Abstract

Background: The growth of aging populations globally has increased the demand for new models of care. At-home, computerized health care monitoring is a growing paradigm, which explores the possibility of reducing workloads, lowering the demand for resource-intensive secondary care, and providing more precise and personalized care. Despite the potential societal benefit of autonomous monitoring systems when implemented properly, uptake in health care institutions is slow, and a great volume of research across disciplines encounters similar common barriers to real-world implementation.

Objective: The goal of this systematic review was to construct an evaluation framework that can assess research in terms of how well it addresses already identified barriers to application and then use that framework to analyze the literature across disciplines and identify trends between multidisciplinarity and the likelihood of research being developed robustly.

Methods: This paper introduces a scoring framework for evaluating how well individual pieces of research address key development considerations using 10 identified common barriers to uptake found during meta-review from different disciplines across the domain of health care monitoring. A scoping review is then conducted using this framework to identify the impact that multidisciplinarity involvement has on the effective development of new monitoring technologies. Specifically, we use this framework to measure the relationship between the use of multidisciplinarity in research and the likelihood that a piece of research will be developed in a way that gives it genuine practical application.

Results: We show that viewpoints of multidisciplinarity; namely across computer science and medicine alongside public and patient involvement (PPI) have a significant positive impact in addressing commonly encountered barriers to application research and development according to the evaluation criteria. Using our evaluation metric, multidisciplinary teams score on average 54.3% compared with 35% for teams made up of medical experts and social scientists, and 2.68 for technical-based teams, encompassing computer science and engineering. Also identified is the significant effect that involving either caregivers or end users in the research in a co-design or PPI-based capacity has on the evaluation score (29.3% without any input and between 48.3% and 36.7% for end user or caregiver input respectively, on average).

Conclusions: This review recommends that, to limit the volume of novel research arbitrarily re-encountering the same issues in the limitations of their work and hence improve the efficiency and effectiveness of research, multidisciplinarity should be promoted as a priority to accelerate the rate of advancement in this field and encourage the development of more technology in this domain that can be of tangible societal benefit.

Introduction

Background

With the general increase in global life expectancy and the ever-increasing ratio of retirement-age to working-age people, research in the scope of health and social care for older people is greatly increasing. As people live longer and the aging population grows, governments and international organizations are recognizing the need for a paradigm shift in the way we care for our older populations [1]. Current methods of care typically include a social care system to look after the most vulnerable and frail older adults, but as the size of this population increases at a faster rate than the working population, these institutional

XSL•FO
RenderX

models of care at the country level become progressively less practical and more costly. In response to this growing crisis, one solution researchers have sought to apply is the use of novel health monitoring technologies to tackle the problem of labor shortages in health care systems and to improve productivity and efficiency in care [2-11]. This can be in direct terms, for example monitoring systems that assist care professionals carrying out their duties within care settings [12] and also indirectly with at-home monitoring devices designed to reduce the occurrence of injuries by, for example, assessing gait [13,14] and predicting fall events [3,15], with the goal of reducing the potential burden on secondary care and ultimately reducing the burden on the care-home sector and keeping people at home, healthy, and independent for longer [9,16,17].

Research Hypothesis and Goals

The goals of this work can be summarized by the following 2 research questions:

1. Can we construct an evaluation framework for at-home health monitoring research and justify that a positive score in said framework broadly correlates with a higher likelihood of the research being effective in real-world use?
2. Can we identify the trends if they exist, between the method of research (single-discipline, multidiscipline, and the use of PPI or co-design) and the increase or decrease in effectiveness of said research?

In the context of this paper, “effective research” can be defined as research that is more efficient by being less prone to making oversights already identified in the existing literature across disciplines. We assert that research that addresses the already existing issues in the literature (and thereby scoring highly on our proposed metric) leads to more effective research and ultimately leads to products and platforms more likely to be usable in real-life applications (refer to the Evaluation Framework Justification in the Methods section for evidence of this).

To answer the research questions, this work is split into 2 phases, a scoping phase and evaluation phase. In the scoping phase, an overview is provided of the various systematic reviews across disciplines in the field of at-home health care monitoring for older adults. In doing this, we synthesize an evaluation framework based on the consensus and concatenation of these studies to measure the degree to which individual pieces of research encounter similar common problems. By defining this framework, observations can be made about the degree to which these problems are acknowledged by different types of research teams operating with or without multidisciplinarity, which types of issues are likely to be identified by which types of research, and how stakeholder involvement can improve the likelihood of developing an effective product. To justify this evaluation criteria and to address the first research question, examples of existing technologies in commercial use are positively evaluated by this approach to assert the positive relationship between a high evaluation score and the generation of more effective research, considerate to existing identified issues with real-world use (refer to the Methods section). To our knowledge, there is currently no evaluation methodology designed to measure research application effectiveness, based on multidisciplinary metrics.

In the evaluation phase. a review of individual works in the application of computerized at-home health-monitoring systems is then presented, with these works evaluated against the metric developed in the scoping phase, and with the results analyzed to address the second research question (refer to the Results section). For this evaluation phase, a total of 350 papers were found from the IEEE Explore, PubMed, and ArXiv databases, of which 60 papers were ultimately used, with the inclusion constraints being that the papers had to be individual pieces of original research relating either to the development of technology associated with the various applications of at-home older adult health monitoring or a review into the effectiveness of existing at-home health monitoring applications. This is including, but not limited to, development and deployment of disease diagnosis and progression analysis, fall detection and prevention, lifestyle monitoring, vital-sign monitoring, and smart-home systems. Candidate papers must present methods that have the prospect of or are already actively being tested in an at-home environment in whole or in part.

For this evaluation phase, a total of 350 papers were found from the IEEE Explore, PubMed, and ArXiv databases, of which 60 papers were ultimately used, with the inclusion constraints being that the papers had to be individual pieces of original research relating either to the development of technology associated with the various applications of at-home older adult health monitoring or a review into the effectiveness of existing at-home health monitoring applications. This is including but not limited to the development and deployment of disease diagnosis and progression analysis, fall detection and prevention, lifestyle monitoring, vital-sign monitoring, and smart-home systems. Candidate papers must present methods that have the prospect of or are already actively being tested in an at-home environment in whole or in part.

The Methods section contains the scoping phase and provides an overview of the literature in health monitoring technologies, constructing from them a concise evaluation framework in the form of a 10-point checklist criteria for research application effectiveness, based on consensus drawn from these works. The Results section presents the evaluation phase, reviewing individual pieces of research across disciplines using this evaluation framework. The interaction between multidisciplinarity and stakeholder involvement through PPI and co-design and the effectiveness of research are also analyzed here. Finally, the Discussion section summarizes the findings of this research and makes recommendations for how future health monitoring research should be conducted in order to improve the effectiveness of research in this field.

Research Contributions

The contributions of this paper can be summarized as follows:
:

1. A review of the recent literature of at-home health care monitoring. This is achieved by providing a 2-stage review of the literature, with the first (scoping phase) being a meta-review of reviews in the relevant literature, and the

XSL•FO
RenderX

second (evaluation phase) being a review of individual works across multiple disciplines in the area of at-home health monitoring.

2. The introduction of a comprehensive evaluation framework for assessing the likely real-world effectiveness of health monitoring application research, based on 10 key issues consistently identified from analysis of 15 literature reviews in the field across disciplines.
3. The identification and demonstration of various links between the manner of research and the effectiveness of research. We find that multidisciplinarity has a consistently positive effect in this respect, reflected by higher scores on the evaluation framework. We also find a convincing increase in scores when PPI and co-design methods are used.

The goal of this research is to concretely illustrate the necessity of multidisciplinarity for the success of at-home medical technology development and deployment and provide a framework for future research to reference when assessing the usefulness of their own applications.

Methods

Scoping Phase: Overview of at-Home Health-Monitoring in Older Adults

To identify the most common barriers to uptake in this field, an overview of 12 systematic and other review papers from 2014 onwards was conducted to identify and collate the common issues within some of the common subdisciplines of at-home health care monitoring: encompassing any autonomous monitoring methods used in a domestic context such as camera-based applications, wearable sensors, remote sensors, and ensemble smart-home systems. Table 1 provides a concise summary of the main reviews investigated, and the presence of each of the commonly identified barriers among them. Broken down in Table 1 are the makeup of the teams involved in the research, multidisciplinary, technical, or application-based. In the context of this work, “Technical” concerns research conducted by engineering or computer science teams, with “Application” making up all other types of research team, but predominantly teams in the fields of medicine and social science. In total, 10 core barriers are identified across these reviews and synthesized to be inclusive of all the barriers identified in all the systematic reviews evaluated in this section. An exact breakdown of the presence or absence of the 10 points in each review is available in the supplementary materials (refer Table S1 in Multimedia Appendix 1).

Table . Overview of systematic reviews and their evaluation score according to the evaluation metric.

Paper title and reference	Description	Research team	Score (%)
Are Active and Assisted Living applications addressing the main acceptance concerns of their beneficiaries? [18]	Overview of opinions of older adults regarding concerns with ambient assisted living technologies.	Multidisciplinary	50
A critical review of smart residential environments for older adults with a focus on pleasurable experience [5]	Review of older adults in focus groups for a variety of smart home applications.	Multidisciplinary	30
Smart homes and home health monitoring technologies for older adults: A systematic review [6]	Investigation of the abilities of various smart-home technologies, alongside feasibility and technical limitations.	Application	70
Health Monitoring Using Smart Home Technologies: Scoping Review [8]	Review of smart home environments, specifically on existing study design limitations alongside technical limitations.	Application	50
Older persons have ambivalent feelings about the use of monitoring technologies [2]	Series of 5 focus groups of older adults attempting to build consensus on the concerns of smart home implementations.	Application	60
Older adults' perceptions of technologies aimed at falls prevention [3]	Systematic review of focus group-based studies to build consensus on the main factors hindering at home uptake.	Application	40
Unobtrusive sensing and wearable devices for health informatics [11]	Overview of 4 main sensor-based monitoring technologies including relative benefits and drawbacks.	Technical	40
Wearable sensors for remote health monitoring [7]	Overview of specifically wearable health monitoring technologies, mostly centered on technical benefits and limitations regarding data.	Technical	40
Unobtrusive health monitoring in private spaces: The smart home [10]	Overview of smart home. Applications with a focus on perceived "unobtrusive" applications.	Technical	20
Detection and assessment of Parkinson's disease based on gait analysis: A survey [14]	Overview of gait assessment monitoring for age-related disease detection using a variety of classical and ML[a]-powered monitoring technology.	Technical	0
Remote patient monitoring using AI[b] [9]	Overview of classical and deep learning-based AI applications in primarily at-home patient monitoring.	Technical	20
Factors Determining the Success and Failure of eHealth Interventions [16]	Overview of smart home. Applications with a focus on discovering the key factors behind the success or failure of med-tech applications.	Multidisciplinary	70

[a]ML: machine learning.

[b]AI: artificial intelligence.

"Research Team" denotes whether the teams conducting the research were technical or medical-based. See further in this section for a breakdown of the 10 common identified points and refer to the supplementary material for a specific breakdown of which barriers are present in each. The score value was computed by aggregating which of the 10 features were addressed in each review. Beyond these key reviews from which the evaluation framework was constructed, there are numerous other reviews and surveys whose findings are inclusive of the framework outlined at the end of this section (refer to Table S2 in Multimedia Appendix 1 for a full breakdown of the 13 reviews). Only the core 12 are included here for brevity, with these 12 being selected as they encompass all of the core at-home health care methodologies, include examples of all 10

XSL•FO
RenderX

key points that make up the framework, and represent a roughly equal variety of research teams, namely multidisciplinary teams (n=3), computer science (n=3) engineering (n=2), medical (n=2), and social science (n=2).

Table . Scoring of 2 current at-home monitoring projects being developed with the intention of widespread use. The factors are numbered corresponding to the attribute list given in the attribute list above. Y or N indicates "yes" or "no" as to the presence of the factors.

Project Name	Description	Factors (Y or N)									
		1	2	3	4	5	6	7	8	9	10
SPHERE[a] [19-21]	Smart-home system for behavior monitoring, under development for several years and the feature of multiple research studies.	Y[b]	Y	Y	Y	Y	Y	Y	Y	N[c]	Y
HALLEY[d] [22]	Internet of things-based Smart-home development project currently in commercial development.	Y	Y	Y	N	Y	Y	Y	N	N	Y

[a] SPHERE is a multi-year smart-home development project based in England which has been involved both in commercial smart-home production as well as research.

[b] Y: yes.

[c] N: no.

[d] HALLEYASSIST is a company based in Australia involved in developing multiple healthcare monitoring devices for a smart home context.

The study by Ghorayeb et al [23] presents a number of insights in their review of the literature regarding older adults using smart-homes, such as identifying solutions to the problems in most research applications. For example, they assert that gradual introduction of smart-home technology combined with the ability to “pause” it at will to provide “emotional release” is highly desired in end users for a more pleasant experience. They also find that more tech-literate people tend to have less concerns with the technology due to an improved understanding of the data being collected and the privacy risks involved, if any. One other concern identified was transmission of data and the insecurities associated with this, leaning to a user-preference that data should be handled manually instead of through remote connection. These findings are all further reinforced by the findings in [24], which similarly conduct interview sessions with 20 older adults regarding which aspects of health-monitoring systems concern them. These findings inform points 4 and 5 in the evaluation metric, defined in Methods section.

Regarding data access, the study by Robinson et al [25] finds that older adults could in some cases want control of data access to withhold the data from certain parties, namely their family and friends, for fear of burdening them as well as the parallel desire some express that they do not want to be micromanaged by their loved ones or health care providers, informing points 6 and 8 of the framework. Cost was also an identified challenge (informing point 3), for example focus group attendees in [2] were concerned by the cost of long-term use of monitoring devices, with the implication being that they would have to buy them outright.

The study by Hawley-Hague et al [3] discovers that when surveyed, there is a broad perception that older people view new advancements in smart-home related technology as good but “unnecessary for them,” as they don’t perceive themselves as being “unhealthy enough” to merit using what they see as a drastic action toward greater care. Mann et al [26] found in their study of 661 older people that a slim majority (56.3%) perceived smart-home technology as not being of use to them specifically.

XSL•FO
RenderX

Ghorayeb et al [23] identify a series of factors through their investigation with older participants which are crucial to account for when considering the integration of new technology into real life. These factors range from societal stigma to technical reliability, covering points 1, 2, 3, and 6 in the evaluation framework. Research in studies by Boström et al and by Boström et al [2] and Liu et al [6] also point to the issues surrounding the implication of autonomous monitoring being a decline in human contact, addressed by point 7. In the systematic review conducted by Ghorayeb et al [23], observations were made regarding the progression of smart-home technologies. Regarding patient acceptability, they note that less than half of the papers reviewed take into consideration the acceptability of their technology where privacy is concerned: with the focus of the paper instead being explicitly about the functions of the novel technology. Some steps taken toward improving privacy in certain papers included encrypting collected data [27] and locking data access behind authorization [28].

Regarding health care professionals, their main concerns with smart-home technology and health care monitoring concern the feasibility of use. Unlike patient acceptability, acceptability by health care professionals is underresearched, where many papers will either focus on the technology being developed and not address it in application or they will focus only on the opinions of the end users and how they will use and accept the technology [29]. This finding is echoed in the lack of surveys found in the scoping review in the Results section, where the focus is on health care professionals rather than patients. Of the 60 papers in the scoping review, only 7 made any explicit use of external medical caregivers in their research development.

Evaluation Framework Criteria

Across the review papers both in Table 1 and the other reviews referenced in this section, the following list of 10 factors were collated to encompass all the common considerations identified when designing and implementing novel monitoring technology for use with older adults in a domestic environment. They are segmented by category of concern (technical, application, or multidisciplinary), where the technical are purely engineering or computer-science implementation concerns and application are concerns involving human interaction with the technology and any adjacent concerns important to medical and social science-based disciplines. The framework is as follows (Textbox 1).

