The information on treatment was sent in a secure manner and could be accessed around the clock by the patient. Connected health care apps have been developed widely in recent years. WiStim is one of the first reliable, secure apps in the field of MAR. Given the growth in demand for the MAR program and the medical team's workload, the time savings provided by the app constitute a nonnegligible advantage.

Abstract

Background: Symptoms of insomnia, nightmares, and trauma are highly prevalent. However, there are significant barriers to accessing evidence-based treatments for these conditions, leading to poor mental health outcomes.

Objective: This pilot trial evaluated the feasibility of a 4-week, digital self-paced intervention combining cognitive behavioral therapy for insomnia and exposure, relaxation, and rescripting therapy for nightmares in survivors of wildfires from Australia, Canada, and the United States.

Methods: Study participants were recruited between May 2023 and December 2023 through social media platforms, workshops, conferences, and radio interviews. Participants had to meet at least one of the following criteria: a score of ≥8 on the Insomnia Severity Index, a score of ≥3 on the Nightmare Disorder Index, or a score of ≥31 on the PTSD Checklist for DSM-5. In total, 30 survivors of wildfires were allocated to either the treatment group (n=16, 53%) or the waitlist control group (n=14, 47%) in a sequential manner. Participants' ages ranged from 18 to 79 years, with a mean age of 52.50 (SD 16.26) years. The cohort consisted of 63% (19/30) female and 37% (11/30) male participants. Participants also completed self-report secondary outcome measures, including the Generalized Anxiety Disorder–7, the Patient Health Questionnaire–9, and the Pittsburgh Sleep Quality Index, via the HealthZone digital platform. Assessments were conducted at baseline, the posttreatment time point, and the 3-month follow-up, with the waitlist group undergoing an additional assessment at the pretreatment time point, after 4 weeks of waiting and before crossing over to treatment. This study used intention-to-treat analysis as a primary analysis and per-protocol analysis as a secondary analysis.

Results: Mixed-effects linear regression models and difference-in-differences analyses were used to assess the intervention's effects. The intention-to-treat analysis revealed significant improvements over time (main effect of time), with a 1.64-point reduction (P=.001) on the Nightmare Disorder Index and 10.64-point reduction (P=.009) on the PTSD Checklist for DSM-5 at the postintervention time point. No significant changes were observed in insomnia symptoms. On the secondary measures, there was an interaction effect of condition × time, with a 2.22-point reduction (P<.001) on the Pittsburgh Sleep Quality Index, and a main effect of time, with a 6.48-point reduction (P<.001) on the Patient Health Questionnaire–9. No changes were detected on

XSL•FO
RenderX

the Generalized Anxiety Disorder–7. The per-protocol analysis yielded comparable results for both the primary and secondary measures.

Conclusions: The findings of this pilot trial demonstrated a reduction in nightmares and trauma symptoms. Future research studies should aim at evaluating the intervention in a more definitive trial with a larger sample size.

Introduction

Background

The consequences of wildfires can be devastating, resulting in significant losses of life, property, and livelihood. According to the Emergency Events Database, wildfires have been responsible for 1890 fatalities and 14,360 injuries between 2000 and 2023, with the highest tolls observed in Australia, New Zealand, Southern Europe, and North America [1]. The impact of wildfires extends far beyond the immediate loss of life and property, with survivors often experiencing a range of physical and emotional challenges that can have long-lasting effects. Physical injuries, such as bodily burns, smoke inhalation, and eye irritation, as well as increased risk of myocardial infarction and certain types of cancers, are a significant concern for survivors [2-4]. In addition, the proximity of wildfires to residential areas can have a profound impact on overall well-being, with research showing that life satisfaction decreases significantly in areas within 0 to 15 km of the fires [5]. The traumatic experience of a wildfire can also leave a lasting emotional impact, with survivors often reporting persistent feelings of fear and unsafety that can linger long after the initial event [5].

Beyond the physical and emotional challenges, many survivors face significant financial pressures, including the cost of rebuilding or relocating. For those who have lost their homes, the decision of whether to rebuild can be a difficult and emotional one, with financial pressures and the loss of a sense of security and community adding to the burden [3]. Others may experience stressors related to the loss of a workplace, hardship, and financial uncertainty. Therefore, the availability and timing of government relief and community support services are critical in facilitating the recovery of communities and individuals, with initiatives such as rehousing and recovery projects, psychological support, and primary producer repair and restoration [3,5] helping mitigate the impact of wildfires. However, when such support is not provided in a timely manner, emotional and psychological distress can intensify, leading to multiple psychological problems that can become highly resistant to treatment.

This is particularly concerning as research has shown that exposure to wildfires can have a significant impact on emotional well-being. Over the past decade, there has been a growing interest in investigating the impact of wildfire trauma on mental health [6,7]. Posttraumatic stress disorder (PTSD) is among the more severe mental health conditions that may arise immediately or in the months following exposure to traumatic events [7]. Exposure to wildfires, which pose a significant threat to life or well-being, can increase an individual's risk of developing PTSD. People with PTSD may exhibit symptoms such as reliving traumatic events through nightmares or flashbacks; sleeping difficulties; irritability; intrusive memories; feelings of horror, shame, and anger; avoidance of reminders of the traumatic event; alterations in arousal state or mood and cognition; and difficulties with work and daily activities [8].

Sleep disturbances are prominent features of PTSD and are frequently reported following trauma [9,10]. The onset of sleep disturbances following exposure to traumatic events is a strong predictor of the development of PTSD [11]. According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*), insomnia and nightmares fall under the re-experiencing and the hyperarousal clusters of PTSD symptoms [8]. Insomnia is the most prevalent sleep disturbance in survivors of wildfires and is characterized by difficulty initiating or maintaining sleep or early-morning awakening [8]. Survivors of trauma also frequently experience nightmares, which are repeated distressing and well-remembered narrative dreams that lead to the individual waking up in a fight-flight state of alertness and having difficulty returning to sleep or even trying to avoid sleeping [8]. A study examining sleep disturbances and PTSD in survivors of wildfires revealed that approximately 49.2% (n=126) experienced symptoms of insomnia, 28.7% experienced nightmares, and 77.9% reported PTSD symptoms [12].

Studies suggest that cognitive behavioral therapy for insomnia (CBTi); cognitive behavioral therapy (CBT) for PTSD; and exposure, relaxation, and rescripting therapy (ERRT) for nightmares are effective treatments for insomnia, nightmares, and other trauma symptoms [13-18]. CBTi includes stimulus control, sleep hygiene, sleep restriction, cognitive restructuring, and relaxation training [19,20]. Nightmare treatment using ERRT is effective in giving those who experience nightmares a sense of control over the nightmare through writing benign dreams that can be rehearsed verbally or mentally [21]. The treatment focuses on addressing the themes presented in the nightmare and incorporates rescripting, imagery or verbal rehearsal, relaxation, and sleep hygiene elements [22,23].

XSL•FO
RenderX

Most research on trauma and sleep disorders has been conducted with military veterans, who have been the primary focus of clinical trials and studies in this area [24-26]. There is a need to focus on developing treatments for people who have experienced the trauma of natural disasters, including wildfires. There have only been 2 clinical trials addressing the treatment of sleep disturbances and PTSD in survivors of wildfires [27,28]. Both trials have shown that the administration of sleep dynamic therapy and CBTi therapist-assisted self-help interventions led to a significant reduction in insomnia and PTSD symptoms following treatment.

Objectives

While studies support the effectiveness of CBT, CBTi, and ERRT in treating trauma symptoms, insomnia, and nightmares, accessing these treatments can be challenging, particularly when wildfires cause destruction to infrastructure. This, in turn, causes difficulty in the delivery of counseling services to remote locations where large numbers of people are affected and in great need. Digital therapies can bridge this gap by delivering evidence-based treatments in communities affected by the trauma of wildfires [29,30]. However, the feasibility of digital therapies should be first examined in clinical trials before they are operationalized in the field [27,31]. Therefore, a brief, digital, self-paced, multicomponent therapeutic approach incorporating CBTi for insomnia, CBT for PTSD, and ERRT for nightmares was developed. The main objective of this pilot trial was to assess the feasibility of an intervention called Sleep Best-i in alleviating symptoms of insomnia, nightmares, and PTSD among survivors of wildfires. A secondary research objective was to undertake a comparative analysis of the degree of symptom reduction between the intervention and the waitlist control groups, with a view to informing an assessment of the feasibility of conducting a future definitive randomized controlled trial. Specifically, this assessment aimed to evaluate the acceptability and usability of the Sleep Best-i intervention. This clinical pilot trial tested the following hypotheses: (1) Sleep Best-i will result in significant reductions in insomnia, nightmares, and PTSD symptoms from baseline to the posttreatment time point compared to the waitlist group; (2) Sleep Best-i will also lead to significant reductions in anxiety and depression scores and improvements in sleep quality from baseline to the posttreatment time point compared to the waitlist group; and (3) both groups (within-group effects) will experience significant improvements in all measures (insomnia, nightmares, PTSD symptoms, anxiety, depression, and sleep quality) from baseline to the posttreatment time point, and these improvements will be maintained at the 3-month follow-up after receiving Sleep Best-i.

Methods

Study Design

This study used a parallel-arm, sequential alternation method of randomizing participants to either the intervention or waitlist group in a 50:50 ratio, with a crossover of the latter group. The alternation method ensures the ability to answer questions about the effectiveness of treatments to inform decision-making in clinical practice [32]. The treatment group completed self-report assessments at baseline, at the posttreatment time point following the administration of Sleep Best-i, and at the 3-month follow-up. The waitlist group completed the same assessments at baseline, at the pretreatment time point (following 4 weeks of waiting and before crossing over to treatment), at the posttreatment time point following the administration of Sleep Best-i, and at the 3-month follow-up. The CONSORT (Consolidated Standards of Reporting Trials) checklist was followed [33]. Please refer to Appendix 1 for the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist (Multimedia Appendix 1).

Ethical Considerations

Following ethics approval from the Federation University Human Research Ethics Committee (approval 2022-153), an advertisement about the study was distributed. Survivors of wildfires interested in the study read a plain-language information statement (PLIS) about the study and provided baseline data. Participants who met the selection criteria provided informed consent by checking a box on a digital consent form hosted on Federation University's HealthZone platform, thereby indicating their agreement to take part in the study. Participants were informed that their participation was voluntary. To ensure the secure storage and handling of collected information, data were stored on a password-protected digital health platform (HealthZone) during the trial accessible only to the researchers involved in the study. To protect participants' confidentiality, names were replaced with unique identifiers, and only country of residence was collected, with no addresses recorded. The data will be retained for 15 years before being destroyed. To manage any potential risks, participants were provided with emergency contact numbers relevant to their country of residence. As a gesture of appreciation, participants who completed the study were offered an Aus $100 e-voucher (approximately US $66.70).

Participants

Participants were recruited between May 2023 and December 2023 via social media platforms, including international Facebook campaigns, radio broadcasts, LinkedIn, Reddit, and online community noticeboards. This study was also advertised on the Natural Hazards Research Australia and the Australian Institute for Disaster Resilience websites.

Adult survivors of wildfires from Australia, Canada, and the United States aged ≥18 years were invited to take part in the clinical pilot trial if they had experienced wildfires at any point in the past and had sleep or trauma symptoms.

An a priori power analysis indicated that a sample size of 50 was required to detect meaningful differences between the intervention and waitlist groups considering an α value of .05, a value of *d* of 1.0, an attrition rate of 20%, and 80% power [34].

Inclusion Criteria

To be eligible to take part in the trial, participants had to (1) provide digital consent; (2) have a score of ≥8 on the Insomnia Severity Index (ISI), (3) a score of ≥3 on the Nightmare Disorder

XSL•FO
RenderX

Index (NDI), or (4) a score of ≥31 on the PTSD Checklist for DSM-5 (PCL-5); (5) be fluent in the English language; and (6) have access to the internet. Exclusion criteria included not being a survivor of a wildfire, diagnosis of a psychotic disorder, suicide risk, diagnosis of sleep apnea or restless leg syndrome, diagnosis of alcohol or drug dependence, and attendance to psychotherapy for either sleep or PTSD conditions. In addition, participants were excluded if they were currently using steroids for any health condition; medications that promote sleep, such as benzodiazepines (eg, alprazolam, clonazepam, and temazepam); or medications that may affect sleep, such as opiates or other pain medications. By excluding these individuals, this study aimed to ensure that participants were suitable for the trial and that the results would not be confounded by other factors.

Procedure

The trial was registered prospectively in the Australian New Zealand Clinical Trials Registry (ACTRN12623000415606). Since its initiation, this study's protocol has undergone only minor revisions, specifically an update to the statistical analysis methodology to include linear mixed methods and intention-to-treat (ITT) analysis.

An advertisement of this pilot study with a URL was distributed on social media platforms displaying Federation University and the Natural Hazards Research Australia affiliations. This study was also promoted in national conferences, sleep workshops delivered to communities affected by wildfires, the Red Cross, and group meetings for people with sleep disorders in Australia. Radio interviews were also undertaken to promote the study. Survivors of wildfires who were interested read a PLIS (refer to Multimedia Appendix 2 for PLIS); signed a digital consent form (refer to Multimedia Appendix 3 for the consent form) to register an account on Federation University's digital HealthZone platform; and provided baseline data by completing a demographic questionnaire as well as self-report measures on insomnia, nightmares, and trauma symptoms. Participants had the option of providing a pseudonym if they wished. However, they needed to provide a valid email address to allow for communication about the study. Their email addresses were also directly connected to their personal dashboard on HealthZone. The baseline data were viewed by 2 researchers to decide eligibility. Those who were eligible (assessed by FI and GAK, both clinical psychologists) were contacted via email to notify them of their eligibility and their randomization and receive instructions on how to access their personal dashboard on HealthZone. Participants were sequentially allocated via simple randomization in the order of their enrollment (using a computer-generated simple randomization sequence), and they were informed about the purpose, allocation, and structure of the study as explained in the PLIS. However, they were not informed about the study's hypotheses. Once participants gained access to their personal dashboard within HealthZone, they were able to access information about the trial, complete the self-report secondary measures, and access the treatment modules consecutively. The treatment modules were provided at no cost, allowing participants to use their own devices and access the program and its modules on various platforms, including mobile devices, tablets, and desktop computers. HealthZone features a responsive web design compatible with both iOS and Android operating systems, making it easily accessible. Participant response data were captured on all devices. The modules were released sequentially to participants over 4 weeks. All data were collected through self-report measures at prespecified intervals. Participants were instructed to complete a module or a set of 2 modules each week along with the required interval assessments. Automated email reminders alerted participants about the release of each module and the specified assessments. If the modules were not viewed within the first 3 days of their release, an automated email reminder was sent to participants, and a second reminder was sent on the seventh day of their release. Automated email reminders at a similar frequency were also used for the primary and secondary measures (self-report scales). The personal dashboard was accessible to participants at any time. A "Contact us" tab was available on the personal dashboard that allowed participants to contact the research team and ask questions about the study or express any concerns. A total of 7% (2/30) of the participants were unsure about how to access the modules, and 3% (1/30) had an inquiry about one of the modules.

The research team sent 2 follow-up emails spaced 2 weeks apart to participants who registered, were randomized, but did not commence treatment, serving as a reminder about the study and to gauge their ongoing interest in participating.

The modules were available to participants from the start of the trial to the end of the follow-up period. Participants were able to access their dashboard for 4 weeks following the 3-month follow-up data collection. HealthZone recorded data about the number of log-ins, number of pages visited, and date of commencement and duration of participation for each participant. Each module was 17 minutes in duration. Therefore, participants were expected to spend at least 3 hours over the 4 weeks to indicate adherence to treatment. This time is optimal for viewing all modules and completing all assessments. No statistical analyses were conducted in the interim of the study. HealthZone was monitored daily during the trial to track any potential concerns or issues associated with the site or the participants.

Treatment Protocol

Sleep Best-i Intervention

Sleep Best-i was specifically designed for this clinical trial by some of the researchers who conducted this study (FI, BK, and GAK). The collated treatment manual draws from evidence-based treatment manuals authored by other sleep researchers [19,21,35-39]. The main therapeutic methods used in the manual were CBTi and ERRT. The recorded digital modules feature human-recorded voice and animated videos using VideoScribe (Sparkol) [40] that explain concepts related to sleep and trauma symptoms. The intervention also offers 2 role-plays of therapeutic sessions to demonstrate the administration of cognitive restructuring, dream rescripting, and sleep scheduling. Sleep Best-i consists of 6 modules administered over a 4-week period. In addition, the program is accessible via a platform that uses a responsive web design, with no requirement for a specific app or download. This allows participants to access the program from a variety of devices

XSL•FO
RenderX

(including mobile phones), as well as their preferred web browser. By being web based, the program can be easily accessed from anywhere at any time, making it a convenient and flexible intervention.

Participants were encouraged to complete the entire Sleep Best-i program, but completion of each module was not mandatory. This allowed individuals to engage with relevant content tailored to their specific needs, whether they experienced nightmares, PTSD, insomnia, or a combination of these conditions. Furthermore, participants had the flexibility to stop and start the program as desired, and all modules were available for the entire study period, enabling them to revisit specific modules should they wish to do so.

Table 1 shows the therapeutic modality offered in each module. Once released, the modules remained unchanged throughout the trial, and the intervention was successfully implemented without encountering technical difficulties. There were periodical checks to ensure that the modules were compliant with the treatment manual. All links have been archived in the Wayback Machine (Internet Archive).

Table 1. Sleep Best-i modules and the treatment offered in each module. All modules were approximately 17 minutes in duration.

Module	Strategies offered
Module 1 (psychoeducation)	Offered at week 1, the module provided psychoeducation about sleep and insomnia, the stages of sleep, and the neurobiology of sleep [14].
Module 2—part 1 (cognitive restructuring and sleep hygiene)	Offered at week 1, the module focused on the cognitive component of CBTi[a], types of unhelpful thoughts, methods to challenge unhelpful thoughts, and sleep hygiene [30].
Module 2—part 2 (sleep scheduling and stimulus control)	Offered at week 2, the module educated participants about specifying regular sleeping and waking up times with as little variation as possible between the 2. Stimulus control restricted the bedroom or the bed to sleep only [34].
Module 3 (trauma, PTSD[b], and flashbacks)	Offered at week 3, the module provided psychoeducation about trauma, PTSD, flashbacks, and how trauma leads to sleep difficulties. It also provided behavioral interventions for trauma symptoms.
Module 4 (nightmares)	Offered at week 4, the module explored nightmare disorder, how nightmares develop, and how to rescript the nightmare into a more neutral dream [16].
Module 5 (relapse prevention)	Offered at week 4, the module focused on identifying early warning signs and methods preventing relapse of symptoms [33].
Mindfulness module	This module offered a recorded progressive muscle relaxation mindfulness, and it was available to participants throughout the study.

[a]CBTi: cognitive behavioral therapy for insomnia.

[b]PTSD: posttraumatic stress disorder.

Waitlist Control Group

Following a waiting period of 4 weeks, the waitlist control group received Sleep Best-i in the same sequence in which it was released to the treatment group.

Measures

Overview

All scales were digital, self-report measures that were administered through HealthZone. The self-report measures as well as the modules were tested by 2 research team members (FI and BK) before being released to participants. The order of the modules and the questions were the same for all participants in the 2 groups.

Demographic Data

Participants provided the following information: name, email address, age, sex, employment status, educational level, marital status, country of residence, experience with wildfires, history of taking steroids, diagnosis of sleep apnea or restless leg syndrome, diagnosis of a psychotic disorder, use of alcohol or drug dependence, type of medications used to assist with sleeping, history of antidepressant use, and whether they were attending psychotherapy for sleep or PTSD.

Primary Measures

ISI Measure

The ISI [41] includes 7 items that assess insomnia severity through the subjective experience of sleep. The score varies from 0 to 28, with higher scores indicating more severe insomnia symptoms. A score of ≥8 indicates the presence of a subthreshold insomnia. Previous studies have demonstrated strong internal consistency for the ISI, with Cronbach α values ranging from 0.87 to 0.92, indicating high reliability [42].

NDI Measure

This scale consists of 5 items that assess symptoms of nightmares according to the DSM-5 criteria by screening for the occurrence of nightmares in a given week. The 5 items are summed to obtain a score between 0 and 20, with higher scores representing greater nightmare severity. The NDI exhibits good internal consistency, with a Cronbach α of 0.80 [43].

PCL-5 Measure

The PCL-5 [44] includes 20 self-report items assessing the presence of PTSD symptoms over a 1-month interval. A global score that ranges between 0 and 80 is obtained by summing the 20 items. A cutoff score of 31 provides optimal sensitivity and specificity in providing a provisional diagnosis of PTSD [45].

XSL•FO
RenderX

The PCL-5 has good psychometric properties, with an internal consistency of Cronbach α=0.94 [46].

Secondary Measures

Generalized Anxiety Disorder–7

This scale is a 7-item, self-report measure that assesses anxiety symptoms over a 2-week interval. A score from 0 to 21 is obtained by summing the 7 items. The Generalized Anxiety Disorder–7 (GAD-7) [47] has a good internal consistency, with a Cronbach α ranging between 0.82 and 0.93 [48]. A cutoff score of 10 discriminates between mild and severe symptoms of anxiety [48].

Patient Health Questionnaire–9

This scale consists of 9 items assessing symptoms of depression over the last 2 weeks. The overall score is obtained by summing all the 9 items and ranges from 0 to 27. A cutoff score of 10 is considered optimal in discriminating between mild and severe symptoms of depression [49]. In this study, the Cronbach α for the Patient Health Questionnaire–9 (PHQ-9) was 0.86.

Pittsburgh Sleep Quality Index

The Pittsburgh Sleep Quality Index (PSQI) [50] consists of 19 items assessing sleep quality and disturbances related to sleep over a 1-month interval. A global score ranging between 0 and 21 is generated by summing 7 components of sleep quality. A global PSQI score of >5 is considered a sensitive and specific cutoff to discriminate between good and poor sleep quality [51]. The PSQI has a good internal validity, with the Cronbach α ranging between 0.79 and 0.81 [51].

Satisfaction and Level of Engagement With Treatment

One question was designed for this study to measure satisfaction with Sleep Best-i. Participants were asked to rate how likely they were to revisit the Sleep Best-i modules on a 5-point Likert scale from *strongly disagree* to *strongly agree* (0-4). To assess level of engagement with treatment, the number of log-ins and amount of time that each participant spent on the site were monitored.

Data Analysis

Data analyses were conducted using the Stata statistical software package (version 18; StataCorp) [52]. All variables were inspected for normality and outliers. An inspection of histograms and *Q-Q* plots revealed normally distributed data. Upon inspection of box plots on all scales, 1 outlier was identified on the PCL-5 at the 3-month follow-up assessment, a second outlier was detected on the PHQ-9 at the 3-month follow-up, and a third outlier was detected on the PSQI at the waitlist assessment (3-month follow-up assessment). The results did not differ upon removing the outliers from the analyses; therefore, the outliers were retained [53,54]. To ensure a robust evaluation of the intervention's feasibility, the ITT analysis with 30 participants and the per protocol (PP) analysis with a sample of 20 were used, allowing for a comprehensive assessment of treatment outcomes, thereby enhancing the accuracy and generalizability of the findings [33,55,56].

For both analyses, missing data were addressed using multiple imputation by chained equations. This approach is more robust than other methods such as single imputation because it generates multiple predictions for each missing value, accounting for uncertainty in the imputations and yielding more accurate SEs [57]. To impute missing data, background variables such as age, sex, educational level, employment status, country, and relationship status; baseline measures; and the most recent observations of each outcome were used.

To address uncertainty, each missing value was imputed 20 times using predictive mean matching based on the 3 nearest values across multiple iterations to create 100 imputed datasets. The imputed values were then averaged to create the final estimates [58]. Predictive mean matching, a partially parametric method, is preferable to fully parametric linear regression as it remains effective even when the normality assumption of the underlying variable is violated. This method also helps preserve the distribution of observed values in the missing data [59]. Missing value analysis indicated that the data were missing completely at random (Little missing completely at random test: $\chi^2_{867}=0.0$, $P>.99$), meaning that the differences between the missing and observed data were related to observed characteristics [60].

Adjusted analyses of intervention effects were conducted using mixed-effects linear regression models. Both fixed and random effects were estimated to assess the impact of the intervention on the change in all outcomes (primary and secondary) over time and by condition. Given that observed covariates were balanced between the 2 conditions (waitlist and treatment), the difference-in-differences (DID) effect for the fixed part of the mixed-effects models was tested by including interaction terms for time point and condition. DID is considered the most appropriate measure to assess causal effects in time-series designs as it effectively controls for time-invariant confounding variables. By doing so, DID reduces bias and enhances internal validity, providing a more accurate estimate of the treatment effect [61].

The appropriateness of the mixed-effects model for each outcome was assessed using chi-square statistics ($P<.05$). Random-intercept linear models were compared with random-intercept, random-slope models using likelihood ratio tests. The random-intercept, random-slope model was reported only if the likelihood ratio test indicated $P<.05$; otherwise, the simpler random-intercept model was selected. A significant effect of the intervention or difference in outcome between groups was assessed using a 2-tailed test of significance with $P<.05$.

A sensitivity analysis was conducted to test whether the model and covariance structures were misspecified. Several major types of covariance structures, including independent, unstructured, exchangeable, identity, and autoregressive structures, were examined. In addition, the model parameters using both maximum likelihood and restricted maximum likelihood methods were estimated. Although the results were generally consistent across different covariance structures, the model with an exchangeable structure was deemed the best fit.

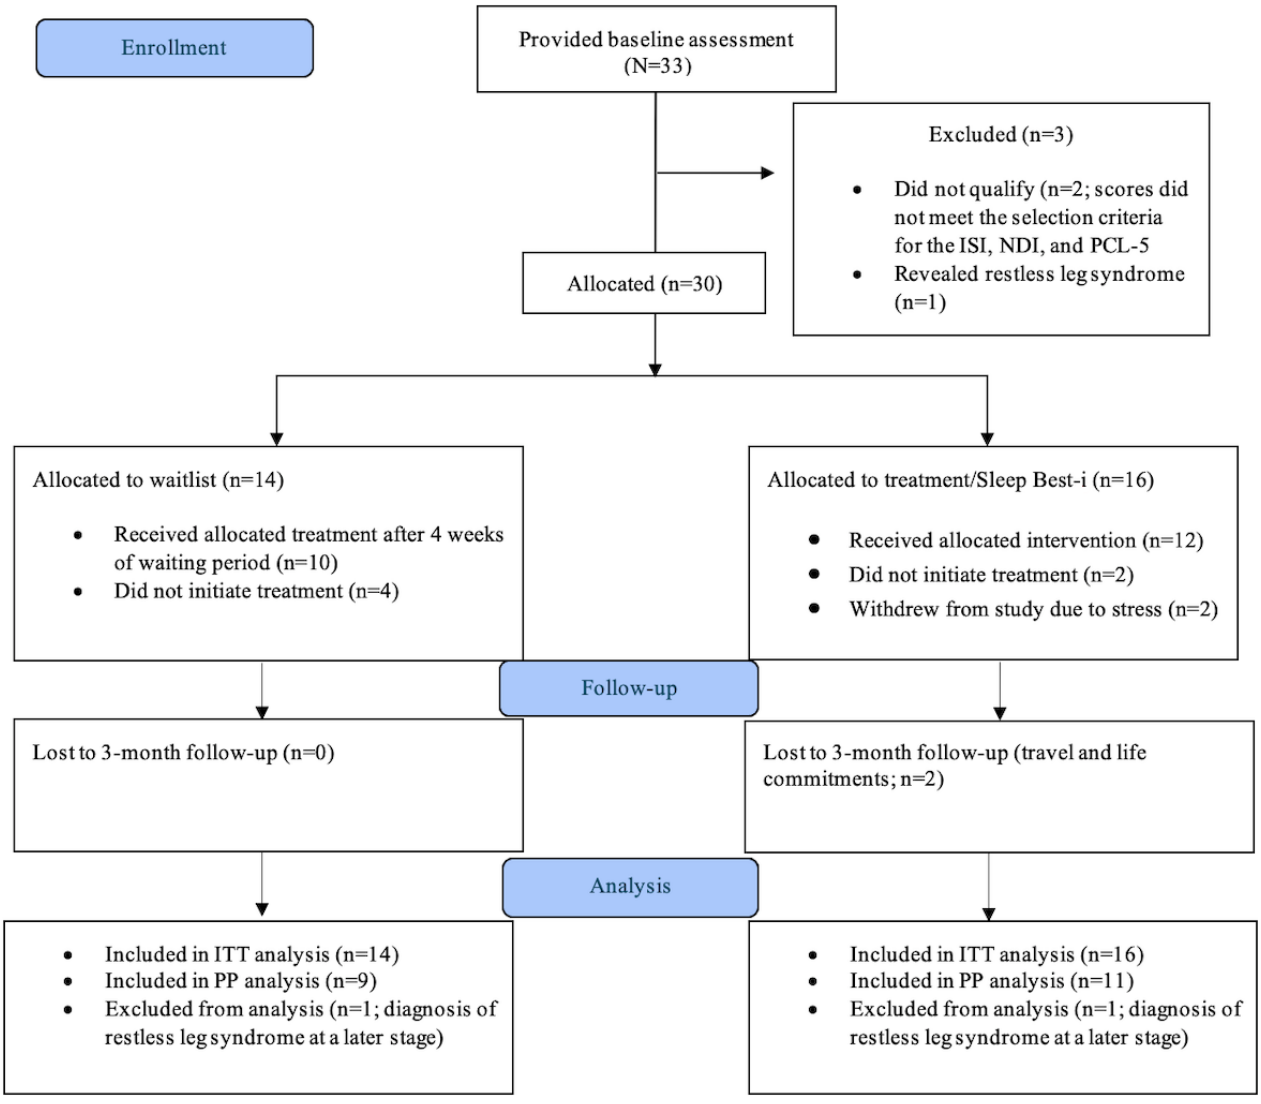
Clinical Significance



Clinical significance was assessed for the 2 groups from baseline to the 3-month follow-up. To evaluate the clinical significance on sleep and trauma measures, specific criteria were used for each scale. For example, for the ISI, a cutoff score of ≤8 with a ≥6-point reduction in scores was used to assess whether participants reached a minimal clinically significant change (MCSC) [26,62]. For the NDI, there are no established criteria for MCSC; therefore, a cutoff score of ≤7 as suggested by Dietch et al [43] was used. Marx et al [63] recommend a score of ≤28 and a drop of ≥18 points on the PCL-5 as a guide for MCSC.

Results

Overview

A total of 33 participants responded to the advertisement, registered an account with Federation University's digital HealthZone platform, and provided baseline data. In total, 9% (3/33) were excluded because they did not meet the selection criteria, and 91% (30/33) were randomized to either the intervention or the waitlist group. A total of 53% (16/30) were randomized into the intervention group, and 47% (14/30) were in the waitlist group (for the participant CONSORT chart, refer to Figure 1). Ages ranged between 18 and 79 years (mean 52.50, SD 16.26 years; N=30), with most participants (19/30, 63%) being female (vs 11/30, 37% male). A total of 67% (20/30) of the participants completed the trial, and their data were analyzed as PP. The ages of the latter group ranged from 18 to 79 years (mean 53.75, SD 16.54 years), with most participants (14/20, 70%) being female (6/20, 30% were male). Demographic variables for the treatment and waitlist groups are shown in Table 2.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flowchart showing participant flow through allocation to the treatment and waitlist conditions. ISI: Insomnia Severity Index; ITT: intention to treat; NDI: Nightmare Disorder Index; PCL-5: PTSD Checklist for DSM-5; PP: per protocol.

[a]Significance level at $P<.05$.

[b]Not applicable.

A total of 4 participants were excluded from the PP analysis for the following reasons: 2 (50%) participants, who completed the pilot trial and provided a complete set of data, revealed that they had restless leg syndrome that was not initially reported during the screening process; 1 (25%) participant received 1 treatment module but withdrew from the study due to illness, providing only baseline measures; and a fourth participant (25%) who provided and completed 50% of the data and modules withdrew due to illness and family commitments. Therefore, the PP analysis was conducted on a sample of 20 participants.

XSL•FO
RenderX

In total, 20% (6/30) of the participants provided baseline data; however, they did not initiate treatment and did not respond to emails sent by the research team. Table 1 indicates that there were no significant differences in demographic variables between the intervention and waitlist groups at the baseline assessment (age, *P*=.28; biological sex, *P*=.51; education level, *P*=.75; employment status, *P*=.64; and relationship status, *P*=.05).

To address hypothesis 1, ITT analysis of the mixed-effects regression, including the effect sizes of the DID in the fixed-effects component and the variability in the random-effects component, showed that, at baseline, the waitlist group had mean scores of 3.16, 0.39, and 45.29 on the ISI, NDI, and PCL-5, respectively. At the postintervention time point, the main effect of time, these scores significantly decreased by 1.64 points on the NDI (*P*=.001) and 10.64 points on the PCL-5 (*P*=.009), but no significant (*P*=.06) change was detected on the ISI. The treatment group showed slightly lower baseline scores than the waitlist group, with mean differences of 0.45, 0.04, and 9.20 for the ISI, NDI, and PCL-5, respectively, suggesting that the 2 groups were relatively balanced at baseline. The adjusted DID effects following the treatment indicated that the treatment group experienced greater improvements in mental health measures compared to the waitlist group, with differences of 1.54 points for the ISI, 1.22 points for the NDI, and 4.98 points for the PCL-5. Notably, the improvement in the NDI was marginally significant (*P*=.06), whereas the improvements in the ISI and PCL-5 were not statistically significant (*P*=.26 and *P*=.37, respectively; Table 3).

Table 3. Mixed-effects linear regression analysis of the effect of the intervention on primary outcomes (intention-to-treat analysis; N=30)[a].

[f]Model fit—*P*<.001 (Wald chi-square test) and *P*=.03 (likelihood ratio test [LRT]) to compare the mixed-effects models with random-intercept linear models.

[g]Model fit—*P*<.001 (Wald chi-square test) and *P*=.001 (LRT) to compare the mixed-effects models with random-intercept linear models.

[h]Model fit—*P*<.001 (Wald chi-square test) and *P*=.19 (LRT) to compare the mixed-effects models with random-intercept linear models.

[i]Not available.

[j]N/A: not applicable as the random-intercept model better fit the data than the random-intercept, random-slope model. Given its better fit, random-intercept model parameters were reported.

In the random-effects part, there was substantial variability among individuals, with average deviations of 1.41, 0.82, and 10.82 points for the ISI, NDI, and PCL-5, respectively, around both the baseline and postintervention means. This suggests considerable individual variability in the outcomes. The positive correlation coefficients between the time point and the intercept indicate that participants with higher baseline scores (above the overall sample mean) were more likely to experience greater decreases in their scores over time compared to those with lower baseline scores. All mixed-effects models for the ISI, NDI, and PCL-5 were statistically significant (*P*<.001). Specifically, the random-intercept, random-slope model was appropriate for the

XSL•FO
RenderX

ISI (*P*=.03) and NDI (*P*=.001), whereas a random intercept–only model was sufficient for the PCL-5, which also fit the data but with a nonsignificant *P* value (*P*>.05 and *P*=.19; Table 3). Figure 2 illustrates the changes in primary outcome measures (ISI, NDI, and PCL-5) from before to after treatment based on the ITT analysis.

For completers only, PP analysis of the mixed-effects regression showed that, at baseline, the waitlist group had mean scores of 5.58, 0.46, and 13.37 on the ISI, NDI, and PCL-5, respectively. At the postintervention time point, these scores did not significantly change for the 3 measures (ISI; *P*=.68, NDI; *P*=.24, PCL-5; and *P*=.35). The treatment group baseline scores were balanced compared to those of the waitlist group, with mean differences of 0.99, 0.04, and 3.05 for the ISI, NDI, and PCL-5, respectively. However, the adjusted DID effects indicated an interaction effect of condition × time, with the treatment group experiencing greater and more significant improvements on the NDI with a decrease of 2.27 points (*P*=.049) and a decrease of 13.46 points on the PCL-5 (*P*=.03) but no significant improvements on the ISI (*P*=.25; Table 4).

There was a substantial variability among individuals, with average deviations of 3.41, 1.81, and 9.42 points for the ISI, NDI, and PCL-5, respectively, at the postintervention time point, suggesting considerable individual variability in the outcomes. All mixed-effects models for the ISI, NDI, and PCL-5 were statistically significant (*P*<.001), with a random-intercept model being appropriate for the 3 measures (Table 4).

In relation to the second hypothesis, the ITT analysis showed that, at baseline, the waitlist group had mean scores of 1.66, 12.01, and 0.69 on the GAD-7, PHQ-9, and PSQI, respectively (Table 5). Only the depression scores decreased significantly (*P*<.001) by 6.48 points at the posttreatment time point (main effect of time) in comparison to the waitlist group. The treatment group showed slightly lower baseline scores than those of the waitlist group on the secondary measures, with mean differences of 0.47, 0.90, and 0.04 on the GAD-7, PHQ-9, and PSQI, respectively, suggesting that the 2 groups were balanced at baseline. The adjusted effects at the postintervention time point indicate that the treatment group experienced greater improvements than the waitlist group on all measures but with only significant results on the PSQI (with a difference of 2.22 points; *P*<.001).

There was variability among individuals, as shown in Table 5, with average deviations of 0.91, 4.89, and 0.73 points for the GAD-7, PHQ-9, and PSQI, respectively, around both the baseline and postintervention means. The positive correlation coefficients for the GAD-7 and PSQI between the time point and the intercept indicate that participants with higher baseline scores (above the overall sample mean) were more likely to experience greater decrease in their scores over time compared to those with lower baseline scores. Mixed-effects models for the 3 measures were statistically significant (*P*<.001). Specifically, the random-intercept, random-slope model was appropriate for the PHQ-9 and PSQI (*P*=.007 and *P*=.001, respectively), whereas a random intercept–only model was sufficient for the GAD-7 (*P*=.08). Figure 3 shows the difference in decrease in scores between the intervention and waitlist groups for the GAD-7, PHQ-9, and PSQI from the ITT analysis.

For those who completed the study, PP analysis showed that the waitlist mean baseline scores were 11.78, 12.22, and 13.00 on the GAD-7, PHQ-9, and PSQI, respectively. These scores decreased significantly only for the PHQ-9 measure by 6.22 points at the posttreatment time point (*P*<.001). There was also a main effect of condition on the GAD-7 measure with a decrease of 4.14 points (*P*=.04) for the treatment group and an interaction effect of time × condition on the PSQI (*P*=.02), suggesting that the treatment group experienced significantly better sleep quality than the waitlist group following the treatment (Table 6).

Table 6 also shows a great variability among individuals on the random effects, with average deviations of 3.69, 3.16, and 2.82 points for the GAD-7, PHQ-9, and PSQI, respectively, around both the baseline and postintervention means. This suggests substantial individual variability in the outcome measures. Mixed-effects models for the 3 measures were statistically significant (*P*<.001), with the random-intercept, random-slope model being appropriate for the PHQ-9 (*P*=.004), whereas a random intercept–only model was sufficient for the GAD-7 and the PSQI (*P*=.28 and *P*>.99, respectively; Table 6).

To address the third hypothesis, separate mixed-effects linear model analyses were conducted for each group (intervention and waitlist) on all primary and secondary outcome measures. The analysis incorporated data from the following time points: baseline, posttreatment time point, and 3-month follow-up for the intervention group and pretreatment time point, posttreatment time point, and 3-month follow-up for the waitlist group. ITT analysis for the intervention group showed a significant reduction in insomnia, nightmares, and trauma symptoms as measured using the ISI, NDI, and PCL-5 both at the posttreatment time point (*P*<.001) with an effect of 3.42, 2.86, and 15.62 points, respectively, and at the 3-month follow-up (*P*<.001) with an effect of 8.64, 4.20, and 22.83 points, respectively (Table 7).

A great variability among individuals was detected on the random effects, with average deviations of 1.56, 0.32, and 11.09 points for the ISI, NDI, and PCL-5, respectively, around both the postintervention and 3-month follow-up means. Mixed-effects models for the 3 measures were statistically significant (*P*<.001), with the random-intercept, random-slope model being appropriate for the ISI and the PCL-5 (*P*=007 and *P*=.02, respectively), whereas the random-intercept model was appropriate for the NDI (*P*=.16; Table 7). Figure 4 shows the decrease in scores over time at the postintervention time point and 3-month follow-up for the intervention group.

For those who completed the study, the PP analysis showed comparable results to those reported in the ITT analysis, with a significant reduction in symptoms at both the postintervention time point (ISI; *P*=.04, NDI; *P*<.001, PCL-5; *P*<.001) and 3-month follow-up (*P*<.001 in all cases). The adjusted effects showed a continued reduction in symptoms from the postintervention time point to the 3-month follow-up, with a difference of 7.81, 4.86, and 23.71 points on the ISI, NDI, and PCL-5, respectively (Table 8).

XSL•FO
RenderX

The analysis also showed a substantial variability among individuals, with average deviations of 1.64, 1.03, and 1.81 points for the ISI, NDI, and PCL-5, respectively, around both the baseline and postintervention means. The positive correlation coefficients between the time point and the intercept on the NDI indicate that participants with higher baseline scores (above the overall sample mean) were more likely to experience greater decreases in their scores over time compared to those with lower baseline scores. All mixed-effects models for the ISI, NDI, and PCL-5 were statistically significant (P<.001), with a random-intercept model being sufficient for all 3 measures with a nonsignificant P value (ISI, P=.18; NDI, P=.07; and PCL-5, P=.42, Table 8).

On the secondary measures, the ITT analysis showed that the intervention group experienced significant improvements on the PHQ-9 and PSQI at both the posttreatment time point and the 3-month follow-up (P<.001). No significant reduction in symptoms was observed for the GAD-7 at the posttreatment time point (P=.21; Table 9). However, all participants in the intervention group experienced a significant reduction in symptoms at the 3-month follow-up (P<.001) on the 3 measures, with adjusted effects showing a decrease of 4.05, 7.50, and 5.12 points on the GAD-7, PHQ-9, and PSQI, respectively. Table 9 also shows variability among individuals on the random effects, with average deviations of 0.001, 5.46, and 0.82 points for the GAD-7, PHQ-9, and PSQI, respectively, around the postintervention and 3-month means. The 3 models were statistically significant (P<.001), with the random-intercept, random-slope model being appropriate for the PHQ-9 and PSQI (P=.03 and P=.002, respectively) and the random-intercept model being appropriate for the GAD-7 (P=.34). Figure 5 shows a change in secondary outcomes over time in the intervention group (ITT analysis).

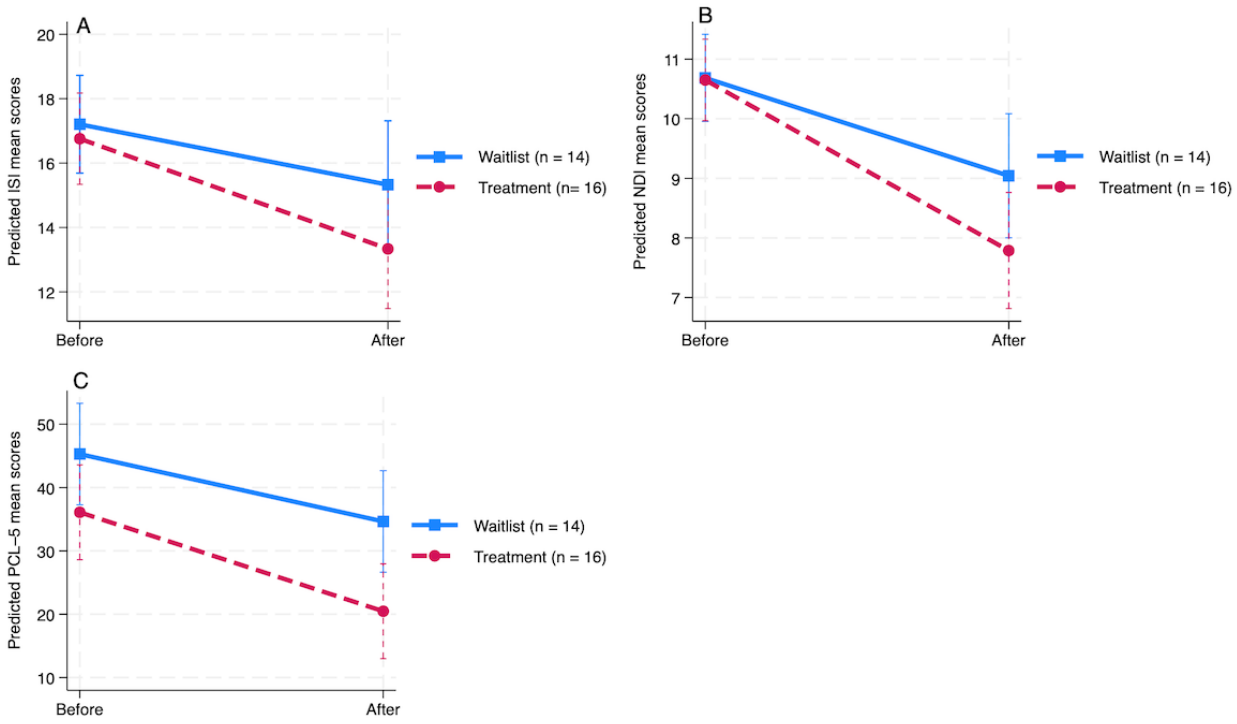
Comparable results were also detected on the PP analysis, with individuals experiencing significant reductions in symptoms following the intervention and also at the 3-month assessments (P<.001 in all cases) except for the GAD-7, which was found to be not significant at the postintervention time point (P=.29). Participants experienced a greater reduction in symptoms at the 3-month assessment, with adjusted effects indicating a reduction of 3.88, 6.98, and 4.62 points on the GAD-7, PHQ-9, and PSQI, respectively (Table 10). The 3 models were statistically significant (P<.001), with the random-intercept model being appropriate for the 3 measures (GAD-7, P=.32; PHQ-9, P=.56, and PSQI, P=.05).

Similarly, ITT analysis results of the mixed-effects regression showed that, at baseline, participants in the waitlist group had mean scores of 10.79, 5.42, and 13.93 on the ISI, NDI, and PCL-5, respectively. The adjusted effects at the postintervention time point indicated that the symptoms significantly reduced by 6.36, 5.78, and 19.37 points, respectively (P<.001), and a significant reduction of 8.21, 7.74, and 27.96 points was observed at the 3-month follow-up for the ISI, NDI, and PCL-5, respectively (P<.001; Table 11).

In the random-effects part, there was substantial variability among individuals, with average deviations of 9.80, 6.18, and 1.73 points for the ISI, NDI, and PCL-5, respectively, around both the postintervention and 3-month means. This suggests considerable individual variability in the outcomes. All mixed-effects models for the ISI, NDI, and PCL-5 were statistically significant (P<.001), with a random-intercept model being appropriate for the 3 measures with a nonsignificant P value (P>.05; ISI, P=.45; NDI, P=.59, PCL-5, P=14 Table 11). Figure 6 shows the changes in primary outcomes over time for the waitlist group at the postintervention time point and 3-month follow-up.

The PP analysis showed similar results, with significant improvements at both the postintervention and 3-month follow-up assessments on the ISI, NDI, and PCL-5 (P<.001 in all cases; Table 12). The mixed-effects models for the ISI, NDI, and PCL-5 were all statistically significant (P<.001). The random-intercept model was used for the 3 measures (P>.05; ISI, P>.99; NDI, P>.99; and PCL-5, P=.34, Table 12).

For the secondary measures, ITT analysis showed that the waitlist group had baseline mean scores of 0.78, 0.36, and 3.31 on the GAD-7, PHQ-9, and PSQI, respectively. The adjusted effects at the postintervention time point indicated that these scores decreased significantly by 4.72 and 5.07 points for the GAD-7 and the PSQI, respectively (P<.001). However, no significant changes were observed on the PHQ-9 at the postintervention time point. Furthermore, adjusted effects showed a significant reduction of 6.51 points on the GAD-7 and 5.00 points on the PSQI (P<.001) against the baseline but no changes on the PHQ-9 at the 3-month follow-up (Table 13).



There was variability among individuals, with deviations of 1.47, 0.06, and 0.92 points for the GAD-7, PHQ-9, and PSQI, respectively, around the postintervention and 3-month follow-up means. The positive correlation coefficients between the time point and the intercept indicate that participants with higher baseline scores (above the overall sample mean) were more likely to experience greater decreases in their scores over time compared to those with lower baseline scores. All mixed-effects models for the GAD-7, PHQ-9, and PSQI were statistically significant (P<.001). Specifically, the random-intercept, random-slope model was appropriate for the GAD-7 and PSQI (P<.001 and P=.02, respectively), whereas a random intercept–only model was sufficient for the PHQ-9, which also fit the data but with a nonsignificant P value (P>.05; P=.17, Table 13). Figure 7 shows the changes in secondary outcomes at the postintervention time point and at the 3-month follow-up for the waitlist group.

For those who completed the study, PP analysis showed similar results for the waitlist group, with significant reduction at the postintervention and 3-month assessments only for the GAD-7 and the PSQI (P<.001); however, no significant changes were detected for the PHQ-9 at either the postintervention time point or the 3-month follow-up (P=.61 and P=.92, respectively; Table 14). For those who experienced significant reductions, there was great variability, with deviations of 1.98 and 1.00 points for the GAD-7 and PSQI, respectively, around the postintervention and 3-month follow-up means. All mixed-effects models for the GAD—7, PHQ—9, and PSQI were statistically significant (P<.001). Specifically, the random-intercept model was appropriate for the 3 measures

Clinical Significance

Table 15 presents the number of participants achieving clinical significance from baseline to 3-month follow-up, based on intention-to-treat (ITT) analysis. The results show that a higher percentage of waitlist group participants achieved clinically significant changes in nightmare symptoms (mean change 7.74, SD 5.12) and PTSD symptoms (mean difference 27.96, SD 16.56) compared to the treatment group (mean change 4.20, SD 4.21 for nightmare symptoms and mean change: 22.83, SD 17.09 for PTSD symptoms). In contrast, a higher percentage of treatment group participants achieved clinically significant changes in insomnia symptoms (mean difference 8.65, SD 5.28) compared to the waitlist group (mean change 8.21, SD 6.96). Two participants were missing 3-month follow-up data on the ISI, NDI, and PCL-5.

The per-protocol (PP) analysis (Table 16) yielded similar results to the ITT analysis. Specifically, a higher percentage of waitlist group participants achieved clinically significant changes in nightmare symptoms (mean change 7.11, SD 5.71) and PTSD symptoms (mean change 28.44, SD 18.58) compared to the treatment group (mean change 4.67, SD 3.04 for nightmare symptoms and mean change: 24.84, SD 18.62 for PTSD symptoms). Conversely, a higher percentage of treatment group participants achieved clinically significant changes in insomnia symptoms (mean change 7.33, SD 5.87) compared to the waitlist group (mean change 7.00, SD 8.34). However, the differences between the two groups were not statistically significant.

Table 15. Distribution of clinically significant responders by condition—intention-to-treat analysis (N=30).

Outcome	Waitlist (n=14), n (%)	Treatment (n=16), n (%)	*P* value
ISI[a]	8 (57)	10 (62)	.77

Satisfaction and Engagement With Treatment

Participants were asked to rate how likely they were to revisit the treatment modules on a 5-point, single-item Likert scale. A frequency analysis showed that most participants responded with *strongly agree* (9/20, 45%) and *moderately agree* (7/20, 35%). In total, 10% (2/20) of the participants responded with *moderately disagree*, and 10% (2/20) of the participants did not respond to this question. The number of log-ins to the site was observed as an indicator of the level of engagement by participants with the modules, and it was found that the 20 participants who were included in the PP analysis had an average of 8.5 log-ins during their engagement with Sleep Best-i. A total of 5% (2/20) logged in 12 times to the site; 5% (3/20) logged in 5 times; 5% (2/20) logged in 7 times; 10% (3/20) logged in 6 times; 15% (4/20) logged in 11 times; and 20% (6/20) logged in 8, 9, and 10 times. On average, participants spent 116 minutes on the site visiting modules and completing assessments.

Discussion

Principal Findings

The aim of this clinical pilot trial was to assess the feasibility of a brief (6 modules over 4 weeks), self-paced, digital intervention for the treatment of insomnia, nightmares, and PTSD symptoms in an international sample of survivors of wildfires. The first hypothesis was partially supported. The PP analysis revealed a significant interaction effect of condition × time on both the NDI and the PCL-5, indicating that Sleep Best-i effectively reduced symptoms of nightmares and PTSD from before to after the intervention in the treatment group compared to the waitlist group. However, no significant changes were observed in insomnia symptoms. The ITT analysis yielded similar findings, with a significant main effect of time showing a reduction in nightmare and PTSD symptoms at the posttreatment time point for the intervention group but no significant changes in insomnia symptoms. In examining the 2 groups separately, Sleep Best-i significantly reduced symptoms of insomnia, nightmares, and PTSD from baseline to the postintervention time point, and this improvement in symptoms was maintained at the 3-month assessment for the 2 groups across both the PP and ITT analyses. This study's findings diverge from those of previous research using CBTi to treat insomnia in survivors of wildfires [27,28] and veterans [25,26]. This discrepancy may be attributed to the brief duration of insomnia treatment in our study, which spanned only the first 2 weeks, unlike in other clinical trials that used CBTi in ≥6 sessions. Research suggests that an average of 6 to 8 sessions is typically required to significantly reduce insomnia symptoms [13,64]. The shorter session duration used in this study may have contributed to the differing outcomes. Nevertheless, the maintenance of improvements at the 3-month follow-up is a promising indicator of the intervention's long-term effectiveness.

These findings further substantiate the efficacy of ERRT in reducing the severity and frequency of nightmares, aligning with those of previous studies [36,65-67]. These results are also consistent with those of other clinical trials demonstrating that CBTi and ERRT can lead to significant reductions in PTSD symptoms at the posttreatment time point [36,68]. Notably, it is possible that symptoms of trauma and nightmares are more malleable and responsive to treatment, whereas insomnia symptoms may be more entrenched and less amenable to change with brief interventions, suggesting a potential explanation for the observed differences in treatment outcomes.

In relation to the second hypothesis, the PP analysis revealed that Sleep Best-i not only alleviated symptoms of nightmares and trauma but also significantly reduced anxiety symptoms (main effect of condition) in the treatment group compared to the waitlist group at the postintervention time point. In addition, the treatment group experienced a significant reduction in depressive symptoms at the posttreatment time point (main effect of time) and a significant interaction effect of time × condition on sleep quality, indicating more pronounced improvements in sleep quality at the postintervention time point compared to the waitlist group. The ITT analysis yielded similar findings, with significant reductions in depressive symptoms at the postintervention time point and a significant interaction effect of time × condition on sleep quality. However, the reduction in anxiety symptoms was no longer significant in the ITT analysis. This is notable as research suggests a strong relationship between insomnia and anxiety symptoms, with the expectation that successful insomnia treatment would lead to a reduction in anxiety symptoms [69].

When analyzing the 2 groups separately, both the PP and ITT analyses yielded similar results, with few exceptions. Notably, both groups showed significant reductions in anxiety symptoms at the 3-month follow-up, although this improvement was only sustained for the waitlist group at the postintervention assessment. In terms of sleep quality, both groups showed significant improvements at both the postintervention and 3-month follow-up assessments. However, only the intervention group exhibited significant reductions in depressive symptoms at both the postintervention and 3-month follow-up assessments.

XSL•FO
RenderX

This study's findings align with those of existing research demonstrating the effectiveness of CBTi-based treatments for comorbid conditions [13,70]. While part of this study's findings corroborates those of previous studies showing a significant reduction in symptoms of depression following CBT treatment for insomnia [27,28], the lack of improvement in symptoms of depression in the waitlist group is not well understood. One possible explanation is that the insignificant improvements in insomnia symptoms may have contributed to the absence of change in depression levels [69]. In addition, external life difficulties may have influenced symptoms of depression during the study period. Notably, the 2 groups had distinct intervention experiences, which may have impacted the outcomes. Specifically, the 3-month follow-up assessment for the waitlist group occurred 4 weeks after the treatment group's follow-up, potentially introducing passage-of-time effects that may have influenced the results. This study's findings are also in line with those of other studies that found improved sleep quality on the PSQI following the administration of CBTi [71].

In terms of clinical significance, a substantial proportion of participants achieved MCSC (according to the PP analysis) in insomnia (9/18, 50%), nightmares (13/18, 72%), and PTSD symptoms (11/18, 61%). Notably, the MCSC rates for insomnia and PTSD in this study were slightly higher than those reported in previous clinical trials using CBTi and imagery rehearsal therapy. For example, Ulmer et al [26] found that 55.4% and 50% of their sample (N=22) achieved clinical significance in insomnia and PTSD, respectively. In contrast, the MCSC rates in this study were lower than those reported by Belleville et al [27], who found that 64.7% and 70.6% of participants achieved MCSC for insomnia and PTSD at the posttreatment time point, respectively, and 64.7% and 58.8% achieved MCSC for insomnia and PTSD at the 3-month follow-up, respectively. The discrepancy in MCSC rates between our study and others may be attributed to the shorter treatment duration of Sleep Best-i (4 weeks) than those of the other trials (6-12 weeks) [26,27].

A significant proportion of participants expressed a high level of satisfaction with the intervention, with approximately 80% (18/20) of users reporting a positive experience. Furthermore, the level of engagement by participants with the modules was measured using the number of log-ins into the site. The 20 participants included in the PP analysis had an average of 8.5 log-in times during their engagement with Sleep Best-i. The log-in frequency was varied, with 5% (2/20) of the participants logging in 12 times; 5% (3/20) logging in 5 times; 5% (2/20) logging in 7 times; 10% (3/20) logging in 6 times; 15% (4/20) logging in 11 times; and 20% (6/20) logging in 8, 9, or 10 times. On average, participants spent 116 minutes on the site visiting modules and completing assessments.

Limitations

This clinical pilot trial has limitations that warrant consideration. The sample consisted of self-selected individuals, and the absence of clinical assessments to confirm diagnoses of insomnia, nightmares, and PTSD introduces a potential source of bias. The small sample size is another impediment, underscoring the need for further testing with a larger and more diverse population to establish the external validity of the intervention. One major concern in relation to Sleep Best-i is the PTSD module and its potential for triggering trauma symptoms. Although this risk was anticipated, participants were provided with emergency numbers. Moreover, throughout the initial 2-week treatment period, participants received training in cognitive and behavioral strategies to effectively manage stress. It is important to note that our study was conducted as an open-label trial. Future research should prioritize addressing the identified gaps and limitations, thereby enhancing the validity and generalizability of the findings in this field.

Future Directions

This feasibility trial provides valuable insights into the effectiveness of the Sleep Best-i intervention, a CBT-based program for survivors of wildfires. While our findings are promising, we recognize that future research could further enhance our understanding of its efficacy and effectiveness. One potential direction for future research could involve stratifying the assessment of outcomes based on the type of survivor by dividing the population into subgroups based on specific characteristics, such as demographic characteristics such as age, sex, and income; life experiences, including previous trauma and social support; experiences with wildfires, such as severity of exposure and proximity to the fire; losses experienced as a result of wildfires, including property damage and loss of loved ones; social support from family, friends, and community resources; and institutional support provided during the recovery phase, including access to mental health services and financial assistance. By doing so, researchers can identify patterns and trends within each subgroup, compare outcomes between subgroups, and develop targeted interventions that address the unique needs of each subgroup. In addition, ecological assessments over longer time frames could provide a more comprehensive understanding of the intervention's impact in real-world settings. We propose that future studies consider these approaches to build on our findings and inform the development of more targeted and effective interventions for survivors of wildfires.

Conclusions

Taken together, these findings indicate that Sleep Best-i incorporating CBTi and ERRT improved nightmares, PTSD, sleep quality, and symptoms of depression from baseline to the posttreatment time point. This positive impact was sustained at the 3-month follow-up for the 2 groups, with some variations on anxiety and depression. Participants in the intervention group, when assessed separately, experienced improvements on all measures from before to after treatment and at the 3-month follow-up, with the exception of anxiety symptoms at the posttreatment time point. The waitlist group experienced a significant reduction in symptoms on all measures from before treatment to after treatment and at the 3-month follow-up except for symptoms of depression. This clinical trial is the first in the field of sleep disturbances to use a concise, digital, self-paced intervention over 4 weeks among survivors of wildfires.

Abstract

Background: Mindfulness-based interventions have been demonstrated to be effective in improving bodily and emotional well-being. However, only a few studies have explored individual differences in the application and use of digital mindfulness among adults aged ≥65 years. Voice-guided mindfulness technologies can increase the accessibility of mindfulness training, but the expected benefits may not be similar in all user groups.

Objective: This study aims to understand how older adults incorporate mindfulness into their habits and routines, explore the digital mindfulness design preferences of older adults, and understand if and how digital mindfulness can facilitate self-perceived well-being among older adults.

Methods: A qualitative interview study built on an interpretive-constructivist paradigm was conducted among older adults in Sweden who used a voice-guided mindfulness app for a 3-week period in their homes (N=15). Semistructured interviews were conducted one-on-one with participants after using the app. Qualitative thematic analysis was used to explore the lived experiences of digital mindfulness, as articulated by participants, which allowed an open exploration of the subjective experiences of digital mindfulness and their possible effects and outcomes.

Results: From the coding stage, 23 codes describing the digital mindfulness experience were identified from the data. These codes were thematized to group the codes together, resulting in 7 subthemes. From these 7 subthemes, three main themes were formed to answer the research objectives: (1) the embeddedness of digital mindfulness in older adults' daily routines and habits, (2) heterogeneity in older adults' design preferences for digital mindfulness, and (3) the consequences of digital mindfulness on the self-perceived well-being of older adults.

Conclusions: This study concludes that digital mindfulness offers a possibility to enhance the self-perceived well-being of older adults by fostering resilience and self-care. However, adverse effects of mindfulness, such as frustration and discomfort, can also be experienced by older adults. The digital mindfulness experiences and preferences of older adults are highly individual, diverse, and manifold, which indicates that personalized approaches are essential for effective engagement. By acknowledging and addressing the heterogeneous design preferences within this demographic, developers can create more personalized and adaptive voice-guided mindfulness apps.

Introduction

Overview

Mindfulness, which can be broadly defined as a state of focusing one's awareness on the present moment [1,2], has gained increasing attention in the field of digital health and mental well-being. Practicing mindfulness has been shown to be associated with reduced levels of stress, anxiety, and depressive symptoms across different population groups, demonstrating the benefits of mindfulness for mental well-being [3-6]. Consequently, digital mindfulness technologies, such as mindfulness apps, virtual reality environments, and wearables, have emerged, which enhance the mindfulness experience and improve the accessibility of mindfulness practice [7,8].

Mindfulness technologies can be considered as digital self-care technologies through which users can engage in the maintenance of physical and mental well-being and prevention of chronic diseases without needing human contact with a health care provider [9]. Self-care is defined as the promotion and maintenance of health and the prevention of disease, with or without the support of health care providers [10,11]. Self-care technologies such as mobile apps can provide a medium for users to collect, monitor, and track health-related behaviors independently, along with guidance and advice on areas that lack accessibility to care professionals or therapy [12,13]. The uptake of digital self-care technologies nevertheless depends on an individual's digital literacy; access to technology; and social, cognitive, and attentional resources, which are unevenly distributed across different social groups [14,15].

Older adults, defined as a group of adults aged ≥65 years, are recognized as a group who could benefit from digital mindfulness. Previous research has mostly explored mindfulness-based interventions (MBIs) from the medical or clinical perspective, demonstrating the clinical effects of mindfulness training for older adults [16-18], whereas only a few studies have explored the use of a mindfulness app with older adults using a qualitative approach [19]. Despite the increasing amount and variance of digital health apps in the market, mindfulness apps are not equally used by all groups. Factors such as age, education, gender, eHealth literacy skills, and privacy concerns may play a role in mobile health (mHealth) app use [20]. The accessibility of digital mindfulness for older adults remains a challenge, as the benefits are influenced by factors such as digital skills and interest toward technology [18]. As a result, the age-specific characteristics of using digital mindfulness have largely remained unexplored, particularly from the perspective of self-perceived benefits and challenges of digital mindfulness.

To fill the aforementioned research gap, we conducted a qualitative interview study to explore voice-guided digital mindfulness among older adults in Sweden. The main objectives are as follows: (1) understand how older adults incorporate mindfulness into their habits and routines, (2) explore the digital mindfulness design preferences of older adults, and (3) understand how digital mindfulness can facilitate self-perceived well-being among older adults. By considering the concept of aged heterogeneity [21,22], our research addresses the individual differences in the experiences and preferences of older adults when using a voice-guided mindfulness app over a 3-week period in their homes.

Background

MBIs in Medical and Clinical Research

Mindfulness originates from the Buddhist practice of meditation [23]. Kabat-Zinn [1], an early pioneer of modern mindfulness in the West, developed mindfulness-based stress reduction (MBSR) in 1979. Kabat-Zinn [1] defines mindfulness as "paying attention in a particular way, on purpose, in the present moment, and nonjudgmentally." In clinical psychology, Bishop et al [2] proposed a 2-component model of mindfulness in order to produce an operational definition. The first component involves the focus of attention so that it is maintained in the present, and the second component involves an accepting and open attitude toward the experiences in the present moment. The Swedish Healthcare Guide (1177 Vårdguiden) describes mindfulness as a method that involves focusing on the present with the help of senses and breathing, which can help an individual develop the ability of conscious presence.

In medical and clinical research, MBIs describe the use of mindfulness training in order to promote health and treat and prevent health-related conditions [6]. MBIs in contemporary psychology have been adopted as a form of mental training to reduce cognitive vulnerability to reactive modes that might otherwise heighten stress and emotional distress [2]. Consequently, MBIs have been developed in the form of mindfulness-based programs such as MBSR and mindfulness-based cognitive therapy for the prevention and treatment of mental health conditions [24].

Mindfulness practice can be considered a holistic way to support the well-being and resilience of older adults [25]. Research shows that MBIs are effective as a treatment for physical symptoms that often occur in later life. In Sweden, Norman et al [26] showed that mindfulness training decreased symptoms of fatigue, dizziness, and shortness of breath in a group of adults aged >70 years with chronic heart failure. Henriksson et al [27] explored the association between mindfulness training and the reduction of chronic pain among individuals aged ≥50 years. The group assigned to mindfulness training showed increased mindfulness skills, reduced pain intensity, reduced pain-related interference, heightened pain acceptance, reduced affective distress, and higher ratings of life satisfaction following the training.

MBIs can also improve mental and emotional well-being in later life. Studies have offered support for the use of MBIs to relieve anxiety, depression, and stress and improve pain acceptance [7,17,28,29]. Randomized controlled trials show that MBIs can improve positive affect and reduce symptoms of anxiety and depression for older adults [7,28]. MBIs can also enhance cognitive functioning [29] and working memory for older adults [8], alleviate chronic insomnia, and improve sleep quality [7,30]. Therefore, mindfulness, by definition, can be considered as an embodied experience, where bodily states shape emotion and cognitive processes [23]. For mindfulness

XSL•FO
RenderX

research, this highlights the reciprocal relationship between the mind and body.

Medical and clinical research has demonstrated the positive effects of mindfulness on well-being, but it remains unclear whether these benefits are strengthened by regular practice and if harmful effects can occur [31]. Galante et al [31] have demonstrated that a wide range of experiences can arise with mindfulness practice, ranging from profoundly positive to challenging and potentially harmful experiences. Unpleasant experiences followed by mindfulness practice have been reported to a relatively high degree in nonclinical contexts. These negative impacts can vary from anxiety issues to traumatic re-experiencing and emotional sensitivity [32]. Among mindfulness app users, reported effects included reduced self-efficacy, lower mood, increased frustration, and inability to control thoughts caused by the lack of supervision associated with self-guided digital mindfulness [33].

Consequently, the expected benefits of mindfulness training are mediated by various individual, social, and cultural factors [31]. At the individual level, the benefits and experiences of mindfulness training are influenced by the duration of practice, previous mindfulness experience, and health conditions [5,17,32]. At the sociodemographic level, social class, education, and cultural background can influence the mindfulness outcomes; yet, these factors have been less studied in previous mindfulness research. For older adults, these mediators in the mindfulness experience can also include familial and social relationships and a sense of community [34]. For these reasons, it becomes important to explore digital mindfulness with a qualitative approach and recognize older adults' experiences with digital mindfulness in relation to their background.

Digital Mindfulness for Older Adults

Digital mindfulness is a specific type of mindfulness training that includes the provision of MBIs through a digital platform, such as a mobile app. Mindfulness apps have increased the availability of MBIs to the public with and without mental health conditions. The most implemented techniques in mindfulness apps are voice-guided mindfulness exercises, self-tracking of mindfulness activities, setting personal goals, and receiving notifications [35]. These activities aim to track and influence the user's emotional state through increasing reflexivity and emotional awareness. Mindfulness apps mostly consist of a self-guided format, where users do not have a personal interaction with a mindfulness instructor [36].

Digital MBIs can increase accessibility and early prevention of mental health, as the provision of digital MBIs makes mindfulness easily accessible and could constitute a feasible alternative to promote mental health at a large scale [37]. However, the success of digital MBIs is reliant on adequate user engagement with digital mindfulness technologies. Several studies have explored mindfulness app users in their everyday contexts, demonstrating the positive effects of the use of mindfulness apps on the overall well-being [38,39]. The continuity of the mindfulness app use nevertheless remains a challenge. It is estimated that <5% of individuals continue using the mindfulness app after 30 days of download [40].

Older adults may have distinct characteristics of engagement with mindfulness apps [16,18,19]. Aged heterogeneity in information and communication technology refers to differences in older adults' backgrounds regarding the resources, needs, skills, and motivation to adopt digital technologies into their daily lives [22,41]. Older adults' use and perceived benefits of mindfulness apps are influenced by their general perceptions and attitudes toward technology, self-efficacy, and skill level [16]. Older adults may use mindfulness apps to improve interpersonal relationships [18,34]. Voice as an interaction modality has been shown to decrease many technology adoption barriers among older adults [42]. However, the conversational style can significantly impact the perceived likability of voice-guided technologies for this age group [43].

Methods

Overview

The app used for the study is Mindfulnessresan, which is a commercially available mobile app available from the Apple App Store. The app was provided free of charge to participants for the duration of the study. Mindfulnessresan was developed by a behavioral scientist and certified mindfulness instructor from the University of Gothenburg. The app has 5- to 10-minute voice-guided mindfulness exercises in Swedish (42 total exercises), with a new exercise available to the user each day. The guided mindfulness practices are based on Vipassana practices [44] and are inspired by the MBSR course by Kabat-Zinn [1]. The mindfulness exercises had varying themes, including focusing on breath, mentally scanning the body, handling negative thoughts, and cultivating a nonjudgmental orientation toward thoughts and experiences.

This study was conducted with 15 participants who reported as volunteers to take part in a 3-stage study using a voice-guided mindfulness app. The sample size was determined based on the principles of purposive sampling, which indicates the selection of "information-rich" cases for in-depth analysis [45]. We considered that the sample size was large enough to allow a new understanding of the self-perceived experiences of the mindfulness app among this age group but small enough to conduct a more in-depth analysis of interview material [46]. In qualitative research, the number of 20 research participants is often considered the saturation point after which little or no new information is generated among participants in one analytically relevant category [45]. In our study, we recruited 20 older adults to take part in all 3 stages of the study, and 15 (75%) participants completed all stages of the study. We aimed to reach a saturation point through the interview procedure, emphasizing open-ended questions, which have shown to contribute to the richness of data.

The study procedure consisted of three stages: (1) preuse study, (2) the use of a voice-guided mindfulness app over a 3-week period, and (3) postuse study. In the preuse study, participants received helped to install the mobile app on their phones, and filled out a questionnaire investigating their previous use of mHealth apps and self-perceived socioemotional well-being. Perceived socioemotional well-being consists of measuring well-being (World Health Organization-Five Well-Being Index

XSL•FO
RenderX

[WHO-5]) and mindfulness (Five Facet Mindfulness Questionnaire [FFMQ] scale). In addition, sociodemographic data variables were collected (age, gender, civil status, and household type).

In stage 2 of this study, participants used the mindfulness app daily for a 3-week period in their homes. Participants were given verbal and written instructions for using the app. Participants were instructed to engage with the mobile app daily at a time of their convenience, but their actual use was not monitored. In this procedure, we expected to better understand participants' authentic use of the app instead of giving participants predefined time frames or strict adherence rules. Participants with Android phones (8/15, 53%) were unable to download the app, as it was available only on the Apple App Store. Hence, those participants accessed screen recordings of the app through a shared drive, where they could follow the same exercises via a file-sharing app on their Android phones.

After having used the mindfulness app for a 3-week period, participants took part in the postuse study by answering a questionnaire and a semistructured interview. The interviews were conducted one-on-one with each participant and lasted approximately 20 minutes. The interviews were audio recorded, and all audio recordings were transcribed for analysis. The data collected during the postuse study consisted of the same perceived socioemotional well-being questionnaires as collected in the preuse study. In addition, participants answered the mHealth App Usability Questionnaire [47].

Analytical Approach

The study analyzed the research material through a qualitative approach, which aimed to address the complexities and subjective meanings of user engagement with a mindfulness app. Qualitative approaches have generated increasing interest in mindfulness research to explain the multifaceted characteristics and embodied nature of mindfulness through the interpretive-constructivist paradigm [48]. Qualitative approaches can provide alternative ways to explore the various subjective experiences of digital mindfulness to complement the medical model of MBIs [49]. They can be considered particularly valuable in addressing the heterogeneity in mindfulness practices among vulnerable populations, which often remain underrepresented in quantitative or medical research [50,51]. This study is reported in accordance with Standards for Reporting Qualitative Research guidelines [52].

The interpretive-constructivist paradigm in mindfulness research draws attention to subjective perceptions and experiences articulated with and through language [48]. The interpretive-constructivist paradigm indicates that the experience of digital mindfulness is socially constructed within language, and the well-being outcomes are subjectively perceived. Therefore, the narratives articulated by older adults can provide detailed accounts on how the subjective experiences of health and well-being are formed under certain contexts or environments [49] or mediated by social or cultural factors [53]. It can also mitigate the potential for a power imbalance between researchers and vulnerable groups as a research population [51] by giving research participants the opportunity to define and identify the experiences of digital mindfulness themselves.

Participant Recruitment

Participants were recruited by sending an email invitation to older adults through one Stockholm municipality that organizes weekly meetings for older adults aged ≥65 years. The Stockholm municipality, through which we recruited participants, represents an average municipality in Stockholm in terms of the sociodemographic background of the population. In the email invitation, we invited older adults interested in mindfulness to join a workshop at their weekly meeting for older adults. Eligibility criteria required participants to be (1) aged ≥65 years, (2) fluent in Swedish, and (3) smartphone owners. We used convenience sampling, selecting participants on a first-come, first-served basis. In the workshop, we presented the project and the Mindfulnessresan app and invited volunteers to take part in the study. From this group, 15 older adults were enrolled in the study and signed an informed consent form. We helped them download the app to their phones and gave verbal and written instructions for using the app. In addition, 5 participants were recruited through distributing the invitation in private yoga studios in Stockholm, following the same procedure as those who were recruited through Stockholm municipality. By recruiting participants in 2 separate locations, we were able to reach a relatively diverse sample of older adults in terms of their sociodemographic background, as shown by Table 1. Of the 15 participants recruited through Stockholm municipality, 10 (67%) completed the study. All (5/5, 100%) participants recruited from yoga studios completed the study.

XSL•FO
RenderX

Table 1. Participants' sociodemographic characteristics (age and gender), previous mindfulness experience, previous mobile health (mHealth) use, self-perceived well-being scores (World Health Organization-Five Well-Being Index [WHO-5]), and mindfulness scores (Five Facet Mindfulness Questionnaire [FFMQ]; N=15).

ID	Age (y)	Sex	Previous mindfulness experience	Previous mHealth use[a]	WHO-5 (0-100)	FFMQ score (0-100)
P1	65	Female	Yes	Intermediate	High (100)	73
P2	65	Female	Yes	High	High (90)	58
P3	66	Male	No	High	High (100)	58
P4	75	Male	Yes	Intermediate	Low (45)	45
P5	66	Female	Yes	Intermediate	High (90)	68
P6	71	Male	No	High	High (95)	60
P7	74	Female	Yes	Intermediate	Intermediate (65)	65
P8	83	Female	Yes	High	Low (40)	70
P9	69	Female	Yes	Intermediate	High (90)	73
P10	78	Female	No	Low	High (100)	58
P11	79	Female	No	Low	High (100)	70
P12	66	Female	No	High	High (95)	65
P13	89	Female	No	High	Intermediate (75)	50
P14	74	Female	Yes	Low	Intermediate (55)	63
P15	77	Female	Yes	Low	High (95)	67

[a]Previous mHealth use is calculated from participants' previous use of mobile technology for health, where daily use indicates high use, 1 to 3 times per week indicates intermediate use, and <1 to 3 times per week indicates low use.

Participant Characteristics

Participants' sociodemographic details are reported in Table 1. Most (12/15, 80%) of the participants were female, and just over half (8/15, 53%) of the participants had previous experience with mindfulness. Most (9/15, 60%) of the participants lived alone, and only 6% (1/15) of the participants lived in a senior living facility. Only 40% (6/15) of the participants were married or in a domestic relationship. Most (10/15, 66%) of the participants evaluated their self-perceived well-being as high (WHO-5 score >75). In total, 20% (3/15) of the participants reported an intermediate well-being (WHO-5 score between 50 and 75). Only 15% (2/15) of the participants reported a low well-being (WHO-5 score ≤50).

In the pre- and postuse study, participants were asked to fill out a survey questionnaire consisting of questions on their previous use of mobile apps, perceived well-being (WHO-5 score), perceived mindfulness (FFMQ scale), and sociodemographic information.

The FFMQ scale is based on a factor analytical study of 5 independently developed mindfulness scales that represent different elements of the conceptualization of mindfulness [54]. The 5 factors value the respondent's degree of observation, description, ability to act with awareness, nonreactivity, and nonjudgment toward inner thoughts and feelings. For this study, a shortened version of the FFMQ scale was used, containing 15 questions. The FFMQ-15 shows valid psychometric properties and can therefore be used in both health care settings and research settings [55]. The raw score was scaled to give a final score between 0 to 100.

The WHO-5 index uses five self-reported measures of overall mental well-being [56]: (1) "I have felt cheerful and in good spirits," (2) "I have felt calm and relaxed," (3) "I have felt active and vigorous," (4) "I woke up feeling fresh and rested," and (5) "My daily life has been filled with things that interest me." There are 5 possible answers, including "daily" (score 4), "1-3 times per week" (score 3), "1-3 times per 2 weeks" (score 2), "more seldom" (score 1), and "never" (score 0). The scores for the 5 questions are summed to obtain a raw score for each participant, and the raw score, ranging from 0 to 20, is multiplied by 5 to give the final score, where 0 represents the lowest well-being and 100 represents the highest.

Results from the prestudy questionnaire revealed participants' previous experience with mobile technology (smartphone, tablet, and portable device), mHealth apps, and conversational agents. Approximately half (6/15, 40%) of the participants used mobile technology daily for health reasons. Only a few participants used mobile technology daily for mental well-being (3/15, 20%), whereas 40% (6/15) of the participants had never used mobile technology for mental well-being. Participants rarely used mHealth apps, except for the Swedish health advice service app, which was used by six (6/15, 40%) of the participants 1 to 3 times per month. Only a few participants had used mHealth apps for tracking steps and sleep and practicing yoga (3/15, 20%). Seven of the participants (7/15, 46%) had used a voice assistant before. The voice assistants they had tried were Google Home, Siri, and ChatGPT. Of those participants who had never tried to use voice assistants, the most common reasons were that they did not need voice assistants or they did not know how to use them.

Data

Semistructured Interviews

In the postuse study, participants were interviewed about the user experience of the mindfulness app and the self-perceived benefits of digital mindfulness training. A semistructured interview topic guide (Multimedia Appendix 1) was prepared, which was guided by previous mindfulness literature. We conducted the interview with an open-minded approach, including questions that would enable the informants to respond as they found suitable. The interview guide was structured around the following themes and questions: (1) perceived health, (2) routines, (3) design preferences and usability of Mindfulnessresan, (4) digital mindfulness and well-being, and (5) ethical considerations.

Thematic Analysis of Semistructured Interviews

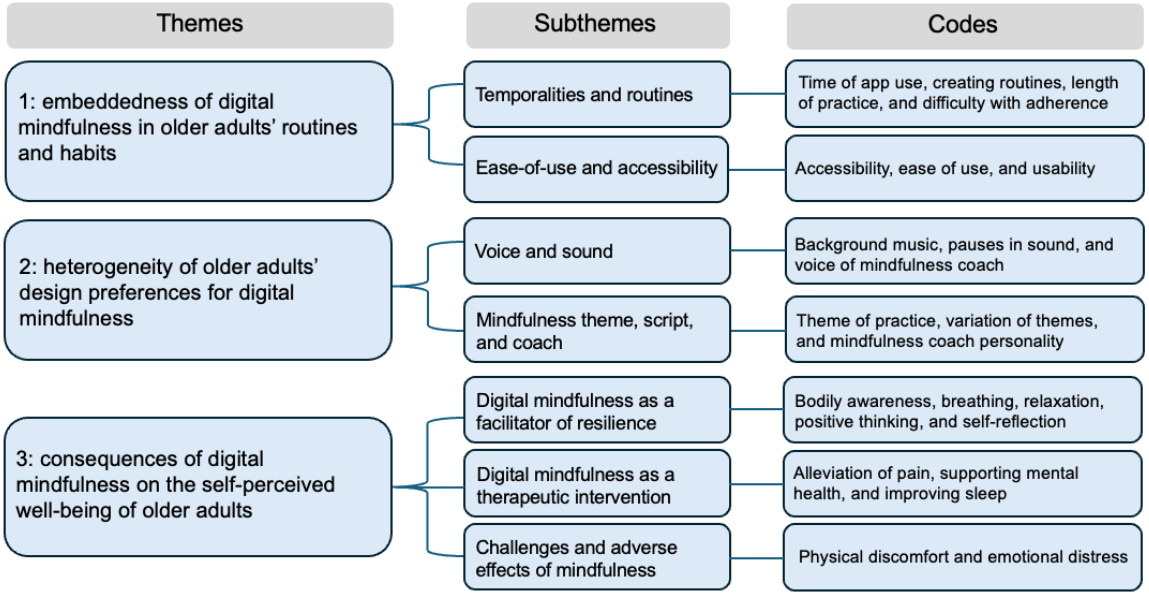
The interviews were conducted, transcribed, and analyzed by 2 researchers using an investigator triangulation method. Investigator triangulation refers to the participation of ≥2 researchers in the same study to provide multiple observations and conclusions that can serve as a strategy to validate the trustworthiness of research findings [57]. Researchers conducting the analysis had complementary expertise in social science methodologies and computer science. One of the researchers had a previous background in serving as a mindfulness instructor.

A thematic analysis was used to detect codes and themes from the interview data through identifying, analyzing, and interpreting patterns [58]. Qualitative thematic analysis is an established method in health research to explore individuals' beliefs, perspectives, and experiences within certain social and cultural contexts [59]. Analysis followed the principles of reflexive thematic analysis with 6 distinct stages described: familiarizing with the dataset; coding the dataset; generating initial themes; developing and reviewing themes; refining, defining, and naming themes; and writing up [59]. Data saturation was discussed throughout these stages, with the notification that no new codes or themes emerged from the data after stages 3 and 4 [45].

The interview transcripts were thematized inductively, indicating that codes were generated from the data to allow patterns and themes to emerge from the data without using any predetermined code lists or framework in the analysis [55]. After both researchers had familiarized themselves with the transcriptions, codes that answered the research objectives were identified from the data. This initial coding was conducted on the entire interview material, and certain keywords were selected to represent the codes (eg, "creating routines," "voice," and "sound"). To further recognize patterns in participants' statements, initial themes were generated that gathered codes together in a way that was representative of the data and research questions (eg, "mindfulness as a therapeutic intervention" or "mindfulness coach persona"). In developing and reviewing the themes, researchers jointly discussed the refining and naming of the themes to involve a level of interpretation and conceptualization in the analysis. Thus, the final themes described the patterns in the participants' experience of digital mindfulness that emerged from the data through interpretative analysis. The codes and themes are presented in Multimedia Appendix 2.

Ethical Considerations

The research was approved by the Swedish Ethical Review Authority (reference number 2023-07682-01). All participants gave informed verbal and written consent for participation in the study and publication of anonymized extractions from the data. Before participants signed the informed consent, they were given both written and verbal information about the effects of practicing mindfulness and potential risks in participating in the study. Participants were given the opportunity to ask questions and withdraw from the study at any time. The privacy and confidentiality of participants were protected by giving all participants an anonymous ID that was used in the analysis and reporting of the results. Participants were given a small financial compensation of a gift card worth 200 SEK (US $20.82) after they completed their participation in the study. The amount of financial compensation was not specified in the recruitment material.



Results

Overview

From the coding stage, 23 codes describing the digital mindfulness experience were identified from the data. These codes were thematized to group the codes together, resulting in 7 subthemes. From these 7 subthemes, three main themes were formed to answer the research objective: (1) the embeddedness of digital mindfulness in older adults' daily routines and habits, (2) heterogeneity in older adults' design preferences for digital mindfulness, and (3) the consequences of digital mindfulness on the self-perceived well-being of older adults. Codes, subthemes, and main themes are presented in Figure 1 and Multimedia Appendix 2.

Figure 1. A map showing the themes, subthemes, and codes that emerged from the thematic analysis of the semistructured interview data.

Theme 1: Embeddedness of Digital Mindfulness in Older Adults' Daily Routines and Habits

Temporalities and Routines

Participants described the use of the app as relatively effortless, because "It takes only 5 minutes so I have time to do it" (P4; male participant aged 75 y). They were able to choose the time of the day for training based on their own preferences. Participants described how the temporality of the app use could significantly influence the experience of mindfulness training. Two participants mentioned that practicing mindfulness in the evening instead of morning can impact the perceived effects of the training:

> *At first, I did it in the evening, but then I started doing it in the morning instead. I almost thought it felt better. Because in the evening, when you do it as the last thing you do, then you end up not hearing what he says, you almost fall asleep.* [P3; male participant aged 66 y]

> *If you listen during the day, you feel a little more calm during the day. But if you listen in the evening, you might sleep better.* [P6; male participant aged 71 y]

Participants recognized that continuity with the app use and embedding the app into the daily routines elicited a sense of well-being:

> *Doing it regularly and creating routines [with the app use] feels good.* [P4; male participant 75 y]

In addition, a participant described that "It worked quite well actually because I did it as a sort of morning routine. [...] I went back to bed and completed the exercise there. It was a very relaxing and pleasant start to the day" (P9; female participant aged 69 y).

The app provided participants with flexibility in finding a suitable time and location for practice, which seemed to improve the user experience. One participant described that practicing mindfulness in familiar locations, such as when lying in bed, helped in creating routines with the app, which contributed to improved user engagement. Mindfulness practice requires concentration, which is easier to do in a familiar location:

> *I liked that I decided to take five minutes. And I almost always did it in the morning. And then I did it while lying in bed. So, I was in the same place. [...] I tried it [once] when I was waiting for a bus. But I found that distracting. [...] So that was the good thing about the app. It took five minutes, a routine.* [P7; female participant aged 74 y]

Some participants enjoyed the fact that the guided mindfulness sessions were short:

> *Yes, it was very good, actually. And it's short as well, just five minutes.* [P6; male participant aged 71 y]

By contrast, others described that they would have enjoyed a longer practice:

> *I thought they were a bit too short. Five minutes is too short to really get into a relaxed state, or whatever you want to call it. [...] I think ten minutes would make it much better.* [P8; female participant aged 83 y]

Some participants described challenges in adhering to the mindfulness routines, which was pronounced as a difficulty in finding a suitable time for digital mindfulness practice. One participant mentioned that her habits, such as having breakfast during a certain time of the day, made it difficult to incorporate the app into her morning routines:

> *It's difficult [...] I'm someone who has very fixed morning routines. So I wake up, and when I wake up, I have to get up and start breakfast immediately.* [P10; female participant aged 78 y]

Another participant mentioned that sometimes she forgot to use the app due to being distracted by other activities and routines of daily life:

XSL•FO
RenderX

> *I must admit I forget it on some days. I try to listen in the mornings, and something always gets in the way. Then I forget it.* [P14; female participant aged 74 y]

Sometimes, participants felt a sense of obligation to conduct the mindfulness training, and missing the daily mindfulness exercises caused a negative feeling. As a participant mentioned, the app provided flexibility in finding a suitable time for training, but this flexibility sometimes resulted in missing exercises:

> *When you miss it and think, now I haven't done it today, but I'll do it tomorrow. Then you feel like you're missing out. It has a slightly negative feeling—yes, it does.* [P5; female participant aged 66 y]

Ease of Use and Accessibility

In total, 27% (4/15) of the participants stated that the app was relatively easy to use, and none of them reported any major technical problems with the app:

> *I didn't have any problems at all. It was easy to use.* [P4; male participant aged 75 y]

Even if the app was considered accessible in technical terms, the graphical interface and symbols associated with training were sometimes considered confusing:

> *It should be clear which exercises you've done or not. The star was a bit confusing—I did not know what it meant.* [P4; male participant aged 75 y]

One participant highlighted that they would have preferred titles for the exercises so that it would have been clear what they were about:

> *I guess it's better that each exercise would have a title. It's not clear what it's about.* [P5; female participant aged 66 y]

One participant suggested that mindfulness apps can increase the accessibility to mindfulness training, in comparison to practicing yoga in a studio, which she considered to be too expensive for her budget as a pensioner:

> *I used to go to medicinal yoga. That was really, really good. So I did two semesters. That's something I miss, but I also miss the money.* [P11; female participant aged 79 y]

Theme 2: Heterogeneity in Older Adults' Design Preferences for Digital Mindfulness

Voice and Sound

Voice interaction and sound in the mindfulness exercises were a significant part of the experience. Many participants described how the voice of the mindfulness coach impacted the perceived benefits of training, such as the sense of calmness:

> *He had a good voice. He spoke clearly, and with a sense of calm.* [P10; female participant aged 78 y]

If the voice of the mindfulness coach was not pleasant or aligned with participants' preferences, this could have decreased the user experience.

Overall, participants expressed diverse preferences for voice interaction and a need to adjust the voice according to their individual desires. The voice interaction should represent qualities such as calmness, quietness, and meditative techniques:

> *I think I would like a quieter voice. A slightly more meditative voice. [...] He speaks in some dialect. He has a very special voice. Maybe that's why I [like] quite a low voice mode. Not so high, but lower. [...] When you try to calm down, you need help with that. A slightly darker voice, not too fast.* [P7; female participant aged 74 y]

Some participants reported inconsistencies in the sound interaction. In total, 27% (4/15) of the participants described how sudden pauses in the sound disturbed the mindfulness practice, which showed the significance of voice and sound interaction in the mindfulness experience:

> *I thought the app's content was quite good, but the way it was done wasn't great. The recording made it so that, when the guy is talking, it sounds good, but then there are pauses now and then, and all the sound and ambient noise disappear.* [P4; male participant aged 75 y]

> *He makes these pauses. They're so long, and then you wonder if there's something wrong with the recording.[...] You get distracted by these pauses. Is this right, or is it wrong? And then you kind of wake up.* [P14; female participant aged 74 y]

Some participants suggested that they would have preferred music in the background to avoid the sudden pauses and to add to the sense of calm:

> *I feel that music adds a lot, so if you would have calm music playing in the background, I think it would create a stronger feeling. [...] It's always so nice when there's a kind of background sound—it's very soothing.* [P3; male participant aged 66 y]

Mindfulness Theme, Script, and Coach

Mindfulness script and content provoked different metaphors among participants. A participant highlighted the effectiveness of figurative descriptions, particularly the metaphor of a wave:

> *I liked the figurative descriptions, like when he said, "feel it like a wave." I felt supported by the app. I had used breathing techniques during pregnancy, but this was completely different.* [P1; female participant aged 65 y]

The imagery of a wave aligns with common mindfulness techniques, where emotions and sensations are framed as transient, reducing resistance and promoting acceptance. Metaphorical language can enhance the practice by linking abstract concepts (eg, transience) to physical sensations.

The content provided by the mindfulness app did not always align with participants' real-life experiences. One participant

XSL•FO
RenderX

indicated that the mindfulness practices in the app may downplay the complexity of real-life struggles:

> *In some exercises, near the end, the person speaking—or this app—seemed to think that big problems could just disappear like that. But it's not that easy.* [P6; male participant aged 71 y]

This comment reflected frustration or skepticism, indicating that while mindfulness can be helpful, it may not provide sufficient depth for more profound personal issues. This aligned with critiques that mindfulness, when decontextualized, may not fully support users with complex psychological challenges.

Some participants valued the soft and reassuring tone of the mindfulness coach. This was illustrated by one participant as follows:

> *He [the mindfulness coach] was nice. His tone was soft as well. He also used those kinds of analogies sometimes. I thought that was nice.* [P15; female participant aged 77 y]

The positive response to the coach's tone suggested that a calm and warm delivery might enhance the soothing effects of mindfulness. In contrast, some participants perceived the coach's persona as too immature for their age group, leading to frustration and disengagement:

> *The guy [mindfulness coach] sounds too childish. He speaks in a way that is a bit immature. It's annoying. It's less authoritative. [...] I was a bit annoyed that his texts can be a little cheesy, a bit childish as well and a bit immature. If you're 65 plus, it's not very smart. That could bother me.* [P4; male participant aged 75 y]

The repeated use of "childish," "cheesy," and "immature" suggested that some older adults preferred a more mature, authoritative style in mindfulness guidance. The critique implied that users may expect more intellectually engaging or sophisticated content. A less authoritative tone may reduce credibility and make the guidance feel less impactful or serious.

Theme 3: Consequences of Digital Mindfulness to the Self-Perceived Well-Being of Older Adults

Digital Mindfulness as a Facilitator of Resilience

Many participants mentioned an increased bodily awareness as an outcome of mindfulness training. A participant stated that "Breathing exercises are what make you get in touch with the body" (P7, female participant aged 74 y). Another participant who had no previous experience with mindfulness and reported only a low use of other mHealth apps noticed that "I feel when I walk, that my shoulders are lower, since I started doing it, that I became aware of my posture" (P11; female participant aged 79 y). By using the app, participants could adopt and increase their bodily knowledge and make changes to improve their bodily postures independently.

A decrease in muscle tension was also described as a self-perceived benefit of digital mindfulness. When mindfulness training involves paying attention to body parts, this can result in improved awareness of the tensions or discomforts in the body. Listening to digital mindfulness can help participants to imagine alternative bodily postures, which can result in a sense of improved bodily awareness. One participant described increased relaxation in the shoulders as a self-perceived benefit in using the app:

> *Some of the exercises include feeling for the legs or the stomach and so on. It's good for bodily awareness. It is very good and useful. [...] For example, if I have pain somewhere, or you are tense somewhere in particular, I tense my shoulders and I can imagine breathing out into my shoulders to relax the shoulders more easily. It's the kind of thing you can put into practice when you use these guided meditations.* [P4; male participant aged 75 y]

Breathing exercises are a central part of mindfulness-based training [22]. To some extent, breathing was considered to be a facilitator and associated with all outcomes of mindfulness training, such as bodily awareness, sleep quality, relaxation, and positive thinking. Participants such as P6, who had no previous mindfulness experience, mentioned an increased awareness of breathing:

> *Breathing—I knew before how important it is, a few deep breaths. But after this exercise, I'm even more motivated, even more aware.* [P6; male participant aged 71 y]

Participants such as P2 and P7 noticed that mindfulness training was connected to improvements in the breathing technique. One of them mentioned feeling better after the breathing exercises, which helped her to improve her breathing technique:

> *Instead of just breathing up here all the time, like I often do. I can say, for that reason, that I feel better.* [P2; female participant aged 65 y]

A participant who had previous mindfulness experience and reported intermediate well-being scores described breathing exercises as a method to pay attention to incorrect breathing techniques, such as holding one's breath:

> *I think the breathing exercises are good. I find it interesting that thoughts affect breathing, and that we breathe too little. We hold our breath a lot. So, I'm always training to breathe with my stomach.* [P7; female participant aged 74 y]

Relaxation was one of the most frequently reported consequences of practicing digital mindfulness through breathing-related exercises, mentioned by 53% (8/15) of the participants. Participants such as P4, P5, and P6 mentioned a sense of calmness, relaxation, and improved focus on the present moment, followed by digital mindfulness training:

> *We even tested my pulse, and with this smartwatch I have, my pulse goes down. It feels really good.* [P6; male participant aged 71 y]

Other participants, such as P10 and P12, mentioned a feeling of joy and a sense of renewed energy associated with relaxation after practicing digital mindfulness:

> *It's about relaxing. When you wake up after ten minutes, you feel like you've come back. You rest,*

XSL•FO
RenderX

> *and your body feels fresher.* [P10; female participant aged 78 y]

For P5 and P6, this sense of relaxation was considered to have cognitive elements, such as maintaining better control of one's own thinking and thoughts:

> *You become calmer because thoughts are focused on breathing [...]. Suddenly, your thoughts don't stick as much, and they might rotate or move away.* [P6; male participant aged 71 y]

Digital mindfulness practice provoked positive thinking among participants. One participant who had previous mindfulness experience described how the mindfulness app increased the ability for self-reflection and harmony and also being in control of one's own emotions:

> *I don't see myself as someone who complains a lot, but I do sometimes meet many people who sigh over just about everything. So yes, reflecting can help. I really like this idea of sitting for a while—it's something that guides you, and you settle into a calmer pace, a nice harmony.* [P5; female participant aged 66 y]

A participant described the emotional awareness associated with the app use. As she described, this awareness of one's own thinking can provoke new approaches for self-reflection, which provides possibilities to change the way one thinks about oneself. From this perspective, mindfulness training has similarities with cognitive behavioral therapy [60]. The participant had previous experience with mindfulness and intermediate self-perceived well-being:

> *You get irritated and frustrated, and you get angry at yourself, you are so frustrated by making a mistake—why did I say this? And then I realise that maybe you can handle it in a different way [...] That maybe I can look at my well-being and my inner self in a different way [...]. I often get stressed by something I have done wrong.* [P14; female participant aged 74 y]

One participant recognized that increasing awareness of breath can help in letting go of negative thoughts. This reflects cognitive defusion, a core principle in mindfulness and acceptance and commitment therapy [61]. Cognitive defusion refers to the process of detaching from thoughts, seeing them as transient mental events rather than absolute truths:

> *You become calmer, because thoughts go on breathing and focus. And it was a good method, to let the mind rest on the sensation of the breath. Suddenly, thoughts don't stick very much, and they might rotate or go away. It felt good, I became a bit more conscious, you could say.* [P6; male participant aged 71 y]

Digital Mindfulness as a Therapeutic Intervention

Several participants recognized the mindfulness training as beneficial for supporting their mental health to alleviate a sense of worry or stress. P6 (male participant aged 71 y), who had no previous experience with digital mindfulness and reported high well-being scores, mentioned mindfulness training as a good method to decrease a sense of worry about "world events, worries about my family—my children, grandchildren."

During the interviews, P2 (female participant aged 65 y) and P4 (male participant aged 75 y), who both had previous experience with mindfulness, shared that they had experienced panic attacks before in life. For this reason, they had used breathing to help calm down and reported a need to find different methods for relaxation. One of them also described his personal experience with having attention-deficit/hyperactivity disorder, which is often accompanied by high energy and heightened emotions. He mentioned that with voice-guided digital mindfulness, he learned new tools to manage this condition:

> *I think mindfulness is very helpful for people with ADHD. I believe it's very, very helpful. That's one reason why I started [mindfulness training]. With ADHD, you have a lot of energy, and your head spins a lot. Learning to manage that better is a big win.* [P4; male participant aged 65 y]

Breathing techniques embedded in the app created a sense of bodily relaxation, which was considered to improve sleep quality. Two participants used the breathing exercises as a method of relaxation in the evenings, which resulted in them falling asleep faster. In this way, digital mindfulness could be used as an intervention to improve sleep in a self-guided format:

> *I have trouble sleeping. I sleep for two hours, then I wake up. But then I get up and sit and listen to it [mindfulness app]. If that doesn't work, I do crosswords for a while, then listen [to the app] again. Then I go back to bed, and I fall asleep.* [P11; female participant aged 79 y]
>
> *What I liked, and which has helped me quite a bit are these breathing exercises. Because it has sort of helped me to fall asleep faster in the evening than I have done before.* [P9; female participant 69 y]

In total, 33% (5/15) of the participants reported that the mindfulness training with the app helped them in managing pain and physical discomfort. Although the app did not alleviate the pain, as such, it could help redirect one's thoughts and "disconnect" from the feeling of pain. A participant described that the mindfulness app helped her to cope with chronic pain caused by rheumatism, which caused physical discomfort in her daily life:

> *I've had PMR [polymyalgia rheumatica] for a year now, and it has been so hard [...], there is a lot of pain sometimes. When you sit and just feel that pain, or lie down and just feel that, then it's very difficult to get your mind off it. But with the mindfulness app, I disconnect from that. So, then the pain disappears.* [P11; female participant 79 y]

A participant mentioned that increased bodily awareness through mindfulness training helped them accept the pain or physical limitations caused by an injury. This self-perceived benefit was connected to the relaxation that the app provided:

> *I am right-handed and the injury is on the right side of the neck vertebrae. [...] Of course, mindfulness helps. Thinking about relaxation, even though there's*

XSL•FO
RenderX

an injury, helps you manage it in the right way. You learn to relax, and that helps. [P12; female participant aged 66 y]

Adverse Effects of Digital Mindfulness

Sometimes participants reported adverse or unexpected negative effects from practicing digital mindfulness. One participant described how practicing digital mindfulness resulted in a sense of discomfort and a sense of physical pain because of not being able to find the right position or location for the training. Her statement also indicated that benefiting from digital mindfulness often requires familiarity with finding locations that are optimal for mindfulness training:

When I sit on a chair, I get back pain, and I don't know if it's because I'm sitting still, but I feel more pain in my back. I have to move around more. It's so rare to sit still in a relaxed way. Now I did get back pain, because of the chair. One should sit on a better chair or lie down, but then you might fall asleep. [P14; female participant aged 74 y]

Another adverse effect of digital mindfulness was mild emotional distress, as mentioned by P3 and P1. P3, who had no previous mindfulness experience, articulated that mindfulness scripts from the app highlighted unpleasant situations in everyday life that provoked distracting emotions and disturbed his sense of calmness:

It almost became annoying then when he brought up different everyday situations. "Why did I say that? Why did I do that?" I don't want to think about that; I just want to continue with the calmness. [P3; male participant aged 66 y]

Similarly, one of the participants described how breathing exercises generated unpleasant memories from a personal life event. For her, this emotional distress was associated with the breathing activity:

Breathing is emotionally charged for me because my brother passed away from ALS [Amyotrophic Lateral Sclerosis], which makes it hard to breathe. So it made me think about that. I've had quite a bit of pain at times in my life—not really now—but it also reminded me of that. [P1; female participant 65 y]

Discussion

Principal Findings

Overview

Previous studies have explored the effects of mindfulness training on the well-being of older adults through randomized controlled trials from the medical or clinical perspective [16-18]. The research evidence indicates the positive effects of mindfulness training on physical well-being [26,27]. Previous studies have also confirmed that MBIs can reduce negative emotions and thoughts in daily life among the general population [24,25,27] and demonstrated the effectiveness of MBIs to reduce stress, anxiety, and depression among older adults [4,17,28,29,62,63]. However, the research evidence on the specific characteristics of voice-guided digital mindfulness for mental and emotional well-being among older adults is rare. This study has filled this research gap by exploring voice-guided digital mindfulness and emphasizing the subjective experiences of digital mindfulness and their possible effects and outcomes among older adults.