Textbox 1. The evaluation framework

- Usability-technical: concerning the use of the technology and how feasible it is to be used by caregivers, health care professionals, and end users.
- Accessibility-technical: this concerns the ease of use by laypeople of the computer technology and the barriers for entry in terms of effectively using the technology.
- Reliability-technical: covers issues relating to the long-term viability of the application, for example, is it expensive, does it require upkeep, charging or maintenance.
- Control-multidisciplinary: concerns the level of access both patients and health care staff should have to the application and the data it records.
- Privacy-multidisciplinary: constitutes issues relating to the intrusiveness of the data being collected, and the manner in which it is collected.
- Stigma-application: anything relating to the societal pressures and negative connotations people may feel by using monitoring technologies for the purposes of personal health.
- Lack of human response-application: concerns the issue of the perception that increased autonomous monitoring would result in a decrease in person-to-person interaction as a result.
- Burden to others-application: regarding the perception of older adults that additional at-home monitoring is representative of applying additional pressure on their caregivers.
- Lack of perceived need-application: concerns a commonly identified phenomenon in the literature that people have a tendency to think a technology is useful but unnecessary for them personally.
- Affordability-application: this concerns the cost both on a personal and institutional level to implement solution applications in real life.

Evaluation Framework Justification

To demonstrate the descriptive power this evaluation system has to the likelihood of success in application, Table 2 provides an overview of papers concerning 2 technologies being developed for commercial use (Sphere [21] and HalleyAssist [22]), and the degree to which the prior research and development of these systems adhere to the criteria in the evaluation metric, with scores being calculated based on all existing literature regarding each technology, as opposed to individual articles. Both have demonstrated a commitment to addressing barriers relating to both technical and human elements, addressing 90% and 70% of the evaluation metrics respectively (the average score across the scoping review in the Results section is 36.2% for comparison). They also both were developed by a multidisciplinary research team from computer science and signal processing to nursing, geriatric medicine and social care, with both systems now being in varying stages of commercialization. The relationship between the absence of certain metrics such as multidisciplinarity and the lack of consideration for common barriers to uptake is further concretely illustrated during the analysis at the beginning of the Results section. While these are only 2 data points and cannot be said to constitute a trend on their own, it can be asserted that they provide a strong positive indication that successful applications are likely to score highly on the introduced metric.

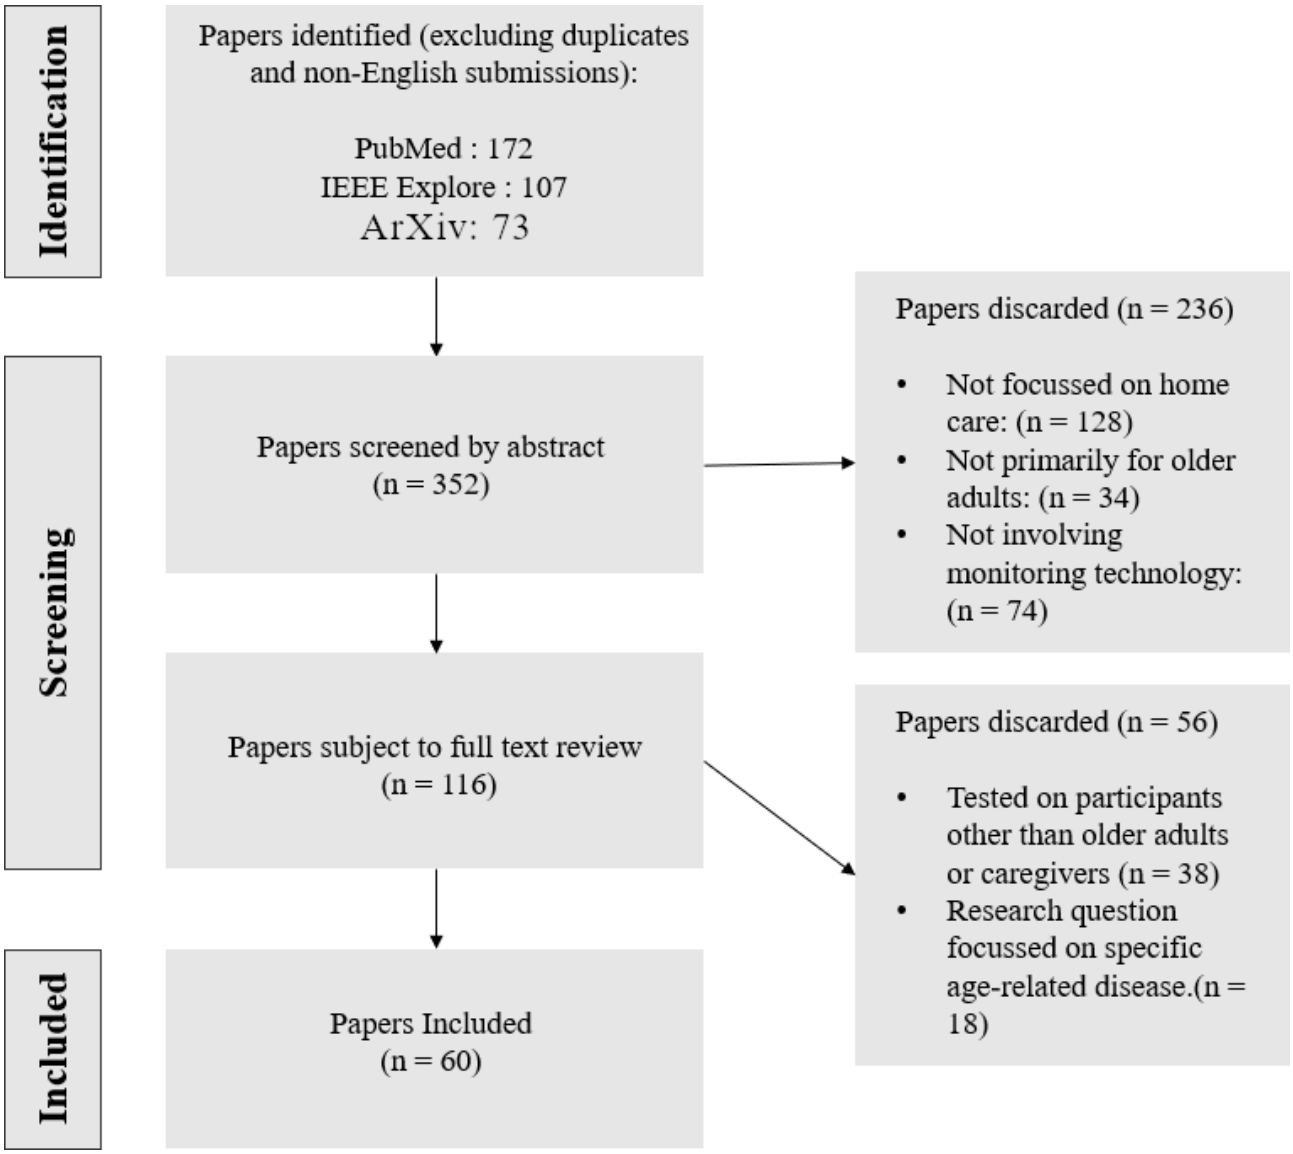
Results

Evaluation Phase: Scoping Review and Parameters

Figure 1 illustrates the selection process for papers considered for the scoping review. From the 3 databases, the following search term was used:

((healthcare monitoring) AND (older adult)) AND ((home) OR (at-home) OR (domestic)) AND ((obtrusive) OR (unobtrusive) OR (intrusive)) AND ((machine learning) OR (AI) OR (artificial intelligence))



with the exception of the ArXiv database, where the

((obtrusive) OR (unobtrusive) OR (intrusive))

section was omitted for a larger range of initial texts. Language was restricted to English and the date was restricted to 2014 or later, with the search commencing on January 7-24, 2024. Excluded were papers that did not in whole or in part reference older adult monitoring as the purpose of their application or review, and papers where the application was specifically designed for care homes or hospitals. The initial search yielded a total of 352 papers. Paper title and abstract analysis excluded 236 papers, which resulted in 116 remaining, with the final count being 60 papers after a full-paper review resulting in 56 more deletions (Figure 1).

The following section is broken down by technical and application-based research, following the definitions for both established in the beginning of the Methods section. Papers defined as multidisciplinary are those in which the research team consist of at least 1 person from each category.

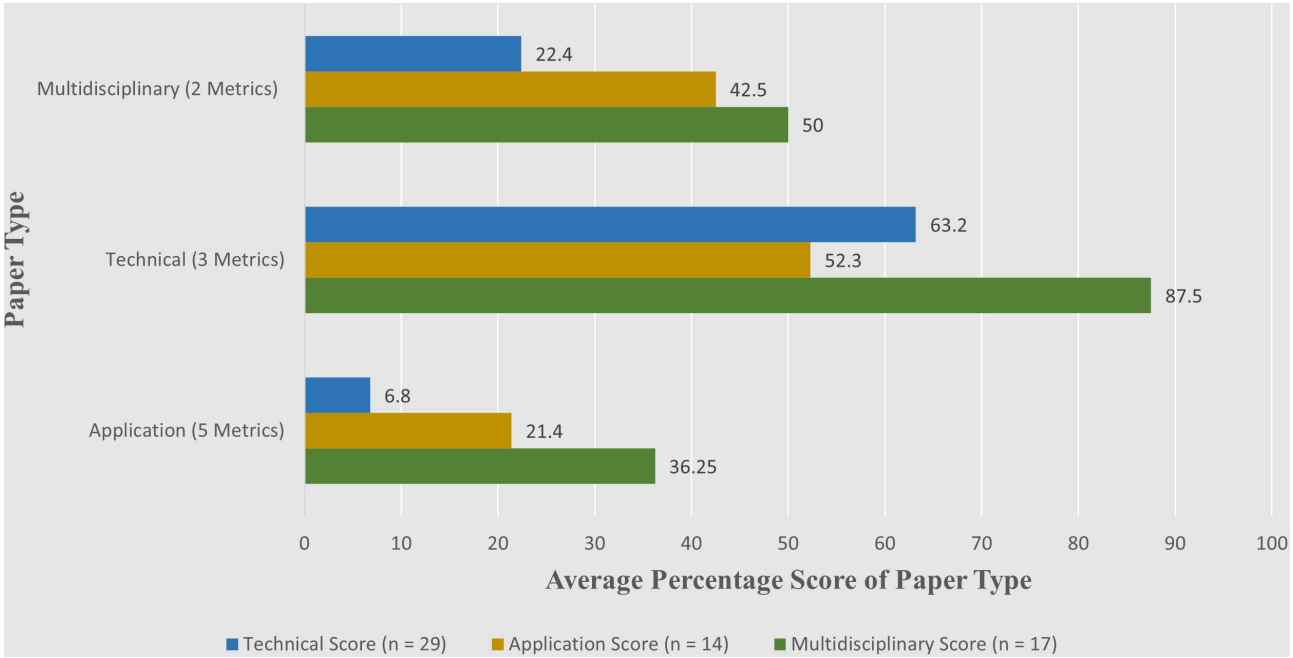
Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram: screening process illustration for the scoping review portion of this research.

Technical Research

The majority of research in this space relies either on traditional or neural network–based machine learning methods to make their systems effective and largely automatic. Researchers in [30] construct a machine learning model that can differentiate between regular, prefrail, and frail gait within a population of 50 older adults at an accuracy of 88.5% based on gait data

XSL•FO
RenderX

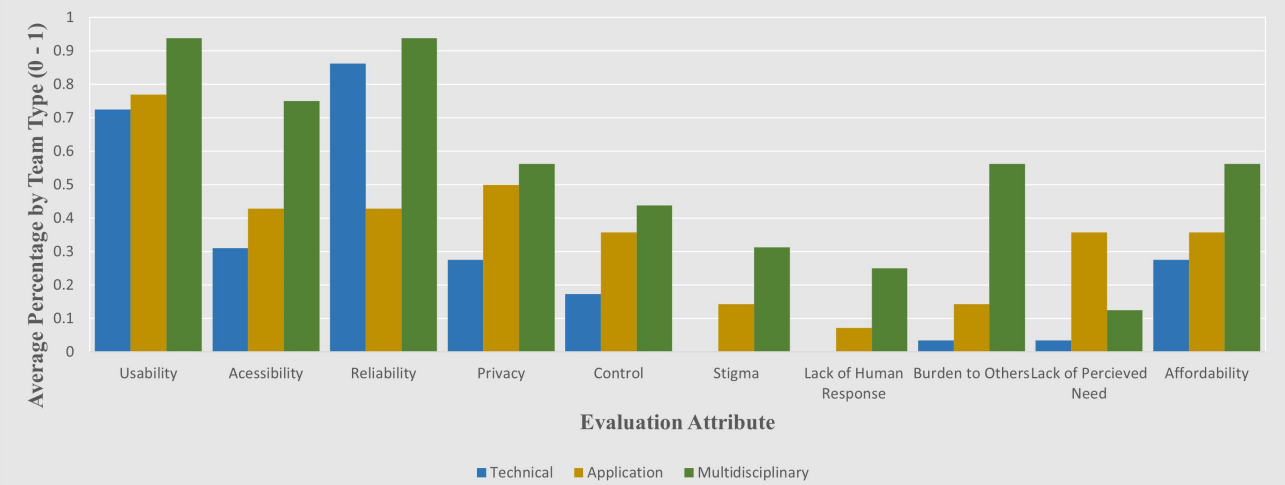
collected from wearable accelerometer signals. They rely mostly on “traditional” methods of machine learning: that is, machine learning methods that don’t use deep neural networks.



With vision-based applications, on the other hand, deep neural networks, especially convolutional networks designed specifically for processing image data, are frequently used. Researchers in the study by Lin et al [31] use a novel 3D convolutional neural network (CNN) to process gait silhouette images from the CASIA-B dataset [32] to achieve a person-identification accuracy of 97.6%. While the question of person identification through gait can be fairly trivially solved with modern CNN frameworks, the question of gait analysis, or assessing health requires a more nuanced approach and is still an active research area.

Researchers in [33] use a Spatiotemporal Graph Convolutional Network (ST-GCN) [34] framework to assess Parkinson disease severity as classified under the Unified Parkinson’s Disease Rating Scale [35]. The ST-GCN is an extension of the standard CNN model that works specifically on skeletal graph data as opposed to raw images, and works by processing input data with sequential attention to both the spatial and temporal dimensions of the input. As gait assessment is a far more complicated problem than simple person-identification or even traditional action recognition, they achieved 53% F_1-score using a dataset of 53 individuals with Parkinson disease.

Recently, in the study by Yin et al [36], the Spatio-temporal joint adjacency GCN (STJA-GCN) was developed that uses 3 input streams for joints, bones and velocities, a novel joint attention module to emphasize spatial data and a simplified skeletal graph input architecture to achieve state-of-the-art results (93.17% and 92.08%) on the domain of recognizing and classifying different types of abnormal gaits compared to other ST-GCN–based methodologies. This was tested on a pair of synthetic gait datasets introduced by the researchers, totalling 22 participants and 8600 instances of gait data collected from a total of 7 sensors across the 2 datasets.



Demonstrably, machine learning methods are extremely capable in multiple health care monitoring applications, necessitating the inclusion of highly technical fields in this type of research. The issue with the papers in this field, however, is that they score poorly on the proposed evaluation framework due to an overt focus on technical innovation at the expense of applicational concerns as well as scoring consistently lower than papers in the applicational and multidisciplinary categories on all but explicitly technical metrics (Figure 2). This analysis indicates a narrow focus almost purely on the effectiveness of the technology at the expense of an omission of application considerations, such as cost or perceived need by end users and medical stakeholders (refer to Figure 3 for a per-category breakdown). End users in this context refers both to patients and health care professionals who would be involved with the use of the technology (such as general practitioners, nurses, physiotherapists, occupational therapy and care workers). Stakeholders, on the other hand, refers to family members, friends or dependents of the patient using the technology. To take a more concrete example of this narrowed focus, research by Brunzini et al [13] is explicitly geared toward the development of a decision-support algorithm for health care professionals, complete with bespoke visual aids. However, there is no evidence of consideration of the requirements of health care professionals who would prospectively use such a system (in this case namely GPs, geriatricians, and nurses) being used in the design of the system itself. Similar issues were found in several studies where technical teams sought to develop assistive tools for caregivers or patients without direct involvement of prospective caregivers or end users, ranging from tools designed for doctors and nurses to carers, physiotherapists, and occupational therapists [37-41].