Creating Routines With Digital Mindfulness Through Temporalities

As a response to the first research objective, the study has characterized the specific conditions for embedding the mindfulness app into the daily routines of older adults, which can be summarized as mentioned subsequently.

First, in order to actively benefit from digital mindfulness, older adults need to integrate the use of the app into their daily routines and schedules. In general, participants found the digital mindfulness app easy to incorporate into their daily schedules, with the flexibility to choose sessions at times that suited their personal routines. The brevity of the sessions, typically approximately 5 minutes, was appreciated by many participants, facilitating regular practice without significant time commitment. This highlights how the flexibility of digital platforms allows personalized engagement, enabling users to select practices that align with their individual preferences and schedules.

Second, interestingly, the challenges in the adherence to mindfulness training were not associated with technical difficulties or the accessibility of the app but rather with the extent to which older adults could find a suitable time to practice digital mindfulness. This underscores the need for apps to provide reminders or integrate seamlessly with users' existing schedules to promote adherence and aligns with existing research highlighting that continuity in app use can be a challenge [40].

Third, although the app itself enabled practicing digital mindfulness "anywhere and anytime," older adults often chose the location and time based on their existing daily habits, thus embedding the app into existing routines and practices. Participants highlighted how the effects of mindfulness varied according to what time of the day they practiced.

Heterogeneous Design Preferences for Voice-Guided Mindfulness

As a response to the second research objective, this study has recognized heterogeneity in the design preferences for voice-guided digital mindfulness. Practicing digital mindfulness is a highly personalized experience, influenced by a person's previous mindfulness experience, health conditions, and motivations for training [32,64]. This study shows that this heterogeneity is particularly pronounced in relation to design preferences of digital mindfulness apps: voice and sound landscape and mindfulness theme, script, and coach persona. The diversity in older adults' experiences and preferences with digital mindfulness underscores the necessity for customizable voice-guided apps. This variability suggests that a one-size-fits-all approach may not be effective, and developers should consider offering adjustable features, such as voice tone, session length, and content complexity, to cater to the unique needs of each user.

XSL•FO
RenderX

This study indicates that design preferences can partly be associated with various emotions and sensations that participants associate with certain types of voices, sounds, and scripts. For instance, the description of some mindfulness scripts as too "childish" or "immature" for older adults is a sign that mindfulness content should be adapted to age-specific characteristics. While other studies have revealed preferences for personalization of a mindfulness app among the younger population [65], the age-specific characteristics for certain interaction modalities or conversational styles have not been explored. This study concludes that the audio landscape of mindfulness apps provides possibilities for enhancing the mindfulness experience in a way that can respond to the age-specific characteristics of this age group.

Building Resilience and Self-Care Through Digital Mindfulness

As a response to the third research objective, this study has addressed older adults' self-perceived experiences of using digital mindfulness as a self-care technology to facilitate well-being. Previous research shows that mindfulness is useful for improving resilience and coping strategies and reducing anxiety and stress levels in older adults [62,63,66]. This study highlighted that digital mindfulness practices could contribute to resilience by fostering positive thinking, bodily awareness, relaxation, and self-reflection. Participants noted a greater ability to manage negative emotions and adopt new perspectives on personal well-being. Beyond emotional benefits, participants perceived digital mindfulness to be a therapeutic tool for managing mental health concerns and pain and improving sleep quality. Participants reported that mindfulness practices helped redirect focus away from pain, providing a sense of relief. This aligns with studies suggesting that web-based mindfulness interventions can lead to improvements in cognitive and psychological measures, with associated modulations in pain perception.

However, the adverse effects of digital mindfulness were also pronounced, in terms of discomfort and emotional distress that resemble re-experiencing unpleasant life events [32]. These findings underscore the importance of personalized mindfulness interventions and the potential need for guidance on adapting mindfulness practices to individual emotional and physical comfort levels.

By incorporating mindfulness practices into their routines, older adults can develop better coping mechanisms to navigate stressors and challenges. The convenience of digital platforms ensures that these resources are readily available, promoting sustained engagement and long-term benefits.

Limitations

This study has explored the use of a mindfulness app as a form of digital self-care among older adults through the lens of aged heterogeneity. Participants were recruited through a municipal organization, which means that research participants were relatively active older adults with a previous interest in health and well-being. Moreover, participants used the app for 3 weeks; therefore, the long-term effects of mindfulness app use are not known. This study focused on the self-perceived benefits of digital mindfulness, as articulated by participants themselves, which means that the actual use patterns remained unexplored in this study. The use, design preferences, and consequences to well-being of the mindfulness app could depend on contextual factors, such as mood, digital skills, and education level, which remain beyond the scope of this study. Despite these limitations, this study has produced new knowledge on the self-perceived benefits of digital mindfulness among older adults, particularly regarding the affective aspects of mindfulness app use and the integration of the app into daily routines. These qualitative findings extend the already existing medical and clinical research on digital mindfulness with older adults [14-16,18] and provide considerations for designing MBIs beyond medical or clinical purposes, such as in the maintenance of cognitive or physical functioning in later life.

Conclusions

The study concludes that digital mindfulness offers a possibility to enhance the self-perceived well-being of older adults by fostering resilience and self-care. However, the adverse effects of digital mindfulness, such as frustration and discomfort, can also be experienced by older adults. The digital mindfulness experiences and preferences of older adults are highly individual, diverse, and manifold, which indicates that personalized approaches are essential for effective engagement. By acknowledging and addressing the heterogeneous design preferences within this demographic, developers can create more effective and user-friendly voice-guided mindfulness apps. Additional research is needed to explore the emerging digital inequalities involving older adults from a more diverse socioeconomic background to explore the benefits of digital mindfulness in relation to an individual's digital health literacy. Furthermore, longitudinal studies could provide deeper insights into the sustained effects of digital mindfulness on well-being over time. Future research should also explore ways to personalize digital mindfulness experiences, considering factors such as previous mindfulness experience, individual emotional triggers, and physical limitations. Future studies should also explore the potential of artificial intelligence to enhance the personalization of mindfulness experience to be more adaptive to older adults' previous mindfulness experience and their personal preferences for certain types of voices, sounds, and mindfulness coaches' personas.

Acknowledgments

The authors would like to thank all participants for their invaluable participation in this study. The authors also wish to thank Sebastiaan Meijer for commenting on the manuscript.

Abstract

Background: Cognitive bias modification for interpretation (CBM-I) is a technique to modify interpretation and is used to reduce unhelpful negative biases. CBM-I has been extensively studied in anxiety disorders where interpretation bias has been shown to play a causal role in maintaining the condition. Successful Treatment of Paranoia (STOP) is a CBM-I smartphone app targeting interpretation bias in paranoia. It has been developed following research on the feasibility and acceptability of a computerized version. This qualitative study extended that research by investigating the acceptability of STOP in individuals with paranoia. The study design and implementation were informed by the Evidence Standards Framework for Digital Health Technologies (DHTs) published by the UK National Institute for Health and Care Excellence (NICE).

Objective: The aim of the study was to involve service users in the design, development, and testing of STOP and understand the degree of satisfaction with the product. We aimed to establish the extent to which STOP met the NICE minimum and best practice standards for DHTs, specifically its acceptability to intended end users.

Methods: In total, 12 participants experiencing mild to moderate levels of paranoia were recruited to complete 6 weekly sessions of STOP before being invited to a feedback interview to share their experiences. Interview questions revolved around the acceptability of the app, its perceived usefulness, and barriers to the intervention, as well as practicality and views on the use of a digital intervention in principle. Interviews were coded and analyzed using the framework analysis method, combining both deductive and inductive approaches.

Results: Framework analysis yielded 6 themes: independent use and personal fit; digital versus traditional approaches; user reactions and emotional impact; impact on thinking, awareness, and well-being; design, engagement, and usability; and intervention relevance and practical fit.

Conclusions: STOP was found to be a broadly acceptable intervention and was positively received by most participants. The study findings are in line with the NICE Evidence Standards Framework for DHTs, as intended end users were involved in the development, design, and testing of STOP and were mostly satisfied with it. These findings will contribute to the further iterative development of this intervention that targets interpretation bias in paranoia.

Introduction

Interpretation Bias and Cognitive Bias Modification

Paranoia refers to unfounded beliefs that others intend to cause harm and exists on a continuum from mild suspiciousness to severe persecutory delusions [1]. Interpretation bias toward threat, defined as the tendency to interpret ambiguous information in a threatening or negative way, is thought to be one of the key cognitive processes involved in the development and maintenance of paranoia. Specifically, individuals with paranoia are more likely to interpret neutral or ambiguous situations as intentionally harmful, often exhibiting hostility interpretation bias (perceiving others as deliberately malicious) and external-personal attribution bias (attributing negative events to the harmful intent of others), as well as biases related to physical threats (such as those involving security devices or medical interventions) [2-6]. While similar biases are seen in anxiety disorders, paranoia is distinguished by its focus on intentional harm, rather than fear of negative evaluation or embarrassment as seen in social anxiety. Cognitive biases, including interpretation bias, have therefore been identified as critical maintenance factors in psychosis and paranoia, highlighting the need for targeted interventions that address these specific processing styles [1,7,8].

Cognitive bias modification for interpretation (CBM-I) is one such technique, designed to reduce interpretation bias toward threat. Research has demonstrated that it is possible to change bias through training [9,10], helping individuals replace maladaptive cognitive patterns with more neutral or positive interpretations. Successful Treatment of Paranoia (STOP) is a smartphone app that delivers CBM-I through a series of ambiguous scenarios, encouraging the user to generate more adaptive interpretations [11]. CBM-I has shown consistent benefits in reducing anxiety and repetitive negative thinking [12-14], but studies applying this approach to paranoia remain limited. One feasibility randomized controlled trial evaluated a desktop version of cognitive bias modification for paranoia (CBM-pa) [15], and a subsequent qualitative study highlighted the need for improvements in the task's audiovisual design to enhance attention and engagement [16]. These findings directly informed the development of STOP, the smartphone app evaluated in this study.

While STOP draws on CBM principles, it differs significantly from the earlier CBM-pa platform. CBM-pa was delivered in a controlled laboratory setting, whereas STOP is a stand-alone smartphone app designed for independent use. Unlike CBM-pa, STOP enables participants to schedule sessions autonomously, receive automated reminders, and engage with a web-based interface designed to enhance immersion. These structural and experiential differences mean that the findings from the earlier CBM-pa evaluation cannot be assumed to generalize to STOP. A distinct evaluation is therefore warranted.

Thus, a qualitative study, such as the one reported here, is essential to determine whether STOP, in its current form, is a product that would be acceptable to users and suitable for use in routine clinical practice. The importance of gathering this type of evidence for any potential new digital therapy is emphasized in the Evidence Standards Framework for Digital Health Technologies published by the UK National Institute for Health and Care Excellence (NICE) [17], which requires evidence of "acceptability with users" and their involvement in development, design, and testing. The qualitative data were contextualized using the User Experience Questionnaire (UEQ), which quantified participants' experience of the app, such as their perception of its attractiveness, ease of use, and creativity [18]. Therefore, descriptive statistics of the UEQ are reported to indicate the overall experience of participants using the digital health technology (DHT).

In addition to assessing acceptability, a growing body of literature highlights the importance of applying a human factors lens when evaluating DHTs. This includes attention to usability, accessibility, and alignment with user needs and preferences. Human factors research considers not only whether an intervention works but also how individuals interact with it—factoring in context of use, autonomy, and digital literacy; for example, the concept of the digital therapeutic alliance has gained prominence in recent years, recognizing that users may form relational connections with digital tools, which in turn can affect engagement and perceived effectiveness. Evaluating STOP through both experiential and design lenses enables a more comprehensive understanding of its acceptability and potential for real-world implementation.

The Rise and Use of DHTs

Digital interventions have become increasingly common over time, and some have proven to be effective [19]. In a scoping review, Zhang et al [19] identified 22 randomized controlled trials exploring the effect of CBM techniques delivered through a web-based intervention and found that CBM could help reduce biases in anxiety disorders and depression in adolescents.

Despite these advancements, there remains a lack of available treatments specifically targeting psychosis and paranoia. Other than pharmacological interventions, the only treatment that NICE recommends for psychosis is cognitive behavioral therapy, a psychological intervention. Smartphone app interventions offer an alternative treatment approach for paranoia. Additional benefits of using smartphone app interventions include their potential to help address long waiting times to access psychological services and to reduce the costs associated with in-person interventions. Furthermore, digital technologies could be considered low-stigma interventions, as service users can access them privately from any location. They could additionally be seen as empowering, enabling service users to take a more active and autonomous role in their care. More specifically for individuals with paranoia, digital health interventions may facilitate help seeking by reducing the need to build a therapeutic alliance and trust in a therapist, both of which can be especially challenging for this population [20,21].

RenderX

Aims of This Study

This qualitative study explored users' views and opinions of STOP, a DHT that targets interpretation bias in individuals with paranoia. The study provided an opportunity for individuals reporting distress from paranoia to voice their attitudes and experiences of using STOP and to offer feedback. The purpose of the study was therefore to explore different views and opinions of the digital intervention and to identify key strengths and weaknesses of the DHT as well as potential improvements. More specifically, the aim was to involve end users in the design, development, and testing of STOP and to assess the extent to which they were satisfied with it. The research questions were therefore formulated as follows:

- To what extent does the smartphone app STOP meet the NICE minimum or best practice standards for DHTs?
- Is STOP acceptable to its intended end users?

Methods

Ethical Considerations

This qualitative study received ethics approval from the London-Stanmore Research Ethics Committee (21/LO/0896). Potential participants were emailed a digital copy of the study information sheet and had at least 24 hours to consider participating in the study. All potential participants had the opportunity to ask questions and were free to withdraw at any stage without giving reasons. Interested, eligible participants were then asked to complete an electronic consent. Participants received £40 (US $52) in vouchers as compensation for their time and effort.

Screening and Recruitment Process

Participants were recruited from various sources, including the South London and Maudsley NHS Foundation Trust's Psychological Interventions Clinic for Outpatients with Psychosis; Psychological Interventions Clinic for Outpatients with Psychosis clinic at the South West London and St George's Mental Health NHS Trust, through MQ (MQ Foundation, mental health research charity); and the McPin Foundation (a mental health research charity that specializes in integrating lived experiences in research).

Research assistants working on the main STOP randomized clinical trial (ISRCTN17754650) screened participants against the main trial eligibility criteria. Some of the main trial criteria were not relevant for this study, including the following: if on psychotropic medication, no change for at least the last 3 months; interpretation bias screening score of ≥−2; and Positive and Negative Syndrome Scale (PANSS) [22] item 6 score of >3. Therefore, suitable participants who were ineligible for the main trial were redirected to this qualitative substudy and were then assessed against this study's inclusion and exclusion criteria (Textbox 1 [23]).

Textbox 1. Inclusion and exclusion criteria.

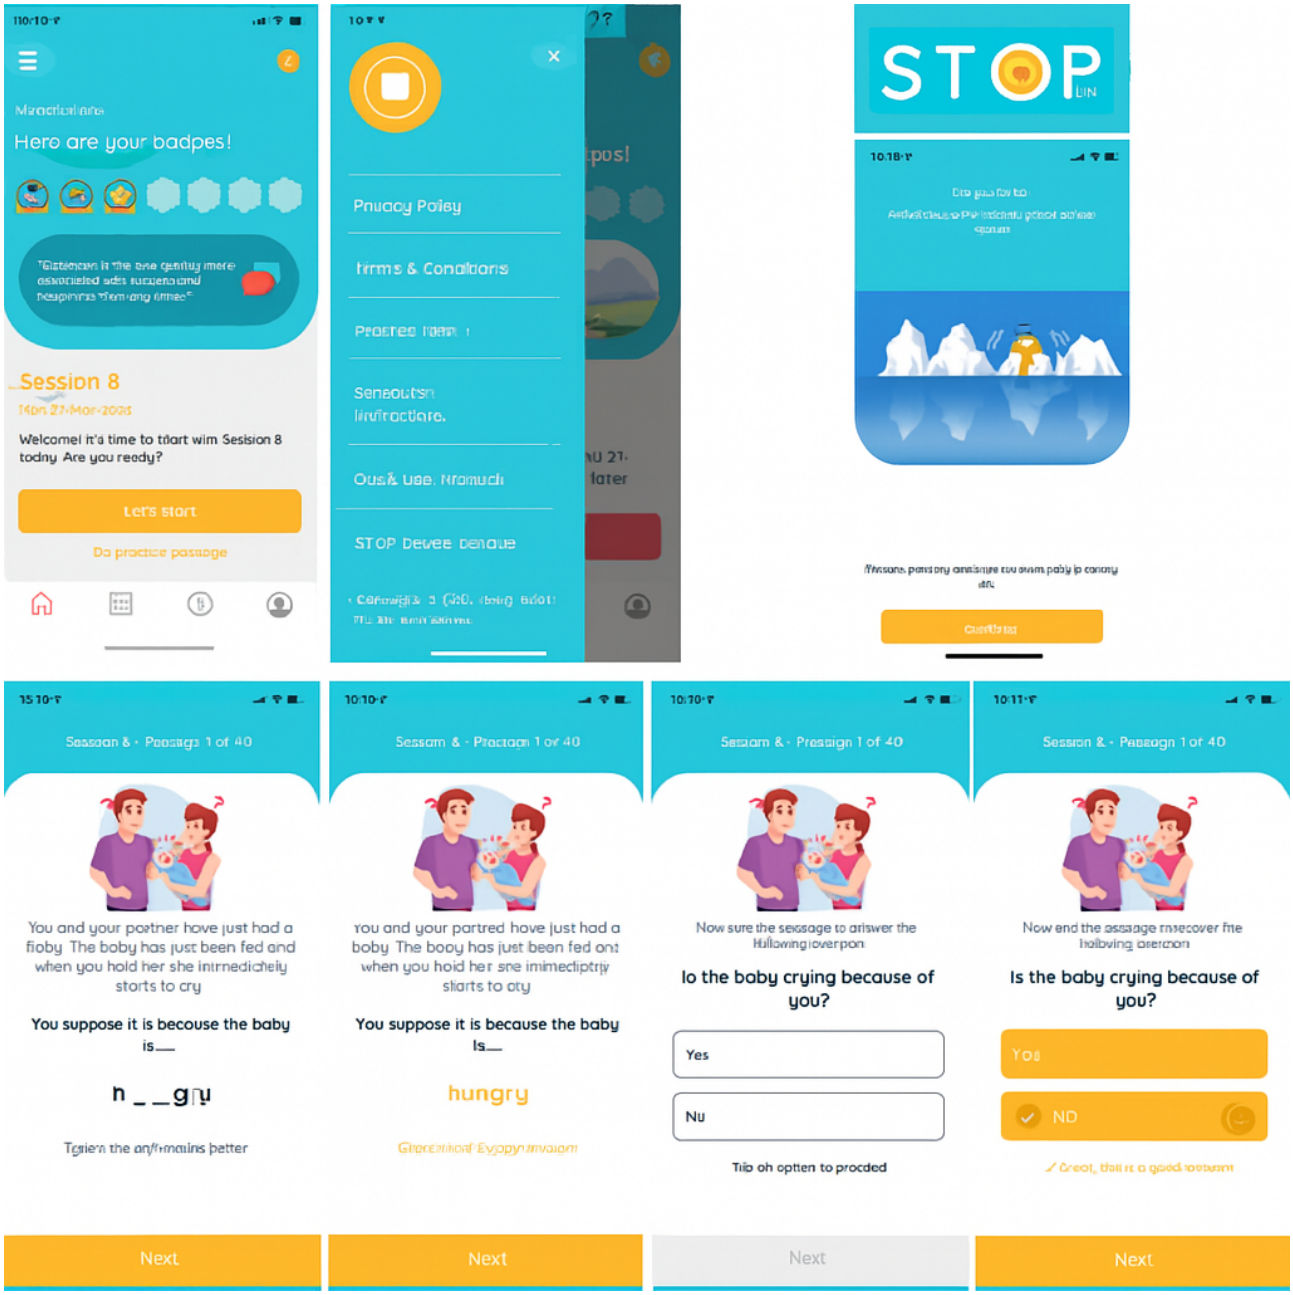
Inclusion criteria

- Self-reported paranoid concerns
- Aged >18 y
- Fluent in written English
- Capacity to consent

Exclusion criteria

- Severe cognitive impairment
- Major current physical illness likely to impact participation
- Substance dependence
- Currently receiving another psychological intervention
- Scoring 7 (defined as "extreme") on the Positive and Negative Syndrome Scale
- At high risk of suicide as per the Columbia Suicide Severity Rating Scale [23]

The choice of the sample size was guided by the concept of information power, which suggests that the number of participants needed for qualitative interview studies decreases as the amount of information held by the sample increases [24]. A smaller sample can be sufficient when the study aim is narrow, the sample is specific, the quality of dialogue is strong, and the analysis is theory informed [24]. Given the focused aim of exploring user experiences of STOP and the relevance of the sample to this aim, the final sample size was deemed appropriate for capturing key insights. Of note, patient and public involvement researcher and coauthor AK also took part in this study as a participant.



The STOP Intervention

STOP was delivered through a smartphone app. It consisted of 40- to 60-minute sessions (depending on reading speed) in which patients were presented with ambiguous scenarios that could be interpreted in either a threatening or a benign way. Each session consisted of 40 scenarios, presented as blocks of 10 items, followed by trivia items to allow users to take a short break (refer to Figure 1 for an intervention item example, a screenshot of STOP's home page, and a trivia example). After reading each scenario, participants were asked to complete a word with missing letters and a comprehension question, both of which aimed to encourage them to interpret the scenario in

XSL•FO
RenderX

a nonthreatening way. Further details regarding the intervention and its development have been published elsewhere [11].

Figure 1. Screenshot of an example of a Successful Treatment of Paranoia intervention item.

Materials

The UEQ is a validated and reliable scale designed to measure users' experiences of using digital products [25]. It consists of 26 items grouped into 6 scales: attractiveness (overall impression; do users like or dislike the product?), perspicuity (is it easy to learn how to use it?), efficiency (can users complete tasks without unnecessary effort?), dependability (does the user feel in control of the interaction with the product?), stimulation (is it exciting and motivating to use?), and novelty (is it innovative and creative? Does it catch users' interest?). Each item presents a pair of contrasting attributes (eg, annoying-enjoyable and confusing-clear), and respondents are asked to express their agreement with the attributes by selecting the point that most closely reflects their impression of the product. The UEQ demonstrates satisfactory reliability and construct validity [25] and provides normative data from 452 prior digital product evaluations, enabling benchmarking against existing products.

Procedure

Participants who provided consent were sent a study Android smartphone with the STOP app preinstalled and ready for use. In line with medical device study requirements, hard copy instructions to use the smartphone and the app were mailed to participants' home addresses. They were then given the opportunity to test the STOP app and were asked to complete 6 weekly sessions of the STOP intervention. They were also offered the option to meet with the researcher (LE) at any time for assistance with navigating the smartphone or app.

XSL•FO
RenderX

All participants had fortnightly check-in calls with the researcher (LE). They were also given the opportunity to ask questions and were offered support for any technical difficulties they encountered.

After the 6 STOP sessions ended, a time was scheduled for a feedback interview and completion of the UEQ. The feedback interviews were semistructured and lasted between 30 and 60 minutes. A topic guide (Multimedia Appendix 1) was used to structure the interview, while allowing flexibility for additional comments. The topic guide was informed by the NICE Evidence Standards Framework for DHTs [17]. Questions revolved around users' experiences of using the digital intervention, its perceived strengths and weaknesses, their opinions of the visual display of the app as well as the CBM scenarios used, session duration and ease of use, and suggestions for improvement. All interviews were conducted via Microsoft Teams, as all participants had access to a computer and a working internet connection.

After the interviews, participants were asked to complete the UEQ. They could choose to receive a digital version or a printed copy sent to their home address and to complete it either at the beginning of the interview together with the researcher or on their own.

Data Analysis

UEQ quantitative data were aggregated across participants, and mean scores were plotted against normative data [25] to enable within-sector comparisons.

The qualitative data from the interviews were coded and analyzed using the framework method [26]. The NICE Evidence Standards Framework for DHTs [15] was used to inform the topic guide, codes, and deductive themes. To enhance quality and rigor, the Reflexive Thematic Analysis Reporting Guidelines were followed [27].

Interview recordings were autotranscribed by the software and then manually corrected by LE. Data familiarization was achieved through repeated reading of the transcripts alongside any additional notes made during meetings.

Initial coding was surface level and descriptive and was conducted by LE using NVivo 14 (Lumivero).

A working analytical framework was developed by grouping and categorizing codes. New or revised codes were developed iteratively throughout coding. The data were then summarized in a matrix. Several group discussions between LE, JY, and PJ led to agreement on a final analytical framework and corresponding matrix. Themes were exclusively and intentionally related to users' experiences of testing, acceptability, and satisfaction with the STOP app. Deductive codes were informed by the topic guide and the NICE Evidence Standards Framework for DHTs [17]. Inductive codes were driven by the data and reflected participants' unique experiences and language.

Research Team and Reflexivity

A critical realist postpositivist stance was adopted to account for the fact that the coding and interpretation of data would be impacted by the researchers' roles in the study. Reflexivity was therefore viewed not as a means of eliminating subjectivity but of making it visible and critically examined throughout the research process. Indeed, based on previous research [28], most researchers involved in the study held beliefs that the app would help reduce interpretation bias in people with paranoia. In addition, the researchers' own views as well as findings from previous research on individuals' experiences with smartphone apps and CBM [28,29] would likely influence the analysis and interpretation of data. Using the topic guide informed by the NICE guidelines, interview questions were phrased to avoid guiding or stigmatizing language. The researcher attempted to embrace each participant's unique and important experiences, as opposed to trying to reach a consensus. A reflective log was maintained throughout recruitment, data collection, and analysis to record reflective thoughts, which were used to inform analysis and interpretation and understand how personal preconceptions and assumptions may influence findings.

Results

Overview

We contacted 34 participants to complete 6 sessions of the STOP intervention, followed by a feedback interview. Of these 34 individuals, 16 (47%) met the eligibility criteria and consented to take part in the qualitative study. Of these 16 participants, 4 (25%) dropped out (n=3, 75% reported that they did not feel that they had the time to commit to the study; n=1, 25% was uncontactable), resulting in a final sample of 12 (75%) participants. The participants' mean age was 36.33 (SD 10.74) years. Of the 12 participants, 7 (58%) identified as female, 8 (67%) were White, and 2 (17%) identified as being from a minority ethnic background (n=2, 17% did not disclose their ethnicity). The mean score on PANSS item 6 was 3.58 (SD 0.79) [22]. Participants' characteristics and individual scores are summarized in Table 1.

XSL•FO
RenderX

Table 1. Participants' characteristics and User Experience Questionnaire (UEQ) scores.

Participants	Sex	Age (y)	Race and ethnicity	Score on item 6 of PANSS[a]	UEQ attractiveness	UEQ perspicuity	UEQ efficiency	UEQ dependability	UEQ stimulation	UEQ novelty	Sessions completed (n=6), n (%)
1	Male	NR[b]	NR	4	−0.33	−0.25	−0.33	0.25	−0.25	0.00	4 (67)
2	Female	57	White British	3	−1.17	−1.25	−2.00	−0.75	−1.00	−1.00	5 (83)

[c]Missing data.

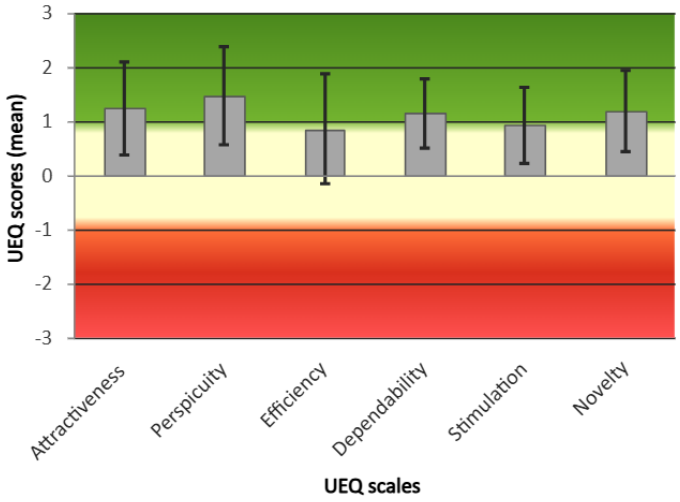
UEQ Results

After the feedback interview, 8 (67%) of the 12 participants completed the UEQ. The results are provided in Table 1. UEQ scores range from −3 (maximum negative evaluation) through 0 (neutral) to +3 (positive evaluation). A bandwidth of −0.8 to +0.8 indicates neutral evaluation, with scores outside this range indicating overall negative and positive evaluations, respectively. Participants who completed the UEQ in this study scored an average of between 0.9 and 1.5 on the different scales, which indicates that they described their experience as positive. The UEQ indicated generally positive user perceptions across all subscales, with the highest mean scores observed for perspicuity (mean 1.464, SD 1.302), attractiveness (mean 1.238, SD 1.224), and novelty (mean 1.179, SD 1.087). Lower, yet still positive, ratings were recorded for dependability (mean 1.143, SD 0.923), stimulation (mean 0.929, SD 1.018), and efficiency (mean 0.857, SD 1.457). Participant 1 showed inconsistencies on 5 scales (attractiveness, perspicuity, efficiency, dependability, and stimulation; Table 1, row 1) and was therefore excluded from the reported averages and from the scale mean and variety plots in Figures 2 and 3, as suggested by the UEQ handbook [18]. Specifically, the handbook defines inconsistency as a lack of uniformity in item ratings within a scale. While it may be possible for inconsistencies to occur in a single scale, due to a misunderstanding of the question or an error, it is less likely to be the case when they occur across multiple scales. The handbook therefore suggests excluding such participants from analysis because it is more likely that the behavior indicates random or nonserious completion of the questionnaire.

Summary statistics are presented graphically by scale (Figure 2) and benchmarked against digital sector norms (Figure 3).

XSL•FO
RenderX

Figure 2. User Experience Questionnaire (UEQ) results. Mean scores on each scale are shown, with error bars representing variance. Green shading indicates a positive evaluation range, cream shading a neutral evaluation range, and red shading a negative evaluation range.



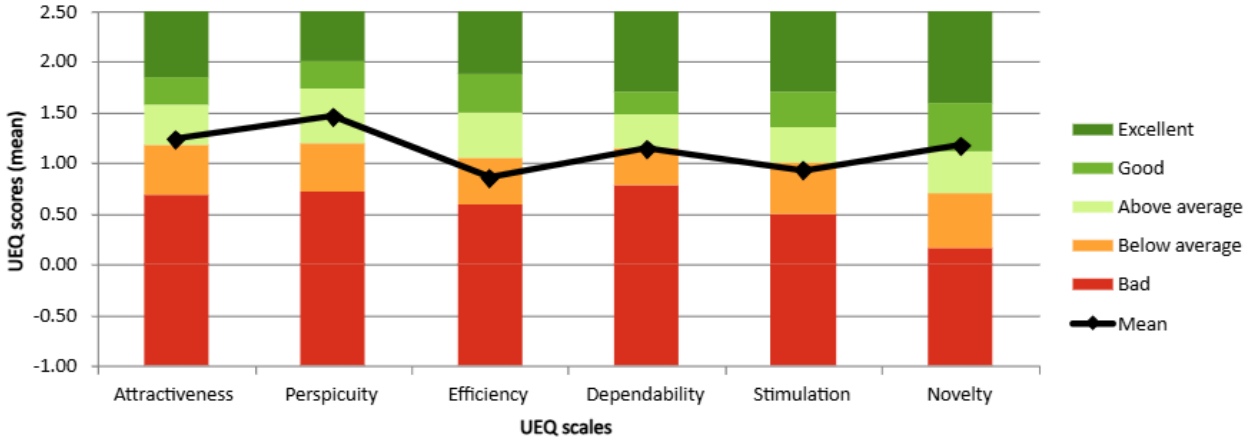


Figure 3. Benchmark graph for Successful Treatment of Paranoia (STOP) based on User Experience Questionnaire (UEQ) scores compared to sector averages. The black data points represent STOP mean scores by scale. The bar colors represent the percentage of other products in the sector falling within that range; for example, a data point falling in pale green ("above average") indicates that 25% of other products scored higher than STOP, whereas a data point falling in orange ("below average") indicates that 50% scored higher.

Qualitative Results

Overview

Through framework analysis of the interview transcripts, 6 themes were identified, along with topic summaries (summarized in the framework analysis): "independent use and personal fit; digital versus traditional approaches; user reactions and emotional impact; impact on thinking, awareness, and well-being; design, engagement, and usability; and intervention relevance and practical fit." Table 2 presents the framework analysis, and Figure S1 in Multimedia Appendix 2 illustrates the relationships between themes.

XSL•FO
RenderX

Table 2. Framework analysis.

Themes and topic summaries	Example quotations
Independent use and personal fit	
Having agency, taking responsibility, self-discipline, and self-growth	• "The advantages are the independence and the self-control and the mindfulness and those skills in themselves, the self-discipline as well, they can [be used] in their own treatments and their own self-discovery journeys." [Participant 10]
Matches lifestyle and preferences	• "So, like an advantage of this is especially for people who are suffering anxiety and PTSD and don't get out." [Participant 5]
Provides privacy, safety, and flexibility	• "When you're on your own, you sort of have time to think and like go through the answers at your own pace and when it suits you." [Participant 12]
Ability, or otherwise, to complete without assistance: neurodiversity, language barrier, and technological proficiency	• "I was able to do it myself but for other people, there's a chance they might need assistance. It could be because they have like dyslexia or there is a language barrier." [Participant 7]
Digital versus traditional approaches	
Advantages of apps over traditional therapies	• "[T]here's less need for human intervention because the app is friendly and fun." [Participant 8]
Disadvantages compared to traditional therapies: digital exclusion, dropout rate, lack of feedback, distractions, and potential dependence on the app	• "You don't get personalized feedback like you would with a person." [Participant 1]
Focused, structured, and specific intervention	• "[Usually a] therapist can guide it, whereas I like the way that this was more structured and forced you to think through different scenarios. And I like that aspect of it." [Participant 1]
User reactions and emotional impact	
Perceived as judgmental, patronizing, and invalidating	• "There is nothing to validate you or to say your initial response actually had some value in it." [Participant 1]
Validating and normalizing	• "It is validating. It's almost as if the researchers have taken into account that we struggle with these thoughts, no matter how insignificant they seem." [Participant 4]
Elicited mixed feelings: confusion, excitement, fear and embarrassment, hope, sadness, or neutral	• "I think I possibly felt more sad at the end of each session." [Participant 9] • "I would look forward to it, it was interesting." [Participant 2] • "It's not good, nor bad." [Participant 7]
Evocative and triggering of actual experiences	• "They're very good at conveying the paranoid thoughts, they were very evocative and brought up quite a lot of feelings when reading them." [Participant 9]
Perceived as restrictive	• "One negative thing was that it doesn't let you say no, I don't agree with that." [Participant 5]
Impact on thinking, awareness, and well-being	
Helpful impact on daily life and thinking patterns, sense of achievement, and general positive feelings	• "I found it really helpful...it has been giving me some clues like some other way of thinking other than like me, always overthinking what other people's intentions are." [Participant 4]
Offers new perspectives	• "I found one of the big values of the app is identifying other options and other ways of looking at things." [Participant 1]
Self-reflection, awareness, and understanding of paranoia and its presence in the user's life	• "It has made me realize how insidious paranoia and anxiety are in my everyday life via the scenarios, for which I was always instinctively drawn to the negative assumptions, and so many of which I regularly worry about." [Participant 9]

XSL•FO
RenderX

Themes and topic summaries	Example quotations
Design, engagement, and usability	
Design and look of the app	• "I think the color scheme is very calming and soothing...I think it's quite good like, it's not really intimidating or like causing people distress." [Participant 4]
Engagement with the app	• "Intuitive, really well designed and written, and very engaging." [Participant 9] • "It was a bit like a reading comprehension for a 7-year-old." [Participant 10]
Suggestions for improvement: managing expectations, personalizing the experience, suggestions for design changes, and access to the app	—[a]
Intervention relevance and practical fit	
Acceptability and testing of scenarios	• "So, about half I think were quite pretty easy to identify with and about half I had to work a bit harder." [Participant 1] • "I thought they're all very relatable...there wasn't a single one that I thought it seemed odd or shouldn't be in there." [Participant 8]
Perceived difficulty of the intervention	• "Yeah, I guess the more effort just like you'd have to think about it more to try and work out what that word is instead of like 'Ohh well, clearly it has this like one word that fits in there.'" [Participant 11] • "It was like there's always a very obvious word that fits in...if it was more challenging, I'd probably focus more on the sentence." [Participant 12] • "I had to think about it more, and that's not necessarily a bad thing...those were the scenarios which helped me the most." [Participant 1]
Session frequency and duration	• "I would say it's just about right, but it's not a little ask. It took me, I would say just over half an hour...that's still a fair commitment. Possibly for some people would need it to be a bit shorter." [Participant 1] • "I would like it to be on a continuous basis." [Participant 4] • "It was quite long as well. The sessions were longer than expected...Maybe if the session were half the length as well, then I wouldn't have got bored so quick so easily." [Participant 10]
Views and suggestions related to implementation	• "I'm severely disabled, that's what's unrelatable. Maybe the app is aimed at people who have less severe disabilities. And yet I did find it helpful." [Participant 11]

[a]Suggestions are presented in Multimedia Appendix 3.

Theme 1: Independent Use and Personal Fit

This theme depicted participants' attitudes toward completing the intervention on their own and explored the extent to which an autonomous treatment was acceptable. An autonomous treatment was defined here as an intervention to be completed independently, meaning on one's own and without additional support from professionals or other individuals, aside from any necessary practical or safety checks (eg, in STOP, fortnightly safety check-in calls with the researcher were required). This theme captured users' views on both obstacles and benefits. Overall, participants seemed satisfied with the intervention being an autonomous treatment.

Some participants indicated that completing STOP on their own gave them a sense of agency and allowed them to take responsibility for their issues and for their progress by deciding to engage with the app and complete sessions on a weekly basis. Some described that STOP helped them monitor their progress and visualize it in the form of badges that they accumulated as they completed sessions. Others thought it could positively impact their self-confidence and allow them to grow:

> *I would say responsibility because...one of the things that can really happen is that you give up responsibility or you lack confidence, whereas with this it's like I'm trying, I'm doing it.* [Participant 1]

Some participants reported satisfaction with the way the intervention was delivered as it fit their preferences and lifestyles. Often, the preferences were associated with mental health conditions getting in the way of seeking help. These participants reported that engaging in a smartphone app was helpful in that it allowed them to access help from their homes. For others, the intervention being an autonomous treatment fit with their personalities and offered them privacy and the space to be honest with themselves as well as the option to complete it at their own pace:

XSL•FO
RenderX

> *It gives you the independence, the privacy, the self-motivation and discipline.* [Participant 10]

Theme 2: Digital Versus Traditional Approaches

This theme described participants' acceptability of STOP compared to other interventions, such as cognitive behavioral therapy or counselling. It captured users' views on both obstacles and benefits related to the intervention's delivery through a smartphone app. Compared to other treatments, participants seemed to be partly satisfied with the intervention, particularly the fact that it offered flexibility and was specifically focused on paranoia:

> *This treatment is different because it's very specific to paranoia and I have not seen any treatment specific to paranoia before.* [Participant 8]

A few noted disadvantages of smartphone apps in general. These included the need for an internet connection and concerns about digital exclusion. In addition, some of the participants highlighted the high dropout rates associated with app-based interventions, while others reported that it can be distracting, potentially lead to dependence on the app, or not be in line with their preferences. Several comments revolved around the lack of human contact and feedback associated with using an app:

> *I mean there is an element, I suppose, of the isolation being extended and not having any human support around you, that you would miss out on.* [Participant 10]

Theme 3: User Reactions and Emotional Impact

This theme depicted the extent to which users were generally satisfied with the app after having completed a few sessions. It encompassed a wide range of emotions and reactions that were elicited and labeled. Two contrasting views emerged in the interviews. Most participants described their experiences as positive; however, some expressed negative views, particularly perceiving the app as invalidating or restrictive because it did not allow them the option to disagree with the answers provided within the therapeutic content:

> *You [are] only allow[ed] to answer the question one way. So not only is it restricting, what are you honestly expecting everyone to have the same opinion?...I can't give you my opinion if you don't let me answer the question in a way I feel right in answering it.* [Participant 6]

> *I found it validating.* [Participant 8]

Overall, emotions ranged from confusion and sadness to hopefulness and excitement. Such a range of emotions, even at an individual level, highlighted the unique experience of each participant and the complexities involved. Some participants explored the feelings elicited and used the opportunity to understand themselves better. Others reported that the scenarios presented in the app were evocative because of their relatability. A few described the experience as triggering their paranoia (which is an expected and possible element of STOP's therapeutic process), whether due to the content of the scenarios or the use of an external smartphone provided by the researcher. However, this was not reported as particularly harmful or distressing. Some participants described STOP as validating because it normalized paranoid thoughts as well as the negative interpretations commonly associated with paranoia.

Theme 4: Impact on Thinking, Awareness, and Well-Being

This theme described users' satisfaction with the app in terms of its impact on their daily lives, changes in thinking patterns, self-reflection, and awareness. Most participants reported that STOP had been helpful in some way.

Some described the impact as emerging from the fact that the app served as a distraction, while others described a sense of achievement from completing the weekly sessions. Some participants highlighted the positive impact on their daily lives, noting changes in their thinking patterns. Some described feeling generally more positive and less stressed after using the app. Some participants, including a few who described the app as restrictive, found it helpful in that it offered alternative ways to interpret situations that they would usually interpret in a threatening or negative manner.

Participants explicitly and spontaneously reported that they perceived the app as a tool for modifying their thinking patterns and also noted that it encouraged reflection and helped them identify themes of paranoia that they related to. They described STOP as helpful in recognizing personal thinking patterns and understanding the extent to which paranoia features in their day-to-day life. Some participants disclosed that the app helped them gain a better understanding of paranoia and how it is perceived by the general population.

Theme 5: Design, Engagement, and Usability

This theme outlined participants' views of the design of the app and explored the extent to which this would be acceptable and satisfying to end users. Participants also spontaneously shared their suggestions for improvement.

Most participants reported feeling satisfied with the design, look, and feel of STOP, including the trivia, audiovisual features, and scheduling and reminder functions. They expressed that they found it "clear" (participant 7) and "not overloading of information" (participant 5). Some reported that they enjoyed the color schemes, the images, and the fact that "it involves all senses" (participant 10), especially if one had "poor eyesight" (participant 1). One participant noted that the images used reinforced binary gender stereotypes, which made the app less relatable. Most users described the app as engaging and interesting, easy to use, and friendly, although a few found it childish. One participant found the app helpful for addressing stigma, noting that its anonymous delivery made it feel discreet. In contrast, another participant felt that the app's colors and sounds made it stand out and attract unwanted attention (the sounds can be switched off within the app).

Although STOP seemed largely well accepted, participants offered suggestions for improvement. The most common suggestions revolved around offering more response options for the scenarios, personalizing the app, and encouraging more flexible use. Suggestions also included managing expectations and providing more introductory and contextual information

XSL•FO
RenderX

about the intervention's aims, mode of action, and length. Some participants offered alternative design ideas that they believed would make the app more attractive and could help address possible issues of digital exclusion. Additional suggestions included making the app more stimulating and challenging to avoid boredom and to increase engagement:

> *If it was me, I would leave a section for another option where you could put your own feedback into, like feedback on what you think of the question or if your idea on the scenario didn't fit into the boxes, boxes of yes or no.* [Participant 6]

Theme 6: Intervention Relevance and Practical Fit

The final theme focused on the core intervention and how it was experienced by users. It reflected the extent to which STOP was perceived as therapeutic, generally acceptable, and satisfying. Some participants indicated that they could strongly relate to the scenarios, while others found some scenarios personally irrelevant. A few reported feeling marginalized or excluded when the scenarios did not reflect the experiences of individuals with disabilities, restrictive lifestyles, or different lifestyle preferences. Some felt that the intervention was too easy and needed to be more stimulating and challenging. They found the more difficult or less relatable scenarios to be the most beneficial. Participants also noted that automatically and systematically completing the missing-letter tasks discouraged them from putting in the effort and therefore did not impact their way of thinking in a positive way.

Most participants commented on the length of the intervention, the frequency of sessions, and the duration of each session. In terms of session duration, most participants felt that the sessions were long and that they would benefit from shorter sessions. Some reported that the session duration interfered with their day-to-day activities and was difficult to fit into their busy schedules, while others said that it suited their lifestyle. Some participants highlighted the benefits of having a weekly session and compared it to therapy, while others expressed a wish to complete the content at their own pace and in shorter blocks throughout the week. In terms of the length of the intervention, some participants reported that 6 sessions would be enough in terms of changing thinking patterns, while others suggested more sessions to enhance the learning. Some participants offered suggestions related to the core intervention, such as shortening the duration of individual sessions, amending the frequency of sessions and length of the intervention, encouraging participants to complete the session, offering the intervention on an indefinite basis, integrating some human contact and additional support if needed, or targeting a specific population.

Other suggestions were related to how participants would envisage the implementation of STOP outside of a research trial:

> *Well, I guess like if the app was going to sort of develop, maybe integrating some sort of like breathing techniques or something. If things get too much, almost like a little like panic button crisis button on it or something.* [Participant 12]

> *I think it should be prescribed by your GP or your psychiatrist or your psychologist or occupational therapist. You should be signposted to it and there's a mandatory one-to-one onboarding session to answer any questions, to explain and yeah.* [Participant 8]

The full list of recommendations arising from themes 5 and 6 is provided in Multimedia Appendix 3.

Discussion

Principal Findings

This study explored the acceptability of STOP for individuals struggling with paranoia, in the context of the NICE Evidence Standards Framework for DHTs. Overall, participants representing the intended end users expressed broadly positive views of the smartphone app, describing aspects of the experience and design as acceptable and well thought out. These findings are consistent with a previous qualitative study exploring the acceptability of an earlier, computer-based version of the intervention [16]. However, given the modest engagement levels and variation in participant feedback, these results should be interpreted cautiously and viewed as indicative rather than conclusive.

More specifically, after up to 6 weeks of using STOP, participants acknowledged its potential as an autonomous treatment that was not directly supported by a therapist. Most participants reported that the way the intervention was delivered fit their preferences and offered them flexibility and privacy, in line with the perceived advantages of internet-based interventions in previous studies [30,31].

The transdiagnostic approach adopted by STOP avoids the use of stigmatizing diagnostic labels and targets a single symptom by seeking to alter its associated underlying maintaining mechanism.

Our findings suggest that the autonomy of STOP (theme 1) gave users a sense of agency, in contrast to the lack of empowerment frequently experienced by individuals with severe mental health conditions. In this respect, our findings concur with those of others suggesting that DHTs can help empower individuals, offering them more control of their condition and a better understanding of it [32,33].

Of the 12 participants, 1 (8%) reported concerns about data protection, which is common in the context of using DHTs in similar populations [33]. Digital therapies designed for use with those experiencing paranoia will need to pay special attention to transparency and reassurance around data privacy and security if these technologies are to benefit this user group.

Some participants reported that factors related to technical proficiency, neurodiversity, and individual preferences may interfere with users' ability to benefit from the intervention, highlighting the need to address these considerations in future versions of STOP. While only 1 (8%) of the 12 participants explicitly reported concerns about digital exclusion, this is a commonly reported barrier in the digital mental health literature. By contrast, other circumstances, such as interpersonal challenges, can lead to digital technology improving access to

XSL•FO
RenderX

appropriate health care [33,34]. It is likely, then, that some health inequalities may be mitigated by DHTs such as STOP, while others will inevitably be introduced. For this reason, STOP, and DHTs in general, are best seen not as a panacea but as a complement to traditional therapies, with the potential to fill some important gaps in provision.

Some disadvantages of using STOP were also reported (captured in the Theme 2: Digital Versus Traditional Approaches subsection), the most common one being the lack of human contact and feedback—absent from many DHTs and often reported in the literature [32]. Participants offered some suggestions to resolve this perceived disadvantage, such as providing the option to contact a mental health professional as needed while using the app or combining sessions of STOP with traditional psychological therapy. The preference for having alternative options to seek help seems to be common in the context of DHT use [33]. Acceptability was also related to user experience (theme 3). Some participants perceived STOP as judgmental and restrictive, mainly due to the language used within the app (despite it having been codeveloped with users). Others described the intervention as validating and normalizing. Some participants held what seemed to be opposing views of the experience, such as frustration and validation or sadness and hope. This may reflect a common experience of therapy, in which patients may have ambiguous and contradicting feelings toward the approach used, the process of therapy, or their therapist. However, in traditional therapy, the therapeutic alliance is examined, feelings about therapy explored, and approaches adapted to the patients' needs and feedback. Such a process may not be achievable in digital interventions where the negative aspects of the experience are not addressed in the moment. Future digital therapies may benefit from accommodating this need, for example, by giving participants the opportunity to report their experience in real time. Indeed, the concept of the "digital therapeutic alliance" is gaining traction in psychotherapy literature and provides a suitable theoretical platform from which to explore and improve the digital therapeutic experience [35].