Figure 2. Illustration of evaluation performance per-evaluation category. Shown here is the impact that the use of multidisciplinarity has on the likelihood of each of the 10 metrics being taken into consideration.

XSL•FO
RenderX

Figure 3. Breakdown of the average presence of each evaluation attribute by research team type.

Application and Multidisciplinary Research

Of the surveyed technical papers (n=29), they scored an average 6.8% on the application-centered metrics in the proposed evaluation framework (Figure 2). In contrast, the application papers (n=14) mainly authored by health care researchers scored 21.4% on application-based metrics. While this indicates that application focused papers typically address more concerns with real-life deployment of research solutions, there is also a notable trend that this focus on application comes at a slightly increased tendency to neglect technical aspects of research (with both technical and multidisciplinary papers outperforming application-based papers on technical metrics). A clear trend can be seen in multidisciplinary papers consistently outperforming technical or application-based papers, even on the metrics specific to their own discipline (Figure 3).

As indicated in the second research question in the Introduction, we speculate that there exists a relationship between the inclusion of different stakeholders in PPI and co-design with the effectiveness of the resultant applications and research. As indicated by Table 1, this type of inclusion is usually implemented using focus groups. In this section, we highlight the typically moderate-to-high scores where this stakeholder input is prioritised, whilst also outlining other areas of shortcomings that follow from lack of multidisciplinarity in other, mainly technical domains.

In the study by Mireles et al [42], a total of 75 health care professionals (mostly nurses, n=47) are interviewed as a means of investigating the effectiveness of 3 different eHealth technologies for at-home monitoring of older adults with chronic conditions. Scoring 40%, this research focuses on the implications of e-health solutions as they affect end users, namely stakeholders, with less consideration for the technical implications of their recommendations. Research in the study by Bjornsdottir and Ceci [43] is similar, conducting qualitative interviews with both health care professionals and also patients. By including the patients and getting their insight, this research scores higher (60%) but suffers on the same technical metrics, highlighting the shortcomings in the systems they are evaluating without explicit consideration of the technical implications of their conclusions. In [44], 5 focus groups were conducted with both older adults and caregivers; namely family and care staff, to help synthesize a consensus on the design of future at-home sensor-based systems, with a focus on acceptability, respect for privacy and how to best provide control of care to the end users themselves. Scoring 50%, the authors neglect aspects such as system reliability at the expense of greater privacy, and other application-driven barriers such as societal stigma and the threat of greater isolation resulting in the deployment of remote monitoring technology. Expanding on this focus-group centered research [45], conduct a series of interviews with both formal and informal caregivers to identify the key parameters which need to be addressed to achieve effective at-home lifestyle monitoring systems. Scoring 60%, their strengths come from the inclusion of both medical and end user input, however they similarly lack extensive consideration for how the parameters being set by stakeholders would affect the performance of the monitoring systems themselves. Itoh et al [46] investigated issues of application from a medical perspective but score only 40%. Not only does their investigation consist only of testing an existing technology without the intention of developing said technology further, they also concern their research only with application concerns as far as the caregivers and medical stakeholders are concerned, with no involvement being afforded to the end users and patients. As a result, issues around stigma and even privacy are completely unaddressed.

As can be seen in Table 3, there is a clear lack of involvement in research and application design from the medical community and caregivers. Overall, 13.7% and 64.2% of single-discipline papers involve end user participation versus a mere 14.2% and 0% exhibiting caregiver or medical participation in the development of the research (for application and technical based papers. respectively). While the likelihood of involving both types of stakeholders (caregivers and end users) is more than double when multidisciplinary teams are involved (14.2% vs 37.5%), this is not conclusive due to the relatively small number of papers in each category when divided by the inclusion of different stakeholder types (end user and caregiver). Likewise, there is a definite trend across all research team types that exhibit lower evaluation scores when neither caregivers nor end users participate in the design or evaluation of research. However, discerning the differing impact between the 2 stakeholder types is difficult due to the small positive sample size (with only 2%

XSL•FO
RenderX

separating end user only and caregiver only scores for both research team types, refer to Table 4). The trend in the research, especially in survey-style research seems to be to focus on end users rather than caregivers or other medical stakeholders with only 7 of 60 papers involving medical stakeholders and 22 of 60 involving end user input.

Table . The presence or absence of caregivers and end users in the co-design of research across the review, split by research team type.

Team type	Caregivers (%)	End users (%)	Total (%)
Multidisciplinary[a]	37.5	56.25	*37.5*
Application[a]	38.4	64.2	14.2
Technical[a]	0	13.7	0

[a] Values are not mutually exclusive and some papers have both caregivers and end users involved. As a result, values may not necessarily add up to 100%.

Table . The average evaluation score by research team type when caregivers and end users are included or not in the research.

Team type	Neither (score %)	Caregivers (score %)	End users (score %)	Caregiver and End users (score %)
Multidisciplinary	35.7	70	68	70
Application	27.5	40	42	43
Technical	24.8	0	35	0

The strongest scores using the evaluation framework come from those where interdisciplinary teams are used (average score of 5.43 versus 3.5 and 2.68 for application-based and technical teams respectively), with a distinct trend shown in Table 4 indicating the presence of caregiver and end user involvement in a co-design or PPI capacity leads to a stronger evaluation score.

In general, as shown in Figure 3, different categories of research team tend to neglect certain aspects identified in the evaluation framework. Technical papers struggle with “Stigma” and “Human Response,” and application-based papers, mostly led by medical teams often omit factors such as “Accessibility“ and “Burden to Others” from their consideration. Both tend to struggle particularly with addressing societal stigma, possibly due to the varying levels and types of stigma for at-home monitoring from researcher’s home countries, or potentially due to considerations for more general issues not directly related to their specific research being deemed as outside of the scope of their work.

A common theme across all of these works is the tendency to make assumptions on the necessity of their application in the eyes of end users (Figure 3), as the lack of perceived need is seldom addressed regardless of the make-up of the research team. Technical issues are generally well addressed such as usability and reliability, however broader human issues such as societal stigma and feelings of end users becoming a burden, or the technology itself being a burden to use by caregivers are likewise rarely addressed. Across the entire evaluation phase, there is a consistent trend of greater representation of every attribute when multidisciplinary teams are involved in the research, with specifically technical teams being especially susceptible to a lack of focus on application-based concerns.

Discussion

Principal Findings

The research presented here concludes that a root problem underlying the issues affecting real-life uptake of research applications is the lack of multidisciplinarity in the research. We find that the developed evaluation metric is effective for quantifying the likelihood an application will transition into further development and effective deployment in real-world use. We also identified a series of common themes across the literature, namely the consistent underrepresentation of end users and other stakeholders in research, a distinct lack of multidisciplinarity in technical applications and the consistent underappreciation of societal factors such as stigma and human contact when developing at-home medical technologies.

Using a novel evaluation metric based on the 10 key barriers to uptake identified in the literature, a concrete trend can be observed that that multidisciplinarity between engineers, computer scientists, medical experts, and social scientists, alongside co-design or PPI-based inclusion of caregivers (such as family, friends, or dependants) and end users (health care professionals or patients) is highly beneficial to the effective development of technology that has direct practical application and tangible social benefit. The evaluation framework itself was also justified by the demonstration of a trend of extremely high evaluation scores on research projects that had reached the point of successful practical application, namely HalleyAssist and SPHERE. Using this evaluation metric, we find an increase of between 19.3% - 27.5% for multidisciplinary teams versus single discipline, and an increase of between 7.4% - 19% when research includes the use of caregivers or end users in a PPI or co-design capacity.

RenderX

Limitations and Future Work

The main limitation of this study is that the results can only demonstrate the lack of multidisciplinarity is a root issue, not necessarily the root issue. For example, many extenuating factors not included in the research itself can explain why effective technology was researched but not developed, such as personal material conditions for the researchers, leading them to be uninterested or unable to develop effective research further. One other limitation is in the methodology of the framework itself. Ways to improve the descriptive power and nuance of the framework could be to introduce more criteria, break the criteria down into further subdisciplines or introduce criteria weighting so that criteria deemed more “vital” or less common are weighted higher when calculating the score. Had more resources been available, a broader review in both phases could have been conducted, using a greater number of papers from a greater number of databases, an especially important factor given the number of different disciplines relevant to this type of research.

In future, a larger study could be conducted on the literature to further verify the effectiveness of the evaluation framework, including the application of the framework to more smart-home technologies in commercial development. The framework itself could also benefit from being imbued with greater complexity for example, additional factors or a bespoke weighting of them to make certain factors more important to the success of a technology in application, and thus scoring a higher score. To our knowledge there is no comparable work in quantitatively assessing the effects of multidisciplinarity on research in at-home health monitoring, so in general, more research is needed to saturate the domain and allow for trends to be more concretely identified. As HalleyAssist and SPHERE are leading examples in the area of in-home monitoring of ageing singles, it would be good to follow up their development and experiences in the future, to see how well the assessment undertaken here was predictive of their successes.

Acknowledgments

This research was funded by the Legal and General Group (research grant to establish the independent Advanced Care Research Centre at University of Edinburgh).

Authors' Contributions

CL and RBF were both involved in the conception of the paper, with CL carrying out the literature reviews and being the primary drafter of the manuscript. RBF was also responsible for supervisory support and redrafting and revising the manuscript. Both authors have given final approval for the manuscript presented for publishing.

Conflicts of Interest

This research was funded by the Legal & General Group (research grant to establish the independent Advanced Care Research Centre at University of Edinburgh). The funder had no role in the conduct of the study, interpretation or the decision to submit for publication. The views expressed are those of the authors and not necessarily those of Legal & General. To the authors knowledge there are no conflicts of interest during the undertaking of this research.

Abstract

Background: Rehabilitation aims to restore and optimize the functioning of impaired systems for people with disabilities. It is an integral part of universal health coverage, and access to it is a human right.

Objective: We aimed to identify the key challenges to rehabilitation services in Sub-Saharan Africa from a user, health system, and service provider perspective.

Methods: This scoping review was conducted in accordance with the 5-stage framework proposed by Arksey and O'Malley. A comprehensive electronic search was run to identify published articles on rehabilitation services in Sub-Saharan Africa. Of the 131 articles retrieved, 83 articles were assessed for eligibility and 15 papers that met the inclusion criteria were considered.

Results: The results show that people with disabilities in Sub-Saharan Africa face multifactorial challenges to access rehabilitation services. Poor access to rehabilitation services is associated with less attention given to rehabilitation by governments, which leads to less funding, negative cultural and social beliefs, fewer rehabilitation centers, poorly equipped rehabilitation units, failure of health systems, lack of training to rehabilitation practitioners, and logistical and financial constraints. This review also reveals that digital rehabilitation reduces costs and improves access to services in hard-to-reach geographical areas. However, digital rehabilitation faces challenges as well, including connectivity issues, inaccessibility to technology, a lack of technical knowledge, a lack of privacy, and ethical concerns.

Conclusions: People with disabilities face multifactorial challenges to access rehabilitation services in Sub-Saharan Africa. It is therefore critical to address these challenges to optimize patients' health outcomes and offer better rehabilitation services.

KEYWORDS

challenges; users; health system; service providers; Sub-Saharan Africa; scoping review; rehabilitation service

Introduction

Rehabilitation refers to a set of therapeutic approaches that are structured to address physical, developmental, emotional, and mental challenges and improve patients' health outcomes and quality of life [1]. Rehabilitation is an integral part of universal health coverage and contributes greatly to the achievement of the United Nations' Sustainable Development Goal 3, which aims to ensure healthy lives and promote well-being for people of all ages [2]. Access to rehabilitation for people with disabilities is a human right, as stated in Article 26 of the United Nations Convention on the Rights of Persons with Disabilities [3]. Rehabilitation services can be either delivered through traditional face-to-face methods or, using remote approaches, facilitated by existing technologies [4,5]. Digital rehabilitation has reduced costs and improved access to rehabilitation services in hard-to-reach geographical areas [5].

Demographic changes that lead to chronic health conditions and accidents have gradually contributed to the increased need for rehabilitation services [6]. It is estimated that 2.4 billion people have a health condition that may benefit from rehabilitation services; however, these services are still

XSL•FO
RenderX

inaccessible due to a shortage of rehabilitation practitioners [1]. A World Health Organization (WHO) report disclosed that the ratio of skilled rehabilitation practitioners to patients is 10 to 1,000,000 in low- and middle-income countries. This leads to a persistent scarcity of health-related human resources and reduced access to rehabilitation services in low-resource regions [7].

Sub-Saharan Africa (SSA) has a shortage of health-related human resources, with the region accounting for only 3.5% of the world's health workers, despite it having a high disease burden that includes several kinds of disabilities [1]. In this low-resource region, there is a significant difference in the availability of and access to rehabilitation services, and this impedes individuals with disabilities from achieving their desired health outcomes [8,9]. The WHO reported that in SSA, 50% of people do not get the rehabilitation services they need, and a high proportion of people with disabilities with unmet needs are in low- and middle-income countries [10].

Demand for rehabilitation services in SSA is well established given the prevalence of unmet rehabilitation needs, the rising cases of noncommunicable diseases, and the significant incidence of road traffic accidents that result in disabilities. Additionally, lack of access to rehabilitation services for people with chronic conditions can lead to a need for assistance with activities of daily living and long-term hospital stays [11]. It is important to explore the rehabilitation challenges faced by users, health systems, and service providers. This scoping review aims to enhance our understanding of the complex demands imposed by these factors in SSA and examine the challenges associated with rehabilitation services from those 3 domains.

Methods

Study Design

This review follows the framework of conducting scoping reviews as proposed by Arksey and O'Malley [12]. This framework consists of 5 distinct stages: identifying the research question; identifying relevant studies; selecting studies; charting the data; and collating, summarizing, and reporting the results.

Identifying the Research Question

The research topic and its associated objectives helped to determine the scope of the review, appropriate literature, search strategy, and inclusion and exclusion criteria. To attain the main aim of this review, the scope of rehabilitation services in SSA was explored and key challenges that users, service providers, and health systems face on the availability of and access to rehabilitation services were identified.

Identifying Relevant Studies

Search Strategy

A comprehensive electronic search was conducted to retrieve published data on the availability of and access to rehabilitation services in SSA. Research studies published in reputable journals and databases such as PubMed, National Center for Biotechnology Information, Scopus, PLOS, BioMed Central, Taylor and Francis, Science Direct, Frontiers, Springer Nature, and Web of Science were chosen, as they yielded the most topic-relevant articles. A search strategy using the keywords "rehabilitation services," "availability," "access," and "Sub-Saharan Africa" was used. To increase the number of accessed literatures, "Sub-Saharan Africa" was replaced by the name of the country, and "rehabilitation services" was replaced by specific types of rehabilitation services such as physiotherapy, occupational therapy, speech and language therapy, and prosthetics services. To maximize the literature coverage and to provide additional evidence, reference lists of primary studies and review articles were screened to identify additional relevant literature.

Inclusion and Exclusion Criteria

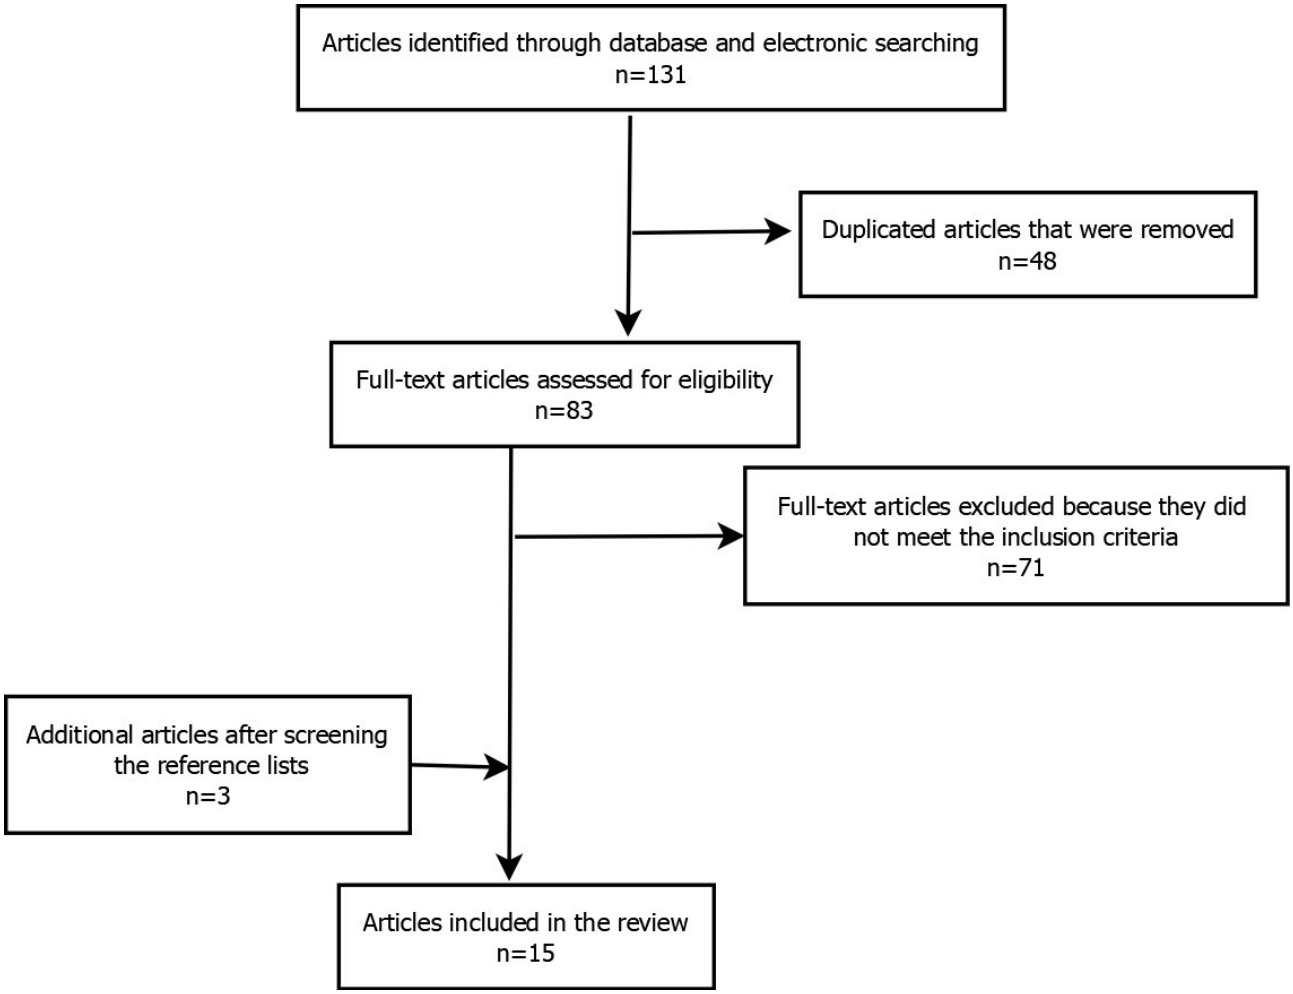
Inclusion criteria were developed to ensure that all relevant publications focusing on availability of and access to rehabilitation services in SSA were included. Works written in English and published in the above-mentioned reputable journals and databases between 2018 and 2023 were considered. Articles not written in English, published before 2018, and that did not report on rehabilitation services in SSA countries were excluded.

Study Selection

One team member led the search and screened the titles and abstracts of all retrieved papers based on the inclusion and exclusion criteria. Articles retained for review were confirmed by the research team after discussion. Duplicates were removed and the articles that satisfied the inclusion criteria were selected for full-text review.

Charting the Data

With the help of Microsoft Excel, data on availability of and access to rehabilitation services were extracted from the full texts. Challenges faced by users, service providers, and health systems were recorded. Information such as the title of the paper, names of authors, year of publication, study setting, study design, objectives of the paper, inclusion criteria, and study findings were extracted and recorded in the Excel table. Reference lists of included papers were also screened to optimize the search. The data extraction document is attached as a supplementary file (Multimedia Appendix 1).



Results

Overview

The search yielded 131 research and review articles overall. Forty-eight articles were duplicates and 71 articles did not satisfy the inclusion criteria. The full texts of the remaining 12 articles were screened, and 3 more articles were identified using the reference lists, resulting in a total of 15 articles eligible for analysis. Six of the 15 (40%) articles were original studies while 9 (60%) were scoping or systematic reviews covering other aspects of rehabilitation. Figure 1 illustrates how the articles were selected. All 15 considered articles indicated the existence of rehabilitation challenges; of these, 6 papers discussed the challenges faced by users, 5 discussed those faced by health systems, 3 discussed those faced by service providers, and 1 review article reported challenges for all.

Challenges to Rehabilitation Services in SSA

A synthesis of the literature revealed 2 categories of challenges to rehabilitation services from user, service provider, and health system perspectives (Table 1).

XSL•FO
RenderX

Table . Challenges to rehabilitation services reported in studies involving users, providers, and health systems.

	Category	
	Accessibility	Availability
Users	Overall challenges: • Unsuitable environment and buildings for people with disabilities • Inaccessibility to technology • Stigma, negative attitudes, and discrimination from therapists and other hospital staff • Long queues and waiting time • Financial constraints to purchasing medicines • Mindset that nothing can be done to help them • Lack of psychological support • Nonsupportive family members • Lack of trust in service providers • Pain during the rehabilitation process • Religious beliefs and socially accepted norms and traditions that claim that disability results from witchcraft or divine origins • Language barriers Digital rehabilitation–specific challenges: • Lack of secure platforms and privacy • Lack of technical knowledge or digital literacy • Connectivity issues • Inconsistency in power supply	• Do not know where to find the services • Long distance between users' homes and health facilities • Lack of reliable transport and logistical affordability • Distant health units
Service providers	Overall challenges: • Insufficient time for consultation • Inadequate follow-up • Inappropriate treatment procedures • Lack of patience • Ethical challenges Digital rehabilitation–specific challenges: • Lack of technical knowledge or digital literacy • Connectivity issues	• Lack of communication skills • Lack of professional training and necessary skills • Lack of maintenance for the assistive tools • Failure to schedule online appointments
Health systems	Overall challenges: • Consideration of rehabilitation as a less important health care strategy that is not well integrated into services • Fragmented health services • Lack of community awareness on rehabilitation services • Failure of the health system Digital rehabilitation–specific challenges: • Financial constraints	• Irregular referral to well-equipped health facilities • Lack of medicines and services • Shortage of health-related human resources • Low attention from governments and underfunding • Limited rehabilitation centers and poorly equipped rehabilitation units

Discussion

Principal Findings

This review revealed that people with disabilities in SSA have limited access to rehabilitation services. The limited access can be explained partly by user, service provider, and health system factors [8,13]. Studies included in this review [5,14] found that rehabilitation was given less priority by governments and not recognized as a crucial health care service. Consequently, the sector faced underfunding; experienced a deficiency in health-related human resources, particularly in therapists; encountered a scarcity of rehabilitation centers; and witnessed inadequately equipped rehabilitation units within health facilities. This contributed to the compromised access to high-quality rehabilitation services [5,14,15].

Another study reported that limited access to rehabilitation services in SSA is attributed to the financial inability to afford treatment, lack of insurance covering service expenses, long waiting times at the health facilities, and lack of drugs at health facilities [10]. Other studies have also found that some patients lack psychological support, are unaware of where to find

XSL•FO
RenderX

services, believe that nothing could be done to help them, and are not involved in making decisions on their health [8,16].

This review identified stigma as an impediment to accessing rehabilitation services. A study conducted in Rwanda [17] found that stigma around disability, coupled with negative attitudes and discrimination from therapists and other hospital staff, negatively impacted the uptake of rehabilitation services. Likewise, the role of family in accessing rehabilitation services is well documented. Patients with family members who do not perceive the need for rehabilitation services and who do not trust service providers may be demotivated to seek rehabilitation services [13,17,18]. Additionally, compromised access to health information, irregularities in referral to health facilities that are well equipped, inadequate policies and standards that govern the services, lack of adequate follow-up, insufficient time for consultations, and pain during the rehabilitation process are all hindrances to accessing rehabilitation services [9,15].

This review found that people with disabilities in SSA lack reliable, affordable, and accessible transportation means to reach health facilities. Furthermore, long distances to services and health units, unsuitable environments, and a lack of wheelchair-accessible buildings prevent users from accessing rehabilitation services. A review conducted in Brazil documented patients' determinants (residential location, economic resources, and social characteristics) and characteristics of services (cost, location, and status of the available facilities) as factors that limit access to rehabilitation services [8].

The results published by Bright et al [18] revealed that compromised health systems, lack of professional training and necessary skills for therapists, inappropriate treatment procedures, and lack of maintenance for the assistive tools reduce access to high-quality rehabilitation services. Health care providers who have not received enough training may lack the skills required to provide successful rehabilitation services. This lack of competence implies that misdiagnoses or outdated and inappropriate techniques could be used, causing harm to patients.

The study conducted by Jones et al [5] on telerehabilitation reported how digital rehabilitation services have addressed some logistical challenges; however, they come with additional challenges, including the absence of secure platforms and privacy, inaccessibility to technology, and lack of technical knowledge for both users and therapists [8]. Other challenges identified include a failure to schedule online appointments, connectivity issues, ethical challenges, and failure of the health systems. Patients and health care providers may struggle to use digital tools for rehabilitation, limiting the effectiveness of remote health services. Additionally, the inability to schedule and failure to maintain digital appointments may result in missed sessions, decreased patient participation, and care delays. Health systems face the challenge of poor policies that lead to a lack of financial capacity to afford digital technologies in health service delivery [19]. Digital technologies such as online medical records, wearable devices, and telemedicine can improve patient care and accessibility to health services, particularly in hard-to-reach areas. When financial limitations prevent the use of these technologies, patients may not receive the necessary high-quality care on time.

This review discerned that religious beliefs, cultural norms, and traditions that attribute disabilities to witchcraft or divinity serve as deterrents for individuals with disabilities seeking rehabilitation services at health facilities. A study conducted in Rwanda found that people with mental disorders believe that traditional and faith healers are more effective at treating mental problems than hospital specialists [20]. Such cultural beliefs dissuade people with disabilities from rehabilitation services, casting doubt on their quality and efficacy. Uncertainties regarding the precise origins of their conditions, which are often intertwined with mystical beliefs, add to this dissuasion [21].

Considering the rehabilitation challenges identified in this review, there is a need to bridge the gaps of infrastructure and social and cultural awareness regarding disability and rehabilitation services. This should be done by decentralizing services, providing continuous professional training to therapists, and promoting regular community awareness about rehabilitation services to inform service seekers and break the stigma around it. While this review has enumerated the challenges to rehabilitation services in SSA, it is worth noting that a majority of articles retained for consideration were scoping and systematic reviews that examined other aspects of rehabilitation. User and health system challenges were mostly highlighted in comparison to service provider challenges, which were limited in content.

Conclusion

This review reveals that rehabilitation services in SSA face multifactorial challenges that negatively impact timely access and quality of rehabilitation services for people with disabilities. As a consequence, those who require rehabilitation services experience longer periods of decreased mobility and functioning, inferior quality of life, and lower socioeconomic well-being. Future studies should examine the application of digital technologies to improve rehabilitation services' accessibility, especially in remote settings.

Abstract

Background: Health professionals face significant psychological burdens including burnout, anxiety, and depression. These can negatively impact their well-being and patient care. Traditional psychological health interventions often encounter limitations such as a lack of accessibility and privacy. Artificial intelligence (AI) chatbots are being explored as potential solutions to these challenges, offering available and immediate support. Therefore, it is necessary to systematically evaluate the characteristics and effectiveness of AI chatbots designed specifically for health professionals.

Objective: This scoping review aims to evaluate the existing literature on the use of AI chatbots for psychological health support among health professionals.

Methods: Following Arksey and O'Malley's framework, a comprehensive literature search was conducted across eight databases, covering studies published before 2024, including backward and forward citation tracking and manual searching from the included studies. Studies were screened for relevance based on inclusion and exclusion criteria, among 2465 studies retrieved, 10 studies met the criteria for review.

Results: Among the 10 studies, six chatbots were delivered via mobile platforms, and four via web-based platforms, all enabling one-on-one interactions. Natural language processing algorithms were used in six studies and cognitive behavioral therapy techniques were applied to psychological health in four studies. Usability was evaluated in six studies through participant feedback and engagement metrics. Improvements in anxiety, depression, and burnout were observed in four studies, although one reported an increase in depressive symptoms.

Conclusions: AI chatbots show potential tools to support the psychological health of health professionals by offering personalized and accessible interventions. Nonetheless, further research is required to establish standardized protocols and validate the effectiveness of these interventions. Future studies should focus on refining chatbot designs and assessing their impact on diverse health professionals.

KEYWORDS

artificial intelligence; AI chatbot; psychological health; health professionals; burnout; scoping review

Introduction

Health professionals are on the front line of patient care, enduring enormous responsibilities and constant pressure. Their work often occurs in an environment in which they must make life-and-death decisions, making them particularly vulnerable to psychological burnout [1]. According to recent studies, more than 50% of health professionals worldwide experience symptoms of burnout, such as fatigue, cynicism, and decreased effectiveness, leading to low job satisfaction [2], high turnover [3], and low-quality patient care [4]. This phenomenon not only causes an individual crisis but also has broader implications for health care systems [2,4]. Since the COVID-19 pandemic, psychological health issues such as anxiety, depression, and burnout among health professionals have become more prevalent because of long working hours, high-stress working environments, and exposure to traumatic events [5]. These issues directly affect health professionals' well-being and work performance and can ultimately negatively impact the quality of health care [6]. Therefore, supporting the psychological health of health professionals and preventing burnout are urgent challenges.

While traditional face-to-face counseling has been used to prevent psychological illness among health professionals, this

XSL•FO
RenderX

method presents various limitations including temporal and spatial constraints, limited availability of mental health professionals, accessibility barriers, and anonymity concerns [7-9]. Health professionals face significant challenges in accessing psychological care owing to demanding work schedules and high work intensity [10]. Additionally, they may feel psychologically burdened when seeking help in situations in which anonymity is not guaranteed [8]. To address these challenges, artificial intelligence (AI) chatbots have emerged as a potential solution, offering a new way to deliver psychological health interventions that can compensate for the limitations of traditional methods [7,8]. AI chatbots have the potential to be accessible anytime and anywhere while maintaining user anonymity, which may provide an alternative approach to psychological health support [7].

Recently, rapid advances in AI and natural language processing (NLP) have opened new possibilities for psychological health interventions, with AI chatbots gaining particular attention in the field of psychological health. Studies have demonstrated the potential of AI chatbots—AI-driven conversational agents—in providing mental health support [11] while emphasizing the importance of their safe and explainable implementation [12]. AI chatbots analyze users' conversation histories and data to provide advice and support tailored to their specific needs. This can help health professionals better manage psychological health issues, such as burnout, and enable timely interventions tailored to individual situations [13]. Previous research has shown that AI chatbots can improve coping skills through natural conversations with users [7], enhance the user experience, facilitate effective intervention delivery [13,14], and provide interventions tailored to specific needs [13,14]. This conversational approach enhances the effectiveness of interventions by fostering positive user engagement, as people are more likely to empathize with and respond to tools that feel engaging and relatable [6,7,14].

Despite the potential of AI chatbots for enhancing psychological health, there remains a lack of research on their effectiveness for health professionals. Much of the existing research has focused on using AI chatbots in patient care, whereas relatively little research exists on the use of AI chatbots to support health professionals. This research gap highlights the need to systematically investigate the characteristics and effectiveness of AI chatbots that target health professionals. Therefore, this study aimed to fill this gap and analyze the characteristics and effectiveness of AI chatbot interventions targeting health professionals to contribute to future research and practice.