Moreover, some users reported noticing a positive impact of STOP on their lives (theme 4), for example, in terms of their well-being, their thinking patterns, self-reflection, understanding, and awareness of their paranoia. Users also reported general satisfaction with both the core therapeutic intervention and its digital interface (themes 5 and 6). However, some participants expressed that they found a 30- to 40-minute session too long to complete in 1 sitting. These findings echo previous literature on CBM, which has noted that the approach can feel repetitive and monotonous [28,36]. Participants offered some suggestions for improvement, such as shortening the intervention, integrating some additional support, amending the duration of each session, personalizing the scenarios, or making the intervention more challenging and stimulating to optimize changes in thinking patterns.

As shown in Figure 3, STOP received average or above average ratings for attractiveness, perspicuity, dependability, and novelty, but it scored below average on efficiency and stimulation. These findings align with qualitative themes in which participants described the task as repetitive or lacking engagement and occasionally reported that the interface did not facilitate smooth or efficient use. The absence of "good" or "excellent" ratings across scales may reflect the early-stage design of STOP and highlight areas for improvement, particularly in terms of enhancing engagement and interactivity. Given the exploratory nature of this qualitative study and the limited UEQ response rate, we present these results descriptively and cautiously. We have clarified this point in the manuscript and reflected on how this feedback can inform future iterations of STOP.

Finally, it is important to note that engagement with the intervention was low, with only 3 (25%) of the 12 participants completing ≥4 sessions and none completing the full 6-session program. Previous reviews of unguided digital mental health tools have consistently highlighted high dropout rates, with engagement often declining sharply after initial use [37]. In this context, the lack of full intervention completion among our participants aligns with broader trends but still raises important questions about the real-world feasibility of STOP as a stand-alone tool.

Comparisons with similar digital interventions show mixed engagement outcomes; for example, the EMPOWER study reported relatively high engagement when supported by peer involvement [38], while other unguided CBM interventions have faced attrition challenges [28,36]. These findings suggest that embedding some form of human support may be critical for boosting sustained use, particularly in populations with paranoia. Future versions of STOP may therefore benefit from exploring hybrid models that balance autonomy with light-touch support or therapeutic onboarding. Furthermore, the role of the digital navigator is becoming increasingly recognized as a valuable component in the delivery of digital interventions, and this will be an important element to explore in future iterations of STOP [39].

Strengths and Limitations

A strength of this study is that a critical realist perspective [40] was adopted during the coding and analysis stages, allowing the researchers to reflect on their views and experiences throughout the study and understand how these may have influenced the analytic process. In line with this perspective, a reflective log was maintained throughout the study. To account for the possibility of response and desirability bias during the interviews, the researcher (LE) attempted to normalize all points of view, including negative experiences of using the app. This was achieved by using open-ended questions and encouraging participants to share their own experiences. To avoid steering responses toward the researcher's expectations, participants were prompted and guided only when necessary. Finally, the researcher adopted a stance of curiosity and nonjudgment during the interviews to encourage participants to share their views openly and without fear of judgment. To our knowledge, this study is the first to explore the acceptability of a digital health intervention delivered via smartphone that targets interpretation bias in individuals with paranoia, in line with the NICE Evidence Standards Framework.

The findings need to be understood in light of possible limitations. Most participants reported mild levels of paranoia,

XSL•FO
RenderX

as indicated by their PANSS scores (Table 1). The sample does not therefore reflect the full spectrum of paranoia that will be experienced by the intended end users. In addition, there was an underrepresentation of ethnic diversity in the sample because most of the participants (7/12, 58%) identified as White British. Moreover, none of the participants completed the full 6-week intervention before the interview. One possible barrier may be related to difficulties engaging with apps in psychosis [41], particularly for service users with more severe paranoid symptoms. This partial exposure may have influenced their views on usability, engagement, and perceived benefit. However, even limited engagement was sufficient for participants to form meaningful opinions about key features of the intervention, and themes were largely consistent across those who completed more versus fewer sessions. Low completion rates are not uncommon in digital interventions for psychosis and may reflect broader challenges around attention, motivation, and trust in technology—particularly among individuals with more severe symptoms [41]. Participant feedback in this study pointed to task repetitiveness, lack of stimulation, and external factors (eg, life stressors and environment) as potential barriers. These insights are valuable for informing future iterations of STOP. Future studies could focus on implementing the suggestions offered by participants and reassessing acceptability in line with NICE guidelines. In addition, it could be helpful to explore the acceptability of different intervention doses (eg, 6 wk vs 12 wk), particularly in relation to the efficacy findings reported for each dose in the main trial [42]. It will also be important to understand clinicians' experiences, opinions, and recommendations regarding STOP, both to improve the intervention further and to assess its "credibility with UK health and social care professionals," as recommended in the NICE Evidence Standards Framework [17]. One other limitation of this study is that, although participants self-reported experiences of paranoia, their interpretation bias and paranoid symptoms were not formally assessed. While this means that our sample did not correspond to that of the main efficacy trial, it was arguably a more appropriate reflection of the likely population when in clinical use. Finally, the absence of contributors offering external critical perspectives represents a further limitation, which we acknowledge as an area for improvement in future work.

Conclusions

This study provides evidence of the central involvement of users experiencing paranoia in the qualitative evaluation and further development of the STOP digital mental health intervention. Participants were generally satisfied with STOP, as reflected in the quantitative survey data (UEQ scores) and views expressed during the qualitative interviews. They found the app broadly acceptable and were mostly satisfied with the way it was delivered, the core intervention itself, and the impact it had on their lives. The findings were in line with the target expectations outlined in the NICE Evidence Standards Framework for DHTs [17]. Participants reported that the intervention provided insight and awareness of their paranoid thinking patterns and offered them alternative ways of interpreting situations they related to. Participants also offered some suggestions for improvement that fit with their preferences and condition. This study therefore incorporates suggestions for future development. It will be important to take the findings into account if STOP is to succeed as a new potential intervention targeting interpretation bias toward threat in individuals with paranoia.

Acknowledgments

This work was supported by the Medical Research Council Biomedical Catalyst: Developmental Pathway Funding Scheme (MR/V027484/1). The authors would like to express their gratitude to the National Institute for Health and Care Research Biomedical Research Centre hosted at South London and Maudsley NHS Foundation Trust in partnership with King's College London. Abstract

Background: Mobile apps are a promising way to improve healthy lifestyle behavior among people with infertility. However, sufficient engagement with mobile health apps is crucial to influence health outcomes, and identifying features to create more effective interventions is urgently needed.

Objective: This study conducted a process evaluation focusing on the use and user experience of the PreLiFe app, a mobile lifestyle app for couples undergoing in vitro fertilization (IVF).

Methods: A mixed methods approach was used among heterosexual couples with infertility undergoing IVF. An objective quantitative study using a tracking-based system assessed the actual use of the PreLiFe app over time in relation to partner use and in relation to the specific fertility treatment. A subjective quantitative study using online questionnaires assessed the acceptability (using the Mobile App Rating Scale) and partner support (based on the Social Support for Diet and Exercise Scale) experienced while using the PreLiFe app. A subjective qualitative study using semistructured interviews evaluated in-depth user experiences with the PreLiFe app.

Results: A total of 106 couples used the PreLiFe app for 2 to 365 days. Overall use was low; 18.9% (20/106) of the men and 49.1% (52/106) of the women used all the modules of the PreLiFe app. Mixed-model analyses revealed that higher app use was observed when a partner used the app as well and during fertility treatment. The average acceptability score was 6 (SD 1) of 10, and patients felt supported by their partners while using the app. Semistructured interviews with 10 patients indicated that the PreLiFe app was easy to use.

Conclusions: Our findings showed good acceptability and user experiences but low actual objective use of a preconception lifestyle app for couples undergoing IVF. To increase use of and engagement with such apps, future studies should further focus on personalization and interaction with partners, health care providers, and other patient data systems.

Introduction

Background

Infertility, defined as the failure to achieve a clinical pregnancy after at least 12 months of regular unprotected sexual intercourse, occurs in 1 in 10 couples [1-3]. Approximately half of these couples undergo fertility treatment, such as in vitro fertilization (IVF), with the ultimate goal of conceiving a healthy child [3]. Infertility and its treatments can be emotionally and financially burdensome to couples and society. An important research priority is to find modifiable factors that can improve the chance of conceiving a healthy child from IVF [4]. Increasing evidence shows that lifestyle is such a potential modifiable factor. IVF success rates are positively associated with a healthy diet, a normal BMI, and moderate physical activity levels [5-12]. Furthermore, a healthy preconception lifestyle benefits offsprings' health [13]. Several international guidelines recommend addressing unhealthy lifestyles before conception, specifically in people with infertility [14-16]. In contrast, a Cochrane review indicated a lack of clear guidance on the content and format of lifestyle programs for improving conception chances [17]. Health care providers also recognize the need for such guidance [18,19].

Evidence from other fields shows that mobile health (mHealth)—defined as the use of mobile and wireless technologies for health—is a promising format to promote healthy lifestyle behavior [20]. mHealth is widely scalable, relatively cheap, and adaptable according to the needs of patients [21]. Using mHealth among people with infertility may counter identified barriers such as lack of time and personnel and is easy to implement in daily life [20,22]. Recent studies on lifestyle apps for people with infertility have shown an improvement in secondary lifestyle outcomes (eg, food intake) but were not effective for the primary clinical outcomes, such as pregnancy rate or live birth [11,23-25]. Adherence is a challenge in traditional lifestyle studies. Therefore, in-depth analyses of use data of mHealth interventions is crucial to identifying factors that enhance use and engagement by participants and effectiveness of mobile preconception lifestyle interventions. In 2016, the World Health Organization mHealth Technical Evidence Review Group developed a guideline for the reporting of mHealth interventions. This guideline emphasized the need for detailed reporting on use [26]. Despite these existing guidelines, a review of mobile lifestyle interventions emphasized the need for improved reporting on the use of such interventions to evaluate their effectiveness more accurately [27].

Objectives

To gain better insights into the effectiveness of a preconception lifestyle app for couples undergoing IVF (PreLiFe study) [22,25], a process evaluation focusing on use and user experiences was conducted with the aim of identifying factors that may lead to higher use and engagement, ultimately enhancing the effectiveness of mobile lifestyle apps.

Methods

Overview

This process evaluation (Table 1) of the PreLiFe app, a mobile lifestyle app for couples undergoing IVF, included stakeholder interviews, quantitative observation, and data monitoring. More specifically, an objective quantitative study (data monitoring) using a tracking-based system assessed the actual use of the PreLiFe app over time in relation to partner use and in relation to the specific fertility treatment. A subjective quantitative study using online questionnaires assessed acceptability and partner support experienced while using the PreLiFe app. A qualitative study (stakeholder interviews) using semistructured interviews evaluated the user experiences with the PreLiFe app in depth in the context of the users' daily lives and in relation to their fertility treatment.

Table 1. Overview of outcomes assessed, timing, and measurement methods.

Outcomes assessed	Type of assessment	Timing of assessment	Method
Actual use of the PreLiFe app	Quantitative and objective	Continuously throughout the PreLiFe study period (2 to 365 days)	App-based tracking (data monitoring)
Acceptability—subjective quality	Quantitative and subjective	At the end of the PreLiFe study period	Subjective quality subscale of the Mobile Application Rating Scale
Acceptability—added value of different modules of the PreLiFe app	Quantitative and subjective	At the end of the PreLiFe study period	Semi–open-ended question
Acceptability—reasons for not using the PreLiFe app	Quantitative and subjective	After 3 months of using the PreLiFe app	Semi–open-ended question
Partner support experienced while using the PreLiFe app	Quantitative and subjective	After 3 months of using the PreLiFe app	Questionnaire based on the Social Support for Diet and Exercise Scale
User experience	Qualitative and subjective	After the PreLiFe study period	Semistructured interviews with stakeholders

PreLiFe App and Study (Background Information)

The effectiveness of the PreLiFe program was evaluated in the PreLiFe study [25]. The protocol for this multicenter, single-blind randomized controlled trial has been registered (ClinicalTrials.gov identifier NCT03790449) and published previously [28]. A detailed description of the PreLiFe program has been published previously [22]. Briefly, eligible couples starting IVF were randomized (1:1 allocation ratio) to an attention control arm or an intervention arm receiving the PreLiFe program. The PreLiFe program is a systematically developed complex preconception lifestyle intervention acting on a combination of lifestyle topics (diet, physical activity, and emotional distress) and offered in a blended care format. It was developed according to the Medical Research Council framework, and patients were involved in the development of this app from the earliest phases of design [22]. The program includes a mobile app (PreLiFe app) with on-demand tailored advice and skill training on diet (food literacy), physical activity, and mindfulness in combination with SMS text messages. In addition, patients receive telephone interaction every 3 months with a health care provider trained in motivational interviewing (Figure S1 in Multimedia Appendix 1). Participants were followed for 12 months or until an ongoing pregnancy was confirmed via ultrasound at 12 weeks of gestational age. Changes in lifestyle and in reproductive outcomes were observed. The study started in January 2019 and was prematurely stopped on March 13, 2020, as, due to the COVID-19 pandemic, all Belgian fertility clinics were closed for an undefined period. As the primary outcome was time to ongoing pregnancy, recruitment was stopped as of March 13, 2020. In addition, couples who had been randomized and were still participating in the trial at that time needed to be censored. The PreLiFe study period varied from 2 to 365 days. Table S1 in Multimedia Appendix 1 provides an overview of the number of couples in the study at each time point and reasons for ending the PreLiFe study. During the PreLiFe study period, all participating couples received standard medical treatment (ie, IVF with or without intracytoplasmic sperm injection) according to the local protocol of the participating fertility clinic. Both partners in couples randomized to the intervention arm additionally received the PreLiFe program.

Ethical Considerations

This study was approved by the Ethics Committee Research of the University Hospitals Leuven and the local ethics committees of the participating clinics (approval s61202 for the qualitative evaluation and s61596 for the quantitative evaluation). Written informed consent was obtained from all participants. Interviews were audio-recorded and transcribed verbatim. All identifying information was removed from the transcripts to ensure anonymity.

Quantitative Evaluation: Actual Use, Acceptability, and Partner Support

Participants and Recruitment

As we aimed to evaluate the use of the PreLiFe app, only participants allocated to the intervention arm of the PreLiFe study were eligible for this study, which included 106 couples undergoing IVF.

Outcomes

Actual use of the PreLiFe app was objectively monitored through app-based tracking (data monitoring) throughout the PreLiFe study period. Initiation of the different modules (diet, physical activity, and mindfulness) was assessed by counting the number of times the modules were opened. Actual use of the different modules was assessed by automatically counting the active clicking on the features of these modules during the PreLiFe study period. Active use of the PreLiFe app was defined as the percentage of participants having used all modules (diet, physical activity, and mindfulness) of the PreLiFe app at least once throughout the PreLiFe study period.

Acceptability of the PreLiFe app was assessed at the end of the PreLiFe study period using the subjective quality subscale of the Mobile Application Rating Scale. This scale has a score from 0 to 10, with higher scores indicating better acceptability. Furthermore, we asked which module (diet, physical activity, or mindfulness) provided the most added value to participants and if there were any specific reasons (time, interest, use of other app or program, injury, or other reasons) for potentially not using the PreLiFe app. Multiple answers could be indicated.

To evaluate whether participants felt supported by their partners while using the PreLiFe app in maintaining a healthy lifestyle, a questionnaire based on the Social Support for Diet and Exercise Scale was developed [29]. The questionnaire consisted of 3 subscales: partner support for diet, physical activity, and emotional distress.

Statistical Analyses

Using mixed-model analyses, we evaluated the actual use of the different modules of the PreLiFe app over time and in relation to partner use. Furthermore, we evaluated the actual use of the PreLiFe app in relation to the stage of fertility treatment. Start of fertility treatment was defined as the start date of the last menstrual period. Descriptive analyses were conducted on the other outcomes (baseline characteristics, acceptability, added value, reasons for not adhering to the PreLiFe app, and partner support).

Qualitative Evaluation: User Experiences

Participants and Recruitment

After the PreLiFe study was ended, participants from the intervention group were invited through email. The study process and accompanying incentives were explained in detail. Respondents who were interested in participating signed an online informed consent form and were scheduled for a semistructured interview through videoconferencing software (Microsoft Teams). Participants received a monetary incentive for taking part. The sample size was based on data saturation, with participants selected to ensure a diverse representation of age, gender, and app use, capturing a broad range of experiences.

Interview Guide and Process

Semistructured interviews were conducted by a researcher trained in qualitative methods according to an interview guide

XSL•FO
RenderX

(Table S2 in Multimedia Appendix 1) and audio recorded for later analysis. The interview guide was developed from a user experience perspective grounded in the unified theory of acceptance and use of technology and behavior change theories [30]. It covered general app use, use and experiences of the different modules of the PreLiFe app (diet, physical activity, and mindfulness), integration into daily life and treatment, social influences, and technology acceptance. Questions were refined through pilot-testing with a small user sample (n=2) to ensure clarity, flow, and sensitivity.

Statistical Analyses

The data collected in the interviews were analyzed according to the principles of thematic analysis [31]. Interviews were audio recorded, transcribed afterward, and coded, after which themes were extracted through an affinity diagram.

Results

Quantitative Evaluation: Actual Use, Acceptability, and Partner Support

Baseline Characteristics of the Participants

The baseline characteristics of the participants are presented in Table 2. More than 70% of the couples were highly educated, and almost all couples were of European origin. The mean duration trying to conceive was approximately 2 years (27, SD 16 months).

Table 2. Baseline characteristics of the study participants.

Characteristic	Qualitative study		Quantitative study	
	Women (n=5)	Men (n=5)	Women (n=106)	Men (n=106)

Actual Use of the PreLiFe App

From January 2019 to March 2020, a total of 106 couples used the PreLiFe app for 2 to 365 days. As shown in Table 3, actual use of the app was low. Active users, namely, participants who used every module of the app at least once, included 49.1% (52/106) of the women and 18.9% (20/106) of the men. Approximately 70% of the women (79/106, 74.5%) and 50% of the men (50/106, 47.2%) used at least one of the modules (diet, physical activity, or mindfulness). Furthermore, passive users, defined as participants who initiated the app without using any of the modules, included 9.4% (10/106) of the women and

XSL•FO
RenderX

37.7% (40/106) of the men. In total, 1.9% (2/106) of the women and 1.9% (2/106) of the men did not initiate the app at all (nonusers).

Actual Use of the Different Modules of the PreLiFe App Over Time in Relation to Partner Use

Figure 1 presents an overview of the average number of daily app uses (diet, physical activity, and mindfulness) by both partners over time. Statistical analyses revealed the following: (1) the average number of daily app uses decreased over time; (2) women used the PreLiFe app more frequently as compared to their partners; and (3) on the days when one of the partners used the app, the other partner also used the app more (Table S3 in Multimedia Appendix 1).

The diet module was the most used. The average number of daily uses per person of the diet module was 0.2149 (SD 0.4636). The mindfulness module was the least used. The average number of daily uses per person was 0.005 (SD 0.0707).

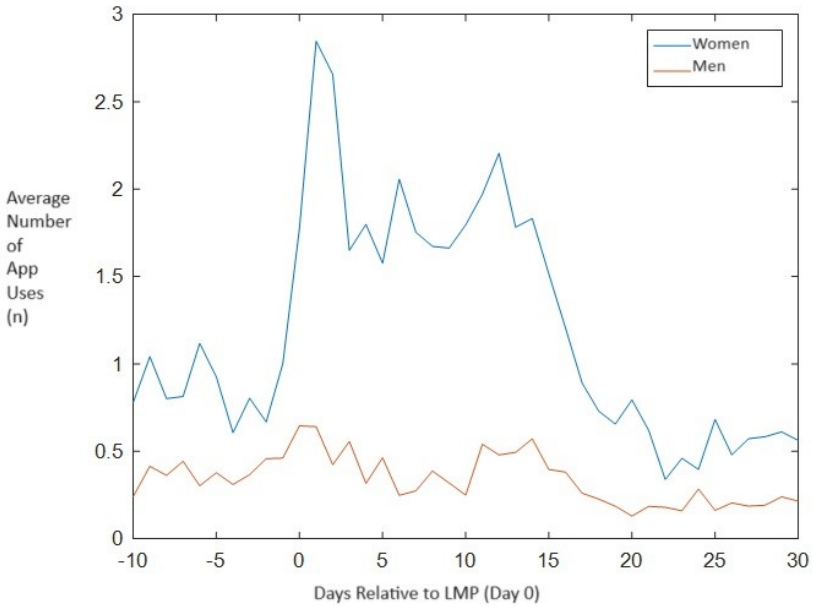

Figure 1. Use of the PreLiFe app over time. MFN: mindfulness; PA: physical activity.

Actual Use of the PreLiFe App in Relation to Fertility Treatment

Figure 2 shows that the use of the PreLiFe app was highest around the first day of the menstrual period (ie, the start of ovarian stimulation in the couples' first IVF–intracytoplasmic sperm injection treatment). We observed no differences in app use during the embryo transfer period. We did observe a decrease in app use across cycles (Figure S2 in Multimedia Appendix 1).

Figure 2. Use pattern of the PreLiFe app during in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI). Day number relative to LMP refers to the day in the IVF and ICSI cycle that treatment was started (0=last menstrual period [LMP] day).

Acceptability of the PreLiFe App

A total of 40.6% (43/106) of the women and 33% (35/106) of the men completed the questions on acceptability of the PreLiFe app. Acceptability of the program revealed an average score of 6/10 (SD 1) from women and men, with a minimum score of 3/10 and a maximum score of 8/10. Women and men would recommend the PreLiFe app to other patients undergoing IVF (Table 4). Men rated the app slightly higher than women. In total, 26% (11/43) of the women gave a 4-star rating to the PreLiFe app versus 46% (16/35) of the men. Both women and men indicated that the diet module provided the most added value to them.

Physical activity	11 (26)	9 (26)
Mindfulness	7 (16)	5 (14)
No reply	6 (14)	6 (17)

A total of 26.4% (28/106) of the women and 22.6% (24/106) of the men completed the questions on reasons for not using the PreLiFe app. Table 5 provides an overview of these self-reported reasons. The most commonly indicated reason for not using the PreLiFe app was lack of time. In total, 14% (4/28) of the women also indicated that the PreLiFe app did not provide enough push messages.

New phone	1 (4)	0 (0)
Failed fertility treatment	1 (4)	0 (0)

Partner Support Experienced While Using the PreLiFe App

A total of 44% (47/106) of the women and 33% (35/106) of the men completed the questions on partner support experienced while using the PreLiFe-app Regarding partner support experienced while using the PreLiFe app, more than half (30/47, 64%) of the women and men practiced a healthy diet often or very often together. One in 3 couples worked on their physical activity together. Furthermore, more than half (32/47, 68% and 25/35, 71%, respectively) of the women felt often supported by their partners in their diet. Only 0.9% (1/106) of the couples practiced mindfulness together. In addition, 38% (18/47) of the women and 46% (16/35) of the men never felt supported by their partners when practicing mindfulness (Table 6).

Qualitative Evaluation: User Experiences

Baseline Characteristics of the Participants

A total of 10 participants (4 couples and n=2, 20% individual participants) took part in 6 semistructured interviews between January 2021 and March 2021. The sample consisted of 50% (5/10) male individuals and 50% (5/10) female individuals who had all participated in the PreLiFe study and received access to the PreLiFe app for 1 year or until ongoing pregnancy occurred. The baseline characteristics of the participants are presented in Table 2.

User Experiences

A total of 112 codes were categorized into eight themes: (1) general evaluation, (2) pick-and-mix functionalities, (3) descriptions of app use, (4) app impact, (5) non–app-dependent behavior, (6) trust, (7) problems with the app, and (8) suggestions.

General Evaluation

All 10 participants mentioned that the PreLiFe app was easy to use and understand and that an app such as this one should be available by default as a part of fertility treatment. However, some added that it should not be mandatory.

Pick-and-Mix Functionalities

An obvious theme within each of the interviews was the on-demand or pick-and-mix approach toward modules and even functionalities within modules that participants used. Participants tended to pick the modules or functionalities that fit best in their lives. They often mentioned finding specific parts of the app useful:

> *The possibility to choose cooking advice suitable to your level of kitchen prowess.* [Participant 1]

Conversely, participants also mentioned that specific modules, especially mindfulness, were “not for them” (participants 2 and 5).

Descriptions of App Use

When asked about the use of the PreLiFe app in different social contexts, many participants (7/10, 70%) mentioned that they would use the app or suggestions from the app together with their partner to support each other in improving their lifestyle and prepare for the fertility treatment. A lot of the app use depended on the time available. Some participants (3/10, 30%) mentioned only using the PreLiFe app when they had some free time. Others mentioned that “the short tips received through notifications also work well when you don’t have much time at your disposal” (participant 6). In addition, the timing and events during IVF treatment could have an impact on people’s app use. Several participants (6/10, 60%) mentioned mainly using the app during key moments of the treatment:

> *We used the app around important doctor visits.* [Participant 8]

One participant mentioned completely pausing their use of the app as they had received disappointing news during their treatment, wanting to step away from the treatment for a little while. Some people (2/10, 20%), mostly men, did not end up using the entire app much or at all:

> *I have more of a supportive role in the process, the application might be more useful for women.* [Participant 3]

App Impact

Several participants (7/10, 70%) mentioned that the PreLiFe app made them aware that a healthy lifestyle was relevant to their fertility treatment. In addition, several participants (6/10, 60%) mentioned that using the PreLiFe app increased awareness

XSL•FO
RenderX

of current behavior and triggered potential behavior change. However, it was mentioned that it was not always easy to adhere to the planned behavior. It was also mentioned that receiving notifications triggered further app use. Participants mentioned that, throughout their treatment, they were trying to find some sense of control over or influence on the results of the treatment. Some participants (4/10, 40%) said that the PreLiFe app helped them obtain this feeling of control.

Non–App-Dependent Behavior

Many participants (8/10, 80%) mentioned that they were already using physical activity trackers and, therefore, did not use those parts of the PreLiFe app as it was not compatible with their wearables.

Trust

The fact that the PreLiFe app was developed through the efforts of a university and hospital and operated by scientists and health care providers had a very positive effect on trust in the app. Participants were also willing to share personal information with the app.

Problems With App Use

One participant mentioned that having a pending update for the app caused her to stop receiving new information. Other experienced problems were with the pedometer, which stopped working or provided inconsistent results as compared to their own activity trackers.

Suggestions

Throughout the interviews, participants made several suggestions that could be added to the PreLiFe app. Participants stated that the functionality could become more automated by integrating current health applications or activity trackers. In addition, participants suggested that it would be interesting if health care professionals could have access to the recorded data, allowing for tailored feedback on their behavior. This aligns with the wish to have a more direct connection to health care providers by, for instance, being able to directly ask questions to the medical staff through the app.

Some participants (4/10, 40%) highlighted the importance of support throughout the emotional aspect of the fertility treatment, for instance, providing contact information for emotional support providers such as fertility psychologists. In addition, it was mentioned that it would be good to have some sort of “emotional guardian” who could step in when things became too much. Others suggested investing in features to improve the social aspect of the app, for instance, designing features that allow for sharing recorded data between partners as a way to help them stimulate and motivate each other. One participant felt that it would be interesting to have a forum attached in which different app users could share experiences and motivations with other people using the app.

Discussion

Principal Findings

This paper describes the quantitative and qualitative evaluation of the use and user experience of the PreLiFe app, as well as the app’s acceptability and the partner support experienced.

Overall, patients were positive about the PreLiFe app, often felt supported by their partners while using the app, and were willing to use it, as revealed by our quantitative and qualitative subjective evaluations. However, our objective use data revealed that actual app use was low, particularly among men. We observed that PreLiFe app use was related to partner app use and to the stage of fertility treatment (higher app use during the start of IVF treatment). Furthermore, we observed that the module that had the highest number of interactions and highest level of tailoring (the diet module) had the highest use.

Implications and Comparison With Previous Work

One of the most remarkable findings of this study was the paradox between the high scores for acceptability and subjective use and the low actual objective use, highlighting the importance of objective measurement methods for app use. In the context of behavior change, these findings could be explained by the fact that the participants were in a phase of being aware of the health benefit (contemplation phase) but not yet having enough motivation or awareness to proceed to action for behavior change (in this case, regular app use and follow-up goals). Focusing on intrinsic motivation and possibly external motivation (intermediate follow-up by a physician or health care professional) could potentially have a synergistic effect. Compliance and acceptability do not reflect the actual use of lifestyle apps. Comparing our results with those of other studies remains difficult. A recent systematic review of lifestyle apps indicated substantial variability in intervention characteristics and inconsistent reporting of use outcomes [27]. Future research should work with core outcome sets on use to address this inconsistency in selecting and reporting of use outcomes [32]. Although previous research has shown that patients undergoing IVF need support in lifestyle modification and prefer a mobile app as a time-efficient format [22], the actual use of our PreLiFe app was low, especially among men. A possible reason may be found in a recent study by Robertson et al [33], who showed that patients undergoing IVF might prefer focusing on their treatment instead of other factors such as emotional management or their lifestyle. Another potential explanation for the low use among men is that we did not consider gender-specific differences when developing our app. Previous studies have shown that men may have different perceptions of lifestyle relevance to the fertility trajectory or different coping strategies to handle infertility [34,35]. Furthermore, lifestyle behavior and motivation to improve their lifestyle might differ between partners. Further characterizing the current needs of both partners and tailoring lifestyle apps to their personalized needs and motivations can contribute to the engagement of both partners in such interventions.

A recent systematic review identified several factors that positively influence adherence to lifestyle apps: personal support, content personalization, individualized push

XSL•FO
RenderX

notifications, and user-friendly design [36]. In our study, we observed that PreLiFe app use was higher when the partner used the app as well and that patients felt supported by their partners. This is in line with previous studies showing that involving both partners in lifestyle interventions can facilitate mutual support, behavior change, and compliance at little additional cost [23,37]. A recent Dutch study providing tailored coaching on vegetable, fruit, and folic acid intake; smoking; and alcohol consumption in a blended approach to couples trying to conceive reported improved lifestyle behavior, which was more robust when both partners participated [38]. These findings suggest that partner-based interventions may offer a comparative advantage over individual-focused apps. Future studies on lifestyle apps for people with infertility should further consider this partner interaction.

PreLiFe app use also increased during fertility treatment, when participants were in contact with health care providers. This supports the idea that blended care models combining digital tools with professional support may enhance engagement. Determining the optimal balance between digital autonomy and health care provider interaction remains a key question [39].

Identifying the balance between time investment and personalization is also key for future research on this topic. Participants indicated lack of time as the most important reason for not using the PreLiFe app. In contrast, we observed the highest use for the diet module, which was the module with the highest level of time investment, interaction (2 push messages per week), and tailoring (personalized goals based on a questionnaire).

Another improvement area defined was the lack of interaction with other data systems such as wearables. Integration of wearables could enhance personalization and efficiency, as observed in other health apps [40]. However, further research on this topic in this specific population is warranted.

Strengths and Limitations

The main strength of this study is that we combined qualitative and quantitative data on the use and user experiences of both partners, allowing for an in-depth understanding of participants' use and experiences with a preconception lifestyle app. Furthermore, to our knowledge, we are the first to provide objective insights into the actual use of a lifestyle app among both partners. We did so using app-based tracking, an objective measure not prone to social desirability bias. In-depth analysis of such use data can contribute to identifying and improving factors that lead to higher use and engagement, ultimately enhancing the effectiveness of lifestyle apps [41,42].

The limitations of this study should also be considered. First, all participants were asked about their rationale for not using the PreLiFe app, but fewer than 1 in 3 women and men replied, potentially not reflecting the views of all nonusers. In general, self-selection of the participants might have played a role throughout the PreLiFe study. Our study population had a higher physical activity level and lower rates of overweight and obesity than the general Belgian population [43,44]. Selection bias could have been present in our study, resulting in participants with a high interest in lifestyle and health. Furthermore, most patients were of European origin and highly educated, limiting the generalizability of our results. Finally, to avoid burdening the participants, the final results of the qualitative study were not returned to them for validation. This decision could potentially lead to misinterpretations of their true thoughts.

Conclusions

In conclusion, our findings show good acceptability and user experiences but low actual objective use of a preconception lifestyle app for couples undergoing IVF. Lifestyle apps can empower patients to feel more in control and supported regarding their reproductive health. However, to increase use and potential effectiveness, future research on lifestyle apps for people with infertility should further focus on the personalization of such apps to individual needs and on the interaction with partners, health care providers, and other patient data systems such as wearables.

Acknowledgments

The authors would like to thank Steve De Backer for the technical development and support of the PreLiFe app, Kevin Sanders for contributing to the user experience research on the PreLiFe app, the advisory committee of our Research Foundation – Flanders–TBM project (Applied Biomedical Research with a Primary Social finality) for their guidance and advice, and all the patients participating in the PreLiFe study. This work was supported by the Research Foundation – Flanders (Belgium; reference: T005417N).

Tang et al's recent study published in *JMIR Human Factors* [1], titled "The Use of Mobile Health Care Among Medical Professionals in the Sichuan-Chongqing Region: Cross-Sectional Survey Study," captured my attention. Their analysis of mobile health (mHealth) device use and influencing factors, using chi-square and multivariable logistic regression analyses, revealed a significant association between age and mHealth use. This study provides valuable insights from China's western region.

However, I would like to offer a few comments and suggestions that I believe would further enhance the study's methodology and findings.

First, the study's reliance on a web-based questionnaire may introduce potential selection bias, as respondents, by nature of accessing web-based surveys, may be more likely to use digital devices and have a stronger interest in digital health in general. A more diverse, mixed-methods approach to questionnaire distribution could help mitigate this potential self-selection toward mHealth use and prevent the exclusion of individuals with limited experience or interest in mHealth.

Second, the study could benefit from a standardized and rigorous methodological framework for survey design and reporting. For instance, categorizing age into three broad groups may overlook essential trends. A finer measurement scale for satisfaction and usage, such as a Likert scale, could provide deeper insights into health care professionals' attitudes. Furthermore, for questions where "uncertain" responses outweigh "yes" or "no" responses, a qualitative or mixed-methods research approach could yield a more nuanced understanding of the underlying reasons. Finally, incorporating years of work experience as a variable could add valuable insights, given its potential correlation with age. Unlike professional titles, years of work experience could provide a more direct measure of professional tenure, potentially enriching the data analysis.

Third, ethical considerations of this study merit further attention. Identifying specific hospitals in the report may compromise confidentiality. Additionally, the exemption of review by an institutional review board (IRB) raises concerns, as the study involves gathering potentially sensitive information from human participants (ie, health care professionals) regarding personal perspectives, workflows, and technology use. Such studies often warrant an ethics board review to protect participant privacy, minimize psychological or social risks, and ensure adherence to ethical standards [2].

Fourth, before conducting logistic regression analysis, normality tests on both independent and dependent variables are recommended to confirm the validity of the chosen statistical methods [3]. If data are not normally distributed, adjustments should be considered.

Lastly, as noted in the "Limitations" section [1], the reliance on convenience sampling may affect the study's generalizability. Only public, district-level hospitals were included, excluding primary and tertiary institutions—this limits the representation of China's complete health care hierarchy in the analysis. Furthermore, only urban areas were sampled, overlooking rural populations. Women comprised 77.1% of the study sample, raising questions about gender representation. A multi-level sampling approach would likely yield a more comprehensive and representative dataset.

To conclude, I would like to highlight that these feedback points are not to challenge the integrity of the authors' work. Instead, I hope they can contribute to ongoing discussions on mHealth research and the development of robust methodologies in this field.

Story Retelling and Verbal Working Memory in Young Adults With a History of COVID-19: Cross-Sectional Study

Hyunsoo Yoo, PhD

Department of Communication Science and Disorders, Baylor University, 1311 S 5th St, Waco, TX, United States

Corresponding Author:

Abstract

Background: The impact of the COVID-19 pandemic has primarily been studied in the context of language delays or developmental disorders in infants and children. However, the effects on young adults have received less attention. COVID-19 not only affects physical health but also cognitive and language functions, which is an emerging area of research. While previous studies have focused on developmental stages, the effects of COVID-19 on the language abilities of healthy young adults remain underexplored. This study aimed to investigate the impact of COVID-19 on the spoken language, particularly in story retelling and working memory, in young adults.

Objective: This study aimed to investigate the effects of COVID-19 on memory-based story retelling and verbal working memory in young adults. Specifically, it examined whether there were group differences in story retelling and working memory performance between individuals with and those without a history of COVID-19, and whether verbal working memory predicted story retelling outcomes.

Methods: The study involved 79 young adult participants, of whom 39 were in the non–COVID-19 group and 40 were in the COVID-19 group. Participants completed the Story Retelling Procedure (SRP) and a verbal working memory task. Story retelling performance was quantified using information units per minute (IUs/min), a measure of informativeness in story retelling. Working memory was assessed using the Alphabet Span Test.

Results: Participants with COVID-19 produced fewer information units per minute (mean 0.53, SD 0.21) than those without COVID-19 (mean 0.63, SD 0.24; P=.049). No significant group differences were found in verbal working memory performance (P=.20). However, regression analysis showed that verbal working memory significantly predicted story retelling performance (R^2=.064, P=.02), suggesting that individual differences in working memory capacity may contribute to discourse informativeness, regardless of COVID-19 history.

Conclusions: Young adults with a history of COVID-19 exhibited reduced story retelling performance compared to those without a history of infection. In contrast, no significant differences were observed in verbal working memory performance between groups. Furthermore, verbal working memory scores significantly predicted story retelling performance, suggesting a functional link between these cognitive-linguistic domains. These findings suggest that story retelling performance may serve as a sensitive indicator of post–COVID-19 cognitive-linguistic changes in young adults.

COVID-19; story retelling; verbal working memory; young adults; cognitive; linguistic

Introduction

COVID-19 is caused by SARS-CoV-2, and this virus is known to cause respiratory illness in humans. After the first case was reported in December 2019, the total cumulative cases worldwide reached 770,875,433 by October 3, 2023, according to the World Health Organization [1]. Since the introduction of vaccines, the number of cases has decreased dramatically.

While hospitalizations and severe cases of respiratory symptoms have decreased, the impact of COVID-19 on cognition has persisted. Numerous studies have reported cognitive dysfunction in individuals with a history of COVID-19. A recent systematic review article [2] reported that the results are inconsistent. Another study [3] found that age was a risk factor, while other study [4] found that middle-aged individuals were the most vulnerable population. Gender differences were also found [5] in cognitive impairment, and women tend to have higher cognitive impairment than men.

Regarding measures tested for the cognitive abilities, the most common neuropsychological screening tests were commonly used in studies [6,7], but an inconsistency was also found here: Quan et al [2] claimed that the timing of cognitive testing might

XSL•FO
RenderX

be the reason for the inconsistency of the results. Other tasks were also used, such as the Digit Span Test-forward and backwards, Trail Making Test-parts A and B, Stroop Word reading and Colour Naming, Corsi backwards, Stroop test, Rey auditory verbal learning test, Free and Cued Selective Reminding Test, Rey–Osterrieth Complex Figure, and Boston Naming Test, Verbal [8-12]. One study [13] found that the severity of COVID-19 was related to poor performance in executive function tasks (Digit symbol, Trail Making Test B, and phonetic fluency). Akıncı et al [14] also found that COVID-19 affected global cognitive skills, which were evaluated using the Montreal Cognitive Assessment and Clock-Drawing Test; memory functions, evaluated using the Öktem Verbal Memory Processes Test; attention span, evaluated using the Digit Span Test; executive functions, evaluated using fluency tests, the Stroop test, and the Trail Making Test; visual perceptual skills, evaluated using the Rey Osterrieth Complex Figure test; and neuropsychiatric status, evaluated using the Neuropsychiatric Inventory.

Although some studies included verbal language tasks such as the Boston Naming Test, discourse-level spoken language, particularly story retelling, has not been examined in COVID-19–related cognitive research in relation to verbal working memory. Story retelling is a cognitively demanding task that engages multiple components of verbal working memory, including temporary storage, manipulation, and retrieval of linguistic information [15,16]. Successful retelling requires not only remembering the sequence of events [17] but also integrating details, maintaining coherence, and regenerating narrative structure [18], all of which rely on both working memory capacity ([19]) and attentional control [20,21].

Emerging research suggests that COVID-19 infection may affect higher-order cognitive functions, such as sustained attention, executive function, and verbal memory [9,22-24]. These functions are closely tied to narrative production abilities, making story retelling a sensitive measure for detecting subtle post–COVID-19 cognitive changes, particularly in young adults with no overt language deficits.

Some of the studies used working memory tasks, but the format of the working memory tasks was based on visual working memory. According to Baddeley's [25, 26] working memory model, visual working memory and verbal working memory are 2 distinct cognitive systems. Visual working memory is responsible for storing information and manipulating visual information such as shapes, colours, and images. Verbal working memory handles language-based information and involves also temporarily storing information and manipulating verbal or auditory information such as words, sentences, and numbers. Therefore, the nature of the information process is different, and it is processed in different systems: the visuospatial sketchpad for visual working memory and the phonological loop for verbal working memory. Considering that spoken discourse production has been shown to be a sensitive clinical indicator of language processing deficits in people with atypical neurogenic language disorders (eg, aphasia) [16,27,28], it is imperative to investigate the impact of COVID-19 on spoken discourse performance.

There are different types of spoken discourse formats depending on how the tasks are administered, and there are mainly 2 different types of tasks, one of which is story retelling. In this format, the examiner read a story, and the participants were asked to retell the story immediately after hearing it. The story retelling type taxes memory capacity [16] and is affected by recency and/or primacy effect [29]. Another format is based on picture description. In this format, participants can rely on the picture in front of them; therefore, the task places lower cognitive demands on memory compared to the story retelling format. Yoo et al [16] found the correlation between the verbal working memory tasks with the retelling type of discourse production results in people with aphasia. This aligns with the connection between verbal working memory and various levels of language processing, as extensively documented in the literature [26,30-32].

Therefore, the primary goal of this study was to examine whether COVID-19 affects memory-based story retelling performance and verbal working memory. The previously reported correlation between performance on the Story Retelling Procedure (SRP) and verbal working memory were correlated based on was assessed [16]. If working memory has declined after COVID-19, it is reasonable to hypothesize that story retelling performance would also be affected by COVID-19. The following questions were investigated in this study:

1. Are there significant differences in measures of story retelling between individuals with and those without a history of COVID-19?
2. Are there significant differences in the verbal working memory between individuals with and those without a history of COVID-19?
3. Is there a predictive relationship between the story retelling and the verbal working memory scores? In other words, can the verbal working memory scores predict the story retelling scores?

Methods

Ethical Considerations

This study was approved by the institutional review board at Baylor University (approval number 1655082 - 11). All participants provided verbal informed consent prior to participation. Some personally identifiable information was collected as part of the study. All identifiable data were removed prior to analysis, and the remaining materials were securely stored on a university-provided cloud platform with restricted access. Only approved research personnel had access to the data through institutional login credentials. No identifying details (such as names, initials, facial features, or other unique identifiers) are included in the manuscript or any submitted materials. All data are presented in a manner that ensures participant anonymity and privacy. No compensation was provided to the participants.

Participants

In total, 79 young participants in their 20s with and those without a history of COVID-19 participated in this study virtually: (1) the non–COVID-19 group comprised 39

XSL•FO
RenderX

participants (age: mean 21.58, SD 1.24 years; years of education: mean 16.32, SD 0.97), and (2) the COVID-19 group comprised 40 participants (age: mean 21.38, SD 1.63 years; years of education: mean 15.60, SD 1.25; Table 1).

Participants in the non–COVID-19 group were recruited between November 11, 2020, and December 4, 2020, and self-reported not having a history of COVID-19. Participants in the COVID-19 group were recruited between April 13, 2021, and September 20, 2022, and provided self-reported information regarding time since infection and number of infections. All COVID-19–positive participants were nonhospitalized, and symptom severity ratings were not collected using a formal scale. Vaccination status was not obtained, and information regarding post–COVID-19 condition symptoms was not collected, as the data were obtained during the early stage of the pandemic, before the concept of post–COVID-19 condition had been clearly defined. Table 2 provides a summary of COVID-19–related participant characteristics.

Table . Demographic information of participants.

Group	Participants, n	Values, mean (SD)
Age (years)		
Non–COVID-19 group	39	21.58 (1.24)
COVID-19 group	40	21.38 (1.62)
Total	79	—[a]
Years of education		
Non–COVID-19 group	39	16.32 (0.97)
COVID-19 group	40	15.61 (1.25)
Total	79	—

[a]Not applicable.

Table . Self-reported COVID-19 characteristics of the COVID-19 group (n=40).

Variable	Values
Time since infection (months)	1 infection: mean 256.6 (SD 199.28); 2 infections: mean 168.56.93 (SD 130.93)
Number of infections	1 infection: n=34 (85%); 2 infections: n=6 (15%)
Symptom severity	Not quantified; all nonhospitalized
Vaccination status	Not obtained
Post–COVID-19 symptoms	Not collected; data were obtained before the concept of post–COVID-19 was clearly defined

Procedures

All data collection procedures were conducted virtually via Zoom (Zoom Video Communications). Each session lasted less than 1 hour per participant.

The SRP Task

The stories used in the SRP task were adapted from the Discourse Comprehension Test [33], which includes 10 stories that were normed and matched on key linguistic complexity variables such as number of words, sentence length, number of subordinate clauses, listening difficulty, and number of main ideas. The validity and reliability of the SRP as a discourse elicitation procedure have been established through validation studies [34,35], which demonstrated strong correlations across multiple linguistic domains with other established elicitation tasks, including picture descriptions and procedural narratives.

SRP participants listened to a short story, and they were asked to retell it immediately afterward. Three short stories were presented, and the averaged raw scores were used for the data analysis. The story information units were checked using the scoring sheet and correct information units per minute was calculated as an outcome variable.

The Working Memory Task

Each participant also completed Alphabet Span Task as a working memory task. In the task, each participant listened to a list of words and was asked to reorder the words in alphabetical order. The list of words was increased as the span increased. The total correct numbers of items were used as the outcome variable for this working memory test.

Statistical Analysis

Statistical analyses for this project were conducted using Python (version 3.10), with the statsmodels and scipy packages for ANOVA and regression modeling. The dataset was assessed for normality, and due to skewed distributions, a natural log transformation (ln) was applied to the story retelling variable (information units per minute [IUs/min]). Two outcome variables were analyzed: (1) log-transformed IUs/min derived from the SRP task and (2) the total number of correct responses

XSL•FO
RenderX

on the Alphabet Span task as a measure of verbal working memory.

To address the first research question, a 1-way between-subjects ANOVA was conducted to compare story retelling performance between the COVID-19 and non–COVID-19 groups. The dependent variable was the number of information units produced per minute, log-transformed to meet assumptions of normality.

Results

Overview

The results revealed a significant between-group difference ($F_{1,77}$=3.99, P=.049), with the COVID-19 group producing fewer information units per minute (mean 0.53, SD 0.21) than the non–COVID-19 group (mean 0.63, SD 0.24). For the second research question, a separate 1-way ANOVA was conducted to compare verbal working memory performance between groups, measured by total number of correct items on the Alphabet Span task. The analysis indicated no significant difference between the COVID-19 (mean 16.21, SD 2.94) and non–COVID-19 (mean 15.30, SD 3.29) groups ($F_{1,77}$=1.66, P=.20). To address the third research question, a simple linear regression was conducted to evaluate the extent to which verbal working memory performance predicted story retelling performance. The regression model was significant ($F_{1,77}$=5.31, P=.02), and accounted for 6.4% of the variance in log-transformed IUs/min (R^2=.064).

The regression equation was:

Story retelling performance (log IUs/min)=−0.493+0.014×verbal working memory performance (Alphabet Span Test: the total correct numbers of items).

The unstandardized regression coefficient (B=0.014) indicates that each additional point on the Alphabet Span Test resulted in a 0.014 increase in log-transformed IUs/min. This corresponds to an approximate 1.4% increase on the raw scale:

(1)exp(0.014)= e{0.014}≈1.014

This back-transformation should be interpreted cautiously. All statistical inferences were based on log-transformed values due to nonnormality in the original distribution. The 95% CI for the slope ranged from 0.002 to 0.026, suggesting a modest but statistically reliable association between verbal working memory and story retelling performance.

Additional Exploratory Analyses

Additional exploratory analyses were conducted within the COVID-19 group to examine whether the number of days since infection was associated with performance on cognitive-linguistic tasks. Time since infection was not significantly associated with story retelling performance (r=.10; P=.57; R^2=.009) or with verbal working memory scores (r=.04; P=.83; R^2=.001). These results suggest that recovery time did not significantly account for performance variability in either task. All additional statistical analyses were conducted using Python (version 3.10) with the pandas, scipy.stats, and seaborn libraries. Exploratory correlation analyses were performed using the Python pearsonr function to assess linear associations between variables of interest, and simple linear regression was conducted using the linregress function.

Discussion

Principal Findings

This study aimed to investigate the impact of COVID-19 on spoken story retelling and verbal working memory and to examine the predictive relationship between the story retelling and the verbal working memory in young adults. The results found that the story retelling performance of the COVID-19 group was significantly lower than that of the non–COVID-19 group. However, despite this performance difference in story retelling, no significant difference was observed between the groups in verbal working memory. This highlights an interesting contrast, suggesting that while the COVID-19 group showed reduced story retelling performance, their verbal working memory capacity did not differ significantly from that of the non–COVID-19 group, indicating that other factors beyond memory might contribute to the observed differences in story retelling performance. In the results of regression analysis, the spoken story retelling performance, measured by %IUs/min, was significantly predicted by the verbal working memory span, even though the prediction was weak, indicating that the relationship between these 2 variables is complex and may be influenced by other factors not captured in this analysis. These results indicate several critical updates of the impact of the COVID-19 on spoken language processing and verbal working memory.

SRP Results

Our findings reveal a surprising impact of COVID-19 on the spoken language of young adults, challenging the prevailing assumption that only infants and children in the developmental stage are susceptible to such effects. Although prior research has predominantly linked COVID-19 with developmental language disorders or delays, particularly in infants and children [36-39], this study underscores the unique vulnerability of healthy young adults to disruptions in story retelling as a result of COVID-19 infection. While children in the developmental stage are generally considered more vulnerable to language impairments, young adults typically exhibit stable story retelling abilities. However, this study suggests that COVID-19 may be associated with disruptions in these abilities. The duration and trajectory of such effects remain unclear, particularly in individuals experiencing post–COVID-19 condition. Future longitudinal research is needed to clarify whether and how story retelling performance may change over time. Additionally, this study suggests that story retelling may be especially sensitive in detecting the cognitive impact of COVID-19. This heightened sensitivity may be attributed to the complexity of the language system, wherein discourse-level processing involves multiple cognitive and linguistic components. In this context, the SRP, which heavily relies on auditory comprehension and various memory functions [16,29,40-42], emerges as a particularly sensitive tool. Both auditory comprehension and memory have been identified as vulnerable indicators of disruptions in language processing abilities [43,44]. Given the complexity of

XSL•FO
RenderX

language processing assessed by the SRP, it holds promise as an invaluable tool for detecting the nuanced effects of COVID-19 on story retelling in young adults.