Methods

Study Design

We conducted a scoping review to identify the available evidence regarding AI chatbot interventions for health professionals' psychological health. A scoping review maps the relevant literature in the field and is useful for identifying gaps in knowledge [15]. This review was conducted in accordance with the scoping review framework of Arksey and O'Malley. The study adopted the following five steps: (1) identifying the research question; (2) identifying relevant studies; (3) study selection; (4) charting the data; and (5) collating, summarizing, and reporting the results. The five stages provided a structured approach to assist in understanding the current evidence by examining the literature. There was no rating of quality performed on the included studies, as scoping studies do not require a quality evaluation [16]. Therefore, a scoping review is suitable for providing a broader perspective on the current research and mapping the relevant literature on AI chatbot interventions for health professionals' psychological health.

Identifying the Research Question and Relevant Studies

The research question was, "What is the status of the current body of knowledge regarding AI chatbots for the psychological health of health professionals?" According to Arksey and O'Malley, the search strategy involves identifying relevant studies, including published and unpublished works, with an emphasis on being as comprehensive as possible [15]. A literature search was performed between May and August 2024 from the following eight databases: seven global search engines in English (Cochrane Library, CINAHL, Embase, ProQuest Dissertations & Theses Global, PsyclNFO, PubMed, and Web of Science) and one Korean search engine in Korean (Research Information Sharing Service). Various combinations of search terms (Textbox 1) were used to either broaden or narrow the search, depending on the results in a specific database. The reference lists of the retrieved studies were searched manually. Finally, gray literature, relevant letters, and editorials were searched.

Textbox 1. Query box

medical team OR medical staff* OR healthcare worker* OR healthcare provider* OR health personnel* OR health professional* OR doctor* OR surgeon* OR physician* OR nurse* OR midwife* OR Licensed Practical Nurse* OR licensed vocational nurse* OR physician assistant OR nurse practitioner OR clinical nurse specialist* OR nurse clinician* OR registered nurse* OR resident* OR therapist* OR pharmacist* OR nurse assistant* OR nurse aid* AND burnout OR burn-out* OR depress* OR depression OR stress* OR exhaust* OR depersonalization OR personal accomplishment OR anxiety* AND chatbot* OR artificial intelligence OR conversational agent* OR dialogue system* OR machine learning OR natural language process*

Study Selection

Overview

Studies published before May 2024 were selected for this review. The studies retrieved from the literature search were reviewed by three researchers using the following inclusion and exclusion criteria.

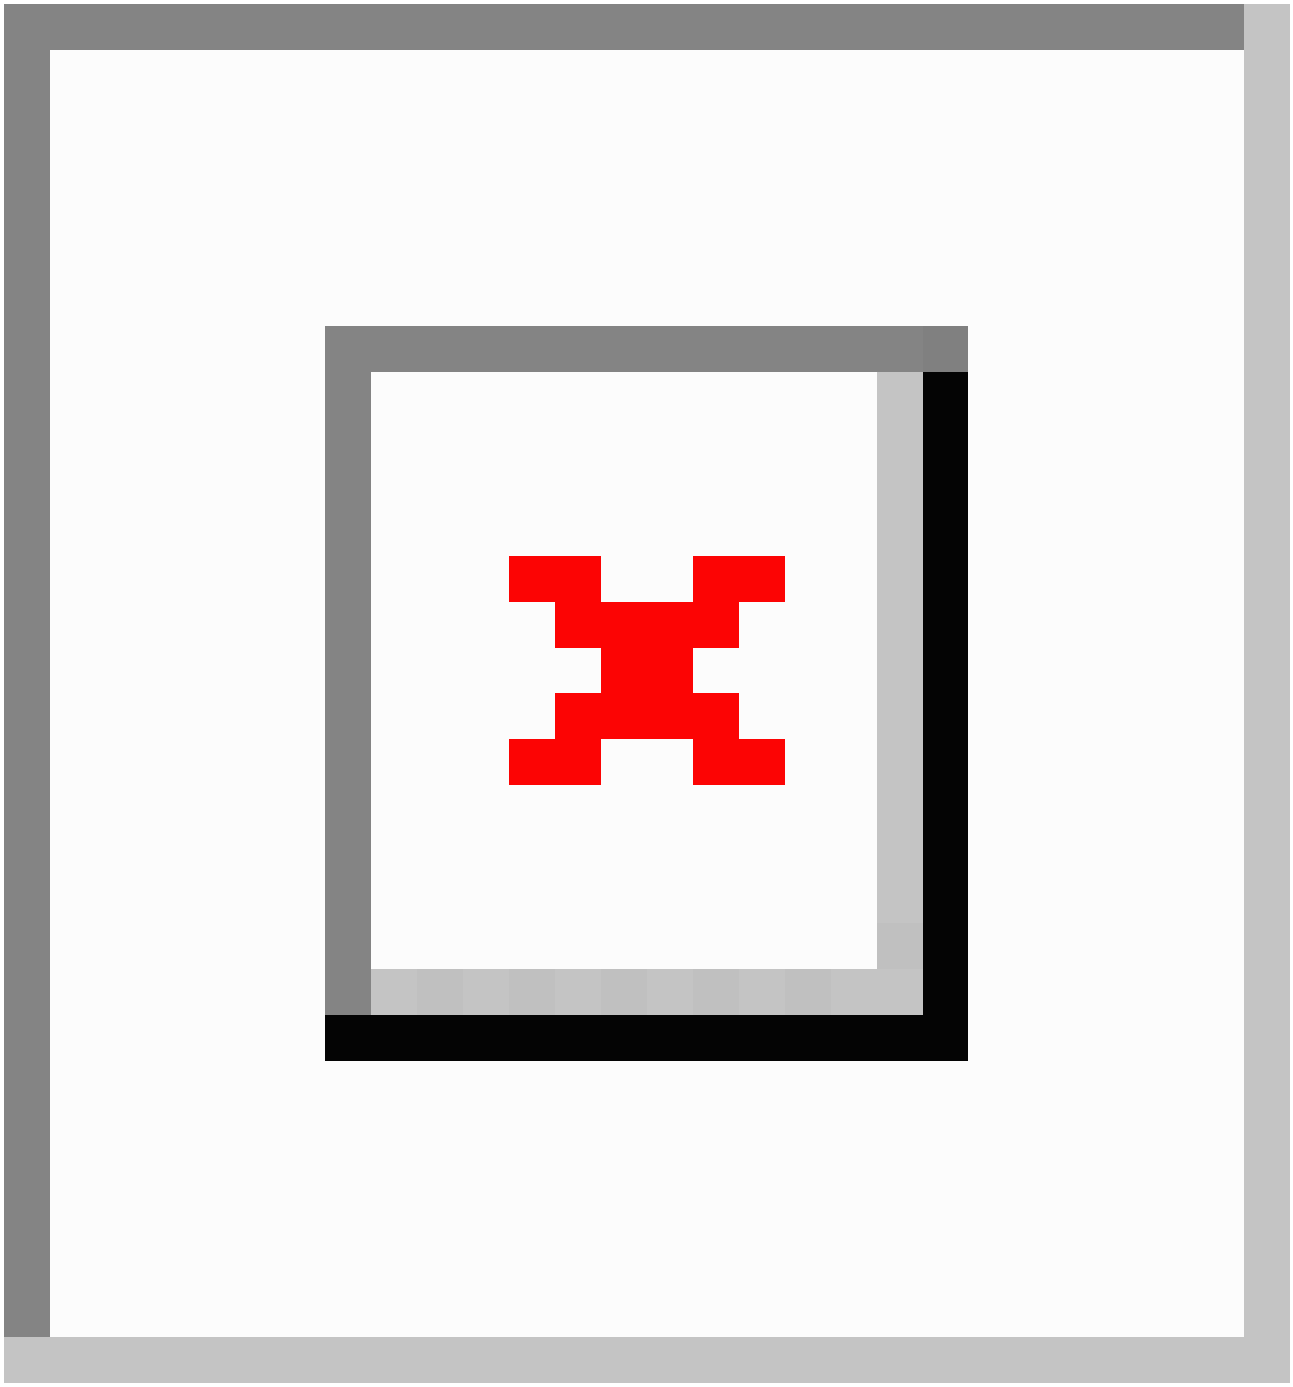
Inclusion Criteria

(1) The purposes of the studies included the development or implementation of AI chatbot interventions. (2) Participants of the studies included licensed health professionals such as

XSL•FO
RenderX

physicians or surgeons, dentists, medical doctors, registered nurses, licensed practice or vocational nurses, pharmacists, and allied health professionals such as respiratory and physical therapists. Studies that included nonhealth professionals in addition to health professionals as part of their participants were included if the main purpose of the AI chatbot was to alleviate the psychological distress of health professionals. (3) The intention of the AI chatbots was to improve the psychological health of health professionals, focusing on outcomes such as stress, burnout, depression, and anxiety. (4) The studies were written in English or Korean.

Exclusion Criteria



Studies in which we could not retrieve the full text were excluded.

A total of 2465 studies were retrieved from the initial database search (Figure 1). After removing duplicates, 1766 studies remained. The titles and abstracts were reviewed, and 1750 studies were excluded, leaving 16 studies for a full-text review. Six studies completely met the inclusion criteria after full-text review. Then, by reviewing the reference lists and manually searching, five additional studies were obtained, of which four studies met the criteria for the scoping review. Finally, 10 studies were included in this scoping review.

Throughout the review process, two researchers (GB and JH) took the lead in data extraction, and all researchers reviewed the content. Any uncertainties and disagreements were resolved through weekly meetings. The literature review software Covidence (Veritas Health Innovation Ltd), a study-managing tool for collaborating researchers [17], was used to manage the retrieved studies and to screen for redundant studies.

XSL•FO
RenderX

Figure 1. Flowchart. AI: artificial intelligence.

Charting the Data

The data are presented in tables, summarized, and synthesized qualitatively according to the purpose and research questions of the review.

Collating, Summarizing, and Reporting the Results

The final stage of a scoping review involves collating, summarizing, and reporting the results [15]. Data extraction was performed by two researchers (GB and JH) and checked for accuracy by all the researchers. Uncertainties and disagreements were resolved through discussions. The data were extracted using a common data extraction format.

Results

General Characteristics

Table 1 presents the characteristics of the analyzed studies. Ten studies published between 2018 and 2024 were retrieved. The studies were published worldwide: in Canada [7,18], Japan [19], Malawi [20], Netherlands [21], Singapore [13,22], Spain [23], and the United States [24,25]. Four studies examined diverse health professionals, including doctors, nurses, nurse assistants, clinical officers, pharmacists, lab technicians, and other allied health professionals [20,21,23,26]. Two studies specifically targeted doctors and nursing staff [13,27] such as nurse practitioners, registered nurses, licensed practical nurses, and nursing assistants, while one study exclusively covered chatbots

XSL•FO
RenderX

for nurses [19]. Three studies identified their participants as health professionals, without specifying the specific types [7,18,22]. Of the ten studies, eight studies focused solely on health professionals [13,19-23,26,27]. Two studies included both health professionals and their families [7,18].

The study designs were diverse. Of the 10 studies, three were development studies [18,23,27], one was a design verification study [26], one was a pilot study [22], one was a randomized controlled trial [20], one was a mixed-method feasibility study [21], one was an intervention study [19], one was a cross-sectional study protocol study [7], and one was a qualitative study [13]. Three studies evaluated the development and feasibility of AI chatbots for psychological health support [23,26,27].

AI Chatbot Characteristics

Table 2 shows the characteristics of the AI chatbots developed or implemented in the retrieved studies. The types of AI chatbot algorithms were diverse; NLP-based AI was the most commonly used algorithm, appearing in six studies [7,13,18,19,21,23]; rule-based AI, an algorithmic method that does not learn from data or create rules on its own, was used in two studies [20,22]; and learning-based AI that learns from data was adopted in two studies [26,27]. AI chatbots were delivered through mobile apps in six studies [13,19,20,22,26,27], and web-based platforms via web links in four studies [7,18,21,23]. The interaction type in all studies was 1:1 interaction: Among them, one study included 1:1 interaction alongside group chat functionality [26], and another study included 1:1 interaction with optional human coach support [22]. In seven studies, the chatbot actively initiated the conversation [7,13,18-20,23,27], while in three studies, the conversation was passively initiated [21,22,26].

Participant completion of the AI chatbot interventions was reported in four studies [20,21,23,27]; among these, three studies provided the percentage of participants who completed the intervention: 14.3% [21], 67.7% [20], and 73% [27] while one study reported the employee access rate of the intervention as 10.88% [27]. Of the 10 studies, six evaluated the AI chatbot's usability [13,20,22,23,26,27]. Four studies relied on participant feedback: 54.6% rated it as useful [26], the average satisfaction score was 4.07 out of five [22], more than 80% reported it as helpful [23], and 91% of the users found the chatbot easy to use [20]. One study used user engagement indicators to identify high subjective usability (acceptability, usability, and satisfaction) but low objective engagement (completion, adherence, compliance, and engagement) [27]. Another study assessed chatbot performance metrics, reporting an intent detection accuracy of 99.1% and an entity extraction accuracy of 95.4% for the Mira Chatbot [18]. Chatbot usability was not evaluated in the remaining four studies [7,13,19,21].

AI Chatbot Intervention Characteristics and Outcomes

Table 3 lists the contents and outcomes of the AI chatbot interventions. The primary component is the screening function for mental health conditions such as anxiety, depression, and stress, which was included in seven studies [19-23,26,27]. Four studies included cognitive behavioral therapy techniques [13,20,22,27]. Additionally, four studies implemented stress management techniques, such as breathing exercises and meditation [13,19,20,22]. Three studies incorporated problem-solving strategies [7,18,22] and psychoeducation [19,22,27]. Two studies used behavioral activation [20,22], cognitive restructuring [21,22], and gratitude training [20,22]. One study featured storytelling [21]. In addition, there was a

XSL•FO
RenderX

function to support portal sites connected to community resources in three studies [7,18,23].

XSL•FO
RenderX

Table . AI[a] chatbot intervention characteristics and outcomes.

Author (year)/ country	Chatbot contents	Additional features	Intervention doses	Main outcomes
Anmella et al [27](2023)/Spain	• Screening and monitoring for self-assessment tools • Personalized psychological modules: CBT[b], mindfulness, DBT[c], and ACT[d] • Psychoeducation and coping strategies for stress management • Chatbot-guided navigation	• Emergency alert for suicidal thoughts • Weekly objective reminders • Audio recording option for reflections after self-assessments	• 1 month (self-assessments conducted at baseline and biweekly)	• Anxiety (t_8=1.000; P=.34) and Depressive (t_8=0.40; P=.70) symptoms were not significant differences • Work-related burnout was moderately reduced (z=–2.07, P=.04, r=0.32)
Chaudhry and Islam [26] (2021)/United States	• iChatBot—provides real-time answers (self-monitoring and stress-tracking information related to patient care and workplace stress management) • PeerChat—enables peer-to-peer support	• AssignedTasks: records stress levels and task completion times • MyNotifications: Sends reminders for health activities like sleep, exercise, and meals • SmartMonitor: connects with devices to track vitals (eg, blood pressure, oxygen, pulse, and temperature) • InfectionCheck: Manual COVID-19 symptom checker via chatbot	• N/A[e]	• Usefulness and willingness: 54.6% found the app useful; 59.1% willing to use it. • Six feature feedback: MyNotifications: useful reminders; PeerChat: positive for peer support; AssignedTasks: good for tracking, but time-consuming; InfectionCheck: useful, potential redundancy; StressMonitor: very helpful for coping; iChatBot: concerns about emergency responsiveness
Chang et al [22](2024)/Singapore	• Mental health assessments: anxiety—GAD-7[f], depression—PHQ[g]-2 • Intervention modules: mindfulness, sleep meditation, guided visualization, thought recording, behavioral activation, psychoeducation, breathing exercises, cognitive restructuring, acceptance, grounding, social support, problem-solving, habit building, gratitude training	• Option to connect with a human coach • Weekly objective reminders and notifications • Gratitude challenge to boost engagement • Audio recording for self-reflection	• Varied among users (on average, users completed 10.9 sessions over 3.80 weeks)	• 495 completed at least one full session; 422 completed two or more sessions • The interventions most used were for sleep and anxiety, with a strong repeat-use rate • 46.2% reported symptoms of anxiety • 15.2% reported symptoms of depression
Jackson-Triche et al [23] (2023)/United States	• Mental health assessment screening: suicide or self-harm thoughts, substance use concerns, emotional distress, social withdrawal and work-related struggles, resource navigation • Web-based self-care resources • Behavioral health services: emergency support	• Telehealth assessments for crisis evaluation • Self-management website offering curated resources • In-person navigator for personalized support • Support groups with regular peer meetings	• Varied based on user interaction	• UCSF[h] cope reached all units • 10.88% (3785/34,790) of employees accessed the technology • 39.7% (708/1783) of employees with psychological distress requested in-person services • Positive feedback on all program elements. • Over 80% of attendees found the experience helpful