Verbal Working Memory Findings

Conversely, we observed no significant impact of COVID-19 on verbal working memory. These findings contrast with those reported in previous literature, which has documented negative effects of COVID-19 on working memory [45]. One possible explanation for this discrepancy is the age group of the participants in this study. According to recent research [45], the detrimental effects of COVID-19 on working memory function are primarily observed in adults aged 25 years and older. In contrast, the average age of the participants in the COVID-19 group in this study was 21.37 years, with the non–COVID-19 group also consisting of individuals in a similar age range. This age-related difference may account for the absence of significant working memory decline in the younger cohort in this study. Another potential factor is that none of the participants had been hospitalized for COVID-19, and most reported only mild symptoms. It is also possible that some were asymptomatic. This limited severity may help explain the absence of significant group differences in working memory performance. Moreover, this study did not collect data on whether the COVID-19 group experienced brain fog or post–COVID-19 condition, as data collection took place shortly after the acute phase of COVID-19 infection. It is possible that participants did not exhibit symptoms of post–COVID-19 condition related to cognitive decline or other persistent neuropsychological impairments. Given these factors, further research is needed to examine verbal working memory in individuals experiencing symptoms of post–COVID-19 condition, as this cohort may exhibit different cognitive outcomes.

Results of Regression Modeling

Regression modeling revealed that the story retelling performance was predicted by the verbal working memory test, specifically the Alphabet Span task. This association between SRP and verbal working memory was previously identified in a study involving stroke survivors with aphasia [16]. Revisiting these results with a narrowed focus on individuals exhibiting symptoms of post–COVID-19 condition is crucial to further clarify this predictive relationship further.

Limitations

As discussed earlier, a notable limitation of this study is the absence of information regarding whether participants with a history of COVID-19 had experienced post–COVID-19 condition. This gap in data collection stems from the timing of the study, which occurred shortly after the onset of COVID-19. In addition, this study was conducted in a virtual testing environment, which may have introduced variability in participants' attention, environmental distractions, or audio quality, potentially affecting performance. Another limitation is the possibility of selection bias, as participants volunteered to complete the study remotely and may not fully represent the broader young adult population. Furthermore, the regression analyses yielded relatively low predictive power, suggesting that while certain predictors showed statistical associations, they may not account for a substantial proportion of variance in story retelling performance.

Conclusion

This study identified differences in spoken story retelling performance between individuals with and those without a history of COVID-19. Additionally, story retelling performance was predicted by the Alphabet Span Test, a measure of verbal working memory. These findings suggest that story retelling may be sensitive to subtle post–COVID-19 cognitive-linguistic changes in young adults. This has potential clinical implications for early cognitive-linguistic screening and targeted support interventions, particularly in educational and clinical settings.

Data Availability

The datasets generated and analyzed during this study are not publicly available due to privacy concerns, but deidentified data may be made available from the author upon reasonable request.

Abstract

Background: The internet is a key source of health information, but the quality of content from popular search engines varies, posing challenges for users—especially those with low health or digital health literacy. To address this, the “tala-med” search engine was developed in 2020 to provide access to high-quality, evidence-based content. It prioritizes German health websites based on trustworthiness, recency, user-friendliness, and comprehensibility, offering category-based filters while ensuring privacy by avoiding data collection and advertisements.

Objective: This study aims to evaluate the acceptance and usability of this independent, noncommercial search engine from the users’ perspectives and their actual use of the search engine.

Methods: For the questionnaire study, a cross-sectional study design was used. In total, 802 participants were recruited through a web-based panel and were asked to interact with the new search engine before completing a web-based questionnaire. Descriptive statistics and multiple regression analyses were used to assess participants’ acceptance and usability ratings, as well as predictors of acceptance. Furthermore, from October 2020 to June 2021, we used the open-source web analytics platform Matomo to collect behavior-tracking data from consenting users of the search engine.

Results: The study indicated positive findings on the acceptance and usability of the search engine, with more than half of the participants willing to reuse (465/802, 58%) and recommend it (507/802, 63.2%). Of the 802 users, 747 (93.1%) valued the

XSL•FO
RenderX

absence of advertising. Furthermore, 92.3% (518/561), 93.9% (553/589), 94.7% (567/599), and 96.5% (600/622) of those users who used the filters agreed at least partially that the filter functions were helpful in finding trustworthy, recent, user-friendly, or comprehensible results. Participants criticized some of the search results regarding the selection of domains and shared ideas for potential improvements (eg, for a clearer design). Regression analyses showed that the search engine was especially well accepted among older users, frequent internet users, and those with lower educational levels, indicating an effective targeting of segments of the population with lower health literacy and digital health literacy. Tracking data analysis revealed 1631 sessions, comprising 3090 searches across 1984 unique terms. Users performed 1.64 (SD 1.31) searches per visit on average. They prioritized the search terms “corona,” “back pain,” and “cough.” Filter changes were common, especially for *recency* and *trustworthiness*, reflecting the importance that users placed on these criteria.

Conclusions: User questionnaires and behavior tracking showed the platform was well received, particularly by older and less educated users, especially for its advertisement-free design and filtering system. While feedback highlighted areas for improvement in design and filter functionality, the search engine’s focus on transparency, evidence-based content, and user privacy shows promise in addressing health literacy and navigational needs. Future updates and research will further refine its effectiveness and impact on promoting access to quality health information.

Introduction

Background

The internet has become a crucial resource for accessing medical information, making it a valuable tool for individuals seeking knowledge about health. In Germany, medical professionals, notably physicians, have long been the primary source of health care information for the general population [1,2]. However, the landscape is evolving, and the internet now stands as the second most significant channel for health-related information [1], indicating a new trend in how people seek medical knowledge. A study conducted by the Bertelsmann Foundation showed a strong and increasing demand for health-related information online, including a rapidly increasing demand by older generations [3]. In 2020, approximately 70% of the German population used the internet to actively engage in searching for health-related content [4]. While these numbers have varied in recent years, there is an overall trend of an increased use of the internet [4].

A major complaint that users have about health-related information online is the lack of clarity regarding the trustworthiness and seriousness of existing websites. The information online has varying levels of quality [5,6]. Frequently used and popular websites are regarded as reliable by users, irrespective of the actual quality of their content, while independent public websites are not as well known and do not seem to be more reliable to users [3]. The reliance on digital platforms for health information also poses a challenge due to the profound influence of the order of the results generated by popular search engines. Users often initiate their search for medical information through well-known search engines, predominantly relying on the first few search results displayed on the search engine results page (SERP), which are often advertising [7-10]. Unfortunately, these top hits are not only clicked on more frequently but are also perceived as more trustworthy, despite the variation in information quality [3,9]. This highlights the ambiguity of users feeling incompetent in finding reliable information online, while at the same time trusting the top results and being satisfied with the information they find. A more recent study evaluated the quality of online health and nutrition information related to cancer supplements through a Google search, using the Health Information Quality Index [11]. The 160 relevant search results yielded median and mean Health Information Quality Index scores of 8, with one-quarter of the results scoring high (10-12). No correlation was found between high quality scores and an early appearance of these results, indicating potential limitations in using Google for obtaining accurate information on dietary supplements and cancer, particularly given the prevalence of advertisements outnumbering search results [11].

The problem with the reliance on search engines becomes even clearer when considering the low health literacy and digital health literacy of the German population [12-14]. The first Health Literacy Survey Germany study in 2014 [13] underscored a significant health literacy challenge in Germany, with 54.3% of the population reporting health literacy problems. This result pointed to challenges in navigating the health care system and understanding health-related information, with identified associations with factors such as age, migrant background, self-assessed social status, and functional literacy. The second Health Literacy Survey Germany study in 2020 [14] reinforced previous concerns with a further increased rate of individuals (58.8%) struggling considerably with health information. Even more so than in 2014, evaluating the trustworthiness of health-related information presented difficulties [15]. Up to 45% of the German population exhibit “problematic” or even “inadequate” internet skills [16]. Many individuals face so-called navigational needs. They depend on support from others to efficiently search and evaluate health information online [17]. As the amount of digital health information grows each year, the challenge of effectively navigating through this vast array of content becomes increasingly daunting, raising concerns about misinformation and health-related misconceptions.

XSL•FO
RenderX

During the work on the comprehensive GAP (Gut informierte Kommunikation zwischen Arzt und Patient, meaning "Well-informed communication between physician and patient" in English) project, which addressed evidence-based information [18-26], we studied the needs and requirements of internet users for health information online [18]. We developed criteria to assess web domains according to these needs. Assessing the quality of websites is nothing new. There are existing seals of approval, such as the afgis (Aktionsforum Gesundheitsinformationssystem eV, meaning "Action Forum Health Information System eV" in English) and Health On the Net Foundation Code of Conduct seals, which check whether the website operator meets certain transparency and quality standards. An afgis certificate is valid for 1 year. However, with Health On the Net Foundation Code of Conduct, there were several issues [27], and on December 15, 2022, the Health On the Net Foundation discontinued its services. Different seals potentially signify different standards of certification. Another issue with these seals is that the pages that have a seal cannot easily be found via a central search. To address these issues by centrally and consistently rating domains inside a search platform, we developed a search engine in 2020. This search engine was originally called "GAP search" and later renamed as "tala-med Suche" in German and "tala-med search" in English.

The topic of data retrieval in medicine is generally relevant and widely researched. Efforts ranging from decentralized search systems for patient data in registries [28] to tools such as Informatics for Integrating Biology and the Bedside (i2b2) [29] that allow the creation of cohorts, for which data security plays an important role [30], have been investigated. In addition, for public data, such as the Medical Subject Headings (MeSH), search capabilities play an important role [31], including the requirement for an intuitive user interface design [32]. In terms of scraping web content, which could be used to create a search platform, the Sampled German Health Web [33,34] created an index of German-language health-related web pages using a special focused crawler. The Sampled German Health Web index was restricted to pages from the top-level domains .de, .at, and .ch, and the domains were automatically filtered for health-related content while crawling using a support vector machine. By contrast, the new tala-med search engine, which was used in this study, relied on hand-picked, high-quality, German-language health websites. These domains—more than 50 of them—underwent a rigorous evaluation process. This evaluation was based on the categories *trustworthiness* (with the subcategories *authority*, *independence*, and *evidence based*), *recency*, *user-friendliness*, and *comprehensibility*. The ratings of these categories influence the order of the results on the SERP. The search engine also values user privacy by avoiding data collection and advertising. The detailed design of the search engine is described in the *Methods* section and in Multimedia Appendices 1-3.

By assessing the acceptance and usability of this new technology, we aimed to improve the implementation of the search tool. Numerous studies in the field emphasize the significance of outcome measures as crucial indicators of a technology's effectiveness, user-friendliness, and potential for widespread adoption. User acceptance, often determined by perceived usefulness, ease of use, and individual attitudes, is critical for a technology's long-term viability [35,36]. Moreover, the usability of a technology, including learnability, efficiency, and user satisfaction, significantly affects user experience and reduces possible adoption barriers [37]. Evaluating these dimensions can provide insight into how well technology meets users' expectations, addresses their needs, and contributes to successful implementation. In the context of health care technology, this scrutiny is particularly relevant because effective tools for accessing medical information can significantly impact health care outcomes [17,38].

In this study, the acceptance and usability of our newly developed search engine was evaluated by means of a questionnaire study and actual use by tracking user behavior during the first months of operation.

Related Works

The usability and accessibility of digital platforms are essential for ensuring that all users, including those with disabilities, can effectively engage with websites and mobile apps. Mateus et al [39] conducted a systematic mapping of accessibility issues, revealing that automated tests covered <40% of accessibility problems on websites and even fewer on mobile apps. The study stressed the importance of including users with disabilities in evaluations because user testing uncovered many issues missed by automated tools and expert inspections. This underscores the need for a comprehensive evaluation approach that combines expert and real-world user input to improve accessibility.

Petrie and Bevan [40] expanded on this by exploring the interplay between usability, accessibility, and user experience. The authors defined usability in terms of effectiveness, efficiency, and satisfaction, focusing on aspects such as learnability, flexibility, and safety. Importantly, they emphasized that accessibility is an integral component of usability and that digital systems should cater to the widest possible range of users, including those with disabilities. They also introduced the concept of user experience, which goes beyond usability to include users' emotional responses and satisfaction with a system. This holistic approach is essential for creating digital platforms that are both functional and engaging for all users.

Belinda et al [41] provided a deeper look into the internal and external usability factors that affect website performance. The authors used automated tools such as GTmetrix and Website Grader to measure internal attributes such as performance, load time, and page size, while external attributes such as ease of navigation and user satisfaction were assessed through surveys. Their findings revealed that some websites performed well from a user perspective but were found lacking in technical performance, particularly in terms of load times and page requests. This highlights the need to address both internal and external usability factors to create well-rounded digital platforms.

Kritz et al [42] explored the online resources and tools used by European physicians to gather medical information. The authors found that physicians frequently relied on general search engines and faced significant barriers in accessing high-quality,

XSL•FO
RenderX

trustworthy medical content. Medical specialists were more likely to use medical research databases, while general practitioners often faced barriers such as lack of time and language restrictions. The study highlighted the need for improved medical search tools tailored to the specific needs of different physician subgroups. Kritz et al [42] concluded that user-centered medical search tools could significantly improve accessibility and the quality of online medical information.

Strecker et al [32] also contributed to the usability of medical search tools, focusing on the MeSH Browser. The authors evaluated a newly developed multilingual MeSH Browser, which introduced improvements in user interface design to enhance the accessibility and usability of medical literature searches. The results showed that contemporary web design principles led to significant improvements in navigation and overall user satisfaction, further underscoring the importance of continual evaluation and enhancement of information systems in the medical realm.

Eysenbach and Köhler [43] studied how consumers search for and appraise health information on the internet. The qualitative study revealed that users, despite using suboptimal search techniques, were able to retrieve health information quickly. However, users rarely checked critical indicators of credibility, such as the “About us” sections or disclaimers, relying instead on superficial factors such as professional design and ease of use. This reliance on superficial credibility indicators poses risks, particularly in the health care field, where the accuracy of information is paramount. Eysenbach and Köhler [43] suggested that further research is needed to develop educational and technological tools that guide users toward high-quality health information.

Zhang [44] expanded the understanding of how consumers select sources for health information by identifying 5 categories of factors that influence source selection: source-related factors, user-related factors, user-source relationships, characteristics of the problematic situation, and social influences. The study also identified a range of criteria that mediate the influence of these factors on source-selection decisions, including accessibility, quality, usability, interactivity, relevance, usefulness, and familiarity. Zhang [44] concluded that a personalized approach to health information systems is necessary to provide effective access to health information because different consumers prioritize different factors when selecting sources. This insight strongly indicates the need for more personalized information services that cater to individual user preferences and needs.

In conclusion, the literature emphasizes the critical role of accessibility, usability, and user experience in the design of digital platforms, especially health care websites. While Saad et al [45] have highlighted general usability problems in health care websites, the studies by Kritz et al [42], Eysenbach and Köhler [43], and Zhang [44] focus on the challenges that users face in retrieving and assessing the credibility of health information online. A personalized and user-centered approach to the design of health care information systems would improve the accessibility and quality of health information, meeting the diverse needs of consumers and health care professionals alike [40,44].

Methods

Search Engine Development

Requirements

The functional requirements for the tala-med search engine included the ability to crawl and index health information websites, implement quality assessment filters, and provide search term suggestions and synonym handling. The nonfunctional requirements focused on maintaining user privacy through self-hosting, ensuring a user-friendly interface, and optimizing performance to handle large sets of synonym mappings efficiently.

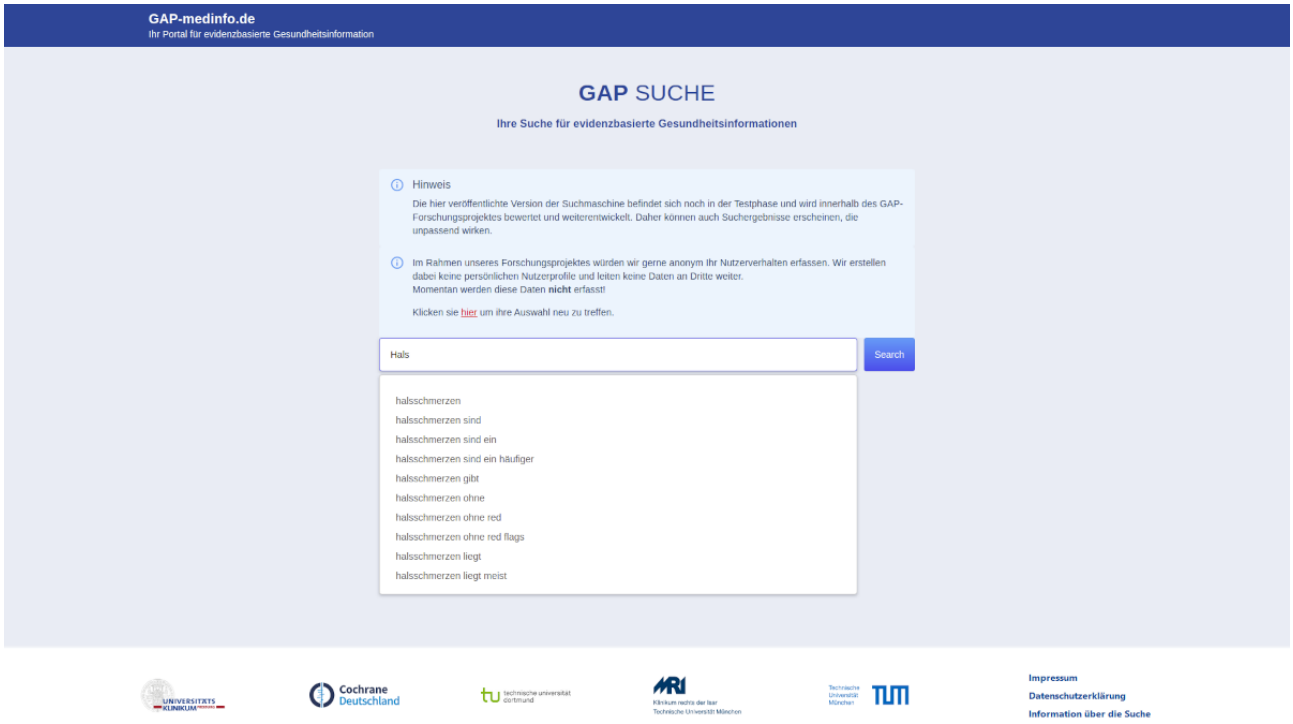
Implementation

Design

To implement tala-med search, we used software with a self-hosting capability because of privacy considerations. Furthermore, modern technology with single-page application design using a web application programming interface was required to compete with modern search engines. Therefore, the selection available was limited. As no single product met all our requirements, we built a search engine stack ourselves, consisting of crawler, middleware, and front end, using existing components and established technologies.

Back End

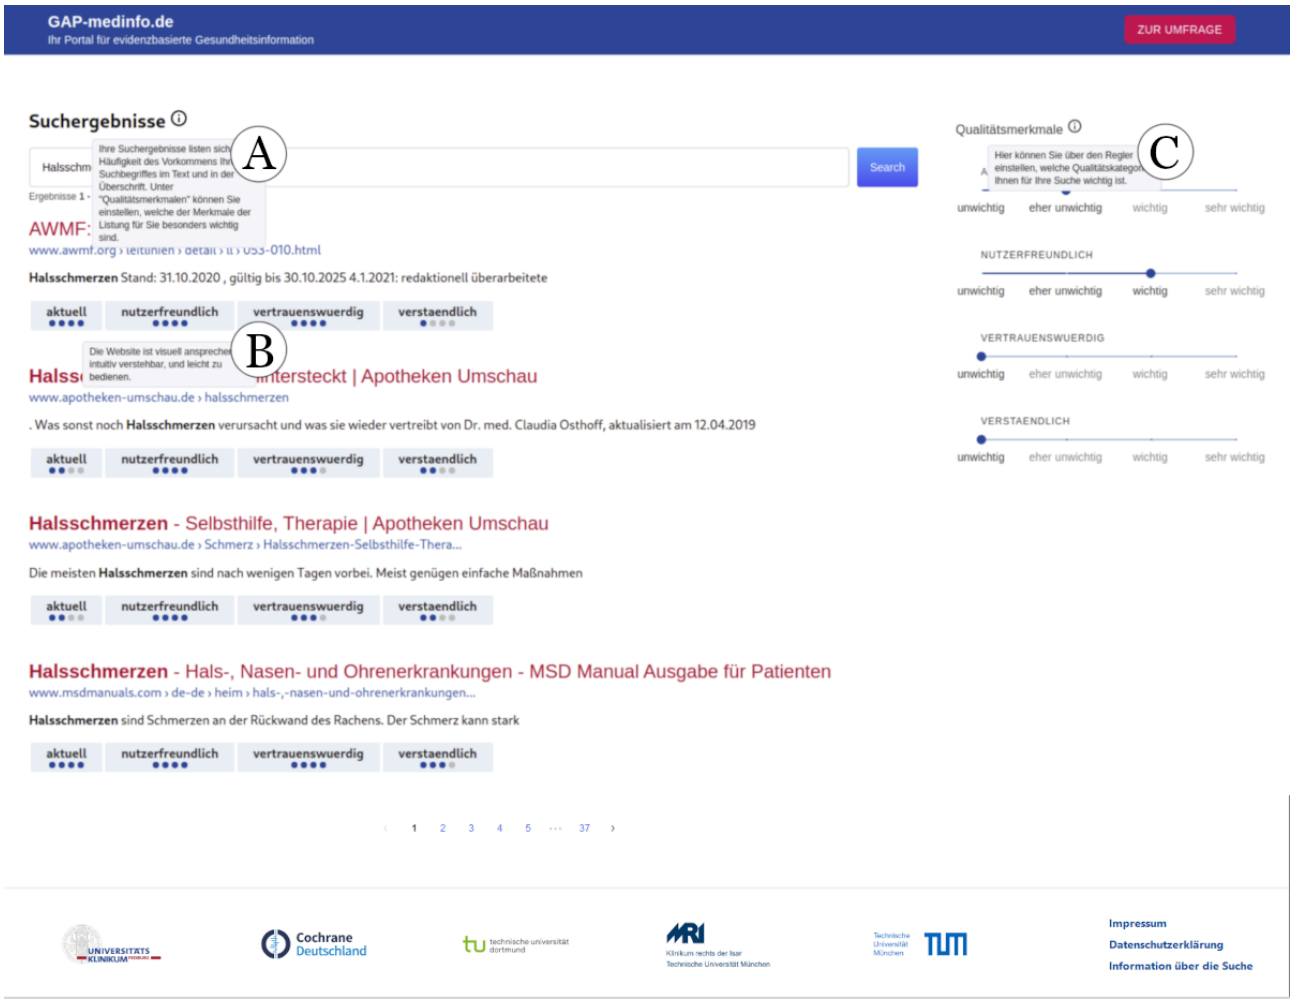
We created the web index using the open-source crawler software Fess [46]. For boilerplate removal, we used Mozilla’s Readability tool to strip HTML tags and display core content, cleaning up crawled websites for our search index [47]. As middleware, we used Elastic App Search [48] (now part of Elastic Enterprise Search [49]), which relies on Elasticsearch. This software allows for setting up weighting mechanisms for the search equation (Multimedia Appendix 1) and configuring filters. In our case, a set of criteria for quality assessment were developed, which we integrated as filters. These quality assessment criteria were adapted from a systematic review by Eysenbach et al [6] that identified criteria used from 1969 to 2001 for evaluating the quality of health information online. We identified 74 criteria [18] to assess the content quality of different health-related websites and rigorously evaluated >50 German-language health information providers (Multimedia Appendix 2) using these criteria, assessing 1 main page and 5 randomly selected subpages per provider. To compile the list of relevant providers, we started with a list from a Bertelsmann study [3] and adapted it with the help of domain experts. The 74 quality criteria were later condensed into 4 categories: *trustworthiness*, *recency*, *user-friendliness*, and *comprehensibility*. The scores of these categories were added to the search index after boilerplate removal and divided into 4 value ranges reflecting the quality of each category, using 4 quantiles for differentiation. These scores served as quality indicators and filter categories, influencing the order of the results on the SERP. More details about the internal mechanisms of the search ranking can be found in Multimedia Appendix 1.



XSL•FO
RenderX

App Search supports the consideration of synonyms, which is crucial in medical language due to varied etymology and numerous abbreviations. Our goal was to enable the search engine to handle synonyms effectively. In App Search, sets of up to 32 synonyms can be created, allowing synonyms of a matched word to be considered in searches. We generated synonym sets by collecting word types and pairs from the document text, filtering against a German stop word list, resulting in approximately 6 million unique entries. These entries were matched against an experimental German interface terminology—SCT-GIT—linked to Systematized Nomenclature of Medicine–Clinical Terms (SNOMED-CT) [50], yielding approximately 40,000 mappings to SNOMED-CT codes. Synonym links in SCT-GIT were then used to add synonyms for each matching string, finding at least 1 synonym for approximately 30,000 SCT-GIT terms. We limited the number of synonym sets to 500 to maintain performance, using only sets with at least 4 synonyms, resulting in a median set size of 4.

Front End



The front end was custom developed with a slim design inspired by Strecker et al [32], featuring search term suggestions and a user-friendly filter selection (Figure 1). After entering a search term, the interface displayed a SERP with evaluated German-language health information providers, showing their scores in the 4 filter categories through graphical indicators (Figure 2). Hovering over these graphics revealed explanations, and the bottom of the page included pagination and a footer with logos and links to pages displaying the imprint and data protection information.

Figure 1. Landing page of the search displaying the initial search query field.

XSL•FO
RenderX

Figure 2. The search engine results page consists of 3 areas. (A) The search query. (B) List of search results. Each search result shows the quality in the 4 filter categories. (C) Slide controls allow users to set a threshold for each filter category (aktuell: recency, nutzerfreundlich: user-friendliness, vertrauenswürdig: trustworthiness, and verständlich: comprehensibility). In each of these areas, more information can be displayed by means of tooltips, as shown in the graphic (next to each label).

Pilot Testing

The search engine was pilot-tested between October 2020 and the end of June 2021. Adapting to the challenges posed by the COVID-19 pandemic, the pilot testing format shifted from a face-to-face setting to a web-based setting with a small group of academic staff from the University of Freiburg. The evaluation, involving 12 participants, consisted of screen recordings of search tasks and a qualitative survey regarding user-friendliness. After the pilot tests, technical enhancements were implemented, guided by the qualitative insights. These findings formed the basis for the subsequent questionnaire study.

Availability

The current version of the search engine can be accessed on the web [51]. Please note that there have been some significant changes to the website structure since this study was conducted.

Evaluation

Design

We used 2 data collection methods to evaluate user behavior. First, we asked users to fill out a questionnaire (self-perception). Second, we recorded user behavior via web tracking independently and unreferenced to the questionnaire (external perception). The study protocol was published in 2019 [22].

Questionnaire Study

The study used a cross-sectional design with data collected through a web-based questionnaire. The questionnaire was developed after pilot testing of the search engine and underwent an internal pretesting round before recruitment began.

Recruitment

The study used a recruitment strategy aimed at enrolling 200 participants. The first rounds of recruitment, starting in October 2020, which involved sending email invitations to local health initiatives, professional networks for physicians, and personal contacts, were unsuccessful in obtaining the desired number of participants. Participants were then recruited from the WisoPanel, an established online panel of German-speaking individuals [52]. The panel provided a pool of 14,900 potential respondents who had previously expressed an interest in participating in research studies. The survey was open for anyone accessing the link, but only participants from the panel (>70% of the data) were included in the analysis of this study to maintain a credible sample. Recruitment via the panel took place in May 2021. The survey ended at the end of May 2021.

XSL•FO
RenderX

Panel members were invited to participate in the study via email. The email informed participants about the project and the aspects distinguishing the new search engine from other platforms.

To ensure that participants had firsthand experience with the platform before proceeding to the survey, they were asked to test the search engine first. We recommended that participants carry out 1 or 2 searches and familiarize themselves with the SERP and the features and functions of the website.

Survey Administration

The hyperlink that led participants to the search engine was sent to the panel members by email. Subsequently, the link to the survey was displayed as a pop-up element after 10 to 20 seconds of interaction with the search engine. Throughout the assessment phase, a button to access the survey was strategically positioned in the top right corner of the website to allow a direct link to the survey interface. No registration was required to complete the survey, ensuring seamless and voluntary participation. Participants had the option to cancel their responses at any time, and there were no time restrictions regarding the completion of the questionnaire. Back buttons allowed participants to review their answers before submitting the survey. Conventional technical methods, such as cookies, were used to prevent visitors from submitting their survey more than once.

The web-based survey was conducted using the Unipark tool [53], with the survey page seamlessly embedded into the search page via a modal window. After inviting panel participants, the survey remained accessible for 11 days and closed at the end of May 2021.

Before filling out the survey, participants were provided with an introductory text outlining the anticipated time commitment, project objectives, details about anonymity, the option to terminate the survey at any point, data protection measures, and contact information for queries. To proceed, participants were required to confirm their understanding by checking a box and consenting to the specified use of their data (informed consent). No personal data were collected in the survey, and participants were instructed not to provide any identifying information in their open responses. Access to the data was restricted to members of the institutions participating in the study.

Survey Characteristics

On the basis of established scales (the German version of the self-assessment eHealth Literacy Scale [G-eHEALS] [54] and the System Usability Scale [55] adapted by Quirmbach [56] and Magin et al [57]), we developed a 25-item questionnaire across five dimensions: (1) sociodemographic data; (2) internet use; (3) digital health literacy; (4) usability, acceptance, and innovative aspects of the search engine; and (5) search filters. The final questionnaire contained 24 single-choice questions and 1 open-ended question (Tables S1 and S2 in Multimedia Appendix 4). The items in the questionnaire were not randomized. No form of adaptive questioning was used. All questions, except for the open-ended question, were mandatory; nonresponse options were not provided. Thus, there was no additional consistency or completeness check before submission. The survey took approximately 5 minutes to complete.

Statistical Analysis

Descriptive statistics were used to summarize the characteristics of the study participants, including age, gender, occupation, educational level, and internet use for health information, as well as self-perceived digital health literacy. Only completed questionnaires were analyzed. No statistical correction was applied to adjust the sample. To assess the acceptance and usability of the search engine, Likert-scale items related to these dimensions were combined to create scale values. The acceptance scale measured participants' willingness to use the search engine again and to recommend it to others. The usability scale evaluated participants' agreement with statements related to comprehensibility, clarity, the effectiveness of the search, confidentiality, advertising, the ease of learning, and using the search engine.

One reviewer analyzed the content of the open-ended question and assigned the comments to different categories inductively.

Multiple regression analyses were conducted to explore predictive factors influencing the acceptance of the search engine. The factors tested in the regression analyses included age, gender, occupation, educational level, the frequency of internet use for health information, and self-perceived digital health literacy.

Reporting

This study is reported based on the guidelines of the Checklist for Reporting Results of Internet E-Surveys (CHERRIES) [58].

User Behavior Tracking

Behavior tracking data were collected from all consenting users accessing the search engine between October 2020 and June 2021 using the web analytics software Matomo (Matomo.org) [59]. Matomo is a powerful open-source web analytics platform designed to help website owners and organizations gain insights into their online presence while respecting user privacy. Its primary purpose is to track website traffic by tracking website visitor behavior. What sets Matomo apart from services such as Google Analytics is its commitment to data privacy and General Data Protection Regulation (GDPR) compliance. Matomo allows users to maintain control over their data by hosting the data on their own servers, ensuring that sensitive information is not shared with third parties. Matomo is easy to integrate into web pages and can also be customized to track specific custom data. Ripp and Falke [60] successfully used Matomo to track user behavior in their research project, where they analyzed search behavior for certain keywords on the online information system Grammis.

We installed Matomo on our own server and integrated the tracking into our search engine's front end. We enabled the tracking to record the filter settings and capture the search term beyond the standard visit data, such as how long users spent on the website, and which of the results they clicked on. Structurally, Matomo records several actions for each visit, containing the duration among other data (Figure S1 in Multimedia Appendix 5). However, for the last action of a visit, the duration is not recorded. We have filled the empty value

XSL•FO
RenderX

with the median of all actions from the particular visit to obtain a more realistic value for the entire visit duration.

Only data from consenting users was recorded and subsequently descriptively analyzed for the 9-month time period. Therefore, this sample differs from the sample of the questionnaire study but may also include users who completed the questionnaire. The data processing for the data analysis was realized with a Python script directly accessing Matomo's database using specific SQL queries.

Ethical Considerations

The study was approved by the institutional review board at the University of Freiburg (Ethikkomission-Freiburg 559/17) as an extension to the GAP study [22], and a document on data protection was agreed upon. As an incentive, the questionnaire study participants could take part in a prize draw for 1 of 25 vouchers to a bookstore worth €20 (US $24.33) after completing the survey.

Results

Questionnaire Study

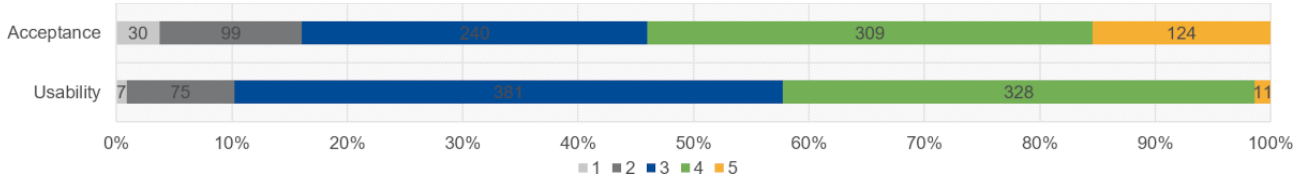
Participants

During the time the survey was open (from October 2020 to the end of May 2021), there were 1577 unique site visitors to the search engine website, with 1426 (90.4%) visitors to the first survey page. Of these 1426 visitors, 1250 (87.7%) agreed to participate in the survey. Of these 1250 participants, 1123 (89.8%) completed the survey.

Of the 1123 survey respondents, 802 (71.4%) were from the panel described in the Recruitment subsection. The age distribution of these participants was approximately normal, with a little more than a quarter of the participants (215/802, 26.8%) falling into the age category of 50-59 years. The gender distribution was also fairly balanced between male and female, with a little more than half of the respondents (432/802, 53.9%) self-identifying as female. Regarding occupational background, the majority of the participants (726/802, 90.5%) did not work in a medical profession.

Educational levels were notably higher than in the general population due to recruitment through the scientific panel, with 69.3% (556/802) of the participants having completed upper secondary education (at least level 3 in the International Standard Classification of Education [ISCED]-2011) and 46.3% (372/802) holding a bachelor's or master's degree or higher (ISCED-2011 levels 5-8).

The study participants recruited from the web-based panel reported searching for health information online more frequently than the general population, with 65.4% (524/802) searching several times a month at the minimum and 27.7% (222/802) searching at least several times a week. Only 1.5% (12/802) of the participants indicated that they "never" searched the internet for health information.



Participants' self-perceived digital health literacy was measured by the G-eHEALS items. Of the 802 participants, 291 (36.2%) felt confident in making health-related decisions based on internet information, while 461 (57.5%) felt capable of distinguishing reliable from questionable information online.

More information about the participants is available in Table S3 in Multimedia Appendix 4.

Acceptance and Usability

Scale values were created by combining items relating to the acceptability and usability of the search engine (Figure 3).

Figure 3. Scale values for acceptance and usability (n=802). The Likert-scale response options were as follows: 1=strongly disagree, 2=disagree, 3=partially agree, 4=agree, and 5=strongly agree. There was one negative question, which was adjusted for calculating the scale values.

The results show agreement regarding the acceptance and usability measures of the new search engine (Figure 3 and Table 1). In particular, more than half of the participants expressed their willingness to use the search engine again (465/802, 58%) and to recommend it to others (507/802, 63.2%). In addition, 79.3% (636/802) of the respondents agreed or strongly agreed that using the search engine was quick to learn, and 77.3% (620/802) to 98.6% (791/802) agreed at least partially with other statements related to usability aspects.

XSL•FO
RenderX

Table 1. Detailed items for acceptance, usability, and innovative aspects (n=802). The Likert-scale response options for acceptance and usability were as follows: 1=strongly disagree, 2=disagree, 3=partially agree, 4=agree, and 5=strongly agree. The Likert-scale response options for the innovative aspects item were as follows: 1=very unimportant, 2=unimportant, 3=neither unimportant nor important, 4=important, and 5=very important.

Content	Scores, mean (SD)
Acceptance	
Item 1: potential reuse	3.58 (1.02)
Item 2: recommendation to others	3.68 (1.03)
Usability	
Item 1: quick to learn	4.03 (0.86)
Item 2: efficient scannability of the SERP[a]	3.63 (1.00)
Item 3: clarity of the SERP	3.75 (1.00)
Item 4: functions *not* comprehensible[b]	2.37 (1.29)
Item 5: appreciation for the absence of advertising	4.66 (0.66)
Item 6: functionality meets expectations	3.45 (1.03)
Item 7: careful handling of personal data	3.59 (0.88)
Item 8: no commercial bias	3.55 (0.95)
Item 9: fast access to relevant information	3.77 (0.99)
Item 10: innovative approach	3.58 (1.03)
Innovative aspects of the search engine (anonymous searches)	4.50 (0.76)

[a]SERP: search engine results page.

[b]Item 4 (comprehensibility of functions) was a negated question.

Users particularly appreciated the absence of advertising on the platform, with 93.1% (747/802) agreeing or strongly agreeing that the absence of advertising was a significant benefit. The search engine's user-friendly interface and the ability to adjust search results through the use of filters were also well received by participants. Furthermore, the unique features of the search engine, notably the anonymous searches without the creation of user profiles and independence from sponsors, received high importance ratings from 91.3% (733/802) of those surveyed.

More detailed results are available in Tables S4-S6 in Multimedia Appendix 4.

Of the 802 participants, 561 (70%) to 622 (77.6%) indicated that they used the filter functions that could be enabled to change what was displayed on the SERP (Table 2; Figure 2). Furthermore, 92.3% (518/561), 93.9% (553/589), 94.7% (567/599), and 96.5% (600/622) of those users who used the filters agreed at least partially that the filter functions were helpful in finding trustworthy, recent, user-friendly, and comprehensible results, respectively. The *recency* filter was particularly well received, with 46% (286/622) of the users strongly agreeing that it was helpful. More detailed results are available in Table S7 in Multimedia Appendix 4.

Table 2. Helpfulness of filters (n=802). The Likert-scale response options were as follows: 1=strongly disagree, 2=disagree, 3=partially agree, 4=agree, and 5=strongly agree.

Content	Participants, n (%)[a]	Values, mean (SD)
Helpfulness of filters for each filter		
Item 1: trustworthiness	599 (74.7)	4.11 (0.92)
Item 2: recency	622 (77.6)	4.25 (0.84)
Item 3: comprehensibility	589 (73.4)	4.05 (0.93)
Item 4: user-friendliness	561 (70)	3.91 (0.93)

[a]All other participants answered, "I did not use this function, I cannot evaluate this question."

In the open-ended question, which aimed to supplement the data with qualitative results, participants were asked to share their comments and suggestions for improvements. Of the 802 participants, 263 (32.8%) replied to the question. Multiple aspects were mentioned. In an inductive approach, 10 main themes were identified (Figure 4). Many of the participants commented on the usability aspects of the website. Of the 236 comments, 76 (32.2%) included constructive criticism and specific suggestions for improving the website in the future. Many commenters made suggestions for improving the design because they found some aspects unclear or overwhelming. Others did not fully understand the methodology behind the

XSL•FO
RenderX

evaluation of the selected providers or the reason why only specific providers, including commercial web pages, were shown on the results page and asked for more clarification. Some commenters were happy with the site as it stood and did not ask for any changes, while some conveyed disappointment with the results they discovered on the SERP.

Figure 4. In the analysis of 263 comments in response to the open-ended question, 10 main themes were identified inductively: design; search results and filter functions; selection of providers; technical details; method of evaluating the website; target audience; text on the website; comments about the survey; general positive responses; and critique, dissatisfaction, and other comments. The illustration shows a hierarchical visualization, with the size of the elements indicating the quantity of comments.

Predictors of Acceptance

We conducted multiple regression analyses to examine the predictive factors influencing responses to the acceptance scale. Age, gender, occupation, educational level, frequency of internet use for health information, and self-perceived digital health literacy were tested as influencing factors. All factors were first tested individually and subsequently tested simultaneously due to the potential error introduced by multiple testing. Overall, only minor discrepancies were identified. Significance levels were set at $P<.05$. Table 3 presents more details.

XSL•FO
RenderX

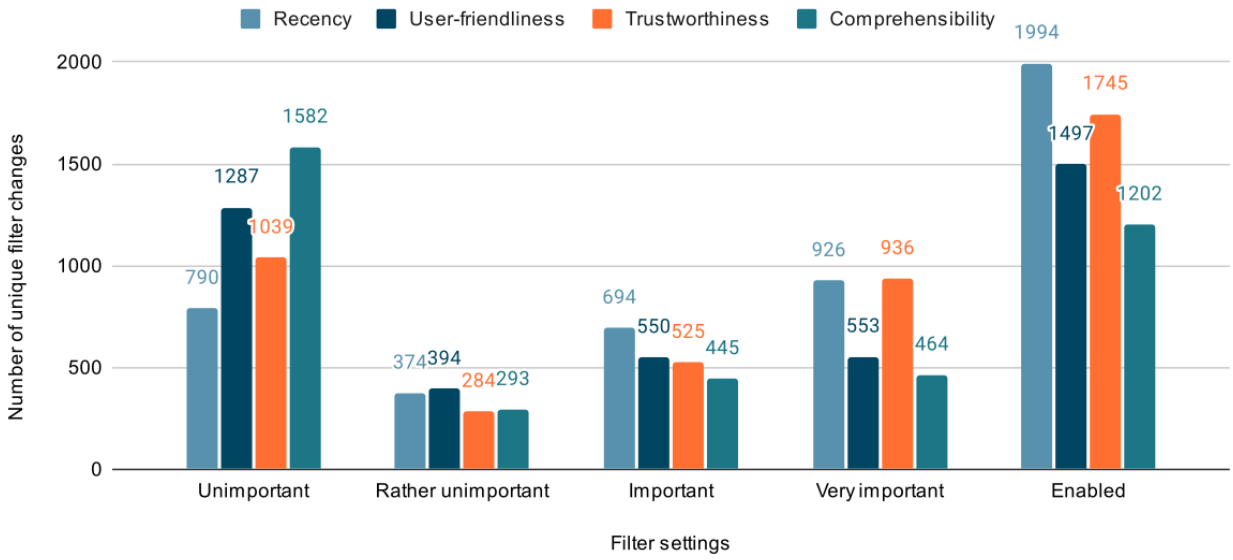
[b]Factors with significant predictions (*P*<.05) are shown in italics.

[c]ISCED: International Standard Classification of Education.

There were 2 significant results in predicting the acceptance of the search engine. First, the acceptance rating increased with age, rising by 0.07 scale points (B=0.07) for each additional 10-year age group. Second, the ratings for acceptance were higher among participants with more frequent internet use for health information.



The factors "highest level of educational attainment" and "self-perceived digital health literacy" only showed significant correlations with the acceptance ratings in the individual tests and slightly lower correlations in the simultaneous tests. Participants with lower levels of education showed stronger acceptance ratings than those with higher levels of education. For this predictor, the reference category was set as "doctorate degree" (ISCED-2011 level 8). Acceptance ratings among persons without any formal secondary education (ISCED-2011 levels 0-1) or with a lower secondary education (*Hauptschulabschluss*, ISCED-2011 level 2) were 0.41 scale points higher than among persons with a doctorate degree (B=0.41). However, if we examine the effect strength using partial eta–squared (η_p^2), only small effects were shown overall for all factors (1%=small effect, 6%=medium effect). No significant results were found for the factors *gender* or *occupation*.

User Behavior Tracking

For a period of 9 months (from October 2020 to the end of June 2021), user behavior of consenting users was tracked using Matomo. The main aspects recorded were the search queries and the use of the filter functions. The data indicated that 1631 visitor sessions had taken place, with 3090 searches using 1984 different search terms across 1924 visits. The search terms had an average lexical token count of 1.74 (SD 1.14). Of the 1984 search terms, 1096 (55.24%) had a lexical token count of 1, while 888 (44.76%) had a lexical token count of >1. The maximum lexical token count was 13. We observed that 28.9% (893/3090) of the search queries were conducted through mobile devices such as smartphones and tablets. On average, visitors conducted 1.64 (SD 1.31) searches per visit, with an average duration of 137.45 (SD 278) seconds and a median duration of 49 (IQR 24-119) seconds. The top 3 search terms were "corona," "rückenschmerzen" (back pain), and "husten" (cough; Table S1 in Multimedia Appendix 5). Each search term was queried 1.57 (SD 3.46) times on average; of the 1984 search terms, 1621 (81.7%) were entered just once. Users could personalize the order of the displayed search results, depending on the prioritization of the different filter categories (*trustworthiness*, *recency*, *user-friendliness*, and *comprehensibility*), all of which were initially set to "unimportant" by default. Within the search interactions, overall, 47,532 actions were performed, among which were 1358 (2.86%) outlink actions (ie, external domains clicked by website visitors) and 34,490 (72.56%) filter changes in total. The high number of filter changes was due to the fact that the filters were often switched back and forth in a search, which led to multiple occurrences of the same filter settings. This behavior was probably observable due to the fact that, given the limited corpus, the result set could be empty for certain search terms in combination with a narrow filter setup; therefore, it was necessary to change back the filter to obtain results. Excluding these repeated changes, of the 34,490 filter changes, 5534 (16.05%) were unique. In addition, after removing the initial filter setup where all categories were set to the default value, we ended up with 2784 nondefault unique filter changes used in 15.37% (475/3090) of the searches. *Recency* was used the most, followed by *trustworthiness*, *user-friendliness*, and *comprehensibility* (Figure 5). Consistent with the results on the usefulness of the filter function from the questionnaire study, the user behavior data showed that the filters for *recency* and *trustworthiness* were adjusted most frequently.

Figure 5. Distribution of the filter settings of the 2784 nondefault unique filter changes across filter categories. We consider a filter category to be "enabled" if a filter category is not set to "unimportant.".

Discussion

Principal Findings

In this study, we evaluated the independent, noncommercial tala-med search for German-language medical information, placing a primary focus on transparency, independence, and evidence-based information. Our questionnaire study and user behavior tracking provide insights into the acceptance and usability of this innovative platform.

The survey resulted in a mean acceptance score of 3.63 (SD 0.98) and a mean usability score of 3.76 (SD 0.61) on a scale of 1 to 5 (1 signifying strong disagreement and 5 signifying strong agreement with acceptance and usability statements). Given that our user interface is similar to that of popular search engines such as Google and Bing and is advertisement-free, it is unsurprising that it was well received. However, there is still a need for optimization to achieve a higher reuse potential and a greater willingness to recommend the platform. Within the usability measures, item 1, which reflected the learnability of the search, achieved a high mean value of 4.03 (SD 0.86; Table 1). In terms of the effectiveness and clarity of our design (refer to items 2, 3, and 9 in Table 1), we still see room for improvement but are satisfied with the results for the initial release. Our findings align with those of Petrie and Bevan [40], who emphasized that usability, particularly learnability, is crucial for ensuring the platform's effectiveness and user satisfaction. Similar to the study by Petrie and Bevan [40], our study highlights the need to continually evaluate and refine

XSL•FO
RenderX

digital systems to cater to user needs and improve overall usability. The survey also revealed that the filters were used by >70% of the 802 users. Among these users, the filters were highly accepted on average, which matches with the tracking statistics revealing the high use of the filter functionality. The most used filter was *recency*, followed by *trustworthiness*, matching the survey outcome, which asked about the helpfulness of the filters. This was not the case for the 2 remaining filters. Although the filter for *user-friendliness* was used more often in our tracking data than the one for *comprehensibility*, it was perceived as less helpful than comprehensibility. In the future, we might inspect these filter categories in more detail and potentially improve their estimation. The insights support our decisions, including basing the design of our search engine on the insights of Strecker et al [32], which demonstrated how improvements in user interface design could lead to higher user satisfaction. The high acceptance of the filters for *recency* and *trustworthiness* in our study also echoes the findings of Strecker et al [32], who highlighted that content navigation and relevance contribute to overall user satisfaction. Nevertheless, the insights encourage us to improve and possibly expand the filters and the design. The fact that our search engine does not share any data with partners or advertisers and does not record the visitor's behavior to create profiles was rated as very relevant, with a mean score of 4.5 (SD 0.76). This result confirms the importance of our general endeavor driven by data privacy and noncommerciality as our fundamental motivations for creating the search engine. This finding is consistent with the work of Eysenbach and Köhler [43], who found that while internet users claimed to prioritize credibility when assessing health information online, they often relied on superficial factors such as website design and ease of use, rather than more reliable indicators such as the "About us" sections or disclaimers. Our platform addresses these shortcomings by offering more explicit filters, such as *trustworthiness*, which help users find credible information without having to rely solely on superficial design elements. In our calculations on the predictors of acceptance, it can be concluded that while the effects may be small, the search engine was particularly well accepted among older users, users with a high frequency of internet use for health information, and those with lower levels of education. This finding suggests that the new search engine may effectively cater to segments of the population with lower health literacy and digital health literacy and greater requirements for navigational assistance, bridging the gap in accessing reliable medical information online. As discussed by Kritz et al [42], general practitioners and medical specialists often face barriers in accessing high-quality medical content due to limited time and the overwhelming amount of information online. Our search engine's focus on evidence-based information and user-friendly design helps mitigate these issues, making it a suitable tool for both health care professionals and the general public.

This reinforces the necessity to consider navigational needs in health information platforms. Digital health literacy has improved in recent years, particularly among persons with low levels of education [14]. The ability to assess health information has also improved over time and over the course of the COVID-19 pandemic. Digital health literacy improved for younger but not for older people over the course of the pandemic [15]. Even with some of these improvements, health literacy is still low within the German population and particularly among people with low levels of education. This observation aligns with the findings by Zhang [44], who identified that source selection for health information is influenced by a wide range of factors, including accessibility, quality, usability, and personal relevance. Our platform's appeal to older users and those with lower health literacy supports the conclusion drawn by Zhang [44] that a personalized approach, considering different user-related factors, is crucial for effectively meeting the diverse needs of consumers when they access health information. The correlation between low educational levels, low social status, higher age, and lower health literacy rates has become even stronger [14]. This emphasizes the need to address low health literacy to improve social inequities. The new search engine attempts to address this need by assessing health information online and by making high-quality information easily searchable.

Many of the comments highlight the fact that at the time of the survey, participants used the first version of the search engine, which still had some technical and appearance-related weaknesses. Since the survey was conducted, a number of revisions have been made, some of which correspond to suggestions made in the comments, such as adding more information about the principles of the quality assessment and the functions of the websites and removing certain commercially funded information sources.

The platform's emphasis on anonymous searches and independence from advertising and sponsors resonated especially well with the participants, underscoring the importance of developing alternatives to commercial search platforms. The usability of our platform, free from external advertising influence, aligns with the findings by Belinda et al [41], who evaluated both internal factors (such as page load time and performance) and external factors (such as ease of navigation and organization of information) as critical to the overall user satisfaction with websites. Our platform similarly emphasizes ease of use and efficient performance, which were key contributors to its positive reception. The general results align with previous findings on the importance of user-friendly interfaces [61-63] and the impact of advertising on users' perceptions [64].

Limitations

Limitations of the Technology

Some participants expressed dissatisfaction with the displayed results. Several respondents found the design of the SERP and individual results confusing due to an overload of information in one place. Potential design changes have been suggested to improve clarity. Currently, some search results are duplicated on the results page. To enhance the appearance of the SERP, it is desirable to deduplicate the search index. This would mean displaying more relevant information and fewer distracting results. To address the fact that sometimes no results were displayed due to strict filter settings, we could display results with nonexact matches for the filter category score below the exact matches and visually indicate them.

XSL•FO
RenderX

Participants encountered difficulties in understanding how the evaluation process worked. Efforts should be made to make the evaluation process easier to understand when using the website. Some improvements have been made over time, such as providing brief explanations of the filter categories when hovering over the graphic showing the score for each domain.

In addition, further clarification is necessary regarding the domains chosen, which comprise both independent and commercial providers. Over time, certain websites were excluded from being displayed on the site because of the conflicts of interest of their publishers (such as the site "Zentrum der Gesundheit" and a site funded by a pharmaceutical company). Currently, the website no longer displays commercial providers.

Limitations of the Questionnaire Study

While the questionnaire study provides valuable insights into the acceptance and usability of the new search engine, several limitations should be acknowledged. First, the recruitment methodology, relying on web-based panel recruitment, unintentionally led to an overrepresentation of individuals with higher educational levels than the general population and potentially more frequent internet use due to the online recruitment process. Among our participants, 46.3% (371/802) had completed tertiary education compared to only 18.5% of the general German population with a university degree or equivalent [65]. Similarly, 65.4% (524/802) of our participants reported searching for health information only at least once a month, while a Bertelsmann Foundation 2018 study indicated that only approximately 50% of the general German population seek such information at least once a month [2]. This potentially influences acceptance and usability ratings. Participants' self-perceived digital health literacy, as measured by the G-eHEALS items, approximately aligned with that of the sample of the validation study of the German version of the questionnaire by Söllner et al [54]. However, this information should be viewed with caution because Kim et al [66] discovered a discrepancy between self-assessments and actual ability. Actual ability was not assessed in our study.

Second, as some of the participants only interacted with the search engine and its features for a brief duration, this short testing time proved to be a limiting factor, hindering the formation of comprehensive first impressions. The responses to the open-ended question suggest that some participants tested the features of the search engine for only a few seconds. This was caused by the pop-up window linking to the questionnaire opening after interacting with the website for 10 to 20 seconds. Such a brief interaction period was likely insufficient for users to thoroughly explore and understand the functionalities and benefits of the search engine. Consequently, the feedback provided by users on the acceptance and usability of the platform may not accurately reflect its true potential. The limited duration of testing may lead to superficial evaluations, whereby participants may base their judgments on initial impressions rather than informed use. This can result in an inaccurate assessment and therefore impact the results presented for the acceptance and usability measures. More extended testing periods could offer a more accurate assessment of the platform's acceptance and usability over time. Furthermore, the implementation of controls for the length of the testing period could provide more reliable data, thereby ensuring that all participants have sufficient time to engage with the platform before completing the questionnaire.

Limitations of the User Behavior Tracking

As Matomo does not record the last action, we decided to substitute this missing value with the median of all actions from the particular visit. However, a more optimal solution would be to record of the last action, which could be triggered when closing the browser, but Matomo does not support this feature.

Unfortunately, due to data protection regulations, we were unable to link the search behavior with the survey data. It would have been interesting to see to what extent the search behavior and the questionnaire would have provided more information.

Future Work

Further Evaluation of the New Search Engine

As these results are based on the first impressions of a group of users, data on long-term use and satisfaction have yet to be compiled. Future work should therefore address the need to evaluate long-term acceptance and usability measures of the site using a longitudinal study design. This could provide valuable insight into whether users actually use the search engine when they have an acute need to seek out medical information and whether they return to the site over time.

Future research should also consider comparing the search engine with other existing and established platforms to gain a deeper understanding of its unique advantages. Such investigations might involve participants executing identical search queries on both the novel search engine and other platforms and sharing their impressions of each experience, similar to the study by Strecker et al [32]. Particular attention should be given to participants' abilities to assess the quality and reliability of the information found. Furthermore, a comparison of the specific results retrieved from both search engines could be undertaken, examining both the congruence and discrepancies in the results.

Further Improvements to the Search Engine

Ongoing revisions and updates to the search engine, including integration on partner websites, hold promise in expanding its reach and use, ensuring that it remains relevant and effective in addressing users' health information needs. Since the data collection for this study was completed, there have been several revisions to the website.

As the qualitative survey showed, some users found the SERP complicated. To address this issue, a potential solution could be a clearly linked help page with a video explanation. Another solution could be to provide an animated assistant that guides users through the page.

One major disadvantage of the search engine in its current state stems from the fact that the evaluation of the domains—more than 50 of them—according to the quality criteria was performed in 2020, and there has not been any update to the evaluations thus far. The domains' quality may have improved or declined

XSL•FO
RenderX

in the time since the evaluation. A continual process with constant reevaluations of the domains is necessary to ensure an up-to-date rating of the domains accessible through the search engine. As we currently do not have the capacity to perform another evaluation or to establish a continual evaluation process for the domains, we have temporarily disabled the display of the filter category scores and the option to adjust the results based on these scores because the scores do not reflect the actual quality of the domains in their current state.

Thus, in future, inspired by Zowalla et al [34], we intend to evaluate various criteria automatically. In the study by Zowalla et al [34], the readability of the language was analyzed supported by a support vector machine. We plan to use more sophisticated approaches that also model contextual context. Therefore, we plan to create classifiers based on Bidirectional Encoder Representations from Transformers (BERT) [67]. We have in mind the domain-specific models GerMedBert [68] and BioGottBERT [69], the latter being a model of the German monolingual Robustly Optimized BERT Pretraining Approach (RoBERTa) [70] model GottBERT [71] specialized on medical language. A further improvement might be the enrichment of the texts with MeSH terms, similar to PubMed. Such approaches would enable us to process and rate documents individually, rather than evaluating domains using random samples.

From a technological standpoint, there are still notable areas for enhancement of the middleware, which could be implemented in the future. As App Search is proprietary and monolithic, to make it customizable and more extensible, we are currently exploring potential improvements. In particular, we are considering alternative technologies, as used by Scheible et al [31]. This would enable us to add features based on modern technologies. Specifically, we are contemplating a different approach to computing synonyms. Instead of using discrete structures, we plan to train and use a FastText model [72].

Conclusions

The development of the independent, noncommercial tala-med search marks a step toward improving access to reliable and evidence-based health information online. By prioritizing transparency, independence, and high-quality content, the platform has the potential to bridge the gap in health information accessibility, especially for older and less-educated individuals. This study achieved its objective of evaluating the acceptance and usability of the platform, using user questionnaires and behavior tracking, and the results have been encouraging. The search engine was well received, with users appreciating its advertising-free design and filtering system, which addresses the navigational needs of individuals with lower health and digital health literacy.

User feedback also highlighted areas for improvement, particularly in the clarity of the design and filter functionality. Nevertheless, the platform's emphasis on anonymous searches and independence from advertising resonated strongly with participants, reinforcing the importance of alternatives to commercial search engines. These findings are based on initial impressions, with long-term use and satisfaction data still to be collected. Future research should compare the search engine with existing platforms to further explore its unique advantages, while ongoing updates and potential integration on partner websites will enhance its reach and relevance.

In conclusion, the tala-med search demonstrates a promising step toward enhancing health literacy and empowering individuals to make well-informed health decisions. By addressing users' navigational needs and promoting equitable access to high-quality, evidence-based medical information, the search engine has the potential to positively impact health literacy, reduce health disparities, and promote patient empowerment in the digital age.

Acknowledgments

The study was funded by the Innovationsausschuss of the Gemeinsamer Bundesausschuss (01NVF17010) as part of the GAP (Gut informierte Kommunikation zwischen Arzt und Patient, meaning "Well-informed communication between physician and patient" in English) project. Furthermore, this work was supported by the German Ministry for Education and Research (01ZZ1801B, 01ZZ1804A, 01KX2121, and 01ZZ2304A). Finally, we acknowledge support by the Open Access Publication Fund of the University of Freiburg.

Klaus Koch of the Institute for Quality and Efficiency in Health Care supported the domain selection for the search index. Julia Serong and Jakob Henke of the TU Dortmund University contributed to the evaluation concept.

Authors' Contributions

RS, NK, and CW planned and carried out the implementation of the search engine supported by FT under the supervision of MB and SV-R. RS carried out the mathematical framework for the search engine and filter estimation with the help of LS. KW and AS-L worked out the criteria with which the domains were evaluated. MS created the procedure for the weighting of the filter categories and evaluated the pages. MS developed the questionnaire under the supervision of AM. CS prepared the data analyses for the predictors of acceptance under the supervision of EF-G. CS and RS prepared the data analyses of the web tracking. RS and LS wrote the manuscript with the help of all authors and under the supervision of AM. The manuscript has been read and approved by all named authors.

Abstract

Background: The rapid expansion of telehealth underscores the need for comprehensive telehealth education among health care professionals. Despite increasing recognition of telehealth's importance, many practitioners remain underprepared, particularly in navigating legal aspects, technology, and patient engagement.

Objective: This study aimed to evaluate the impact of a web-based telehealth training course on health care professionals' telehealth acceptance and their perceived barriers to telehealth adoption.

Methods: An interventional study with a pre-post design was used in Austria. A total of 365 health professionals enrolled in an asynchronous web-based course covering general telehealth principles (concepts, legal and technical aspects, practical implementation) and profession-specific content (eg, nursing, speech therapy, and physiotherapy). Of these, 217 completed the course, and 185 met inclusion criteria for analysis. Participants' telehealth acceptance (covering telemetry, telephasis, and telepraxis) and perceived barriers were assessed via standardized questionnaires before and after the course. Satisfaction with the training was measured post-intervention using the Training Evaluation Inventory. Qualitative insights were gathered from open-ended survey questions and 2 focus groups, transcribed, and summarized.

Results: Post-intervention, overall telehealth acceptance increased significantly (P<.001, r=0.21), particularly for telemetry (remote assessment and monitoring), telepraxis (remote interventions), video call–based, and asynchronous telehealth. Perceived barriers to telehealth use—such as uncertainty about legal frameworks, data protection, and reduced quality of care—diminished significantly (P<.001, r=0.39). Post-intervention satisfaction was high, with a total median Training Evaluation Inventory score of 76 (IQR 13). Participants rated the course highly for its clarity, breadth of content, and inclusion of profession-specific modules. Qualitative feedback highlighted a desire for more hands-on demonstrations, interactive components, and guidance on institutional support and patient accessibility.

Conclusions: A structured, on-demand telehealth course significantly improved health professionals' awareness, acceptance, and intention to use telehealth and reduced perceived barriers. While the findings highlight that targeted web-based training can increase clinicians' confidence and readiness to use telehealth, it remains uncertain whether this will lead to an increase in its utilization. Future initiatives should incorporate blended-learning formats with additional practical examples, real-time discussions, and ongoing support to enhance long-term integration of telehealth into clinical workflows. On a policy level, we suggest coordinated actions at the EU, national, and institutional levels to standardize telehealth education and facilitate its practical implementation in everyday clinical practice.

Introduction

Background

The rapid adoption of telehealth technologies has underscored the necessity for adequate training among health professionals. Telehealth education is increasingly recognized as essential in preparing health care providers to deliver remote care effectively [1]. However, inconsistencies in integrating telehealth into curricula have been identified, along with a notable lack of formal study designs assessing telehealth education [2].

A significant barrier to the adoption of telehealth among providers is the deficiency of specific education and training [2,3]. For instance, graduate nursing programs often lack adequate telehealth preparation, leaving future nurses unprepared for remote patient care [4]. Similarly, allied health curricula exhibit substantial educational deficits in telehealth training, indicating an urgent need for primary research to enhance the quality and consistency of telehealth education [5].

Students acknowledge the significance of telehealth in their future professions but report low levels of knowledge and experience with telehealth applications. This gap highlights the importance of equipping students with the necessary competencies in a rapidly evolving health care landscape [6]. Training initiatives in specific disciplines, such as occupational therapy and physical therapy, have shown potential in enhancing telehealth usage [7,8]. Those have been demonstrated to improve confidence and proficiency in telehealth among practitioners [7]. However, existing telehealth training programs often are either not specifically developed for certain professions or fail to address all the unique capabilities required for remote care delivery [8]. This limitation may hinder the effective adoption of telehealth practices.

Despite these challenges, outcomes from telehealth education and training studies demonstrate high student satisfaction, with many expressing a willingness to incorporate telehealth into their future practice. Improvements in students' problem-solving skills, acceptance of technology in patient care [2,9], improved telehealth knowledge and confidence [9,10], and enhanced telehealth and communication competencies [1,4,11] have also been noted. Moreover, it fosters a belief that they will use these skills in future practice [12]. Web-based learning tailored to learners' needs has the potential to change knowledge, attitudes, and willingness to incorporate telehealth into routine care [13].

Despite the recognized importance of structured telehealth education and the positive outcomes associated with such training, there remains a lack of formal study designs evaluating its impact on health care professionals' acceptance and perceived barriers. Moreover, there is a scarcity of educational offerings for already qualified health care professionals who did not receive telehealth education during their initial training. This gap leaves many practicing clinicians without the necessary skills and knowledge to adopt telehealth technologies effectively.

Aim

Therefore, this study aimed to evaluate the impact of a web-based telehealth training course on health care professionals' acceptance of telehealth and the perceived barriers to its adoption. By using a pre-post design, the study seeks to provide insights that can contribute to the improvement of telehealth education and promote the integration of telehealth into clinical practice.

Methods

Study Design

This study used a pre-post design to evaluate the impact of an interprofessional web-based telehealth training course on health care professionals' acceptance of telehealth and perceived barriers to its adoption.

Participants

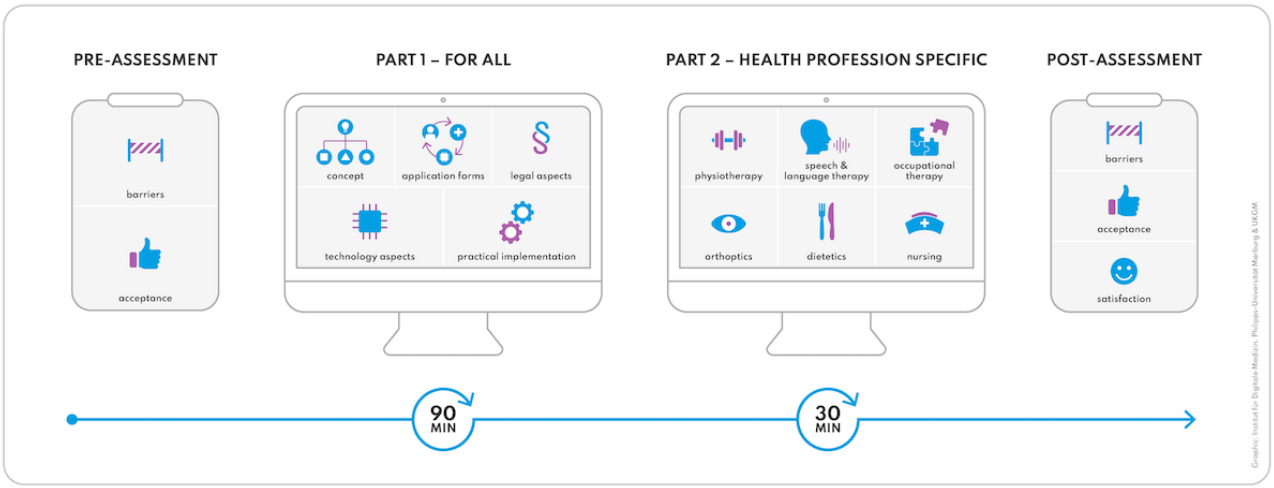
Participants in this study were health care professionals. Inclusion criteria required participants to be physiotherapists, occupational therapists, orthoptists, nurses, speech and language therapists, or dietitians. Professionals from other health care fields were also eligible to participate in the course and study, but the course content was specified for the aforementioned professions.

Procedure

Participants were recruited through professional associations of the targeted professional groups. Interested individuals were invited to register via a web-based form. On May 1, 2024, a participation link was emailed to all registered participants, and they were able to participate in the study until August 31, 2024. As a measure to increase the response rate, 2 reminder emails were sent to registered participants on August 8 and August 26, 2024.

The web-based training as well as the pre- and post-intervention questionnaires were administered using the web-based survey platform "LimeSurvey." Participants completed the initial questionnaire prior to commencing the web-based course and filled out the follow-up questionnaire upon completion of the training. Participants were able to pause their participation at any time during the study.

Ethical Considerations



The survey followed ethical research practices as outlined in the Declaration of Helsinki, ie, voluntary participation; assurance of anonymity, data protection, and confidentiality; advance information about the purpose and content; provision of contact information; and disclosure of the organization conducting the research and the funding source. In accordance with the regulations of the Ethical Committee at FH Campus Wien, assessments involving non–health-related data from non-vulnerable persons do not require formal ethical approval. All participants received written information before participation. By completing the questionnaire, participants provided informed consent for the anonymous use of their data for research and publication purposes. Participation was entirely voluntary, and participants could pause or withdraw at any time without consequences. Participants received continuing education credits upon completion of the course.

XSL•FO
RenderX

Intervention: Telehealth Training Course

The web-based telehealth course was structured into a general and profession-specific video format (Figure 1). The general part of the course, which all participants were required to complete, consisted of the following videos: concept clarification (6:00 min), application forms (18:07 min), legal aspects (18:44 min), technology aspects (18:01 min), and practical implementation (30:20 min). Following the general part, participants were asked to watch a video tailored to their specific profession with a duration of approximately 30 minutes.

Figure 1. Structure of the assessments and the telehealth training course.

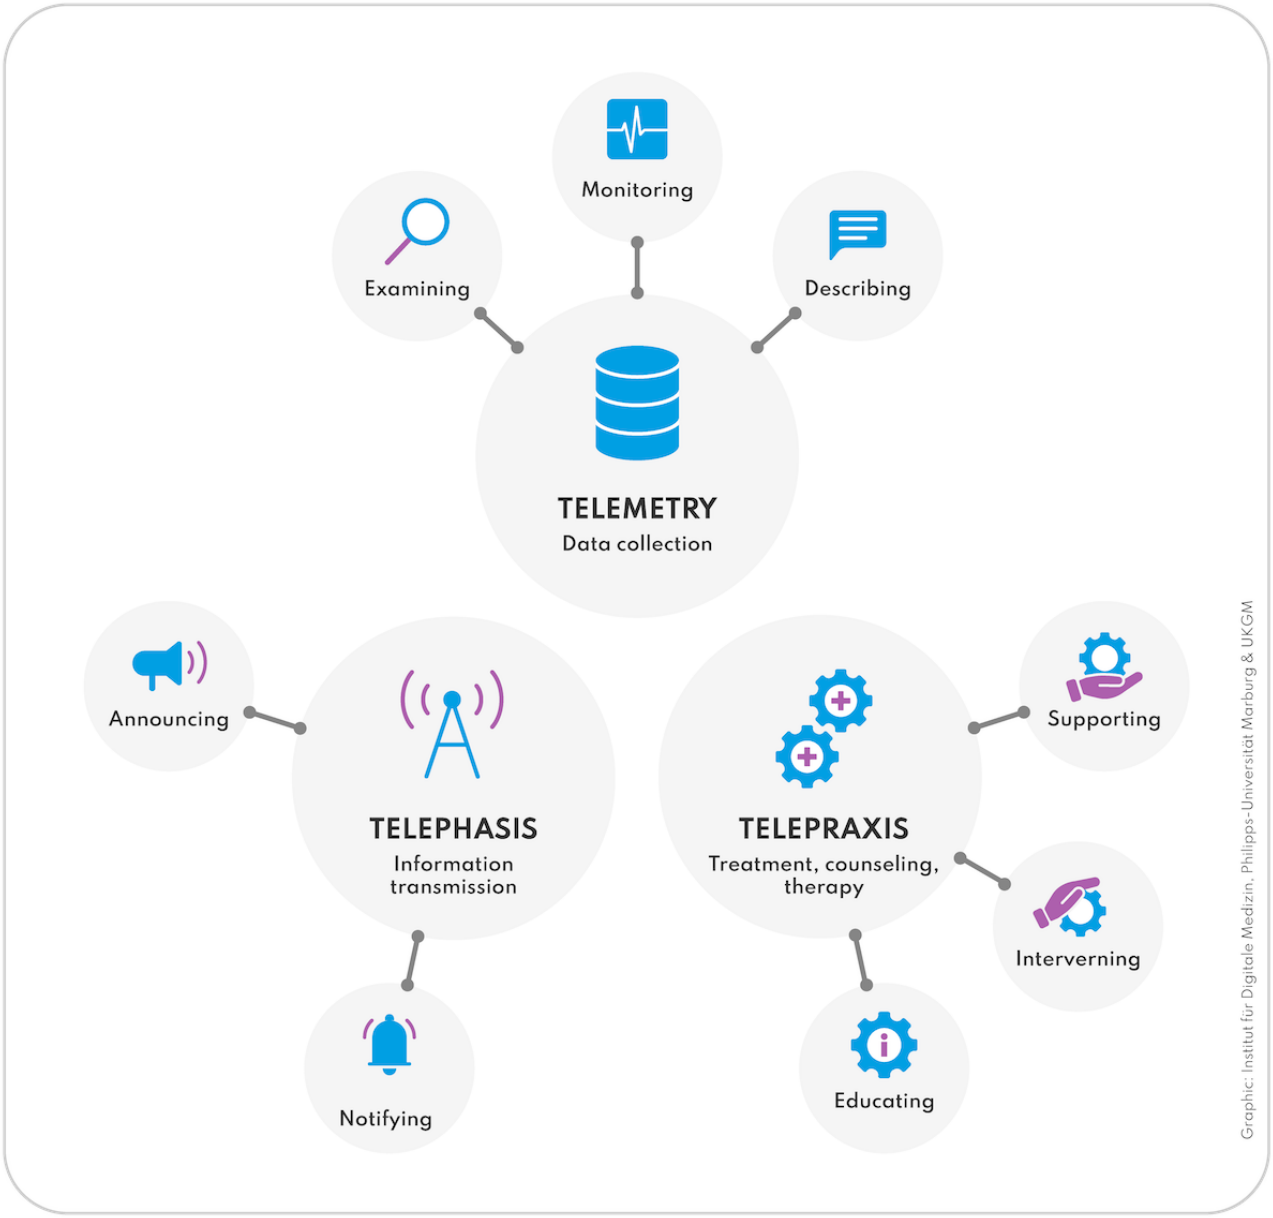
Participants from other professions were able to choose one of the specialized videos that best matched their area of practice. A detailed summary of the video content can be found in Multimedia Appendix 1.

Data Collection

Before watching the training videos, participants were asked to complete a demographic survey to collect data such as age, gender, profession, current employment status, years of experience, primary client group, federal state, population density, perceived patient access (based on health profession), and general and specific telehealth experience. Data on acceptance (willingness to adopt) and perceived influence of telehealth barriers were also collected both before and after the intervention using standardized scales. Finally, the participants rated their satisfaction with the course.

Telehealth Experience and Acceptance

We measured specific telehealth experiences and acceptance using a classification system based on the work of Colucci et al [14]. This system defines telehealth according to its communication processes, including telemetry, telephasis, and telepraxis (Table 1 and Figure 2). Participants self-reported whether they had experienced each telehealth application via phone, video calls, or asynchronously (yes or no). They also indicated their willingness to adopt each telehealth process through these modes, using a Likert scale from 0 (not at all willing) to 4 (fully willing).



XSL•FO
RenderX

Table . Adapted classification system based on Colucci et al (2019) to assess specific telehealth experience and acceptance of the participants.

Function and application	Description or example
Telemetry	
Data collection	
Examining	Obtaining findings, performing measurements
Monitoring	Monitoring of vital data, movement, or activity behavior
Describing	Verbally or in writing, recording the client's medical history
Telephasis	
Information transmission	
Announcing	Public dissemination of health information, eg, on blogs, videos, websites
Notifying	Individual forwarding of information; eg, about findings, measurement results
Telepraxis	
Treatment, counseling, and therapy	
Supporting	eg, implementing therapy recommendations at home, providing environmental support
Intervening	eg, direct treatment or therapy
Educating	eg, health education, informing about lifestyle modifications

XSL•FO
RenderX

Figure 2. Visual representation of the classification system based on Colucci et al (2019) to assess specific telehealth experience.

Perceived Influence of Barriers

The barriers were measured based on a framework developed by Rettinger and Kuhn [3]. Participants rated the extent to which each of the 24 barriers influenced their willingness to adopt telehealth, using a Likert scale ranging from 0 (no influence) to 4 (strong influence).

Satisfaction With the Course

After the course, participants completed the Training Evaluation Inventory [15] to assess their satisfaction with the course content, subjective enjoyment, perceived usefulness, perceived difficulty, subjective knowledge gain, and attitude towards training. Additionally, they were asked for feedback in their own words. In September 2024, two focus groups were held with participants who volunteered to discuss the course in more detail.

Data Analysis

Participants who engaged with at least 40 minutes of the total 120-minute video content were included in the analysis; this threshold was established to ensure sufficient exposure to the intervention. Participants not meeting this criterion were excluded from subsequent analyses. Demographic data were summarized using means and standard deviations for continuous variables and frequencies and percentages for categorical variables.

Sum scores for telehealth acceptance were calculated: total telehealth acceptance (max 96), telemetry acceptance (max 48), telephasis acceptance (max 24), telepraxis acceptance (max 48), acceptance of telehealth via phone (max 32), acceptance of telehealth via video call (max 32), and acceptance of asynchronous telehealth (max 32). A total barrier score was calculated also with a sum-score (max 96). Acceptance of telehealth processes and perceived barriers, both before and after the intervention, were analyzed using medians and

XSL•FO
RenderX

interquartile ranges (IQRs) due to the ordinal nature of the data. The Wilcoxon signed-rank test was used to assess differences between pre- and post-intervention scores, with the significance level set at alpha=.05. This test evaluates differences in the distribution of repeated-measures data by calculating the sum of the ranks. This test can reveal significant differences between repeated measures, even when their medians are equal. Effect sizes were calculated using the r statistic, calculated as z/sqrt(n), and interpreted according to Hattie's guidelines [16,17], where $r<0$ indicates a negative effect, $r=0.00$ indicates no effect (developmental effects), $r=0.05$ indicates a small effect (teacher effects), $r=0.10$ indicates a medium effect (zone of desired effects), and $r \geq 0.15$ indicates a large effect, thereby providing context for the magnitude of the findings.

Satisfaction with the web-based course was evaluated post-intervention and presented as medians and IQRs. These satisfaction scores were further analyzed by professional groups to identify any differences across professions.

Qualitative data were obtained from 2 focus groups and written feedback collected through questionnaires. The focus group discussions were transcribed using MAXQDA AI-Assist. The transcribed and anonymized texts were then summarized using ChatGPT (version o1-preview). To ensure the validity of these summaries, the first 2 authors—who also moderated the focus groups—reviewed the summarized results for accuracy and completeness, adjusting where needed.

Sensitivity Analysis for Non-Representativeness of the Sample

When comparing the occupational and gender distribution of the sample to the population, male participants and participants from the nursing profession were found to be severely overrepresented. Therefore, an additional sensitivity analysis was conducted to take non-representativeness into account by case weighing. In this procedure, all data related to inferential statistics were post-harmonized on the basis of known population distributions, available from the annual report of the Austrian Register of Health Professions [18]. For this purpose, the following weighting factors (as shown in parentheses) were calculated for four strata: (1) female therapists (0.19), (2) male therapists (0.43), (3) female nurses (8.81), and (4) male nurses (3.48). Physiotherapists, occupational therapists, orthoptists, and speech and language therapists were thereby combined under the category "therapists." Weighting factors were calculated by dividing the target stratum proportion by the actual stratum proportion. The post-harmonized data can thus be considered representative of occupation (therapists vs nurses) and gender (female vs male). However, none of these post-harmonized inferential analyses (data not shown) differed from the unadjusted analyses in terms of statistical significance and effect interpretation, and therefore only the unadjusted results are reported in the results section.

Results

Participants

A total of 365 health professionals enrolled in the web-based course. Of these, 217 participants completed the course. Among the completers, 185 were included in the analysis: 63 physiotherapists (34%), 48 occupational therapists (26%), 38 orthoptists (21%), 20 nurses (11%), 9 speech and language therapists (5%), and 7 other health professionals (dietitian, diabetes counselor, midwife, psychologist, paramedic in training, student, and administrator). Mean engagement with the video content was 198 minutes (minimum 40; maximum 3015). In total, 32 course completers were excluded from analysis for not meeting the 40-minute minimum engagement threshold. The demographic characteristics of the participants are summarized in Table 2.

Telehealth Experience

In total, 71% (131/185) of the participants stated that they had never performed telehealth before, 11% (20/185) had telehealth experience but did not use it currently and 18% (34/185) currently use telehealth.

The participants had used phone or video calls or asynchronous communication for a variety of telehealth services. Telemetry was applied for describing by 95/185 (51%), for examining by 35/185 (19%), and for monitoring by 38/185 (21%); telephasis for announcing by 64/185 (35%), and for notifying by 91/185 (49%); telepraxis for supporting by 100/185 (54%), for intervening by 49/185 (26%), and for educating by 69/185 (37%). Further details on the usage of phone, video call, or asynchronous communication are listed in Figure 3.

Telehealth Acceptance Pre and Post Web-Based Training

The total telehealth acceptance (P<.001), acceptance for telemetry (P<.001) and telepraxis (P<.001), acceptance for telehealth via video call (P<.001) and asynchronous telehealth (P=.007) changed significantly, while acceptance for telephasis (P=.203) and acceptance for phone call–based telehealth (P=.1) had no significant changes (Table 3 and Figure 4).

Qualitative Results

Participants across all feedback sources generally found the telehealth training informative, well-structured, and valuable. They appreciated the comprehensive overview of telehealth, the professional presentation style, and the flexibility offered by the web-based format. The training expanded their

XSL•FO
RenderX

understanding of telehealth possibilities, especially for those with little to no prior experience. However, participants expressed a desire for more practical examples, interactive elements, and ongoing support to bridge the gap between theory and practice. Concerns were raised about challenges in implementing telehealth, particularly regarding data protection, patient accessibility, and institutional barriers. More details on the qualitative results can be found in Multimedia Appendix 2.

Discussion

Principal Findings

This study, to our knowledge, is the first to evaluate the effect of an interprofessional on-demand postgraduate telehealth course for health care professionals on acceptance of telehealth and their perceived barriers to its adoption. The main findings indicate a significant positive impact, underscoring the value of structured telehealth education. According to the Technology Acceptance Model, the intention to use a technology is primarily driven by 2 key factors: perceived usefulness and perceived ease of use [19]. Our results suggest the course might affect those key factors, but its impact on telehealth use behavior remains unclear.

Key Findings and Their Implications

The results showed a significant increase in telehealth acceptance and a significant reduction in perceived barriers among participants, consistent with previous research that highlights the role of training in improving telehealth knowledge and confidence [20,21].

Participants acknowledged the informative and structured nature of the course, aligning with studies that emphasize the importance of tailored web-based learning for health care providers [22]. This highlights the critical need for comprehensive telehealth training, particularly for practitioners with little to no prior telehealth experience, who represented the majority in this study (71%).

Participants identified key challenges, including concerns about data protection, patient accessibility, and institutional barriers, echoing previous findings in telehealth literature [2,3,23]. Addressing these issues through additional practical examples, interactive learning opportunities, and ongoing support could further enhance the effectiveness of telehealth training.

The most significant result was the increase in overall telehealth acceptance after the intervention. Particularly, the acceptance of telemetry and telepraxis increased, as well as the acceptance of video call-based telehealth and of asynchronous telehealth. This suggests that the training helped them to envision a broader range of applications and modalities for delivering remote care. While improvements were noted in several domains, some—such as telephasis and phone-based telehealth—did not show significant changes. The stability in these areas may reflect that certain forms of telehealth were already well understood or already integrated into the workflows, such as, eg, notifying patients by phone.

Additionally, it is important to consider that while the training significantly increased participants' intention to adopt telehealth, this does not necessarily translate into its actual use in daily practice. Incorporating more hands-on training components by establishing blended-learning formats with practical simulations or real-time demonstrations could facilitate the transition from intention to actual use.

Beyond simply making professionals more open to telehealth, the training also reduced the perceived influence of a wide range of barriers. Before the intervention, participants identified multiple obstacles. After completing the course, there were notable reductions in perceived barriers. This finding indicates that structured education can address knowledge deficits and clarify implementation pathways, thereby making telehealth seem more feasible. The course appeared most effective in reducing concerns related to a lack of training and standardized guidelines. By providing clear information on legal frameworks, technology usage, and practical strategies, the training directly addressed these issues. Barriers linked to patient factors and the therapeutic environment were also diminished. Notably, participants' perceived drawbacks regarding telehealth quality and satisfaction, as well as concerns about reduced client-practitioner interaction and communication, were lowered following the training. One possible reason for this improvement is that the course provided concrete strategies and examples of how telehealth can maintain, or even enhance, meaningful therapeutic engagement. However, some barriers were not significantly reduced by the web-based course, such as individual technology skills, network, or safety issues. The course also did not influence either the barrier of clients' or the practitioners' negative attitudes toward telehealth. Maybe lowering those barriers requires more focus on experiential learning, systemic change, or a more sustained intervention.

The qualitative findings underscore the value participants placed on the course's comprehensive, well-structured content and profession-specific modules. At the same time, they highlight a need for ongoing, practical, and interactive support to embed telehealth into everyday practice. Addressing unresolved questions—such as establishing mentorship channels, refining legal guidance, and developing strategies for patient engagement—will be critical to ensure that telehealth initiatives are both clinically viable and inclusive.

These insights serve as a roadmap for future iterations of the training. Given the significant attitude shifts observed after only 2 hours of content, such short "gateway" modules could be deployed first to boost health professionals' readiness before rolling out more intensive skill-based or certification courses. Incorporating blended learning and flipped classroom settings, more hands-on examples, offering supplementary materials, and facilitating interactive forums could further amplify the course's impact. By combining either self-developed or third-party massive open web-based courses or open educational resources content with synchronous, hands-on sessions, educators could create a rich, interactive learning environment. Learners can engage with the theoretical components digitally at their own pace, while live sessions focus on practical exercises, discussions, and application of telehealth strategies. By integrating these educational strategies, future training initiatives can better equip health care professionals with both

XSL•FO
RenderX

the conceptual understanding and practical skills necessary to overcome barriers to telehealth adoption.

For policymakers, the results highlight the importance of fostering a supportive environment that translates EU-level digital health policies into effective national education strategies. Policy makers should collaborate with academic institutions to promote the adoption of standardized telehealth training programs and to integrate digital competencies into health education.

Strengths and Contributions

The study provides valuable insights into telehealth education, particularly its ability to enhance acceptance and reduce barriers across diverse professional groups. The inclusion of a broad participant base from various health care disciplines reflects the cross-sectoral applicability of telehealth education, aligning with prior research that underscores the interdisciplinary relevance of telehealth [5,24].

Moreover, the findings support the notion that telehealth training fosters not only technological acceptance but also a broader understanding of telehealth's potential applications. This is particularly relevant considering the resources of specialist staff and increasing demand for digital skills and remote therapy and care delivery, as identified in earlier studies [25,26].

Limitations

Despite its strengths, the study has several limitations that warrant consideration. Due to the design of the study, a control group was absent. Without a control group, it is difficult to attribute observed changes solely to the intervention. Future studies should consider randomized controlled designs to strengthen causal inferences.

Another limitation is the representativeness of the study population. The participants were self-selected, which may limit the generalizability of the findings to the broader population of health care professionals. Also, because professional associations deployed the participation link via differing formats (website postings, newsletters, and direct emails), we cannot determine the exact number of recipients or calculate a precise response rate, which may affect assessments of self-selection bias.

The third limitation corresponds with the uncertainty of course content exposure due to the on-demand character of the training. The web-based format did not guarantee that participants fully engaged with the course content, potentially impacting the results. This limitation was mitigated by filtering the results and excluding participants who did not engage with at least 40 minutes of the total 120-minute video content in the analysis. This threshold was established to ensure sufficient exposure to the intervention.

Future Directions

Building on these findings, future research should explore the following main aspects to broaden the findings. A future study should also examine long-term effects of telehealth education on clinical practice and patient outcomes, including a follow-up assessment. In addition, education programs would benefit from practical training enhancements, such as case-based simulations and interactive modules to bridge the gap between theory and application.

Finally, integrating telehealth education into initial health care training programs could ensure that future professionals are better prepared to embrace telehealth as part of routine care delivery. To achieve policy goals, significant investments in digital infrastructure and targeted workforce training are needed to turn technological potential into practical use. Building partnerships across sectors and creating ongoing feedback among regulators, health care organizations, and practitioners can help ensure that telehealth initiatives remain flexible, sustainable, and responsive to the evolving needs of clinical practice and patients.

Conclusions

This study reinforces the critical role of structured telehealth education in enhancing health care professionals' acceptance of telehealth and reducing perceived barriers. While challenges remain, particularly in implementation and institutional support, the findings may indicate the potential of short-term, remote, and targeted training programs to advance telehealth adoption. We recommend systematically integrating telehealth modules into continuing professional development and national licensing requirements. Further research and investment in education and infrastructure are essential to fully realize the benefits of telehealth and digitalization in modern health care.

Abstract

Background: ChatGPT excels in natural language tasks, but its performance in the Chinese National Medical Licensing Examination (NMLE) and Chinese medical education remains underexplored. Meanwhile, Chinese corpus–based large language models (LLMs) such as ERNIE Bot, Tongyi Qianwen, Doubao, and DeepSeek have emerged, yet their effectiveness in the NMLE awaits systematic evaluation.

Objective: This study aimed to quantitatively compare the performance of 6 LLMs (GPT-3.5, GPT-4, ERNIE Bot, Tongyi Qianwen, Doubao, and DeepSeek) in answering NMLE questions from 2018 to 2024 and analyze their feasibility as supplementary tools in Chinese medical education.

Methods: We selected questions from the 4 content units of the NMLE's General Written test (2018 - 2024), preprocessed image- and table-based content into standardized text, and input the questions into each model. We evaluated the accuracy, comprehensiveness, and logical coherence of the responses, with quantitative comparison centered on scores and accuracy rates against the official answer keys (passing score: 360/600).

Results: GPT-4 outperformed GPT-3.5 across all units, achieving average accuracies of 66.57% (SD 3.21%; unit 1), 69.05% (SD 2.87%; unit 2), 71.71% (SD 2.53%; unit 3), and 80.67% (SD 2.19%; unit 4), with consistent scores above the passing threshold. Among the Chinese models, DeepSeek demonstrated the highest overall performance, with an average score of 454.8 (SD 17.3) and average accuracies of 73.2% (unit 1, SD 2.89%) and 71.5% (unit 3, SD 2.64%), as well as average accuracies of 70.3% (unit 2, SD 3.02%) and 78.2% (unit 4, SD 2.47%). ERNIE Bot (mean score 442.3, SD 19.6; unit 1 accuracy =70.8%, SD 3.01%; unit 2 accuracy =68.7%, SD 3.15%; unit 3 accuracy =69.1%, SD 2.93%; unit 4 accuracy =68.3%, SD 2.76%), Tongyi Qianwen (mean score 426.5, SD 21.4; unit 1 accuracy =67.4%, SD 3.22%; unit 2 accuracy =65.9%, SD 3.31%; unit 3 accuracy =66.2%, SD 3.08%; unit 4 accuracy =67.2%, SD 2.89%), and Doubao (mean score 413.7, SD 23.1; unit 1 accuracy =65.2%, SD 3.45%; unit 2 accuracy =63.8%, SD 3.52%; unit 3 accuracy =64.1%, SD 3.27%; unit 4 accuracy =62.8%, SD 3.11%) all exceeded the passing score. DeepSeek's overall average accuracy (75.8%, SD 2.73%) was significantly higher than those of the other Chinese models (χ^2_1 =11.4, P=.001 vs ERNIE Bot; χ^2_1 =28.7, P<.001 vs Tongyi Qianwen; χ^2_1 =45.3, P<.001 vs Doubao). GPT-4's overall average accuracy (77.0%, SD 2.58%) was slightly higher than that of DeepSeek but not statistically significant (χ^2_1 =2.2, P=.14), while both outperformed GPT-3.5 (overall accuracy =68.5%, SD 3.67%; χ^2_1 =89.8, P<.001 for GPT-4 vs GPT-3.5; χ^2_1 =76.3, P<.001 for DeepSeek vs GPT-3.5).

Conclusions: GPT-4 and Chinese-developed LLMs such as DeepSeek show potential as supplementary tools in Chinese medical education given their solid performance on the NMLE. However, further optimization is required for complex reasoning, multimodal processing, and dynamic knowledge updates, with human medical expertise remaining central to clinical practice and education.

KEYWORDS

ChatGPT; Chinese National Medical Licensing Examination; medical student; ERNIE Bot; Tongyi Qianwen; artificial intelligence; AI

Introduction

Natural language processing (NLP) is an artificial intelligence (AI) technology that aims to allow computers to understand, process, and generate natural language [1]. ChatGPT is the most successful commercial model of NLP technology that enables high-quality natural language comprehension and generation, and its core algorithm is a transformer, a deep neural network structure based on a self-attentive mechanism with strong sequence modeling capabilities and representation learning [2-4]. Through the process of pretraining and fine-tuning, the ChatGPT model can understand and generate natural language text and be useful in various application scenarios, such as automatic question answering, intelligent customer service,

XSL•FO
RenderX

speech recognition, and machine translation. The success of the ChatGPT model is attributed to the excellent performance of the transformer and the maturity of the pretraining technique. In the pretraining phase, the ChatGPT model can learn the patterns and features of language from large-scale text data through unsupervised learning, allowing the model to be fine-tuned on a limited dataset and achieve excellent performance [5-7].

Considering that ChatGPT is an evolving NLP model that has been successfully used in many fields, several medical education research groups have been investigating its feasibility as a valuable tool for clinical support and medical education. Gilson et al [8] applied ChatGPT to the US Medical Licensing Examination, and the experimental results showed that it met the passing criteria. However, Huh [9] found in their study that, during a Korean parasitology examination, 77 out of 79 medical students performed better than ChatGPT. Specifically, ChatGPT's scores were lower than those of the medical students, and its correct response rate showed no correlation with the knowledge difficulty level of the examination items. Although the version of ChatGPT at that time was still at GPT-3.5 and not the state-of-the-art GPT-4, questions were raised about the ability of ChatGPT to provide medically accurate answers when using non-English languages, especially Chinese [10].

Therefore, to explore the capability of large language models (LLMs) in medical education in Chinese, in addition to applying GPT-3.5 and GPT-4, developed by OpenAI, this study applied ERNIE Bot [11], developed by Baidu; Tongyi Qianwen [12], developed by Alibaba Cloud; Doubao (ByteDance); and DeepSeek to evaluate the feasibility of LLMs and compare multiple LLMs and the advantages and disadvantages of multiple bigrams in Chinese medical education. This is considering that ERNIE Bot, Tongyi Qianwen, Doubao, and DeepSeek, being deeply rooted in the Chinese language environment, use large and rich Chinese datasets in the training process, which may endow them with stronger Chinese comprehension than that of ChatGPT. However, the advantages and disadvantages of multiple LLMs for Chinese medical education need to be corroborated through experiments.

While previous studies have explored the potential of LLMs in medical education, their performance in the context of the Chinese National Medical Licensing Examination (NMLE) remains largely unexplored. As a rigorous and standardized assessment that determines the eligibility of medical professionals in China, the NMLE presents unique challenges due to its specific focus on Chinese medical knowledge, cultural context, and clinical practices [13,14]. Given that existing research on language models in medical education has primarily centered on Western-based examinations and English-language models, there is a critical need to evaluate how models such as GPT-3.5, GPT-4, ERNIE Bot, Tongyi Qianwen, Doubao, and DeepSeek perform in this distinct Chinese medical assessment environment. By systematically comparing these models' performance on NMLE questions, this study aimed to fill a significant gap in the literature, providing empirical evidence on the feasibility of LLMs in Chinese medical education. The findings of this research will not only contribute to the understanding of how these models can be integrated into Chinese medical curricula but also offer valuable insights for enhancing the education and training of future medical professionals in China. The results may offer preliminary insights into the potential applications of these models in Chinese medical education and contribute to ongoing discussions on integrating such technologies into medical curricula.

Methods

The dataset used in this study comprised the original Chinese NMLE test questions from 2018 to 2024. Each annual examination consisted of 4 units, as delineated in Table 1, with each unit containing 150 multiple-choice questions, adding up to a total score of 600 points. A minimum score of 360 is required to pass the examination. Given the varying capabilities of LLMs in processing multimodal content, a protocol was established, which is outlined in this section.

Table . Exam content and scores for the 4 units of the Chinese National Medical Licensing Examination.

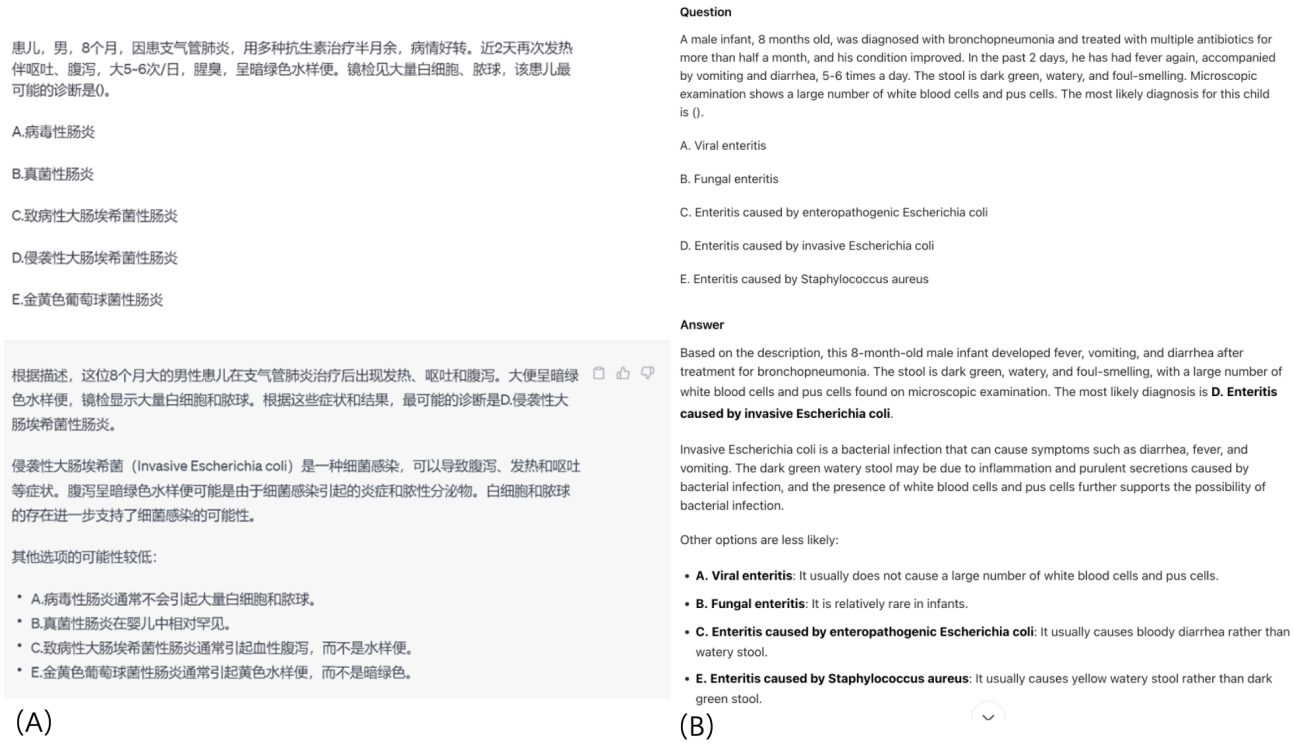
Unit	Maximum possible score	Exam content
1	150	Infectious diseases, psychoneurology, endocrinology, pharmacology, physiology, biochemistry, medical regulations, medical ethics, medical microbiology, medical psychology, preventive medicine, and medical immunology
2	150	Infectious diseases, pathology, psychiatry, endocrinology, respiratory medicine, urology, digestive medicine, cardiovascular medicine, hematology, physiology, biochemistry, exercise science, and medical immunology
3	150	Psychiatry, urology, gastroenterology, cardiovascular medicine, hematology, symptoms and signs, sports medicine, and pharmacology
4	150	Female reproductive system, pediatrics, and psychiatry

This study evaluated six LLMs with distinct capabilities for handling visual content.

1. GPT-3.5: lacks native image processing capabilities.

XSL•FO
RenderX

2. GPT-4: supports limited image input in specific use scenarios (eg, direct image insertion in its official interface), but for the standardized testing in this study—where all models were evaluated under uniform text input conditions to eliminate variability from different multimodal processing capabilities—visual elements were manually converted to descriptive text.
3. ERNIE Bot: includes optical character recognition functionality but was tested using text-based descriptions to ensure consistency.
4. Tongyi Qianwen: a multimodal version exists, but the internal test version used relied on text inputs.
5. Doubao: it is primarily text based; visual content was converted to descriptive text.
6. DeepSeek: while it is advanced in medical reasoning, visual elements were preprocessed into text to maintain uniform evaluation criteria.