XSL•FO
RenderX

Author (year)/ country	Chatbot contents	Additional features	Intervention doses	Main outcomes
Kleinau et al [20](2024)/Malawi	• Mental health assessments: anxiety (GAD-7), depression (PHQ-9), burnout (OLBI[i]), loneliness (UCLA Loneliness Scale)[j], resilience (RS-14)[k] • Careline programs (thematic mental health conversation tracks) • Intervention: CBT techniques, positive psychology strategies, behavioral activation, gratitude exercises, breathing, relaxation, and meditation exercises,	• Mood tracking with emojis for human-like interaction • Gamification for engagement • Emergency support with local psychologist contact info for high-risk users	• 8 weeks -First 4 weeks: daily interactions • Second 4 weeks: interactions every other day	• GAD-7 showed a decrease (–0.44), but the result was not statistically significant. • OLBI showed a decrease (–0.58), with borderline significance. • PHQ-9 showed a significant decrease. • UCLA loneliness scale: no significant • RS-14 showed a significant increase.
Kroon [21](2018)/Netherlands	• Awareness of inner critics: storytelling, encouraging reflection • Identification of inner critics: assessment tool • Cognitive restructuring techniques • Self-compassion development	• Humor: adds humor for engaging interactions • Tokens: rewards for task completion • Compliments: encourages users with motivating feedback	• 2 weeks	• ProQOL[l] and SCS[m] no significant. • Quantitative results: no significant changes in self-compassion or compassion fatigue. • Qualitative results: Positive feedback on the iThrive intervention, with increased awareness of inner critics and changes in thinking patterns. • Chatbot interactions reportedly reduced stress and improved self-compassion.
Matsumoto et al [19](2021)/Japan	• Digital-SAT[n] method: self-guided stress management, techniques to convert stress-related physical discomfort into positive sensations, image-based therapeutic exercises • Mental health assessments: self-esteem, anxiety, emotional support, depression, problem-solving abilities • Stress management: guided stress relief sessions, emotional stabilization exercises, visualization techniques	• Automated daily messages with reminders and psychoeducational content • Gamification elements such as progress tracking • Immersive VR[o] experiences	• 4 weeks	• Self-esteem and family support significantly improved. • Self-repression showed a trend of improvement but was not significant. • SDS scores and counseling needs increased in the VR + CB[p] group. • Maximal blood pressure decreased significantly in the VR group and showed a decreasing trend in the VR + CB group. • Minimal blood pressure significantly decreased in the VR group.
Noble et al [7](2022)/Canada	• Mental health education and information: problem-solving • Personalized resource navigation • Self-help strategies and coping skills		• N/A	• The findings will be reported in follow-up research

XSL•FO
RenderX

Author (year)/ country	Chatbot contents	Additional features	Intervention doses	Main outcomes
		• Emergency contacts for urgent mental health support • Hybrid AI approach: free-text input and predefined options • Crisis support referrals for suicidal thoughts		
Yoon et al [13](2021)/Singapore	• Personalized goal setting: tailored goals for lifestyle improvements (eg, sleep, exercise), feedback on progress to encourage behavioral changes, reminders to support adherence to personal goals • Educational resources: mindfulness exercises and short wellness studies, stress management techniques	• In-app counseling and peer support • Reminders and notifications • Gamification elements: point-based rewards • Engaging features to promote continued app use • Mood tracking and progress monitoring	• N/A	• Mood-tracking reminders were helpful, but workers struggled with self-awareness. • Goal-setting and resources were valued; frequent notifications were distracting. • A built-in counselor chat was preferred for accessibility and privacy. • Gamification was not well-received. • Peer support was needed, but app-based interactions raised concerns. • Motivation, usability, and rewards were crucial for app use.
Zamani [18](2022)/Canada	• Information on mental health topics, including substance use and coping strategies: problem-solving • Delivers personalized recommendations • Facilitates access to local mental health services and programs through a resource portal	• Emergency contact option for users experiencing distress • Stores conversation logs • Feedback system	• N/A	• Intent detection: 99.1% accuracy in identifying user needs. • Entity extraction: 95.4% accuracy in recognizing key terms for resource recommendations.

[a]AI: artificial intelligence.

[b]CBT: cognitive behavior therapy.

[p]VR-CB: virtual reality-chatbot.

XSL•FO
RenderX

Across the studies, a variety of additional features were incorporated. Seven studies included AI chatbot functionalities for crisis management and support [7,13,18,20,22,27]. Specific features encompassed emergency contact information for crises [7,18,20,27], peer support groups and in-app forums for social support [13], expert support through in-app counseling, and options for connecting with human coaches [13,22,23]. Six studies incorporated reminders to encourage chatbot use [13,18,19,22,26,27]. Gamification elements, such as point-based rewards to encourage participation, were featured in four studies [13,19-21]. Peer support functionalities were available in three studies [13,23,26]. Two studies included mood-tracking features for health and lifestyle management [13,20], while another two studies provided an audio recording option [22,27]. Additionally, one study integrated devices for tracking vital signs [26] and provided an immersive virtual reality experience [19]. A total of 4 out of 10 studies explicitly stated the duration of chatbot use or intervention dose ([19]: 4 wk; [20]: 8 wk; [21]: 2 wk; [23]: 1 mo) while it was not specified in six studies. The dose varied among users in two studies [22,23].

The research in four studies evaluated psychological health outcomes [19-21,27], whereas, in six studies, the focus was primarily on the development and description of user perceptions of the AI chatbot without providing specific outcome measures [7,13,18,22,23,26]. The most commonly measured psychological health outcomes were anxiety and depression, which were examined in three studies [19,20,27]. Burnout was investigated in two studies [20,27]. Compassion fatigue [21], loneliness [20], resilience [20], and self-compassion [21] were also evaluated. Anxiety was measured in three studies: one reported a significant reduction of scores [20] while the other two reported no significant differences in anxiety scores [19,27]. Burnout was assessed in two studies, and each reported a significant decrease in its scores [20,27]. Depressive symptoms were measured in two studies: one reported a significant reduction of scores [20] while the other did not [27]. Other psychological variables were measured in one study each; of those, the variables that showed significant change in scores were health counseling needs [19] and resilience [20].

Discussion

Principal Results

The studies retrieved for this scoping review were published during the past seven years, between 2018 and 2024, and reflect the rapidly evolving trend of AI chatbot technology for supporting psychological health. The global distribution of studies across countries indicates a widespread interest in using AI for psychological health support and health professionals' psychological health.

Our review revealed that chatbots were used by a broad spectrum of health professionals, highlighting their diverse applications. This diversity underscores the potential for universally designed chatbots to effectively address psychological health needs across different professional settings. However, prior research has shown that nurses, who have direct and continuous patient contact, experience greater mental health distress compared to other health professionals [24]. Therefore, future studies should consider incorporating role-specific options into chatbot designs to create tailored interventions for diverse professional groups.

The diverse research methods used in the retrieved studies signify the nascent stage of research on AI chatbots for psychological health support, emphasizing technology refinement and user experience comprehension. Such a variety of research approaches is crucial for validating the efficacy and safety of AI chatbot technology, enabling iterative improvements and a deeper understanding of how health professionals interact with AI chatbots [25]. However, it is noteworthy that only 4 out of 10 studies measured psychological health outcomes. This limitation underscores the significant gap between technological developments and clinical validation. As the field matures, it becomes imperative to quantitatively assess the impact of AI chatbots on psychological health indicators. Further studies measuring outcome variables to demonstrate the clinical effectiveness of AI chatbots are needed.

The studies reviewed here demonstrate the variety of AI algorithms used in chatbot design, including NLP-based-, rule-, and learning-based approaches. NLP-based AI chatbots which provide personalized responses by analyzing user inputs [28] are the most commonly used AI algorithms. Evidence has shown that an NLP-based AI chatbot, which simulates natural conversations, is successful at delivering tailored interventions [29]. Rule-based AI algorithms, adopted in 2 studies out of the 10 retrieved studies, are effective in providing fixed and predetermined responses; however, they lack the adaptability required to provide more dynamic and engaging psychological interventions [30]. Previous research has shown that NLP technology, which interprets psychological health cues from user-generated texts, significantly improves the effectiveness of interventions [31,32], a finding consistent with our review [7,13,18,19,21,23]. Moreover, the development of deep learning techniques has led to the widespread use of general-purpose pretrained language models in various NLP applications [33]. This suggests that NLP-based algorithms are particularly suitable for delivering personalized psychological support in real-time interactions. Machine learning and deep learning algorithms show promise in enhancing AI chatbots' effectiveness by continuously learning through user interactions. These algorithms can provide accurate and personalized interventions over time [34]. Future studies should investigate how these advanced algorithms can be used to offer more precise psychological support tailored to individual user experiences.

User engagement is a critical factor in the success of mental health interventions; however, several studies did not report intervention completion rates [20,21,23,27]. These issues might become more pronounced in real-world settings, where factors such as interface complexity, the chatbot's ability to provide meaningful and personalized feedback, and technical issues impact the overall user satisfaction and perceived effectiveness of the intervention [35]. This underscores the need for further exploration of how chatbot interactions can be designed to maintain user engagement, possibly through improved user experiences and personalization techniques [36,37]. From a different perspective, unlike traditional interventions, which are typically designed to be completed from start to finish, chatbot

XSL•FO
RenderX

interactions often do not follow this linear structure. Users may terminate interactions once their immediate concerns are addressed, reflecting the unique flexibility of chatbots [38]. For instance, if a chatbot provides critical information for crisis management and the user responds affirmatively, the user is likely to exit the chat after their need is met. This immediate resolution highlights the efficiency of chatbot interventions in addressing user concerns promptly, even if the interaction appears incomplete. Recognizing this distinction is essential for accurately interpreting dropout rates and evaluating chatbot effectiveness.

The AI chatbots reviewed here comprised various therapeutic approaches. The incorporation of established psychological treatment techniques such as cognitive behavioral therapy, mindfulness, and dialectical behavior therapy into AI chatbots represents a novel approach to delivering psychological health interventions. This approach is considered novel because it uses AI to deliver evidence-based psychological techniques 24/7, serve multiple users simultaneously, tailor interventions based on individual responses, and combine various therapeutic modalities on a single platform.

This multidisciplinary therapeutic approach has the potential to address health professionals' diverse psychological needs [31]. AI chatbot interventions are characterized by a digital and responsive design, which allows for integrating practical tools such as stress management techniques, mood tracking, and personalized goal setting [39]. These features align with the immediate and personalized support often required by health professionals. However, while personalization is a key advantage of AI chatbots, a need also exists for some level of standardization to ensure the interventions' quality and effectiveness [40]. This standardization should focus on establishing evidence-based core components and assessment methods while still allowing for personalized delivery [31]. Future research should focus on identifying the most effective components of these chatbots and tailoring them to the specific psychological health needs of health professionals while maintaining a balance between standardization and personalization.

In this study, a temporary increase in depression scores was observed in one study [20], whereas previous research has reported AI chatbots' positive effects in reducing anxiety, depression, and work-related burnout among health professionals [41]. These contrasting findings may reflect the challenges faced by such professionals, who frequently experience high levels of stress and emotional demands [42]. This suggests the complexity of psychological interventions and highlights the importance of careful monitoring to determine the appropriate duration and intensity of chatbot use.

Some studies in our review demonstrated the potential of AI chatbots to act as first-line responders in identifying and managing mental health crises. Prior research has also shown the potential benefits of AI chatbots not only in improving mental and emotional well-being but also in promoting behavioral changes [43]. While these features may only benefit a subset of users, their impact on preventing escalation to severe mental health conditions or emergencies is invaluable. Future research should prioritize the integration and evaluation of these features to enhance the safety and efficacy of chatbot interventions.

Although AI chatbots address the unique time constraints and stress among health professionals, balancing automated responses with genuine therapeutic interactions remains a significant challenge. Personalization technologies that provide tailored features to AI chatbots have emerged as key factors in their effectiveness, with studies reporting increased user engagement and satisfaction through customized responses and immediate support [29]. Consequently, the development of tailored intervention strategies that consider the individual needs and preferences of health professionals is essential to maximize AI chatbots' effectiveness. These strategies should integrate ongoing user feedback and dynamically adapt interventions to maintain long-term user engagement and effectiveness. Future research should focus on larger sample sizes, extended follow-up periods, and diverse health care professional groups of health professionals. Such comprehensive studies will play a crucial role in developing evidence-based guidelines for implementing AI chatbots in psychological health and in advancing the sophistication of personalization algorithms.

Limitations

This scoping review has several limitations. First, the limited number of studies adopting diverse study designs and using various AI algorithms complicated making direct comparisons among the retrieved studies. Second, the findings' generalizability is restricted because many studies were published in specific regions, particularly high-income countries. Additionally, the short duration of many interventions and limited follow-up periods make it difficult to evaluate the long-term effectiveness and sustainability of AI chatbots. Future research should address these limitations by conducting more rigorous trials, standardizing the outcome measures, and exploring the long-term applications of AI chatbots across diverse populations and settings.

Conclusions

This scoping review explored the current state of AI chatbots aimed at supporting the psychological health of health professionals. Although the reviewed studies demonstrated AI chatbots' potential to reduce stress, anxiety, depression, and burnout, research in this area remains in its early stages. The diversity of study design, AI algorithms, therapeutic approaches, and outcome measures highlights this field's innovative but fragmented nature.

Despite promising results, particularly with NLP-based chatbots, a significant need exists for more rigorous and standardized studies to fully evaluate their clinical efficacy. Challenges such as usability issues and limited generalizability of the findings must be addressed to enhance the long-term application and effectiveness of AI chatbots in real-world settings. Future research should focus on refining chatbot designs, expanding the research to diverse populations, and conducting long-term studies to clarify the role of AI chatbots in supporting the psychological health of health professionals. Thus, AI chatbots could become a valuable solution for addressing the

XSL•FO
RenderX

psychological health challenges faced by health professionals worldwide.

Abstract

Background: Clinical decision support systems (CDSSs) play a pivotal role in health care by enhancing clinical decision-making processes. These systems represent a significant advancement in medical information systems. However, optimizing their effectiveness requires accounting for various human-computer interaction (HCI) elements that influence their functionality and user acceptance.

Objective: This study aimed to identify and categorize key HCI elements that impact CDSS performance to enhance system usability, adaptability, and decision-making accuracy.

Methods: We conducted a systematic literature review, identifying 923 studies from the databases PubMed, Scopus, and Web of Science. Papers were screened and selected based on predefined inclusion criteria. A rigorous quality assessment process was applied to ensure the relevance and reliability of the included studies. Ultimately, of the 923 papers identified, 43 (4.7%) that specifically addressed HCI elements applicable to CDSS environments were included in the final analysis. Data extraction and synthesis were performed to answer the research questions regarding HCI elements.

Results: A total of 12 distinct HCI elements were identified, each with the potential to influence CDSS functionality. These elements align with the International Organization for Standardization (ISO) 9241-11 framework, which defines usability in terms of effectiveness, efficiency, and satisfaction. “User satisfaction,” “flexibility,” and “individuality” enhance satisfaction by improving system adaptability and user acceptance. “Visibility,” “explainability,” and “user control” strengthen effectiveness by supporting decision-making and error prevention. “Ease of use” improves efficiency by streamlining interactions and reducing cognitive load. Some elements influence effectiveness and efficiency, such as “data entry,” which ensures structured inputs for decision accuracy while optimizing workflows. Likewise, “alerts” provide timely information for effective decision-making and, simultaneously, are designed to avoid overwhelming users and maintain system efficiency. “Simplification” and “mental effort” also optimize workflows and reduce complexity. Furthermore, “interface” impacts effectiveness and efficiency by supporting accurate decision-making and streamlining user interaction. This categorization, aligned with ISO 9241-11, underscores the context and task dependency of usability, highlighting that HCI elements must be adapted to different user needs and environments for effective clinical decision-making.