To ensure equitable comparison, all image- and table-based questions across units were preprocessed using the following methods:

1. Structured tables were converted into CSV format with headers (eg, "Parameter," "Value," and "Unit").
2. For medical images, all descriptions (including chest x-rays, computed tomography screenshots, and pathological section diagrams) in this study were generated based on the 3 elements of clinical standard terminology+visual key features+diagnostic correlation information. Taking chest x-ray images as an example, a description template was used ("[Examination type] shows the presence of [visual features, such as patchy shadows/nodules/fluid accumulation] in [anatomical location], accompanied by [associated clinical information, such as blurred boundaries/mediastinal displacement], consistent with [common disease indications, such as typical manifestations of community-acquired pneumonia]. Before generation, extract the official reference answers and analysis of the image questions in the NMLE real test, ensuring that the description does not contain direct diagnostic conclusions (only objectively presenting visual information), and avoiding premature disclosure of answers. The image description was independently completed by 2 attending physicians with more than 5 years of clinical experience (both holding Chinese physician qualification certificates and specializing in respiratory medicine and radiology, respectively), and then cross-reviewed by a deputy chief physician (affiliated with the clinical imaging diagnosis department). If there were differences in the descriptions of the 2 attending physicians (such as inconsistent expressions of "shadow density"), a consensus was reached through 3-person negotiation to ultimately form the "NMLE Image Question Text Description Manual," ensuring the objectivity, consistency, and clinical accuracy of all descriptions.
3. Diagrams were translated into step-by-step textual explanations (eg, "Flowchart depicting the diagnostic pathway for diabetes mellitus").

Each model was tested using the same protocol: preprocessed NMLE questions from 2018 to 2024 were systematically input, and responses were recorded. To ensure consistency in the experimental conditions, each NMLE question (after preprocessing) was prompted once to each model—no repeated prompting was conducted for the same question as repeated inputs might lead to inconsistent response adjustments by the models, which would interfere with the accuracy of the performance comparison. Regarding the parameter settings of the models: for GPT-3.5 and GPT-4, the temperature parameter was set to 0.2, and the top-p parameter (also known as nucleus sampling, a parameter that controls the diversity of model outputs by limiting the selection range to the smallest set of tokens whose cumulative probability exceeds the specified value) was set to 0.95; these settings were chosen to balance the stability and accuracy of the models' responses—temperature of 0.2 reduces the randomness of the generated content to avoid arbitrary answers, whereas top-p of 0.95 ensures that the models still retain a moderate range of token selection to cover potential correct reasoning paths. For the Chinese models (ERNIE Bot, Tongyi Qianwen, Doubao, and DeepSeek), we used their default parameter configurations (consistent with the settings in their official public interfaces for general question answering tasks) as their internal adjustable parameter details (eg, specific temperature and top-p ranges) were not publicly disclosed by the developers at the time of the study. All parameter settings and prompting rules were recorded in the study's experimental log to ensure the reproducibility of the results. Answers were scored against the official answer keys. The input process, standardized for all models, is illustrated in Figure 1.

XSL•FO

Figure 1. Test question input process: (A: Chinese, B: English translation).

Results

Comparison of GPT-3.5 and GPT-4

This study analyzed the scores of GPT-3.5 and GPT-4 in the NMLE exams from 2018 to 2024. The results are outlined in this section.

As shown in Figure 2, GPT-4, represented by the gray squares, consistently surpassed the pass mark (set at 360 points, indicated by the blue-triangle series) across the 7 examination years. From 2018 to 2024, scores exhibited fluctuations (2018: 441; 2019: 417; 2020: 439; 2022: 466 [peak]; 2023: 401; 2024: 432). GPT-3.5, indicated by the red circles, had a more inconsistent performance. While it passed the exam in 2018 (scoring 363), 2020 (351), 2021 (382), 2022 (400), and 2024 (386), it fell below the pass mark in 2019 (329) and 2023 (342).

Overall, GPT-4 demonstrated a more stable ability to meet or exceed the passing criteria in the NMLE exams over the 7-year period compared to GPT-3.5.

Considering that the test questions of the NMLE exam consist of 4 units, the content of each unit of the exam is highly differentiated. Therefore, this study used GPT-3.5 and GPT-4 for different units and counted their score rates.

XSL•FO
RenderX

Figure 2. GPT-3.5 and GPT-4 scores in the 2018 to 2024 Chinese National Medical Licensing Examination.

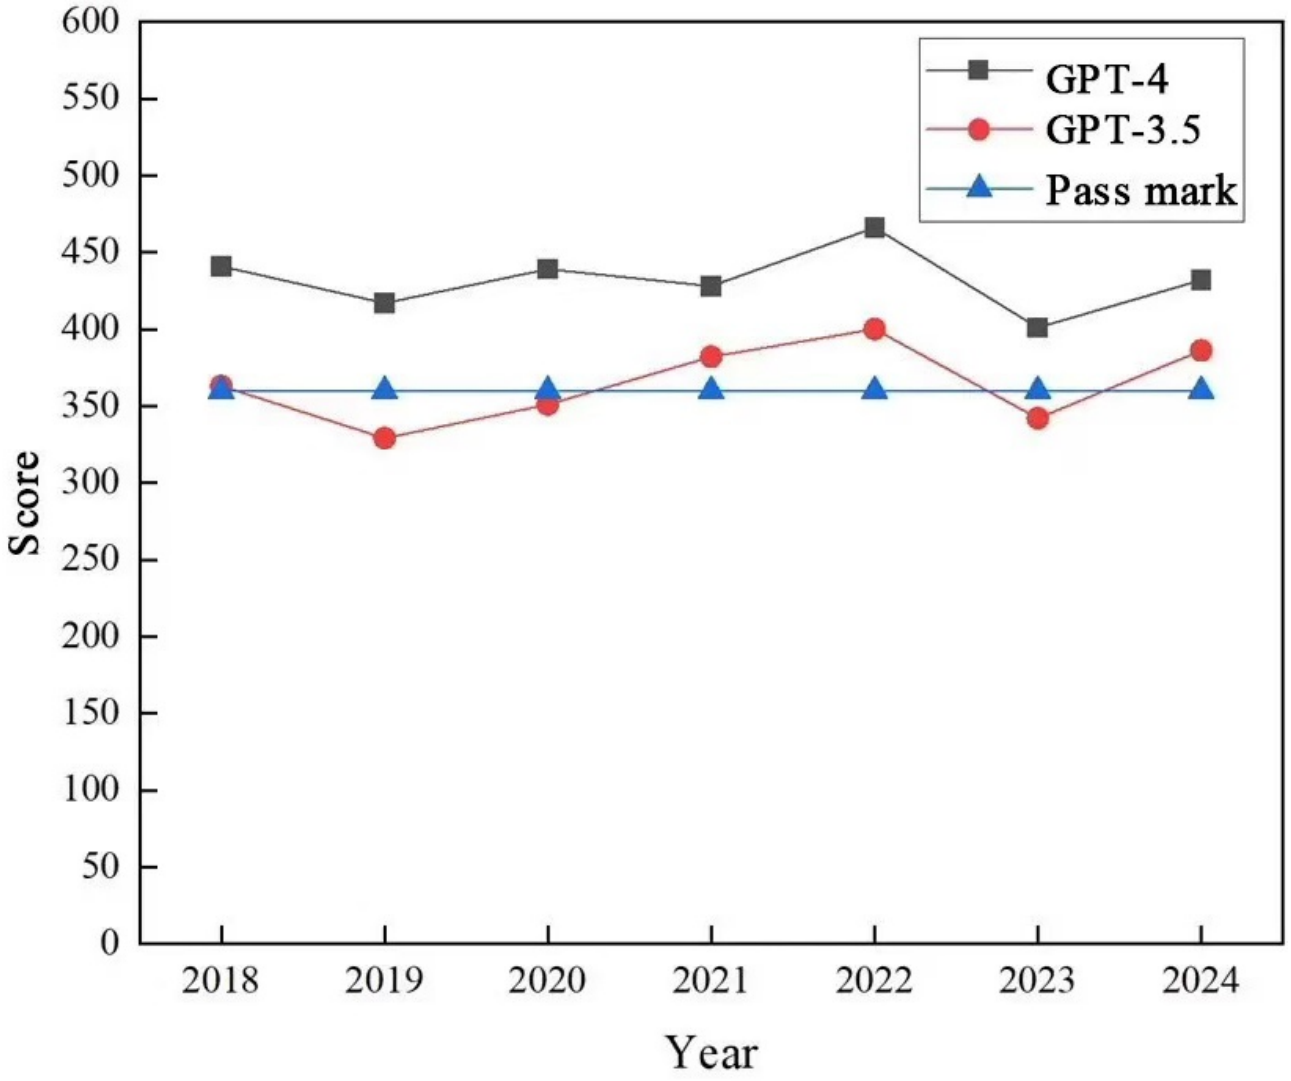

Table 2 compares the score performance and average accuracy of GPT-3.5 and GPT-4 across different units of the Chinese NMLE from 2018 to 2024. The data reveal that GPT-4 outperformed GPT-3.5 comprehensively in all units and years. Specifically, for units 1 to 4, GPT-4 achieved average accuracies of 66.57%, 69.05%, 71.71%, and 80.67%, respectively, which were higher than GPT-3.5's accuracies of 61.24%, 58.67%, 56.86%, and 66.38%, respectively. To verify the statistical significance of this performance difference, we conducted a chi-square test on the correct and incorrect answers of GPT-4 and GPT-3.5 across all 4200 questions (2018 - 2024 NMLE) with a significance threshold of $P<.05$. The results showed that GPT-4's accuracy was significantly higher than that of GPT-3.5 in all units (unit 1: $\chi^2_1 = 12.4$, df=1; P<.001, unit 2: $\chi^2_1 = 15.7$, df=1; P<.001, unit 3: $\chi^2_1 = 19.0$, df=1; P<.001, and unit 4: $\chi^2_1 = 23.1$, df=1; P<.001). This indicates that GPT-4 exhibits stronger capabilities in understanding and applying medical knowledge, and the performance gap between the 2 models was statistically significant.

XSL•FO
RenderX

Table . Comparison of GPT-3.5 and GPT-4 scores in different units.

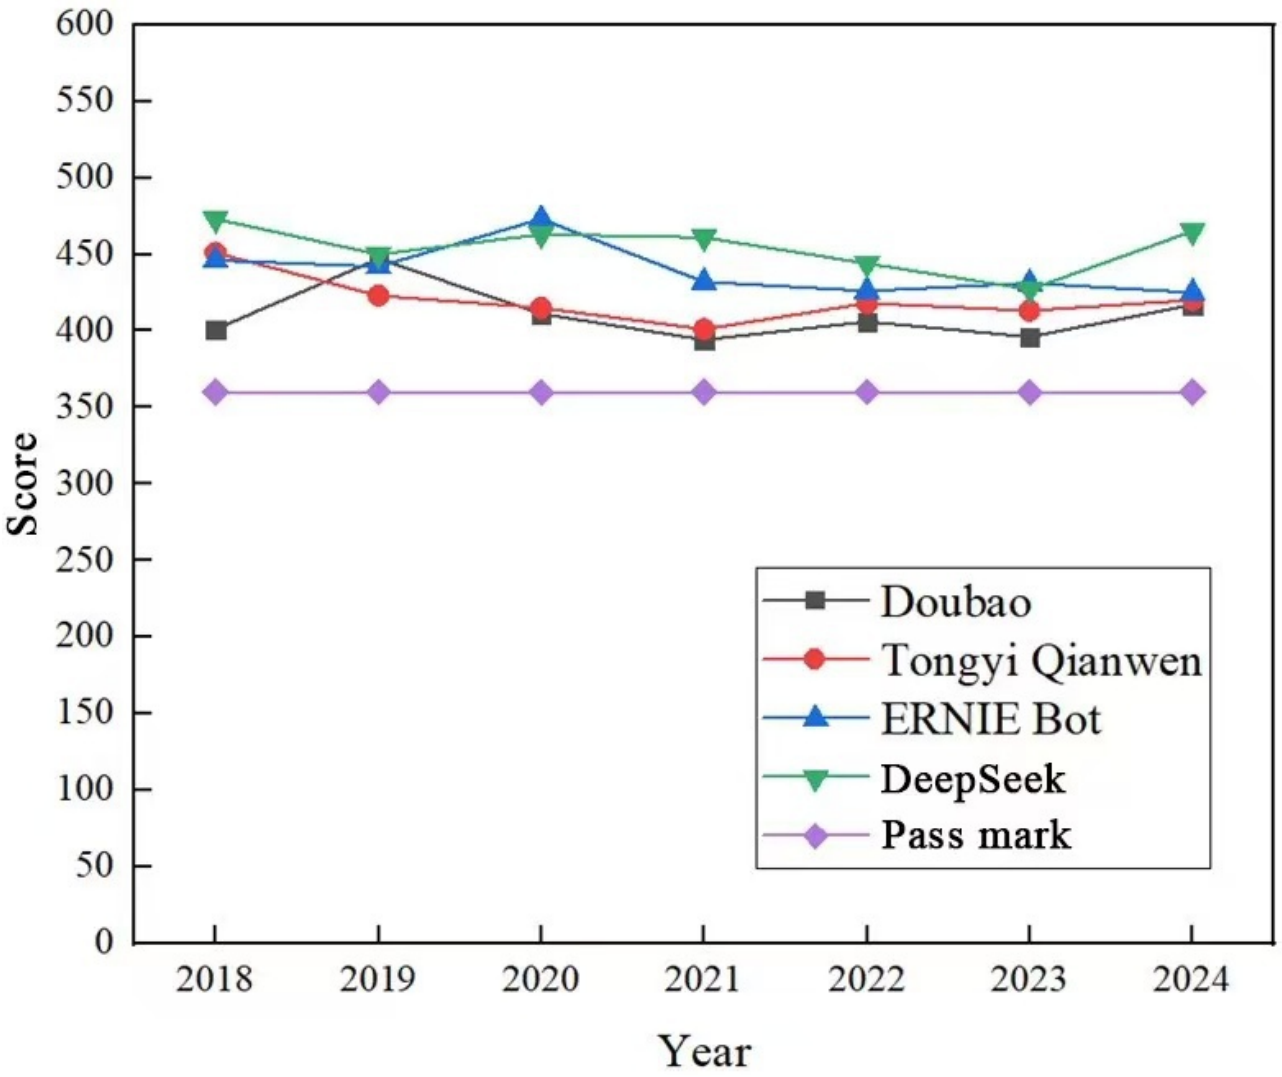
	GPT-3.5				GPT-4			
	Unit 1	Unit 2	Unit 3	Unit 4	Unit 1	Unit 2	Unit 3	Unit 4
2018 score	88	92	81	102	102	99	112	128
2019 score	78	84	74	93	97	102	100	118
2020 score	83	80	76	112	89	107	113	130
2021 score	102	91	86	103	106	98	104	120
2022 score	98	97	101	104	101	113	118	134
2023 score	92	83	80	87	94	92	111	104
2024 score	102	89	99	96	110	114	95	113
Accuracy (%)	61.24	58.67	56.86	66.38	66.57	69.05	71.71	80.67

Regarding the annual score patterns, neither GPT-3.5 nor GPT-4 showed a predictable year-on-year increase in performance, which aligns with the expectation that model performance is not inherently tied to the exam year. Instead, the score fluctuations observed for both models (eg, GPT-3.5's 14-point and 6-point declines in unit 2 and unit 3, respectively, in 2023 compared to the previous year and GPT-4's 24-point drop in unit 4 in 2023) primarily reflect variations in exam difficulty across years rather than inherent changes in model capability. Importantly, neither model's performance showed a substantial decline across the 2018 to 2024 period relative to their initial performance, indicating that the models likely did not encounter or memorize the specific NMLE questions during their training (given the training cutoff periods before the later exam years). While GPT-4 did not exhibit a clear upward trend, its fluctuations were more moderate than those of GPT-3.5, and it maintained consistent performance above GPT-3.5 across all years—with unit 4 showing a 5-point difference between its 2018 and 2024 scores—further reflecting its stronger stability in adapting to the varying content and difficulty of complex medical scenarios.

Moreover, the 2 models demonstrated distinct performances across different units, with statistical significance verified via chi-square tests (P<.05) on their correct and incorrect answers across all questions in each unit. GPT-3.5 showed relatively better performance in unit 4, although the difference was less pronounced (χ^2_1 =4.2, df=1; P=.04), whereas GPT-4 had a clear and statistically significant edge in both unit 3 (χ^2_1 =27.6, df=1; P<.001) and unit 4 (χ^2_1 =19.9, df=1; P<.001). This variation may be related to the differences in the content focus of each unit: unit 3 emphasizes clinical reasoning and comprehensive case analysis, which aligns with GPT-4's strengths in complex logical deduction, whereas unit 4 covers basic medical knowledge, which is more accessible to both models.

To contextualize the performance of the tested LLMs, it is necessary to reference the human score data of the NMLE from 2018 to 2024 as publicly reported by China's National Medical Examination Center. During this period, the average score of human examinees (primarily medical graduates and practicing physicians) in the NMLE General Written test ranged from 420 to 455 points (out of 600), with an average accuracy rate of 70% to 75.8%. Specifically, in 2018, the average human score was 425 points (70.8% accuracy); in 2020, it was 432 points (72% accuracy); in 2022, it was 448 points (74.7% accuracy); and in 2024, it was 452 points (75.3% accuracy). GPT-4 (mean score 435.3 points; 72.6% accuracy) showed comparable overall performance to that of average human examinees, whereas DeepSeek (mean score 454.8 points; 75.8% accuracy) slightly exceeded the average human score. In contrast, GPT-3.5 (mean score 373.3 points; 62.2% accuracy) and Doubao (mean score 413.7 points; 68.9% accuracy) remained below the average human performance. Notably, top-performing human examinees (top 10% of test takers) consistently achieved scores above 510 points (85% accuracy), a threshold that no tested LLM reached in this study.

Comparison of ERNIE Bot, Doubao, DeepSeek, and Tongyi Qianwen in the NMLE (2018-2024)



The comparative analysis of these 4 LLMs revealed distinct performance patterns across the 7-year period (2018-2024). As shown in Figure 3, DeepSeek consistently outperformed its counterparts in most examination years, demonstrating remarkable stability in medical knowledge assessment.

Among the 4 Chinese LLMs, DeepSeek achieved the highest overall average score across the NMLE in 2018 to 2024, with a mean score of 454.8, which was notably higher than those of ERNIE Bot (442.3), Tongyi Qianwen (426.5), and Doubao (413.7). Further analysis of performance across exam units (reflecting different medical topic domains) revealed that DeepSeek exhibited consistent strengths in unit 1 (medical ethics, regulations, and basic medical sciences) and unit 3 (comprehensive clinical reasoning involving the cardiovascular, digestive, and hematological systems), with average accuracies of 73.2% and 71.5%, respectively. ERNIE Bot showed the most prominent variability in domain-specific performance: it achieved competitive accuracy in unit 1 (70.8%) comparable to that of DeepSeek but exhibited relatively lower performance in unit 4 (pediatrics and the female reproductive system; 68.3%) than the other models. Notably, ERNIE Bot recorded the highest single-unit accuracy (75.1% in unit 1; 2020) among all the Chinese models, although its overall performance was characterized by greater variability across different topic domains rather than year-to-year fluctuations.

XSL•FO
RenderX

Tongyi Qianwen demonstrated relatively stable performance, with scores consistently ranging between 401 and 451. The model showed particular strength in the early years (2018-2019) before experiencing a moderate decline in subsequent years. Notably, it maintained a narrow performance band of 413 to 420 during 2022 to 2024.

Figure 3. Comparison of ERNIE Bot, Doubao, DeepSeek, and Tongyi Qianwen in the Chinese National Medical Licensing Examination (2018-2024).

Doubao exhibited the most pronounced performance volatility among the 4 models. Starting at 401 in 2018, it reached its peak of 447 in 2019 before experiencing significant fluctuations (394 in 2021 and 417 in 2024). This variability suggests potential sensitivity to examination content changes or model architecture adjustments in certain years.

All models consistently exceeded the passing threshold (360), confirming their fundamental competence in medical knowledge assessment. Compared with the ChatGPT results in Figure 2, the Chinese LLMs showed comparable results to those of GPT-4 in the NMLE, with a score rate far exceeding that of GPT-3.5.

Discussion

The findings of this study offer a nuanced understanding of how LLMs navigate the complexities of the Chinese NMLE, shedding light on their strengths, limitations, and implications for medical education.

Model Performance Dynamics and Underlying Mechanisms

GPT-4's consistent dominance over GPT-3.5 across all exam units—particularly its 14.39% accuracy advantage in unit 4 (female reproductive system and pediatrics)—reflects the tangible benefits of increased parameter scale and refined medical domain training. The model's ability to maintain high scores in units requiring integrated clinical reasoning (eg, unit 3: cardiovascular and digestive systems) suggests that its pretraining on diverse medical literature and case studies enhanced contextual understanding. In contrast, GPT-3.5's occasional failure to meet the passing threshold (eg, 329 points in 2019) underscores the critical role of model updates in medical accuracy as its performance improved significantly in later years with probable algorithmic refinements.

Among the Chinese LLMs, DeepSeek's sustained excellence—scoring above 450 points in 4 consecutive years (2018‐2021)—can be attributed to its specialized architecture optimized for medical terminology and reasoning. DeepSeek's

XSL•FO
RenderX

2024 score (465 points) following a 2-year decline aligns with the 2024 exam's focus on basic medical sciences—a domain where the model consistently demonstrated strengths in our unit-specific analysis—rather than reflecting adaptive adjustments to changing exam standards. ERNIE Bot's 2020 peak (473 points), surpassing even DeepSeek, highlights the potential of knowledge-enhanced models in specific assessment contexts, although its subsequent decline to 425 points in 2024 raises questions about knowledge base timeliness or training data diversity. Tongyi Qianwen's steady but unremarkable performance (401‐451 points) suggests a balanced but generalized approach to medical knowledge, whereas Doubao's volatility—spanning 394 to 447 points—may stem from its broader design focus on multidomain assistance rather than specialized medical precision.

A notable observation from this study is that the performance of all tested LLMs—including GPT-4 (highest average accuracy=80.67% in unit 4) and the top-performing Chinese model, DeepSeek (highest average accuracy=73.2% in unit 1)—did not exceed 80% across all NMLE units and years. This performance ceiling stems from 3 key factors consistent with broader medical AI research findings. First, the NMLE emphasizes high-order clinical reasoning (eg, integrating symptom clusters, laboratory results, and imaging findings for differential diagnosis) rather than just rote knowledge recall, and current LLMs struggle with such contextual nuance—evident in our study's lower accuracy in unit 3 (focused on complex case analysis, eg, GPT-3.5's 56.86% accuracy), where models often failed to prioritize key diagnostic indicators or account for comorbidities [15,16].

Second, training data timeliness and domain specificity limitations contributed to the sub-80% performance. Most LLMs have training data cutoffs that may exclude the latest clinical guidelines or emerging medical knowledge relevant to recent NMLE questions (eg, 2024 exam content). This was reflected in our study by GPT-4's 24-point drop in unit 4 between 2023 and 2022 and DeepSeek's fluctuating scores in unit 3 (cardiovascular and digestive systems), where questions on new pharmacotherapies or revised treatment algorithms likely fell outside the models' training scope [17,18].

Third, the text-based input processing used in this study (to standardize comparisons) inevitably lost critical visual details from medical images (eg, chest x-ray infiltrate density and blood smear leukocyte patterns). Medical licensing exams increasingly rely on multimodal content to mirror real-world practice, and LLMs' inability to directly interpret images reduces their engagement with such questions—observed in the lower accuracy across models in unit 2 (which includes pathological and radiological content, eg, GPT-4's 69.05% accuracy vs 80.67% in unit 4) as text descriptions could not capture subtle visual cues for distinguishing conditions such as pneumonia and pulmonary edema [19].

Implications for Chinese Medical Education

The consistent passing scores of all models (≥360 points) validate their utility as supplementary educational tools, particularly for foundational knowledge review. However, the performance gaps in specialized units reveal critical insights: GPT-4's 80.67% accuracy in unit 4 contrasts with Doubao's 59.87% average in the same unit, highlighting disparities in handling nuanced clinical scenarios. For Chinese medical curricula, DeepSeek and ERNIE Bot's proficiency in Chinese medical ethics and regional clinical guidelines (eg, unit 1's medical regulations) demonstrates their cultural and contextual relevance, making them more suitable for training students in China's health care framework. This aligns with prior research emphasizing the importance of language-specific models in accurately interpreting culturally embedded medical practices.

Limitations and Pathways for Advancement

This study's focus on text-based questions—with all images and tables converted to text—represents a notable constraint as real-world medical practice frequently requires multimodal interpretation. Additionally, the exclusion of the 2023 to 2024 clinical guidelines (due to dataset limitations) may have impacted the models' responses to emerging medical protocols. Future research should prioritize the following:

1. Multimodal model development—integrating computer vision algorithms to process radiology images or electrocardiograms, as seen in experimental medical AI systems
2. Dynamic knowledge integration—implementing real-time updates from sources such as the Chinese Medical Association's guidelines to address timeliness gaps (discrepancies between the latest medical knowledge and guidelines and the information covered in model training data)
3. Human-LLM collaborative models—designing hybrid systems in which LLMs assist in diagnostic reasoning while human experts oversee complex decisions, reducing reliance on autonomous AI in high-stakes scenarios.

Alignment of LLM Performance With Real-World and Literature Trends and Underlying Machine Learning Process Lacunae

The performance percentages of all tested LLMs align with trends reported in existing literature on medical AI and licensing exam assessments while also reflecting gaps consistent with documented limitations in machine learning (ML) processes for clinical tasks. Worldwide, studies on LLMs in medical licensing exams—such as evaluations on the US Medical Licensing Examination, Korean parasitology examinations, and prior NMLE analyses—show that even state-of-the-art models rarely exceed 85% accuracy, with most falling in the 60% to 80% range; this matches our findings, where GPT-4 (highest average accuracy=80.67%) and DeepSeek (73.2%) fit within this established spectrum. For instance, similar to our observation that GPT-3.5's accuracy (68.5%) occasionally fell below the NMLE passing threshold, prior research on non–English-language medical exams has noted lower performance in models with less domain-specific fine-tuning, confirming consistency between our results and real-world model capabilities.

Notable lacunae in the ML process underlying these performance constraints include 3 key areas. The first is limited domain-specific fine-tuning for localized medical contexts.

XSL•FO
RenderX

Most LLMs (including Chinese models) are pretrained on general medical corpora but lack targeted fine-tuning on region-specific clinical practices, guidelines, and NMLE-style question logic. For example, the NMLE emphasizes Chinese national medical regulations, regional disease prevalence (eg, specific infectious disease management protocols), and culturally aligned clinical decision-making—areas in which general ML training fails to deepen model understanding, leading to lower accuracy in unit 1 (which includes medical ethics and regulations) for models such as Doubao (average accuracy below 70%). The second key area is inadequate handling of low-resource clinical cases in training data. ML processes for LLMs rely heavily on large-scale, high-quality labeled data, but rare diseases, comorbid cases, and atypical symptom presentations (all critical to NMLE questions) are underrepresented in training datasets. This led to inconsistent performance in unit 3 (complex case analysis), where models such as GPT-3.5 (56.86% accuracy) frequently misdiagnosed rare comorbidities due to lack of training exposure. The third key area is static knowledge integration and absence of real-time learning. ML pipelines for current LLMs use fixed training data cutoffs (eg, pre-2023 data for many models), with no mechanism for real-time updates to incorporate new clinical guidelines, pharmacotherapies, or diagnostic criteria. This gap is reflected in our study's 2023 to 2024 score fluctuations (eg, GPT-4's 24-point drop in unit 4) as the models could not adapt to posttraining changes in medical knowledge—a limitation also highlighted in broader ML research on clinical AI.

Broader Context and Ethical Considerations

The results also raise ethical questions about LLMs in medical assessment. While models such as GPT-4 and DeepSeek demonstrate impressive recall and reasoning, their lack of clinical experience may lead to oversights in rare cases or nuanced patient interactions. For instance, GPT-4's occasional overconfidence in ambiguous questions (eg, 2023 unit 3 errors) highlights the risk of algorithmic bias. Therefore, educators must approach LLMs as diagnostic aids rather than substitutes for human judgment, emphasizing their role in enhancing efficiency rather than replacing professional expertise.

Conclusions

This study provides the first comprehensive quantitative evaluation of LLMs in the NMLE, demonstrating that GPT-4 and Chinese models such as DeepSeek and ERNIE Bot can achieve reliable performance in structured medical assessments. GPT-4's global generality and DeepSeek's localized excellence each offer unique value: the former excels in cross-cultural medical reasoning, whereas the latter thrives in Chinese-specific medical contexts. However, all models face challenges in dynamic knowledge updating, multimodal processing, and contextual nuance—areas requiring urgent research attention. As AI continues to permeate health care education, these findings advocate for a hybrid approach: leveraging LLMs for scalable knowledge dissemination and formative assessment while preserving human-led training in clinical judgment and ethical decision-making. Ultimately, the integration of these technologies should enhance, not replace, the humanistic core of medical practice.

Funding

This research was funded by the Natural Science Foundation of Anhui Xinhua University (2023zr013 and 2024zr016), the Anhui Provincial University Students Innovation and Entrepreneurship Program (S202312216119, S202312216029, S202412216215, and S202412216192), the University Natural Science Research Project of Anhui Province (2024AH050621), and the Anhui Province Quality Engineering Project (2022xsxx089).

Authors' Contributions

YP and YD studied the literature and conceived this study. MW and JX participated in the formulation of the study implementation plan (including the design of National Medical Licensing Examination question selection protocols, model testing procedures, and evaluation criteria for response accuracy or comprehensiveness) and data analysis. YP and YD wrote the initial draft of the manuscript and serve as guarantors. All authors reviewed and edited the manuscript and approved the final version.

Correction: Identifying Contextual Factors and Strategies for Practice Facilitation in Primary Care Quality Improvement Using an Informatics-Driven Model: Framework Development and Mixed Methods Case Study

Related Article:

Correction of: https://humanfactors.jmir.org/2022/2/e32174

(JMIR Hum Factors 2025;12:e84390) doi:10.2196/84390

Following the publication of "Identifying Contextual Factors and Strategies for Practice Facilitation in Primary Care Quality Improvement Using an Informatics-Driven Model: Framework Development and Mixed Methods Case Study" [1], concerns were raised regarding the corresponding author Jiancheng Ye's rate of self-citation within the article's reference list. Further investigation into this matter identified that numerous self-citations were added to the manuscript following acceptance of the article without adequate disclosure.

All authors were contacted for a response regarding this matter. Author Theresa Walunas indicated that they were unaware of the addition of references post acceptance. Authors Donna Woods, Jennifer Bannon, Lucy Bilaver, Gayle Kricke, Megan McHugh, and Abel Kho did not respond. Corresponding author Jiancheng Ye responded with a scientific justification for each added self-citation within the published article.

Following review of these responses, the JMIR Publications Editorial Office determined that several of the added references were not relevant to the article or were used to support a generic statement where another reference could have been used instead of self-citation. Therefore, the JMIR Publications Editorial Office is issuing this corrigendum to remove the following references:

Abstract

Background: Generative artificial intelligence (AI) chatbots have the potential to improve mental health care for practitioners and clients. Evidence demonstrates that AI chatbots can assist with tasks such as documentation, research, counseling, and therapeutic exercises. However, research examining practitioners' perspectives is limited.

Objective: This mixed-methods study investigates: (1) practitioners' perspectives on different uses of generative AI chatbots; (2) their likelihood of recommending chatbots to clients; and (3) whether recommendation likelihood increases after viewing a demonstration.

Methods: Participants were 23 mental health practitioners, including 17 females and 6 males, with a mean age of 39.39 (SD 16.20) years. In 45-minute interviews, participants selected their 3 most helpful uses of chatbots from 11 options and rated their likelihood of recommending chatbots to clients on a Likert scale before and after an 11-minute chatbot demonstration.

Results: Binomial tests found that Generating case notes was selected at greater-than-chance levels (15/23, 65%; *P*=.001), while Support with session planning (*P*=.86) and Identifying and suggesting literature (*P*=.10) were not. Although 55% (12/23) were likely to recommend chatbots to clients, a binomial test found no significant difference from the 50% threshold (*P*=.74). A paired samples *t* test found that recommendation likelihood increased significantly (19/23, 83%; *P*=.002) from predemonstration to postdemonstration.

Conclusions: Findings suggest practitioners favor administrative uses of generative AI and are more likely to recommend chatbots to clients after exposure. This study highlights a need for practitioner education and guidelines to support safe and effective AI integration in mental health care.

KEYWORDS

artificial intelligence; ChatGPT; mental health care; practitioner perspectives; mixed methods; digital health

Introduction

Overview

Globally, the prevalence of mental illness is rising and health care systems are under increasing pressure [1]. In Australia, individuals face barriers to mental health care, including financial costs and extended wait times for appointments, while practitioners are struggling to meet demand [2,3]. In this context, artificial intelligence (AI) is a potential game changer, offering 24/7 support for individuals, thus alleviating pressure on mental health practitioners [4,5]. Current models engage users in therapeutic conversations, with many using "rule-based" scripted responses and predefined dialog structures [6]. This technology differs from generative AI chatbots, such as ChatGPT (OpenAI), which generate original content and provide lifelike interactions that closely imitate humans.

Generative AI can offer more empathetic emotional support in comparison to rule-based chatbots [4,7-9], making it more effective in counseling conversations and more acceptable to clients. A recent qualitative study exploring the efficacy of ChatGPT in supporting 24 individuals with mental health conditions found that more than 50% of participants found ChatGPT to be empathetic and 80% said the tool helped to manage symptoms [10]. However, participants also raised concerns regarding data privacy and the risk of personal data theft, uncertainty in the reliability of the information shared and the quality of training data, and a lack of understanding of cultural determinants of mental health.

XSL•FO
RenderX

Generative AI chatbots may also provide improved access to mental health information and psychoeducation. Preprint and peer-reviewed studies assessing the quality of psychoeducational information generated by ChatGPT on depression, anxiety, psychosis, and substance abuse found that it was accurate, clear, clinically useful, relevant, and empathetic [11-13]. Furthermore, studies have found generative AI chatbots to be effective in supporting adherence to psychological treatments [14] and delivering positive psychology interventions [15,16]. These studies indicate that generative AI chatbots may improve individuals' access to information and basic therapeutic exercises, allowing clinicians to focus on more complex tasks, such as diagnosis and treatment.

Studies have identified a variety of uses of AI for practitioners, including research, documentation, administering psychological assessments, clinic management, and triaging [5,17-19]. Generative AI could enhance these functions by offering faster processing speeds, more comprehensive client histories, and higher empathy [20,21]. However, like rule-based AI models, studies have found generative AI chatbots are prone to mistakes, with one study finding that ChatGPT included incorrect information in 36% of client documents in a medical setting [21]. Another study evaluated ChatGPT's performance in conducting mental health assessments and found that, while responses for simple cases were acceptable, recommendations for more complex cases were inappropriate and potentially harmful [22]. These findings highlight the risks associated with AI, including hallucinations and misinterpretations.

Generative AI may also be capable of more sophisticated functions, such as recommending diagnoses and treatment options. Bartal et al [23] found that ChatGPT was able to accurately identify posttraumatic stress disorder (PTSD) following childbirth by analyzing individuals' birth stories, achieving high sensitivity (85%) and specificity (75%), aligning with commonly accepted benchmarks of reliability [24,25]. Similarly, another case study demonstrated that ChatGPT can identify treatment-resistant schizophrenia and suggest appropriate treatment options [26]. Despite these innovative applications, some argue that there is a need for significant improvement before AI is adopted in mental health care [27].

Clinicians appear cautious about the use of AI and feel more education and training are required [28,29]. In a systematic review of AI in mental health care, Rogan et al [28] found that most studies highlighted a need for clinician training, emphasizing that "AI will only be useful if clinicians understand and feel comfortable using it". Similarly, in a survey of 138 American psychiatrists, Blease et al [29] found that 90% of participants agreed that clinicians need more support to understand generative AI. Qualitative responses were mixed, with some participants expressing uncertainty and concerns relating to potential harm and others overestimating the readiness of generative AI to deliver clinical tasks.

While practitioners have expressed a need for more training and support, many may already be using AI tools for internal purposes. Blease et al [29] found that more than half of psychiatrists surveyed had used generative AI chatbots to answer clinical questions. A survey of 86 Australian mental health professionals found that 43% had used AI and that ChatGPT was the most commonly used tool [19]. Likewise, a systematic review preprint on the use of generative AI in health care found that the technology is "heavily applied" for documentation, research, and administration among medical practitioners [30].

Research examining practitioners' use of generative AI chatbots with clients is more limited. One study found strong support among clinicians to use chatbots with clients, with 80% of participants reporting they would be either very likely (24%) or somewhat likely (56%) to recommend AI mental health chatbots to clients within the next 5 years [31]. Participants may have been more supportive as they were asked to consider their future likelihood and, therefore, the potential for evolution of both the technology and their understanding.

Objective

This study aims to explore which functions of generative AI chatbots mental health practitioners think are most useful, and to what extent they would recommend them to clients. In addition, this study will investigate the impact of exposure to a generative AI chatbot on participants' likelihood of recommending chatbots to clients.

This study uses both quantitative and qualitative data to address 3 research questions (RQ) aligned with corresponding hypotheses. These RQs address key gaps in the literature, including limited insight into which functions practitioners prefer, a lack of empirical data on their willingness to recommend generative AI chatbots to clients, and minimal understanding of how exposure to the technology might influence those attitudes.

RQ1 explores practitioners' views on the most useful functions of generative AI chatbots in mental health care. It is hypothesized that functions such as generating case notes (hypothesis 1), supporting session planning (hypothesis 2), and identifying literature (hypothesis 3) will be prioritized. Previous research suggests clinicians favor using AI for internal tasks like documentation and research [29,30].

RQ2 examines the likelihood of mental health practitioners recommending a generative AI chatbot to clients. It is hypothesized (hypothesis 4) that fewer than 50% will do so, as practitioners typically have low technology literacy [28,29,32].

RQ3 investigates whether practitioners are more likely to recommend an AI chatbot after a demonstration, with the prediction (hypothesis 5) that exposure to a demo will significantly increase their likelihood to recommend it. Research indicates that familiarity with health care technologies improves clinician adoption [33].

Method

Participants

Participants were recruited using a purposive, convenience sampling method. Digital flyers were distributed on forums including the Australian Psychological Society (APS), Australian Association of Psychologists Inc (AAPi), through Melbourne University channels, and with friends and family.

XSL•FO
RenderX

Individuals who were not working in a client-facing, mental health role were excluded from the study.

In total, 23 individuals participated in the study, and all were working in Australia. Sample demographics are presented in Table 1.

Table . Sample demographic information (N=23).

Demographic variables	Participants (N=23)
Gender, n (%)	
Men	6 (26)
Women	17 (74)
Age (years), mean (SD)	39.39 (16.20)
Clinical role, n (%)	
Psychologist (including provisional)	10 (30)
Counselor or psychotherapist	6 (26)
Mental health social worker	4 (17)
Psychiatrist	2 (9)
Mental health support worker	1 (4)
Ethnicity, n (%)	
Caucasian or European	15 (65)
Asian	5 (22)
Mixed ethnicity	3 (13)
Area of work, n (%)	
Private sector	8 (35)
Public sector	9 (39)
Mixed	6 (26)
Years of work experience, mean (SD)	10.78 (14.31)

Procedure

The study team devised interview questions (Multimedia Appendix 1) to explore practitioners' perspectives on generative AI chatbots in mental health care. The interviews were of 45 minutes and conducted over Zoom (Zoom Video Communications, Inc.) between May and August 2024. Open-ended, Likert-scale, and ranking questions were used to collect both qualitative and quantitative data. Interviews were recorded and transcribed using AI software, Notta (Notta Inc), to support qualitative analysis.

Uses of Generative AI Chatbots in Mental Health Care

Participants were asked to select their top 3 "most useful" functions of generative AI chatbots from a list of 11 options and explain their reasoning. The uses were:

1. Generating case notes
2. Support with session planning
3. Client triaging
4. Client onboarding processes
5. Administering psychological assessments
6. Supporting therapist-directed exercises
7. Supporting self-directed exercises
8. Symptom tracking and monitoring
9. Identifying and suggesting literature relevant to a client's profile
10. Psychoeducation and socialization to therapeutic models
11. Counseling

An option to select "Other" was offered and subsequently removed from the analysis as it was not selected by any participants.

Likelihood of Recommending a Chatbot to a Client

Participants were asked, "How likely are you to recommend a chatbot to a client?" on a Likert scale of 1 (Highly unlikely) to 4 (Highly likely). This question was asked both before (T1) and after (T2) viewing a demonstration of a generative AI chatbot.

The demonstration was an 11-minute screen recording of a generative AI chatbot that had been built using GPT-4o (OpenAI) for the purposes of this research. During the demonstration, a fictional client ("Saman") interacted with the chatbot to illustrate a range of use cases, from triaging, psychological assessment, clinic onboarding, counseling, and completing a gratitude exercise. The demonstration also showed Saman's fictional therapist using the chatbot to generate case notes, identify literature relevant to Saman's profile, and plan future sessions (Multimedia Appendix 2).

Although the demonstration featured a chatbot built using GPT-4o, participants were asked to rate and reflect on generative AI chatbots for mental health support more generally, rather than the specific tool presented. Only the text-based

XSL•FO
RenderX

conversational capacity of GPT-4o was used, with safety filters (mechanisms that monitor and restrict the model's output to reduce risk of harm), and real-time context (allowing the chatbot to access external data and information) active by default. These features were not explicitly evaluated but were considered reflective of current generative AI chatbot capabilities.

Data Analysis

Quantitative

RQ1: Uses of Generative AI Chatbots

Data were analyzed to determine the proportion of participants who selected each use and plot the SE. To test statistical hypotheses (hypothesis 1, hypothesis 2, and hypothesis 3), 3 binomial tests were conducted to assess whether specific uses were selected at greater than chance levels.

RQ2: Likelihood of Recommending a Chatbot to a Client

A binomial test was conducted to test hypothesis 4 and analyze whether less than 50% of participants would be likely to recommend a chatbot. A Bayesian binomial test was conducted to evaluate the strength of the evidence in favor of the alternative hypothesis.

RQ3: Increase in Likelihood of Recommending a Chatbot After a Demonstration

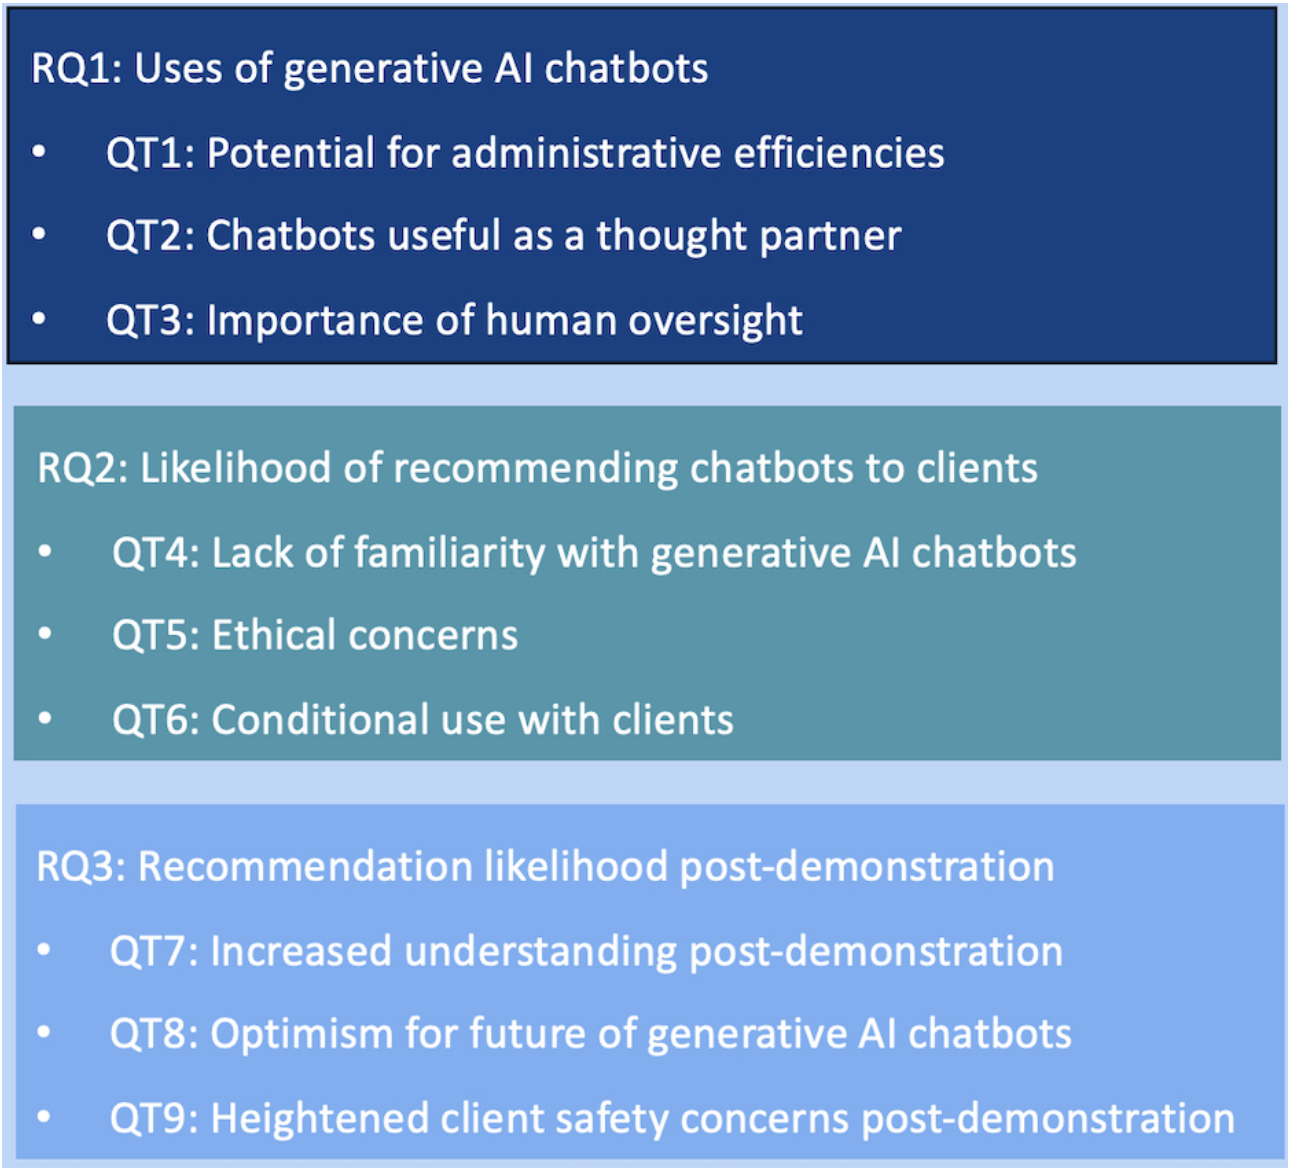
To test hypothesis 5, a paired-samples *t* test was conducted to measure whether there was a significant difference in the mean likelihood of recommending a chatbot before (T1) and after (T2) the demonstration. A Bayesian paired samples *t* test assessed the strength of the evidence in favor of the alternative hypothesis (a significant increase in recommendation likelihood from T1 to T2).

Qualitative

A thematic analysis was conducted following Braun and Clarke's [34] 6-phase framework. Analysis began with familiarization, where transcripts were reviewed to identify initial ideas. Themes were then generated based on recurring concepts, iterated, and refined to ensure they captured core insights. Finally, qualitative themes were considered alongside the quantitative results to identify key research findings. Where participants are quoted, a reference is provided with their participant identification number (#), gender (men or women), and age.

Ethical Considerations

All participants provided informed consent and no compensation was offered. Participants were informed in advance that participation was voluntary, and they could withdraw at any time without consequence. Data were stored securely, and participant confidentiality was secured by anonymizing all data. Ethics approval was obtained from the University of Melbourne Human Research Ethics Committee (#28479).



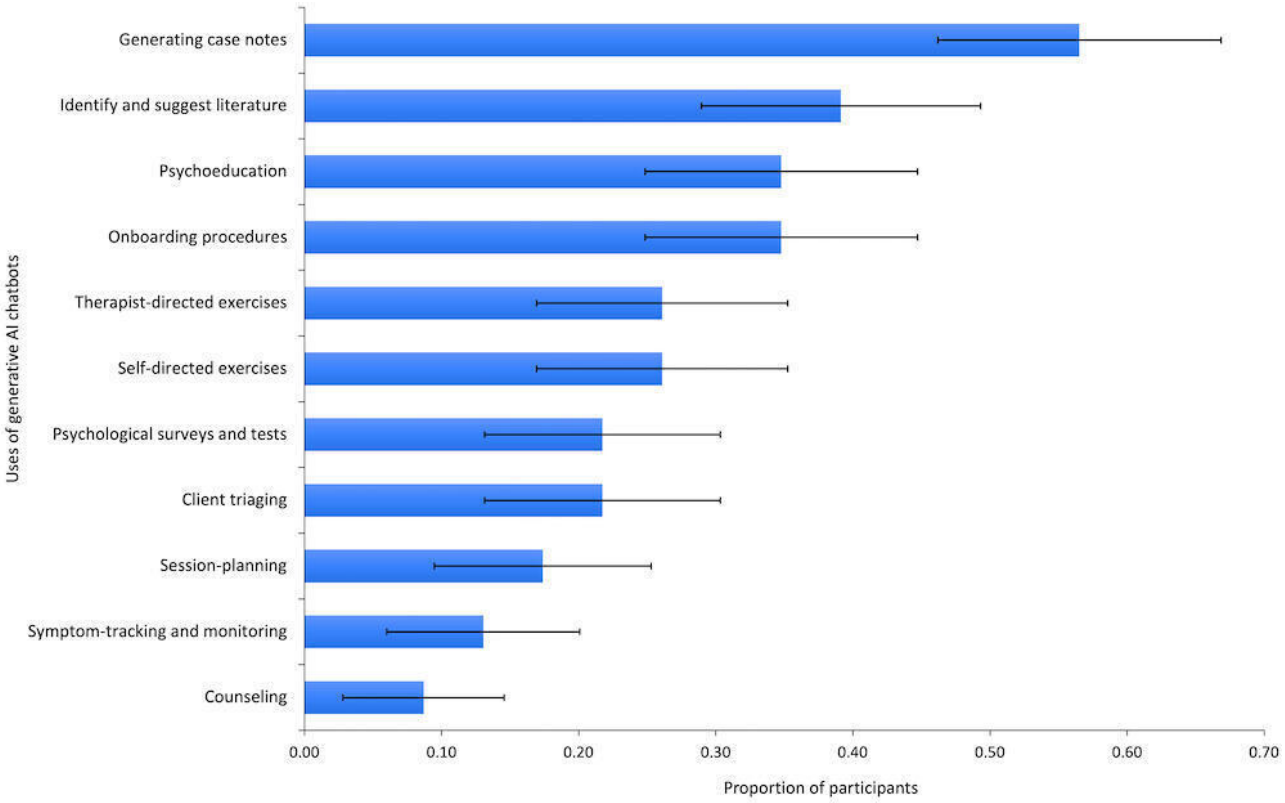
Results

Overview of Qualitative Themes

Thematic analysis produced 9 qualitative themes (QTs), each aligned to a particular RQ, as shown in Figure 1. These themes are reported in further detail throughout the following section.

XSL•FO
RenderX

Figure 1. Summary of qualitative themes.



RQ1: Uses of Generative AI Chatbots

Proportions of participants who selected each use in their top 3 are presented in Figure 2.

A binomial test was conducted to assess whether Generating case notes was selected in participants' top 3 choices at greater than chance levels. The chance probability was calculated at 0.25, based on the probability of a participant selecting an option, acknowledging that they had 3 choices and could not select the same option twice (P(selected)=1 - [1- 1/11] x [1 - 1/10] x [1- 1/9]). The results were significant, P=.001, indicating that Generating case notes was selected at greater than chance levels. A binomial test indicated that Support with session planning was not selected in participants' top 3 choices at greater than chance levels (0.25; P=.86). A binomial test indicated that Identifying literature and Suggesting literature was not selected in participants' top 3 choices at greater than chance levels (0.25; P=.10).

XSL•FO
RenderX

Figure 2. Proportion of participants selecting each use of generative AI chatbots. Error bars represent the SE of the proportion of participants selecting each use.

QT1: Potential for Administrative Efficiencies

Qualitative analysis indicated that participants value the potential of generative AI chatbots to reduce time spent writing case notes. One participant explained:

> *Writing clinical notes, that takes up probably more time in therapists' days than they would like... having a process to be able to. dump your very verbatim notes from a session and have it spit out a very succinct summary of the mental state formulation. That would be awesome* [#20, F, 29.]

Another participant emphasized that using a chatbot to document case notes would enable them to spend more time with clients,

> *Generating case notes strikes me as just a time-consuming and aversive activity… you save yourself time to spend more time with clients and less time on admin* [#4, M, 42.]

QT2: Chatbots Useful as a Thought Partner

Qualitative responses indicated that participants saw the potential of generative AI chatbots to assist with session planning by providing new ideas, though it wasn't seen as a necessity. One participant stated,

> *For help with session planning I feel like well it's good with just reflecting on ideas and you know talk about things that you maybe haven't thought about* [#2, F, 27.]

Another explained,

> *I mean, you could do it without it, but it's always helpful to just to maybe get another perspective or consider something else* [#17, F, 35.]

QT3: Importance of Human Oversight

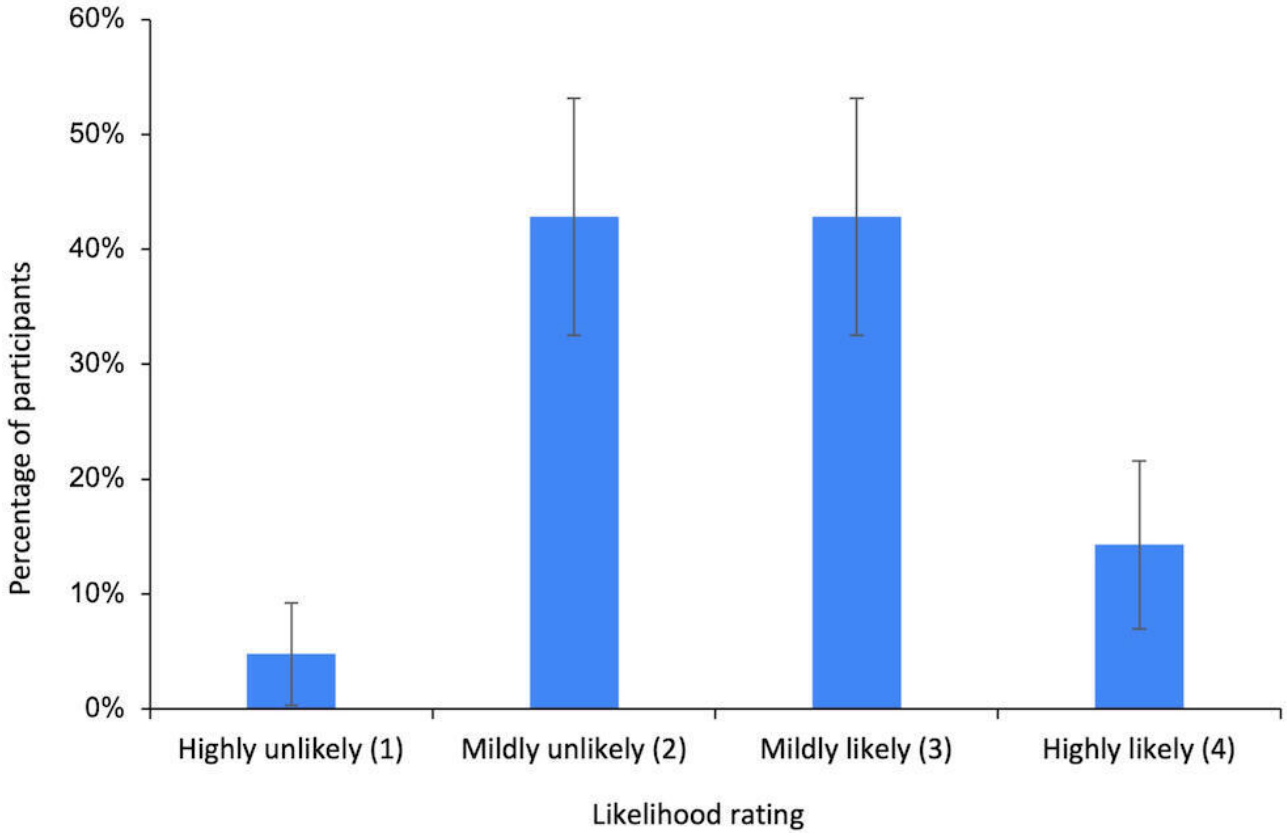
While qualitative responses indicated that participants hoped generative AI chatbots might enhance their research, many stressed the importance of maintaining human oversight. One participant explained:

> *[Identifying literature] is something that we do digitally anyway and if we're able to customize a search to a client specific profile, that might make the search better. And then obviously, the clinician can still have the final say on that, but it would be helpful* [#9, F, 24.]

Several participants raised concerns around accuracy, with one participant remarking that,

> *It would be great to have a reliable source that can give us the latest research in what is best practice CBT [Cognitive Behavioral Therapy] for OCD [Obsessive Compulsive Disorder]... [ChatGPT] just never seems quite accurate* [#11, F, 25.]

Another explained,



> *I know that there's been a lot of speculation around finding accurate references… I would always, you know, [use ChatGPT] in addition to my own search as well, just to be sure* [#2, F, 27.]

XSL•FO
RenderX

RQ2: Likelihood of Recommending a Chatbot to a Client

The distribution of participants' likelihood of recommending a chatbot to a client at T2 is presented in Figure 3. Data from T2 (postdemonstration) was used for the analysis, as it best reflected participants' informed perspectives of generative AI chatbots. One participant responded, "I don't know," and their data were excluded from the quantitative analysis.

Figure 3. Distribution of participants' likelihood of recommending a generative AI chatbot (n = 22). Error bars represent the SE of the percentage of participants selecting each rating.

A binomial test was conducted to determine whether participants would be likely to recommend a generative AI chatbot to a client (defined as a response of 3 or 4 on the 4-point Likert scale). The proportion of participants likely to recommend was 55% (12/22), which was not significantly different from the 50% threshold (P=.74; odds ratio 1.20 [95% CI 0.47-3.17]). A Bayesian binomial test provided moderate evidence for the null hypothesis that more than 50% of participants would be likely to recommend a chatbot (BF_{01}=5.24).

QT4: Lack of Familiarity With Generative AI Chatbots

Most participants were not familiar with generative AI chatbots in mental health care. One participant noted,

> [I don't feel like I understand the market well enough yet to recommend it to clients. I would need more experience and a chance to evaluate different models before trusting them for client use] [#4, M, 42.]

Others explained that they simply "don't know enough about it". During introductory questions, only one participant reported having experience using an AI chatbot for mental health support for themselves or with a client.

QT5: Ethical Concerns

Ethical concerns were frequently cited. One participant explained,

> *I don't think that it would be prudent or appropriate to recommend [chatbots] to clients just the same way that we wouldn't recommend unapproved treatments that we can't be fully confident in to clients because then we basically have liability* [#9, F, 24.]

Another commented,

> *Privacy would be my main concern. How do we manage to keep client information confidential if we're using it for note purposes?* [#20, F, 29.]

QT6: Conditional Use With Clients

For many participants, their likelihood of recommending a chatbot was dependent on the type of client. One participant stated,

> *I do see a use for it as an emergency point of contact, but for anything beyond that, especially involving complex risk, I wouldn't feel comfortable recommending it* [#9, F, 24.]

Another explained that their etiological formulation would inform whether a chatbot would be appropriate:

> *A lot of people's addictions and mood disorders are born out of childhood trauma, and I think there is also a certain percentage of those who are*

XSL•FO
RenderX

> *enduringattachment wounds. And that's where AI is not going to be able to help* [#12, F, 66.]

Others suggested their likelihood of recommending would be based on age, with one participant explaining,

> *It depends on the demographic. Maybe if it was a young person, I would. But in my practice, I don't actually come across many young people. So personally, probably no, because most of my demographics are older* [#6, F, 54.]

RQ3: Change in Likelihood of Recommending a Chatbot to a Client After the Demonstration

A one-tailed paired samples *t* test was conducted to assess whether there was a statistically significant increase in the likelihood of recommending a chatbot from T1 (mean 2.09 [SD 1.07]) to T2 (mean 2.64 [SD 0.79]). Results were significant, t_{21}=3.20; *P*=.002, with a mean difference of 0.55. The effect size (*d*=0.68) was medium-to-large [35], suggesting a meaningful increase in recommendation likelihood.

A Bayesian paired samples *t* test provided strong evidence in favor of the alternative hypothesis (*r*=0.707; BF_{10}=20.08), indicating that participants were more likely to recommend a chatbot after the demonstration (T2) compared to before (T1).

QT7: Increased Understanding Postdemonstration

Qualitative analysis suggested that the demonstration improved participants' understanding of how generative AI chatbots can be used in mental health care. One participant stated,

> *I have a better sense of the additional value that AI can provide particularly around screening and triage* [#4, M, 42.]

Another stated that, "It gave me new ideas on onboarding and case notes" (#1, F, 25). Some participants were satisfied with how the chatbot performed client-facing tasks such as counseling, with one participant stating,

> *I was quite happy with how [the chatbot] dealt with everything in terms of like when it realized that the issues were quite severe and that it didn't jump to try to diagnose* [#2, F, 27.]

QT8: Optimism for Future of Generative AI Chatbots

After the demonstration, several participants expressed optimism about the potential of generative AI. One participant remarked,

> *I imagine as the technology gets better and we're able to further program them to work in a really safe and diligent way around this sort of stuff, it probably will work quite smoothly and reliably* [#7, F, 27.]

One participant likened the introduction of AI chatbots to the evolution of telephone counseling, while another stated:

> *I know a lot of people firmly believe that AI will never be able to deliver that human touch. And I just think that I just think they're delusional, frankly, I think, I think they need to… realize what's coming* [#4, M, 42]

QT9: Heightened Client Safety Concerns Postdemonstration

Of the 10 participants who reported an increased likelihood of recommending a chatbot, 4 indicated that the demonstration had heightened their concerns regarding client safety. One participant stated,

> [I was spooked by how the AI responded when the person expressed suicidality… it slightly ups my sense of the risk based on current technology] [#5, F, 41.]

Another commented,

> [The user was feeling a bit flat and all he was left with was a phone number, like rather than 'I will put you through to Lifeline right now', for example, just leaving risk like that, that's probably not helpful] [#8, F, 58.]

Discussion

Principal Findings

This study found that practitioners appear to prefer administrative uses of generative AI chatbots, such as generating case notes, and are uncertain about recommending chatbots to clients. While exposure to a demonstration may increase the likelihood of recommending a chatbot, concerns regarding client safety and risk persist.

The first hypothesis (hypothesis 1) was supported. Generating case notes was selected as the most useful function of generative AI chatbots at greater than chance levels. The second (hypothesis 2) and third (hypothesis 3) hypotheses were not supported. Support with session planning and Identifying and suggesting literature were not selected at greater than chance levels. The fourth hypothesis (hypothesis 4), that less than 50% of participants would be likely to recommend a chatbot to a client, was not supported. The fifth hypothesis (hypothesis 5) was supported; participants were significantly more likely to recommend a chatbot to a client postdemonstration, and Bayesian analysis provided strong evidence for this increase.

Practitioners Prefer Administrative Uses of Generative AI Chatbots

The results indicate a preference among practitioners for using generative AI chatbots for simple, administrative tasks. Quantitative and qualitative data highlight that practitioners see value in generative AI chatbots for drafting and summarizing case notes. Participants expressed enthusiasm for the potential administrative efficiencies that using a chatbot would allow more time to focus on client-facing work. This aligns with previous studies where practitioners reported using generative AI tools for documentation and research [19,29,30]. This preference is also evident in the influx of AI-based tools for case note documentation in the market, such as Heidi (Heidi Health), Upheal (Upheal), and Autonotes (Autonotes AI, LLC) [36-38].

There is; however, some nuance in the types of administrative tasks practitioners are willing to use generative AI chatbots for. While descriptive data showed that Identifying and suggesting

XSL•FO
RenderX

literature was the second most frequently selected use, it was not selected at greater than chance levels. Similarly, there was a lack of support for Session planning. Participants emphasized the importance of human oversight, indicating a lack of trust in generative AI. This aligns with findings from Blease et al [29], where psychiatrists were cautious of using generative AI for tasks that require clinical expertise and raised concerns about accuracy. As such, while practitioners may not be willing to delegate more complex administrative tasks to generative AI chatbots, this study suggests that there is potential for the technology to be applied in a supporting capacity.

Practitioners Are Uncertain About Recommending Generative AI Chatbots to Clients

This study found no clear preference for or against recommending a chatbot to clients, with uncertainty evident in both quantitative and qualitative results. Both the frequentist and Bayesian analyses reflected statistical uncertainty regarding the true proportion of participants who were likely to recommend a chatbot to clients. Qualitative analysis highlighted several ethical concerns, ranging from professional liability to confidentiality and data security, and a lack of familiarity with the technology. This aligns with previous research, which found that practitioners often harbor ethical concerns and lack education on the appropriate use of generative AI tools in practice [29,32].

This uncertainty contrasts with Sweeney et al [31], where 80% of practitioners were likely to recommend a chatbot to a client. This variance may be explained by the difference in how questions were phrased. In Sweeney et al [31] study, participants were asked whether they would recommend a chatbot "in the next five years," allowing practitioners to consider how the technology, and their understanding of it, may evolve. In contrast, the present study focused on immediate likelihood, which may have biased participants toward considering current limitations. Participants also expressed optimism about the future of generative AI, suggesting they may have been more supportive if asked to consider their likelihood of recommending a chatbot in the future.

Practitioners' Use of Generative AI Chatbots May Be Conditional on the Client

A unique insight from this study was practitioners' support for conditional use of generative AI chatbots, depending on factors unique to the client. Qualitative responses indicated that participants were more inclined to recommend chatbots for low-risk, less complex cases (ie, stress, sleep issues, and life transitions) compared to high-risk (ie, suicidal intent) or trauma-related cases. The existing literature on the appropriate client profiles for generative AI chatbots presents mixed views. Some propose that AI is appropriate for use with clients with complex clinical histories, on the basis that the technology can analyze and track data on, for example, genetic markers and behavioral patterns [39]. Others suggest that AI chatbots may be most appropriate in prevention and psychoeducation in low-risk populations [40]. Ultimately, like any mental health treatment, the success of generative AI tools will depend not only on the technology, but also on its fit for the client.

Exposure Increases Recommendation Likelihood and May Heighten Client Safety Concerns

This study found that participants' likelihood of recommending a generative AI chatbot to a client increased significantly after a demonstration. Qualitative insights provided depth to the quantitative results, as participants explained that the demonstration had increased their understanding of how chatbots can be applied in mental health care. This result aligns with earlier findings of a positive correlation between health care practitioners' knowledge of generative AI chatbots and positive attitudes toward the technology [41]. Similarly, previous studies have found that negative perceptions of AI among mental health professionals may be due to minimal exposure [29,42].

Alternatively, participants' increased recommendation likelihood postdemonstration may be reflective of novelty bias, where individuals tend to exhibit increased enthusiasm toward a new or unfamiliar technology or idea [43]. Qualitative data suggests that for 22 out of 23 participants (96%), the demonstration was the first time they had seen a generative AI chatbot used in a mental health setting. In a similar study by Liu et al [16], it was observed that participants responded more positively to a chatbot trained to deliver positive psychology interventions during initial interactions.

Surprisingly, despite the quantitative increase in recommendation likelihood, qualitative responses indicated that the demonstration heightened client safety concerns for some participants. Of the ten participants who reported an increased recommendation likelihood, 4 described being more concerned about the risks. This suggests that a greater understanding of the associated risks of using generative AI chatbots may play a role in adoption among practitioners. This aligns with results from Zhang et al [42], where participants described the importance of understanding the risks of AI to "clinician buy-in" and adoption of the technology in practice. While an examination of potential risks was beyond the scope of this study, this finding underscores the importance of providing evidence-based, objective education to practitioners.

Limitations and Future Directions for Research

Several limitations of this study should be addressed. First, convenience sampling may have introduced selection bias, as individuals who were more supportive of AI technologies may have been more likely to participate, leading to an overrepresentation of positive attitudes. Future studies should apply random sampling methods to reduce selection bias, ensure representativeness, and improve external validity [44]. In addition, participants may have been aware that the interviewers created the chatbot demonstration, introducing demand characteristics and potential bias toward more favorable responses. The use of independent researchers to administer questionnaires may assist in mitigating potential bias in future research.

A primary focus of this research was to gather in-depth qualitative data to allow for greater exploration of practitioners' perspectives. Due to project constraints and the time required of participants, the study sample size was small (N=23). While this number is appropriate for qualitative thematic research [45],

XSL•FO
RenderX

it limited the statistical power and reliability of the quantitative analyses [46]. No a priori power calculation was conducted, as the study was primarily exploratory and qualitatively focused. In addition, the sample was Australian, predominantly female (17/23, 74%) and mostly psychologists and counselors (13/23, 56%). Caution should be exercised when generalizing these findings to other health systems or sociocultural contexts. In the future, researchers should recruit larger, more representative samples in different cultural contexts, while still maintaining the qualitative analysis that is crucial for understanding the nuanced perspectives of practitioners.

Participants were asked to rate their likelihood of recommending a chatbot to a client on a 4-point Likert scale. While the absence of a neutral midpoint encouraged participants to share their perspectives, it may have forced practitioners to choose a position that they did not fully support.

This study did not consider recent developments in generative AI chatbot technology, such as voice recognition or more sophisticated emotional detection capabilities [47]. Researchers may consider partnering with AI developers to test emerging technologies to ensure that studies remain relevant, while also allowing for practitioner and user feedback on tools before they are released to market.

Practical Implications

For practitioners, the findings suggest that generative AI chatbots could be valuable in alleviating their administrative burden. However, the study also highlights the need for careful consideration as to how AI is applied and the need for practitioners to improve their understanding of AI chatbots, particularly as their clients may already be using them [22].

Educational institutions and industry associations play an important role in ensuring practitioners have appropriate AI skills and literacy and are prepared to deliver services in a field where technology is playing an increasingly important role [48]. Practical, evidence-based guidelines for the use of AI tools should address concerns expressed in this study regarding liability, client safety, and ethics, while also enabling effective use of technology to support positive mental health outcomes. Practitioners should also be informed of emerging research so as to help validate their decision-making and points of view.

For AI developers, insights from this study may support iteration and refinement of generative AI chatbots for mental health care. For example, developers should ensure practitioners' concerns regarding client safety, data security, and accuracy are addressed in AI tools and service agreements. This study also highlights the need for developers to engage practitioners, as well as users, throughout the design process to support safe and effective technology implementation.

Conclusion

Generative AI chatbots have significant potential to play an important role in the delivery of mental health care. In the immediate term, their greatest value may be in administrative, nonclient-facing tasks, to alleviate practitioner workload and allow greater attention to be directed to therapeutic work. This study highlighted the complexity and nuance of practitioners' perspectives on generative AI chatbots. While there is interest and optimism, there is a lack of familiarity with AI tools and uncertainty regarding client-facing uses. Furthermore, exposure to AI technology may play an important role in supporting adoption among practitioners.

Future research should continue to explore practitioners' views on administrative and client-facing uses with larger, more representative samples to enhance the reliability and generalizability of findings. It would also be beneficial to explore hybrid models and the benefits of therapist-AI collaboration. Such evidence could inform objective guidelines to allow practitioners to make informed decisions on their use of generative AI chatbots. Ultimately, this study provides valuable contributions as to "how," rather than simply "whether," generative AI chatbots may be integrated into mental health care, guiding more thoughtful, stakeholder-informed implementation.

Abstract

Background: Generative artificial intelligence (AI)—particularly large language models (LLMs)—has generated unprecedented interest in applications ranging from everyday questions and answers to health-related inquiries. However, little is known about how everyday users decide whether to trust and adopt these technologies in high-stakes contexts such as personal health.

Objectives: This study examines how ease of use, perceived usefulness, and risk perception interact to shape user trust in and intentions to adopt DeepSeek, an emerging LLM-based platform, for health care purposes.

Methods: We adapted survey items from validated technology acceptance scales to assess user perception of DeepSeek. A 12-item Likert scale questionnaire was developed and pilot-tested (n=20). It was then distributed on the web to users in India, the United Kingdom, and the United States who had used DeepSeek within the past 2 weeks. Data analysis involved descriptive frequency assessments and Partial Least Squares Structural Equation Modeling. The model assessed direct and indirect effects, including potential quadratic relationships.

Results: A total of 556 complete responses were collected, with respondents almost evenly split across India (n=184), the United Kingdom (n=185), and the United States (n=187). Regarding AI in health care, when asked whether they were comfortable with their health care provider using AI tools, 59.3% (n=330) were fine with AI use provided their doctor verified its output, and 31.5% (n=175) were enthusiastic about its use without conditions. DeepSeek was used primarily for academic and educational purposes, 50.7% (n=282) used DeepSeek as a search engine, and 47.7% (n=265) used it for health-related queries. When asked about their intent to adopt DeepSeek over other LLMs such as ChatGPT, 52.1% (n=290) were likely to switch, and 28.9% (n=161) were very likely to do so. The study revealed that trust plays a pivotal mediating role; ease of use exerts a significant indirect impact on usage intentions through trust. At the same time, perceived usefulness contributes to trust development and direct adoption. By contrast, risk perception negatively affects usage intent, emphasizing the importance of robust data governance and transparency. Significant nonlinear paths were observed for ease of use and risk, indicating threshold or plateau effects.

Conclusions: Users are receptive to DeepSeek when it is easy to use, useful, and trustworthy. The model highlights trust as a mediator and shows nonlinear dynamics shaping AI-driven health care tool adoption. Expanding the model with mediators such as privacy and cultural differences could provide deeper insights. Longitudinal experimental designs could establish causality. Further investigation into threshold and plateau phenomena could refine our understanding of user perceptions as they become more familiar with AI-driven health care tools.

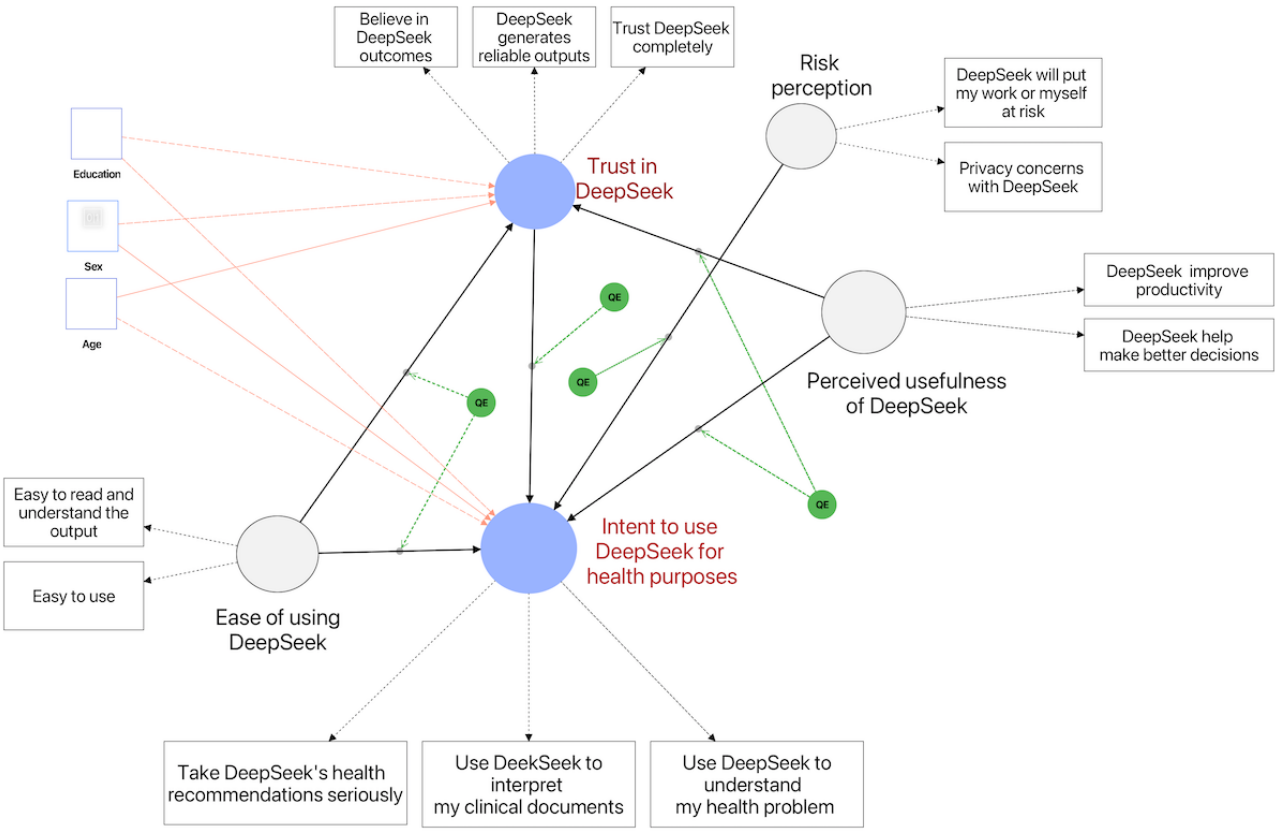
Introduction

Over the past few years, generative artificial intelligence (AI)—particularly large language models (LLMs)—has transitioned from research laboratories to widespread public use, sparking unprecedented interest in applications ranging from everyday question and answer to health-related inquiries. Media narratives often amplify these systems' capabilities, leading individuals to adopt them in ways that can exceed their original design intentions. While such enthusiasm has undeniably broadened the reach of LLMs, it also carries risks—biased training data [1], fluctuations in output quality, and users' lack of domain expertise all converge in potentially problematic ways. Indeed, existing research, including our own previous work, suggests that many users consult LLMs (eg, Chat Generative Pretrained Model) for medical advice despite



XSL•FO
RenderX

having limited or no formal clinical background. As new LLMs such as DeepSeek emerge—touting features such as cost-effectiveness, human-like conversation, and comparable performance to established systems—the likelihood that nonexpert populations will rely on AI tools to inform health care decisions appears poised to intensify.

However, little is known about how everyday users decide whether to trust and adopt these technologies—particularly in high-stakes contexts such as personal health. Studies show that while an LLM may provide *convincing* outputs, its accuracy can shift unpredictably due to biases or changes in model parameters. Thus, a recommendation that proves correct today does not guarantee reliability tomorrow. The media equation theory further underscores how human-like dialogue can encourage users to treat an AI system as though it were a trustworthy human advisor, heightening the risk of overreliance [2-5]. Against this backdrop, there remains a gap in understanding how perceptions of ease of use, perceived usefulness, risk, and trust coalesce to shape user intentions to use LLMs for health-related queries. Specifically, while prior studies on ChatGPT and similar platforms have begun to shed light on user attitudes, few have examined the human factors by which trust is established—or eroded—when individuals face important decisions about their well-being.

In this study, we add to the body of knowledge by focusing on DeepSeek, an open-source LLM that rapidly gained popularity after surpassing other competitors in App Store rankings. Public and media hype surrounding DeepSeek's purported superiority can create a halo effect, wherein users generalize competence across all domains without adequately accounting for potential inaccuracies or biases. Drawing on technology acceptance models and behavioral theories [6,7], we propose and empirically test a conceptual framework that explores the association among ease of use, risk perception, and perceived usefulness in determining user trust in-and-intentions to rely on DeepSeek for health-related advice. Figure 1 shows the conceptual model. A key focus centers on *ease of use*—a construct traditionally linked to technology acceptance. Specifically, the study posits that ease of use will significantly foster trust in DeepSeek and increase users' intent to adopt it for health purposes. This expectation aligns with the view that a user-friendly interface reduces cognitive strain, instilling an impression of competence and reliability [8]. Moreover, straightforward navigation of an AI system in a clinical or personal health setting can lower barriers to initial adoption, prompting individuals to incorporate the technology more readily into their decision-making.

Figure 1. Conceptual structural framework. Education, age, and sex are the control variables. Latent constructs are represented by circles and observed variables by rectangles. QE: quadratic effect.

Another central component is trust, which is widely recognized as a pivotal determinant of individuals' willingness to delegate sensitive tasks to AI systems. Here, trust is posited to positively influence intent to use DeepSeek, reflecting the premise that users must believe in the system's credibility and accuracy before relying on its outputs for personally significant choices, such as querying about personal health or symptoms. In parallel, the model predicts that perceived usefulness—the degree to which users believe that DeepSeek effectively aids in accomplishing tasks—will both feed into trust and directly

XSL•FO
RenderX

motivate the decision to adopt [9]. If DeepSeek demonstrably improves efficiency, offers relevant information, or yields better outcomes, individuals are more likely to view the technology as beneficial and deserving of confidence, thus reinforcing their intention to use.

In contrast, risk perception is anticipated to negatively impact the intent to use. Particularly in health-related scenarios, concerns over data privacy, the possibility of incorrect diagnoses, or broader ethical dilemmas can inhibit adoption. Users who sense a high level of risk may hesitate to rely on an AI system, even if they recognize certain advantages [10].

In addition, the framework addresses mediation pathways, where trust operates as an intermediary in 2 distinct relationships. First, the study investigates whether trust mediates the link between ease of use and intent to use, positing that user-friendly design can bolster trust, reinforcing the inclination to adopt DeepSeek. Second, perceived usefulness is hypothesized to enhance trust, which in turn increases intent to use, reflecting the theory that tangible benefits establish an underlying belief in the system's reliability.

We explore the following 8 hypotheses (Hs):

- H1: ease of use positively influences trust in DeepSeek.
- H2: ease of use positively influences intent to use DeepSeek for health-related purposes.
- H3: trust in DeepSeek positively influences intent to use DeepSeek for health-related purposes.
- H4: risk perception negatively influences intent to use DeepSeek for health-related purposes.
- H5: perceived usefulness positively influences trust in DeepSeek.
- H6: perceived usefulness positively influences intent to use DeepSeek for health-related purposes.
- H7: trust in DeepSeek mediates the relationship between ease of use and intent to use DeepSeek.
- H8: trust in DeepSeek mediates the relationship between perceived usefulness and intent to use DeepSeek.

Although canonical technology acceptance models often posit linear relationships among constructs such as ease of use, perceived usefulness, and intention to adopt, scholars have long recognized scenarios where user perceptions follow threshold or plateau patterns rather than increasing in a straightforward incremental manner [11,12]. Our study also acknowledges the possibility of nonlinear relationships [13]. In practice, once an interface or system achieves a certain baseline of usability, additional refinements may produce diminishing returns—that is, users do not perceive incremental gains in simplicity as adding meaningful value [14]. For instance, a health-focused AI system that goes from moderately user-friendly to extremely user-friendly might not see a proportional rise in users' trust or adoption if people already consider the interface easy enough. Likewise, risk perception can display an inverted-U or other nonlinear patterns, where a just-right amount of perceived risk may be beneficial in prompting vigilant, responsible usage, whereas extremely low levels of risk can lead to complacency, and extremely high levels can deter adoption outright. From a cognitive and behavioral standpoint, Kahneman and Tversky's Prospect Theory also illustrates that people exhibit loss aversion in nonlinear ways: even a small increase in perceived risk can disproportionately reduce willingness to adopt [15].

By incorporating quadratic (QE) terms for both ease of use and risk perception, this study accommodates the possibility that these factors do not scale linearly with trust or intent to adopt. Specifically, we test whether user attitudes intensify, plateau, or invert once certain inflection points in usability or perceived risk are reached. A similar rationale applies to perceived usefulness, as exceedingly high levels of perceived utility may lead to skepticism—users might become suspicious of a too good to be true system promising flawless performance, thus reducing their trust or perceived credibility.

Methods

Ethical Considerations

The West Virginia University Institutional Review Board approved the study (protocol number 2302725983; classified as a flex protocol type). All participants were required to provide informed consent statement through an individualized survey link, before proceeding to the primary survey. All data were anonymized. Participants were compensated by the paid audience panelling service.

Survey Instrument

The survey items were adapted from established measurement scales commonly used in technology acceptance and human-computer interaction research [16,17]. A preliminary literature review identified key constructs (eg, ease of use, trust, risk perception, perceived usefulness, and usage intentions) pertinent to AI-driven applications, particularly in health care [18,19]. Existing, validated items were then modified linguistically to reflect DeepSeek's functionality. For instance, several questions included references to reliability and accuracy, adapted from trust in automation scales. At the same time, risk perception measures were framed to address data privacy and potential adverse outcomes in health-related tasks [20-22].

As shown in Textbox 1, the resultant questionnaire comprised 12 primary items, each measured on a 4-point forced Likert scale. The decision to use a 4-point format was motivated by the desire to encourage decisive responses and minimize the fence-sitting effect often observed with neutral midpoint options. In the context of LLM usage, truly neutral opinions are comparatively less likely; users typically find these AI systems either useful or problematic in some capacity. By eliminating the neutral choice, the instrument sharpens distinctions in participant attitudes and prevents potential ambivalence from masking genuine inclinations. Still, we acknowledge that the absence of a neutral category can suppress expressions of ambivalence.

Questions were grouped to form latent construct and validated. The instrument also had questions about participant demographics. In addition, the survey incorporated a checking question to verify that respondents thoroughly read all questions before providing their answers, further ensuring data quality.

XSL•FO
RenderX

Textbox 1. Survey questions used in the study model.

Trust in DeepSeek

- To what extent do you agree or disagree with the following: I would trust DeepSeek completely. (T1)
- To what extent do you agree or disagree with the following: DeepSeek generates reliable outputs. (T2)
- To what extent do you agree or disagree with the following: I believe in DeepSeek outcomes. (T3)

Intent to use DeepSeek for health-related purposes

- To what extent do you agree or disagree with the following: I would take DeepSeek's health-related recommendations seriously. (IU1)
- To what extent do you agree or disagree with the following: I will use DeepSeek to interpret my clinical documents. (IU2)
- To what extent do you agree or disagree with the following: I want to use DeepSeek to understand minor health problem I occasionally get. (IU3)

Ease of using DeepSeek

- To what extent do you agree or disagree with the following: I find it easy to read and understand the output generated by DeepSeek. (E1)
- To what extent do you agree or disagree with the following: DeepSeek is easy to use. (E2)

Perceived usefulness of DeepSeek

- To what extent do you agree or disagree with the following: DeepSeek-generated outcomes will help me improve productivity. (PU1)
- To what extent do you agree or disagree with the following: DeepSeek-generated outcomes will help me make better decisions. (PU2)

Risk perception

- To what extent do you agree or disagree with the following: using DeepSeek will put my work or myself at risk. (R1)
- To what extent do you agree or disagree with the following: I have privacy concerns with DeepSeek. (R2)

Pilot Testing and Data Collection

Before launching the main data collection, the survey was piloted with a small convenience sample (n=20) who met the criterion of having used DeepSeek at least once in the previous 2 weeks. Pilot participants were asked to provide feedback on item clarity, redundancy, and overall length. Minor revisions were made, including refining the wording of risk-related items and adjusting the Likert scales for consistency.

Following pilot testing, a web-based version of the final questionnaire was administered via Centiment, a paid audience paneling service. Centiment maintains a prescreened database of respondents for market research. Panelists opt in by agreeing to Centiment's terms of use and privacy policy, and they are profiled in advance based on demographic and firmographic criteria. This approach enabled us to target specific audiences (eg, certain regions or demographic subgroups) and apply quotas to approximate a more representative sample. Centiment's quality controls—such as IP-based fingerprinting, proxy detection, and fraud scoring—were used to minimize duplicate or low-effort responses.

The survey was distributed to India, the United Kingdom, and the United States. Participant recruitment targeted adult users (aged 18 years or older) who reported using DeepSeek at least once in the preceding 2 weeks. Exclusion criteria included individuals with no prior exposure to DeepSeek.

Data Collection Procedure

Data collection took place over 2 weeks. Each participant received an individualized survey link, which led to a landing page containing an informed consent statement. After consenting, participants proceeded to the primary survey. The survey platform automatically recorded session details, including session ID and IP address (to prevent duplication only). All identifying information was removed before data analysis. Participants could terminate the survey at any point without penalty.

Statistical Analyses

First, we conducted a frequency analysis of the survey responses related to participant characteristics and DeepSeek perception. Given that all data were gathered using a single survey instrument, common method bias (CMB) represented a potential concern. To evaluate the extent of CMB, we conducted Harman's single-factor test, wherein the principal components analysis revealed that the highest variance explained by any single factor was 33%, falling below the commonly referenced threshold of 50% [23]. Consequently, these results indicate that no substantial CMB threat exists in our dataset.

Second, we used nonparametric Partial Least Squares Structural Equation Modeling (PLS-SEM) to investigate the relationships between the latent constructs and their observed indicators. PLS-SEM is suitable for analyzing complex models with multiple dependent and independent variables. The method allows for simultaneous evaluation of the measurement model, which assesses construct reliability and validity, and the structural model, which examines the hypothesized relationships between constructs [24]. The PLS-SEM method is also suitable for nonnormal data [25].

Our measurement model consisted of five reflective latent constructs, namely, (1) trust in DeepSeek, (2) intent to use DeepSeek for health-related purposes, (3) ease of using

XSL•FO
RenderX

DeepSeek, (4) perceived usefulness of DeepSeek, and (5) risk perception (Textbox 1). Each construct was measured using multiple observed indicators, with 3, 3, 2, 2, and 2 items, respectively. The constructs were assessed based on factor loading greater than 0.5. The reliability and validity were evaluated based on composite reliability (rho_C) greater than 0.70 [26] and average variance extracted (AVE) greater than 0.50 [26,27]. Variance inflation factor values were calculated to detect multicollinearity.

The validated measurement model was bootstrapped with 10,000 iterations to obtain the *P* values, bias-corrected standardized parameter estimates (β), and CIs. The model was controlled for education level, age, and sex. These were used as covariates in the model.

Sample Size Justification

Relatively large sample sizes are commonly used in structural equation modeling (SEM) to ensure robust parameter estimation and adequate statistical power. Although guidelines in the SEM literature vary, several rules of thumb have been proposed. Some recommend a minimum of 200 participants for most SEM applications. In contrast, others suggest having at least 5-10 respondents per estimated parameter in the model [28-30]. Our study's final instrument contained 12 key items spanning multiple latent constructs (eg, ease of use, trust, risk perception, perceived usefulness, and intent to use). Consequently, typical rules of thumb would indicate a desired sample size of 300 - 500 participants to meet assumptions of stable parameter estimation.

Results

Participant Characteristics

A total of 556 complete responses were collected. Geographically, 184 individuals were based in India, 185 in the United Kingdom, and 187 in the United States, reflecting an almost even split across these 3 locales. Regarding education, most respondents (n=214, 38.4%) held a bachelor's degree, followed by master's degree holders (n=153, 27.5%), high school graduates (n=142, 25.5%), those with some high school (n=24, 4%), and those with doctoral-level degrees (n=23, 4%). The sex distribution was nearly balanced, with 49.2% (n=274) identifying as male and 50.7% (n=282) identifying as female. In terms of age, 24.6% (n=137) were aged 26 - 35 year, 14% (n=78) were aged 18 - 25 years, 19.4% (n=108) were aged 36 - 45 years, another 19.4% (n=108) were aged 46 - 55 years, 15% (n=85) were aged 56 - 65 years, and 7% (n=40) were aged 66 years or older. Nearly 32.9% (n=183) used DeepSeek "once a month," 46.0% (n=156) used DeepSeek "once a week," 24.6% (n=137) used it "more than once per week," and 14% (n=80) used it "almost every day." Out of 556, about 55.4% (n=308) used DeepSeek primarily for academic and educational purposes, approximately 50.7% (n=282) used DeepSeek as a search engine, and 47.7% (n=265) used DeepSeek for health-related queries.

Participants' Perception of AI in Health Care

Responding to the question, "Will you be ok if your healthcare provider (doctor) uses similar AI tools for clinical purposes?" out of 556 respondents, only about 9% (51) were uncomfortable with their health care provider using similar AI tools for clinical purposes. About 59.3% (330) were fine with it as long as their doctor verifies the AI's input, while approximately 31.5% (175) would be enthusiastic about their provider using AI without any conditions. This suggests that while there are some reservations about the direct use of AI in clinical settings, most people are open to it if professional oversight is maintained.

As a response to this survey question, "To what extent can using such AI diagnoses increase patient safety?" nearly 5% (27) felt that using AI for diagnoses would not improve patient safety and might even put patients at risk. In contrast, 20.5% (114) believed that it would increase safety somewhat, while 29.3% (163) thought that it would do so moderately, and 27.5% (153) felt that it would enhance safety quite a lot. An additional 18% (99) believed that AI could increase patient safety to a great degree. Most respondents see a positive potential for AI in improving patient safety, with most expecting at least a moderate benefit from its use.

Participants' LLM Use Pattern

Responding to the question "In the last 6 months, how often have you used any large language model?" about 25.2% (140) indicated that they used an LLM once a month, while the largest group, 43.7% (243), reported using it weekly. Approximately 20.3% (113) of respondents mentioned using an LLM almost daily, and 11% (60) stated using it multiple times daily.

Participants' Intent to Adapt DeepSeek Over Other LLMs

As a response to the question, "How likely are you to switch over and use DeepSeek instead of other large language models like ChatGPT?" only a small fraction reported no intent to switch over to DeepSeek, with 3% (18) indicating that they would not consider it and 16% (87) saying that they are unlikely to make the change. A significant majority are open to the idea, with 52.1% (290) stating that they are likely to switch and an additional 28.9% (161) expressing that they are very likely to do so. This suggests that many users are ready to transition from LLMs such as ChatGPT to DeepSeek.

Measurement Model and Survey Validation

Table 1 shows survey responses on ease of use, trust, usefulness, intent for health use, and risk perception of DeepSeek. Respondents generally view DeepSeek favorably regarding ease of use, trust, and perceived usefulness. For instance, both ease of use items (E1 and E2) received strong positive responses, with nearly 90% of participants somewhat or strongly agreeing that DeepSeek is easy to use. Trust in the platform is similarly high, as indicated by most respondents strongly or somewhat agreeing with all trust-related items (T1, T2, and T3). perceived usefulness ratings are also robust, with most users acknowledging the benefits of DeepSeek. In addition, the intent to use DeepSeek for health-related purposes is positive, although slightly more moderate than the other categories. However, risk perception responses are more mixed, with a relatively even distribution across all levels of agreement.

Table 2 indicates a robust measurement model with strong evidence of convergent and discriminant validity across all

XSL•FO
RenderX

latent constructs. Convergent validity is supported by high AVE values: each construct exceeds the commonly accepted 0.50 threshold (ranging from 0.650 to 0.820), indicating that the items explain a substantial portion of their respective constructs. Likewise, rho_C and Cronbach alpha values are mostly well above the 0.70 benchmark, confirming internal consistency among indicators.

Table . Participants' responses to the survey questions used in the conceptual structural framework.

Observed variables	Strongly disagree	Somewhat disagree	Somewhat agree	Strongly agree
Ease of using DeepSeek, n (%)				
E1	17 (3.10)	39 (7.00)	267 (48.00)	233 (41.90)
E2	5 (0.90)	32 (5.80)	214 (38.50)	305 (54.90)
Trust in DeepSeek, n (%)				
T1	26 (4.70)	96 (17.30)	240 (43.20)	194 (34.90)
T2	8 (1.40)	46 (8.30)	268 (48.20)	234 (42.10)
T3	11 (2.00)	71 (12.80)	267 (48.00)	207 (37.20)
Perceived usefulness of DeepSeek, n (%)				
PU1	10 (1.80)	65 (11.70)	246 (44.20)	235 (42.30)
PU2	12 (2.20)	66 (11.90)	257 (46.20)	221 (39.80)
Intent to use DeepSeek for health-related purposes, n (%)				
IU1	27 (4.90)	80 (14.40)	246 (44.20)	203 (36.50)
IU2	36 (6.50)	108 (19.40)	233 (41.90)	179 (32.20)
IU3	25 (4.50)	71 (12.80)	257 (46.20)	203 (36.50)
Risk perception, n (%)				
R1	132 (23.70)	127 (22.80)	167 (30.00)	130 (23.40)
R2	66 (11.90)	139 (25.00)	185 (33.30)	166 (29.90)

Table . The measurement model and validation and reliability.

Constructs and observed variable	Factor loading	AVE[a]	Rho_C
Trust in DeepSeek		0.65	0.85
T1	0.82		
T2	0.78		
T3	0.82		
Intent to use DeepSeek for health-related purposes		0.70	0.88
IU1	0.85		
IU2	0.84		
IU3	0.82		
Ease of using DeepSeek		0.82	0.90
E1	0.90		
E2	0.91		
Perceived usefulness of DeepSeek		0.77	0.87
PU1	0.86		
PU2	0.90		
Risk perception		0.66	0.79
R1	0.97		
R2	0.64		

[a]AVE: average variance extracted.

Discriminant validity is supported by the Heterotrait-Monotrait ratios, nearly all of which fall below the critical value of 0.90 or 1.00. Variance inflation factor also ranged between 1.76 and 1.20, which is within the acceptable limits (less than 2.50) [31], indicating no multicollinearity. In addition, the R^2 values of 0.55 (adjusted 0.54) for intent to use DeepSeek for health-related purposes and 0.60 (adjusted 0.59) for trust in DeepSeek indicate that the explanatory power of the proposed paths is moderate to strong. The significant *t* statistics and *P* values across the key relationships further verify that the conceptualized constructs have been measured accurately, with only a few nonsignificant quadratic paths. These findings validate the measurement instrument and confirm that the theorized latent variables—ease of using DeepSeek, perceived usefulness, trust in DeepSeek, risk perception, and intent to use DeepSeek for health-related purposes—exhibit sufficient reliability and validity to warrant confidence in subsequent structural analyses. In addition to the overall validity of the measurement model, the findings also support the validity of the individual survey questions that served as indicators for each latent construct. First, the high factor loadings (as implied by the satisfactory AVE values) suggest that each item meaningfully contributes to measuring its intended factor, that is, users' responses to questions about ease of use, trust, perceived usefulness, risk, or intent to use strongly correlate with the respective latent constructs they were designed to represent. Second, the internal consistency indices (Cronbach alpha and composite reliability) confirm that groups of questions intended to measure the same construct hang together well, indicating that the survey items reliably capture the same underlying concept. Finally, the discriminant validity checks confirm that questions targeting one construct do not overlap excessively with those measuring other constructs; this indicates that the items' wording and content domains effectively capture distinct dimensions of user perceptions toward DeepSeek. These indicators demonstrate that the survey questions—and not just the overarching constructs—exhibit satisfactory validity.

SEM (Direct, Indirect, and Total Effects)

Table 3 shows that the path coefficients and mediation analyses provide strong evidence for most of the hypothesized relationships, although one notable exception emerged regarding risk perception. *Ease of use* (*H1*) has a significantly positive direct effect on trust in DeepSeek. This indicates that when users perceive DeepSeek as more intuitive and less effortful to operate, their trust in the system increases correspondingly. However, the direct relationship between *ease of use* and *intent to use DeepSeek for health-related purposes* (*H2*) is not statistically significant. Despite this, a significant total effect and a strong indirect path through *trust* confirm that trust fully mediates the impact of ease of use on user intentions. Hence, while there is no direct link between ease of use and intent, ease of use indirectly drives intent via trust, satisfying *H2's* broader premise when mediation is considered. *Trust in DeepSeek* (*H3*) exerts a strong, positive influence on *intent to use DeepSeek.* This suggests that once users develop confidence in DeepSeek's outputs, they are more inclined to rely on it for health-focused tasks. *Risk perception* (*H4*) shows a significant negative path coefficient, supporting the hypothesized relationship. This implies that higher perceived risk—as captured in the current measurement—correlates with a lower intent to use DeepSeek,

XSL•FO
RenderX

deterring adoption. The findings strongly support both direct and mediated effects concerning perceived usefulness.

Table . Direct, indirect, and total effects observed in the proposed structural framework.

	β[a] (SD)		
Paths	Direct effect	Indirect effect	Total effect
Ease of using DeepSeek → intent to use DeepSeek for health-related purposes	0.07 (0.058)	—[b]	0.25 (0.06)[c]
Ease of using DeepSeek → trust in DeepSeek	0.36 (0.05)[c]	—	0.36 (0.05)[c]
Perceived usefulness of DeepSeek → intent to use DeepSeek for health-related purposes	0.17 (0.05)[c]	—	0.40 (0.04)[c]
Perceived usefulness of DeepSeek → trust in DeepSeek	0.52 (0.04)[c]	—	0.52 (0.04)[c]
Risk perception → intent to use DeepSeek for health-related purposes	0.20 (0.03)[c]	—	0.21 (0.03)[c]
Trust in DeepSeek → intent to use DeepSeek for health-related purposes	0.45 (0.05)[c]	—	0.45 (0.05)[c]
Ease of using DeepSeek → trust in DeepSeek → intent to use DeepSeek for health-related purposes	—	0.16 (0.02)[c]	0.16 (0.02)[c]
Perceived usefulness of DeepSeek → trust in DeepSeek → intent to use DeepSeek for health-related purposes	—	0.24 (0.03)[c]	0.24 (0.03)[c]
Control variables			
Age → trust in DeepSeek → intent to use DeepSeek for health-related purposes	—	−0.02 (0.01)	−0.02 (0.01)
Age → intent to use DeepSeek for health-related purposes	0.09 (0.03)[c]	—	0.07 (0.03)[d]
Age → trust in DeepSeek	−0.05 (0.03)	—	−0.05 (0.03)
Education → intent to use DeepSeek for health-related purposes	−0.06 (0.03)	—	−0.04 (0.03)