Conclusions: This study addresses a critical gap in CDSS research by offering a comprehensive framework of HCI elements tailored to the CDSS environment. Incorporating these elements into system design can improve user satisfaction, reduce data errors, and enhance the accuracy of medical decisions. The findings lay the groundwork for future research, offering practical guidelines for developing more reliable and efficient CDSS systems in medical informatics fields.

KEYWORDS

human-computer interaction; clinical decision support system; usability; user-centered design; artificial intelligence

Introduction

Background

Clinical decision support systems (CDSSs) provide clinicians with computer-generated clinical knowledge and patients with relevant health information presented at the right time to support optimal patient care [1]. Poorly designed user interfaces (UIs) may impede structured data entry, potentially compromising data quality and resulting in incomplete datasets [2]. Such shortcomings can negatively impact the effectiveness of integrated medical information systems when used within a CDSS framework [3]. CDSSs, as a prominent method for enhancing clinical decisions effectively, rely on patient-entered data in electronic medical records (EMRs). Data scientists face challenges in analyzing data obtained from EMRs due to the prevalence of errors, including typos and incorrect entries. In other words, incomplete medical advice originates from incomplete and unstructured prepared data for CDSSs [4]. Physicians often express these errors as stemming from an inadequate interaction with the system [5]. Human-computer interaction (HCI), based on the solid principles of ergonomics, cognitive science, and psychology, is pivotal in creating practical and beneficial technology for all users [6]. Indeed, HCI science advocates for physicians through technological solutions and enhances their comprehension of the significance of their daily processes and the subsequent use of data stored in electronic health records (EHRs) [7].

Although the HCI concept typically encompasses how computer systems are designed for ease of use, efficiency, and effectiveness [8], HCI in the medical realm implies the investigation and design of computer systems that expedite productive and intuitive interaction between physicians and technology to boost user experience (UX) and achieve the desired result [9].

Neglecting HCI elements in medical systems can lead to inadequate graphical UIs, potentially hindering physician adoption and efficacy within the digital health care landscape [10]. Conversely, some studies have demonstrated that incorporating HCI elements improves user acceptance and enhances the effective use of CDSS functionalities [11]. Despite several studies addressing HCI elements and their components, the lack of studies on HCI elements that can affect CDSS performance is quite noticeable. In this regard, related concepts, such as usability, UX, or user-centered design (UCD), all of which contribute to physician satisfaction, need to be investigated. HCI assists in identifying system requirements, including text style, fonts, layout, graphics, and color. Meanwhile, usability focuses on efficiency, effectiveness, utility, ease of learning, and ease of assessment. Combining these perspectives ensures a comprehensive approach to designing a CDSS that meets technical and user-centric demands [12].

The necessity of distinguishing HCI elements specifically for CDSSs, in comparison with decision support systems (DSSs), is derived from the unique demands of the health care environment [13]. CDSSs must seamlessly integrate complex medical knowledge, ensure adherence to stringent clinical guidelines, and accurately handle sensitive patient data, all while minimizing the cognitive load on health care professionals [14]. These systems support clinical decisions that directly impact patient outcomes. This is why elements of usability and UX must be considered. Unlike generic DSSs, CDSSs must navigate the intricate nature of medical decision-making**.** Hence, a tailored approach to HCI elements is needed to address these specialized requirements effectively [15]. In addition, EMRs must be designed using comprehensive HCI elements to serve as a gateway to the data required by the CDSS. Poorly designed HCI in EMRs can lead to improper data entry or retrieval [16]. These errors can have serious consequences, potentially impacting patient safety and even leading to loss of life. Conversely, well-designed HCI can facilitate accurate data handling, improving patient care and significantly enhancing outcomes [17].

Due to the absence of targeted studies that focus on leveraging HCI elements within the CDSS environment, conducting this research is crucial. By systematically identifying and evaluating practical HCI elements specific to CDSSs, this study provides a comprehensive guide to enhance the performance and usability of these systems. This focused investigation offers a unique framework that health care professionals and system developers can use to implement more effective and user-friendly CDSS solutions. The scientific contribution of this study lies in providing a structured methodology to improve CDSS performance, ensuring better integration of HCI elements tailored to the health care context.

Systematic Literature Review

Conducting a systematic literature review (SLR) [18] was the most effective method for this research because it allowed for a rigorous and comprehensive collection of existing studies in the field. An SLR provides a transparent and replicable process for identifying, evaluating, and synthesizing relevant literature. Using the SLR approach, we endeavored to extract and categorize HCI elements that are especially applicable within the CDSS environment, ultimately paving the way for improved CDSS performance.

On the basis of the concerns highlighted in this study, we formulated the following research questions (RQs):

- RQ1: Which HCI elements in medical information systems can affect CDSS functionality?
- RQ2: How does incorporating the identified elements improve CDSS performance?

By seeking a response to the first RQ, we aimed to identify and extract HCI components that have the potential to affect CDSS functionality, as pointed out in the reviewed papers. The second RQ focuses on investigating how the identified HCI elements, when applied within medical environments and information systems, contribute to enhancing CDSS performance.

XSL•FO
RenderX

The remainder of this work is organized as follows. The Methods section describes the methodology and the review steps. The Review Planning subsection details the SLR planning phase, while the Review Process subsection presents the review and data extraction steps. The Results section presents the findings from the analyzed studies to answer the RQs. Finally, the Discussion section presents the principal findings, with some clues and future research lines outlined in the Conclusions subsection.

Methods

Overview

This study followed the SLR methodology outlined by Kitchenham [19] and Kitchenham and Charters [20] to ensure a thorough and unbiased synthesis of existing research. The SLR was complemented by a systematic literature mapping following the method proposed by Kitchenham et al [21]. This segment outlines the protocol used to perform the SLR, providing the necessary information to support the subsequent findings. According to the guidelines provided by Kitchenham [19] and Kitchenham and Charters [20], the SLR process consists of 3 principal phases: planning, conducting, and reporting the study. We adhered strictly to the defined SLR protocols and methodological nuances articulated in the study by Pati and Lorusso [22] to ensure transparency in both the research process and results.

Before planning this SLR, a preliminary search was conducted to ascertain that no recent SLR had been undertaken to identify HCI elements within CDSSs. This preparatory appraisal involved searching various electronic databases, including Scopus, Web of Science, and PubMed, using terms related to the methodology (eg, *SLR* or *systematic literature review*) and the review focus (eg, *HCI*, *usability*, *user experience*, *elements in CDSS*, and equivalent concepts). The results of this preliminary search confirmed the absence of an SLR on the specified theme, thereby justifying the implementation of this review to fill the identified research gap.

Review Planning

The review planning process involves identifying and defining various dimensions to provide the foundation for executing the review, such as formulating the RQs, detailing the protocol followed, and any other relevant information to ensure the traceability of the review process. We outline these dimensions in this subsection.

Mapping Questions

This study's main concerns and RQs are outlined in the Introduction section. To further explore the context and breadth of our SLR, we formulated 4 mapping questions (MQs) to guide our analysis:

- MQ1 (geographic distribution of studies): Where have studies related to HCI elements in CDSSs been conducted worldwide?
- MQ2 (year-wise distribution of studies): What is the distribution of studies by identified HCI element over the years?
- MQ3 (publication venues): What is the distribution of studies between journal papers and conference papers?
- MQ4 (focus distribution): What percentage of the identified studies discuss each HCI element (eg, alerts, interface, system design defects, and mental effort)?

It is important to note that MQ4 (focus distribution) does not have a dedicated subsection. Instead, it has been addressed throughout the identification and discussion of each HCI element. By addressing these MQs, we aim to provide a comprehensive overview of the current research landscape, highlighting key trends and patterns that inform the influence of HCI elements on CDSS performance and user interaction.

Population, Intervention, Comparison, Outcome, and Context Framework

Regarding the questions posed, the population, intervention, comparison, outcome, and context method proposed by Petticrew and Roberts [23] (outlined in the following subsections) and which provides a structured framework for research reviews was used to define the review scope.

Population

We considered all studies that involved software solutions, regardless of their implementation or design. Although the review focuses on the properties and attributes of EMRs, the target studies addressed HCI elements within CDSSs.

Intervention

The interventions of interest included those that suggested or introduced some elements addressing HCI issues in EMRs or eHealth systems, excluding stand-alone solutions such as mobile health apps.

Comparison

No comparison between interventions was planned.

Outcome

The fundamental outcome of this review is to identify key HCI elements that can enhance the functionality of CDSSs.

Context

We considered all studies relevant to EMR and eHealth systems. The review includes all papers describing the successful implementations and designs of EMRs in medical environments, such as hospitals and medical centers worldwide.

Inclusion and Exclusion Criteria

After defining the review's scope, we established inclusion and exclusion criteria (Textbox 1) to choose pertinent literature for addressing the RQs.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- The paper proposes a pragmatic and implementable solution (eg, method, technique, model, tool, or framework).
- The proposed solution is applied to software, applications, platforms, services, infrastructures, or systems.
- The study focuses on electronic medical records, electronic health records, or eHealth.
- The proposed solution supports or addresses the tailoring of attributes and criteria to improve medical decision support capabilities.
- The paper is written in English.
- The paper was published between 2000 and July 2024 (when the search queries were executed).
- The full paper is available.
- The tailoring capabilities relate to human-computer interaction, usability, user interface, user experience, or user-centered design.
- The article is published in a peer-reviewed journal, book, or conference (including only conferences ranked B or higher in the CORE Conference Ranking list or classified in the top 2 quartiles in the Scimago Journal Rank index).

Exclusion criteria

- The paper does not propose a pragmatic and implementable solution (eg, method, technique, model, tool, or framework).
- The proposed solution is not applied to software, applications, platforms, services, infrastructures, or systems.
- The study is not focused on electronic medical records, electronic health records, or eHealth.
- The proposed solution does not support or address the tailoring of attributes and criteria to improve medical decision support capabilities.
- The paper is not written in English.
- The paper was published before 2000 or after July 2024 (when the search queries were executed).
- The full paper is not available.
- The tailoring capabilities do not relate to human-computer interaction, usability, user interface, user experience, or user-centered design.
- The article is not published in a peer-reviewed journal, book, or conference (including only conferences ranked B or higher in the CORE Conference Ranking list or classified in the top 2 quartiles in the Scimago Journal Rank index).

Search Strategy

It is imperative to identify the most significant databases regarding the search domain in which the queries will be executed to obtain relevant outcomes from the investigation. For this study, 3 electronic databases were selected: Scopus, Web of Science, and PubMed. These databases were chosen based on the following criteria:

- They serve as reference databases in the research domain.
- They are highly relevant to the study context.
- They support the use of search strings and Boolean operators to augment the results of the retrieval process.

On the basis of the research context used to construct the search query, the following terms were included:

- Usability—this concept refers to efficiency, effectiveness, and physician satisfaction [24,25]. It emphasizes maximizing system facilitators to enhance usability [26,27].
- All terms related to HCI—HCI involves interaction and communication between users and computer systems, encompassing the exchange of information, symbols, and actions to facilitate seamless interaction between humans and computers [28]. In this regard, *HCI elements* are defined as the specific elements or attributes that influence user interaction and experience within the determined framework [29]. *HCI elements* and *HCI factors* in medical settings highlight the importance of UCD, ensuring that medical staff are integrally involved in developing and refining medical systems for enhanced performance and satisfaction [30,31]. The terms *HCI factors* and *HCI elements* are sometimes used interchangeably in HCI literature. *HCI factors* often refer to broader influences on usability, while *HCI elements* represent specific design components.
- User-centered design (UCD)—UCD emphasizes the essentiality of considering end users' viewpoints in shaping or evolving a product or software, predominantly based on end-user feedback [32].
- User interface (UI)—in medical information systems, the UI serves as the direct interface between the system and physicians. It can be categorized as static, appearing the same for all users; or dynamic, adapting to varying circumstances based on user interactions with the system [33].
- CDSS—CDSSs encompass a broad range of tools and interventions, both computerized and noncomputerized, to aid clinicians in their complex decision-making processes [34,35]. They are being integrated into EMRs and computerized clinical workflows worldwide, empowering health care providers to access timely and pertinent information, ultimately leading to better patient outcomes through informed decision-making during clinical care [14].
- Artificial intelligence (AI)—in medicine, AI refers to the ability of medical systems to respond to environmental factors and support decision-making, achieving results

XSL•FO
RenderX

comparable to human medical professionals [36]. CDSSs that use AI function as digital dynamic knowledge systems that leverage patient data to create tailored recommendations for clinicians [37]. In other words, CDSSs are meant to assist rather than perform clinical decision-making [38].

In line with the research goals, we only investigated HCI elements that directly or indirectly impact systems designed for medical decision-making. Hence, HCI elements not relevant to this context were excluded from consideration.

Quality Assessment

Overview

Although inclusion and exclusion criteria help identify relevant works for a study, they do not address the quality of the papers retrieved regarding their ability to address the RQs. Therefore, we developed a separate set of quality assessment criteria. We adopted a scoring system in which each coauthor independently evaluated the studies using the quality questionnaire proposed by Kitchenham and Brereton [39]. The scoring was as follows: a "yes" response earned 1 point, a "partially" response earned 0.5 points, and a "no" response earned 0 points. The maximum score a study could receive was 7 points. The quality questionnaire and its corresponding assessment phases are detailed in the following subsections.

Design Clarity and Relevance

Are the research aims and objectives clearly stated and aligned with the study's focus on HCI elements in CDSSs?

Data Collection and Relevance

Does the paper provide comprehensive and relevant data pertinent to HCI elements in CDSSs, including metrics for evaluation?

Empirical Measurement and Methodology

Are the HCI elements empirically measured with well-defined metrics? Is the methodology for evaluating these elements clearly described?

Analysis and Documentation

Are the research results documented with granularity, including participant information, observational units, and analysis methods?

Conclusion Validity and RQs

Do the study's conclusions adequately answer the RQs? Are the implications for HCI and CDSSs clearly articulated?

HCI Evaluation Method

Is the HCI evaluation method used in the study justified and described in sufficient detail?

Relationship Between HCI Elements and CDSS Outcomes

Does the study adequately illuminate the relationship between the applied HCI elements and the CDSS outputs or results and their consequences?

Quality Assessment and Interrater Reliability

The maximum score a study could receive was 7 points. To advance to the next phase of the review, studies were required to score at least 5 out of 7 points. To validate the quality assessment results and demonstrate process consistency, we computed a measure of interrater reliability using Krippendorff α [40]. The Krippendorff α value was 75.33%, indicating that the data were interpreted similarly and acceptably among the coauthors. When discrepancies arose, we engaged in discussion sessions to reach a consensus.

Query Strings

Overview

The search strings for each considered source were generated using relevant search terms derived from the population, intervention, comparison, outcome, and context methodology outcomes [41], connected by Boolean "and" or "or" operators. The canonical search equation provides a standardized template that ensures consistency across different databases. This canonical search equation is then adapted to fit the specific syntax of each database. The canonical search equation is as follows: ("human-computer interaction" OR "HCI" OR "usability" OR "user experience" OR "user interface" OR "user-centered") AND ("electronic medical records" OR "EMR" OR "electronic health records" OR "EHR") AND ("clinical decision support systems" OR "CDSS" OR "decision support system*" OR "DSS" OR "artificial intelligence" OR "AI").

Using the canonical search equation, we formulated the following queries tailored to each of the 3 selected databases to retrieve all relevant studies, including those addressing the implications of physicians' interactions with systems. Each database required distinct syntax, as outlined in Textbox 2.

XSL•FO

Limiting Retrieved Results

Each database required distinct syntax, as outlined in the query strings presented above. In subsequent stages of this review, the retrieved results were limited to those that had the potential to address the predefined RQs.

Review Process

The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [42] were followed for reporting this SLR. Refer to Multimedia Appendix 1 for the PRISMA checklist.

The data-gathering process was segmented into several stages, during which various inspections were performed.

Once the search was completed on July 25, 2024, the paper selection process was conducted in the following stages:

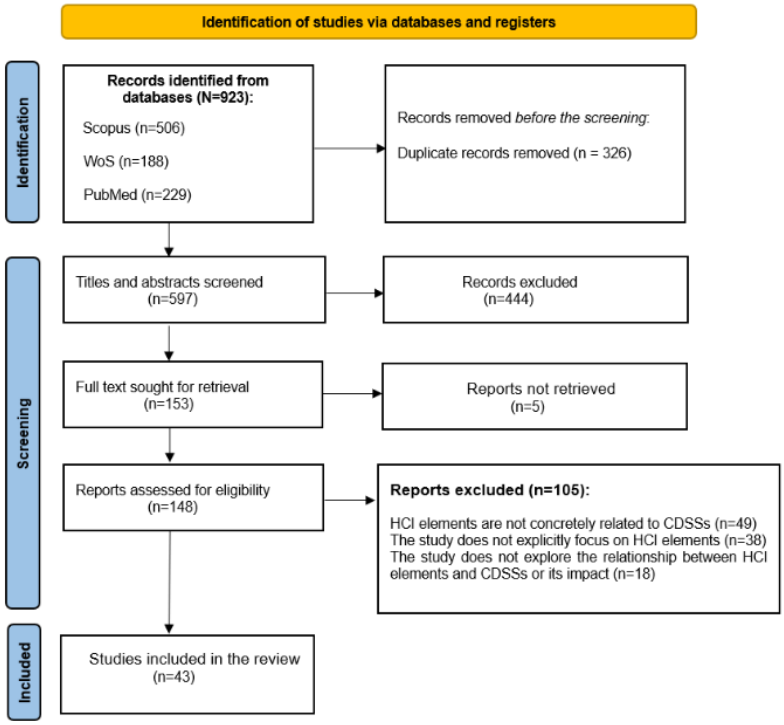
1. The raw data, consisting of records retrieved from the 3 databases, were compiled into a Zenodo repository (Multimedia Appendix 2). This dataset, which contains data from 923 papers, is organized into separate sheets for each database: Scopus (n=506, 54.8%), Web of Science (n=188, 20.4%), and PubMed (n=229, 24.8%).
2. After arranging the records, duplicate papers were eliminated. Of the 923 papers, 326 (35.3%) were removed, leaving 597 (64.7%) for the next stage.
3. At the first step of the screening, reading the titles, abstracts, and keywords and applying the inclusion and exclusion criteria resulted in 444 (74.4%) of the 597 papers being excluded, leaving 153 (25.6%) for the next phase.
4. Of these 153 papers, the full text of 5 (3.3%) was not accessible; hence, we read in detail and further scrutinized 148 (96.7%) papers. After an exhaustive examination of these 148 papers, we removed 105 (70.9%) for the following reasons: 49 (46.7%) involved HCI elements in medical environments, but these elements were unrelated to CDSSs; 38 (36.2%) did not explicitly focus on HCI or usability elements, although they discussed CDSS functionality; and 18 (17.1%) did not clearly explain the relationship between the identified HCI elements and CDSS functionality.
5. Ultimately, of the initially identified 923 papers, 43 (4.7%) were selected for the final analysis and review (Multimedia Appendix 3 [7,43-84]).

Results

Overview

This section provides a detailed analysis of the findings derived from our SLR on HCI elements that influence CDSSs. By thoroughly examining the 43 articles included for analysis, we aimed to answer the formulated RQs and MQs, thereby delineating the boundaries of this research area.

Our RQs focused on identifying the HCI elements that influence medical data management and CDSS functionality (RQ1) and understanding how these identified HCI elements can impact CDSS performance (RQ2). These questions were essential for understanding the relationship between HCI elements and the efficiency, accuracy, and usability of CDSSs.



In addition to these RQs, we formulated several MQs to comprehensively explore the scope and context of the studies. These included understanding the geographic distribution of research efforts in this area, analyzing the temporal distribution of the included studies, and identifying their publication venues. Furthermore, we examined the topic distribution in this SLR to determine the percentage of attention each identified HCI element received across the reviewed studies.

This analysis provides insights into the HCI elements investigated in the studies and how they influence CDSS functionality. This comprehensive overview offers valuable information on how HCI elements can be optimized to enhance the overall performance and effectiveness of CDSSs, ultimately contributing to improved patient care and decision-making within medical settings.

The PRISMA flow diagram [42] illustrates the steps taken to extract the required data (Figure 1).

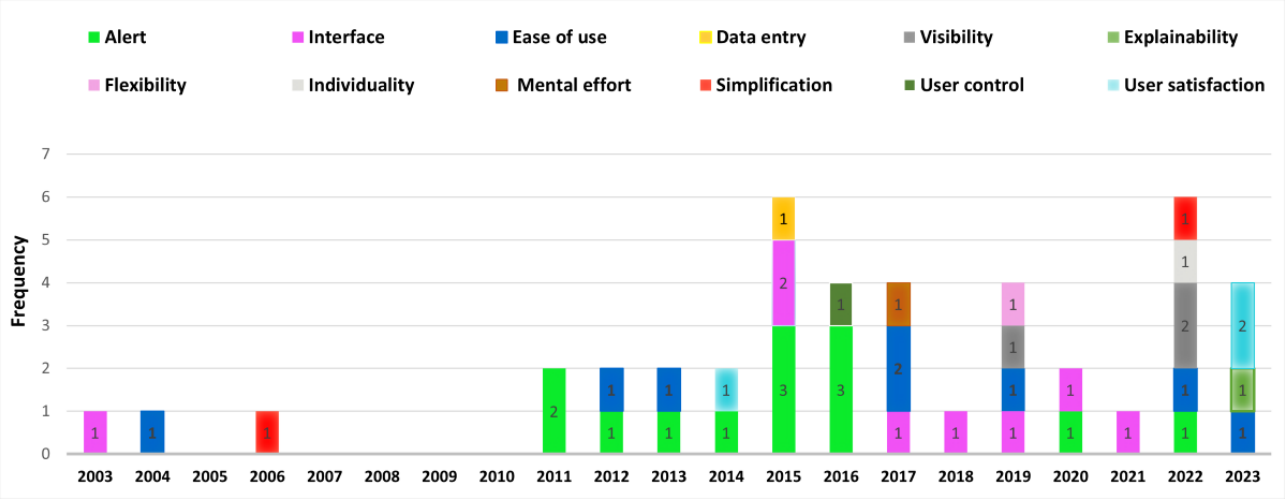
Geographic Distribution of Studies

Our investigation to address MQ1 was carried out by considering the affiliations of all authors. Consequently, a study with authors from Spain, the United Kingdom, and Sweden was attributed to all 3 countries. In total, 43 studies were conducted across 14 countries. As depicted in Figure 2, the geographic distribution reveals a significant concentration of research in the United States and Europe, reflecting global interest in enhancing CDSSs through improved HCI elements. The United States contributed the most publications, with 51% (22/43) of the relevant studies, followed by the United Kingdom with 12% (5/43); Canada with 7% (3/43); and Russia, Spain, France, and Australia with 5% (2/43). The remaining countries—Sweden, South Africa, Norway, New Zealand, Finland, and Germany—each accounted for 2% (1/43) of the studies.

Figure 2. Geographic distribution of the included studies.

Despite the rapid technological advancements and growing health care needs in Asia, our analysis revealed a notable lack of studies relevant to HCI elements in the CDSS realm from Asian countries. Addressing this discrepancy is crucial for developing cultural and contextual usability solutions to enhance CDSS performance.



XSL•FO
RenderX

Our exploration indicates that the emphasis on distinct HCI elements varies by country based on specific demands, policies, and priorities. In the United States, which has the highest research activity in this field, studies have predominantly investigated HCI elements related to CDSS alerts (9/22, 41%), UI (3/22, 14%), and ease of use (2/22, 9%). Although these core HCI elements are imperative, some specific HCI demands may be considered depending on cultural differences and local needs [85].

Year-Wise Distribution of Studies by Identified HCI Elements

Through the review process, we identified 12 HCI elements. Each included paper primarily focuses on 1 main element, as shown in Figure 3. While some papers discuss multiple HCI elements, the figure presents the dominant HCI element addressed in each paper. The bar graph illustrates which HCI elements related to CDSS received attention each year. Although the gradual formation and evolution of CDSS technology began in 1990 [14], HCI elements have gained significant attention in medical settings since the 1990s, with increasing emphasis on usability, UX, and interface design in health care technology [86]. This study depicts the conjunction of 2 concepts—HCI and CDSS functionality—that have emerged since 2003 and have seen significant advances, especially since 2015. Figure 3 highlights this growth, which is tightly related to MQ2. As shown in Figure 3, an investigation gap existed in this realm between 2006 and 2011, and most studies on this subject were carried out in 2015 and 2022. Since 2011, there has been a growing interest in exploring the relationship between HCI elements and CDSS functionality.

Figure 3. Scattering leverage of human-computer interaction elements in clinical decision support systems over the years.

This trend reflects the increasing comprehension of the importance of UCD in health care technology, aiming to improve the usability and effectiveness of CDSSs in supporting clinical decision-making processes [87].

Publication Venues: Distribution by Study Type (Journal, Conference, or Book Chapter)

Nearly all of the included papers (42/43, 98%) were published in academic journals. This indicates a strong preference for disseminating research findings related to HCI elements in CDSSs through journal publications, which are often peer reviewed and highly regarded in the academic community. Moreover, 1 (2%) of the 43 papers was a book chapter, which provides comprehensive overviews and in-depth discussions on specific topics, contributing valuable insights to the field.

This distribution, as the explicit answer to MQ3, highlights the credibility and rigor of the selected studies, ensuring that the insights and conclusions drawn from this review are thoroughly examined and well substantiated.

Identified HCI Elements That Influence CDSS Functionality and Performance

Overview

As discussed in the previous subsections, regarding our explicit question about HCI or user perspective elements with the potential to impact CDSS functionality, we identified 12 elements after a full-text study of 43 selected papers. These elements were categorized based on their inherent nature, application context, and significance to the UX, particularly from the perspective of medical staff. As illustrated in Table 1, these elements address different HCI concerns. Although HCI elements such as “interface” inherently encompass subelements such as “visibility,” “user control,” and “data entry,” these subelements have been presented independently to highlight their unique roles and distinct contributions to CDSS functionality and usability; for example, “data entry” focuses on minimizing input errors through standardized workflows, whereas “visibility” prioritizes intuitive data presentation—distinct concerns that have been highlighted in studies on clinical efficiency and user trust [60,88].

HCI elements and topics and addressed concerns	References
Accurate and structured data entry	[82]
Individuality	
Individualized and user-centered approach	[83]
Mental effort	
Cognitive load	[84]

This categorization of HCI elements aligns with the International Organization for Standardization (ISO) 9241-11 framework [89], which defines usability as a combination of effectiveness, efficiency, and satisfaction in achieving specific goals within a particular context. We found some studies (3/43, 7%) that directly evaluated CDSSs to assess "user satisfaction," focusing on the outcomes of user-system interaction. These studies align with the satisfaction component of the ISO 9241-11 standard, emphasizing users' subjective experience and acceptance of the system. In comparison, "visibility" supports the effectiveness dimension of this standard by ensuring that users remain informed about the system's status in a timely manner, facilitating accurate decision-making. Conversely, "ease of use" corresponds directly to the efficiency dimension of ISO 9241-11 because it minimizes the cognitive and physical effort required to interact with the system, enabling users to achieve their goals with minimal waste of resources or time. Moreover, "explainability" enhances effectiveness by improving users' understanding of system outputs, while "alerts" contribute to both effectiveness and efficiency, ensuring that critical information is promptly communicated without overwhelming users. Another HCI element, "user control," also strengthens effectiveness by aiding error prevention and recovery, allowing users to rectify mistakes and maintain workflow reliability. As the "interface" element impacts decision accuracy and interaction speed, it is strongly related to effectiveness and efficiency. "Flexibility" and "individuality" primarily support satisfaction because they enable system adaptability to different user needs and preferences, fostering trust and engagement. "simplification" and "mental effort" impact both efficiency and effectiveness because they reduce cognitive load, eliminate unnecessary complexity, and optimize workflow processes. Another HCI element, "data entry," contributes to accurate information for decision-making (effectiveness) and streamlines the input process to save time and reduce effort (efficiency).

The rationale for this categorization is clarified in Table 1, which outlines the main concern addressed by each study and explains how it relates to a specific HCI element. The subsections that follow provide a detailed explanation of each HCI element listed in the table.

Alerts

Overview

Alerts have been identified in this study as a major HCI element. Alerts in CDSSs are essential for enhancing patient safety and clinical efficiency. They provide immediate, actionable information to health care providers. They can warn about potential drug interactions, highlight critical patient allergies, or flag abnormal laboratory results [48]; for instance, an alert might notify a physician about a dangerously high potassium level in a patient, prompting immediate intervention. These alerts help prevent errors, ensure timely responses, and support adherence to clinical guidelines, ultimately improving patient outcomes and streamlining clinical workflows [90].

To explicitly investigate alert-related concerns within CDSSs, it is crucial to differentiate between alerts and reminders because conflating these elements can hinder effective system design. In the context of HCI within CDSSs, alerts and reminders should be discussed separately, given their distinct functions [91]. Alerts are immediate notifications requiring urgent attention, supporting real-time decision-making with minimal cognitive load. Reminders are persistent prompts designed to ensure that critical tasks are not overlooked, thereby improving adherence to clinical guidelines. They are defined as a communication or message to ensure that physicians remember critical tips [92]. Reminders can cause cognitive overload and frustration if they are too frequent or irrelevant—in such cases, they are categorized as barriers. Conversely, when reminders assist physicians, they are considered facilitators [93]. This distinction ensures a more effective optimization of HCI elements in CDSSs, balancing support and usability.

The findings from this SLR demonstrate that 31% (13/43) of the selected papers addressed alert-related topics, while Figure 3 shows that this element was mostly studied between 2011 and 2016 (11/13, 85%), although some studies (2/13, 5%) have been conducted in recent years (2020 and 2022). Research on alerts has focused on 3 main areas. Table 1 presents the studies that have addressed these categories, which are detailed in the following subsections.

Alert Fatigue

Alert fatigue poses a significant challenge for CDSS instruments because users may begin to neglect or override activated alerts due to their frequent occurrence [94]. In 2016, Gong and Kang [47] presented five solutions to address alert fatigue: (1) augmenting alert specificity, (2) tiering alerts based on severity, (3) applying human factors principles (such as format, content, legibility, and color), (4) customizing alerts based on patient attributes, and (5) providing tailored alerts for medical practitioners.

The timing of alerts is crucial because they should be presented at moments conducive to informed medical decision-making. It is important to strike a balance: alerts should be intrusive enough to capture attention, but they should not distract or divert users from the primary care pathway [45]. Maintaining this balance prevents alert fatigue, sometimes referred to as habitual override.

XSL•FO
RenderX

Usability Flaws

Usability flaws relevant to CDSSs that diminish alert performance have been identified as follows [43]:

- The distinguishing visualizations do not illustrate the variety of severity levels in the alerts.
- The information presented within alerts is dense and lacks brevity.
- A low signal-to-noise ratio, reflecting a high proportion of erroneous alerts compared to correct ones, often results from nonupdated or incorrect data.
- Alert content issues stem from missing information relevant to alert goals, data interpretation, or necessary practical recommendations.
- There is a scarcity of transparency regarding the reasons that have led to the triggering of the alert.
- The clinicians are not directed at fixing the problem identified by the alert.
- Adaptability issues point out the insufficient adjustability of the system to accommodate all types of users.
- Workload issues arise when too many tasks need to be performed to correct errors or obtain the required information.

In medical information systems, 2 main types of alert flaws are commonly observed: general and specific. General alert flaws occur when alerts lack specificity or fail to distinguish between different severity levels [44]. Specific alert flaws arise when alerts do not adequately address individual patients' or health care providers' unique contexts or needs, leading to ineffective or irrelevant notifications [95].

Alert Design Recommendations

Alert design recommendations have been addressed across the following aspects to enhance alert effectiveness (Textbox 3). Enhancements in alert functionality within CDSSs can optimize clinical workflows, ensure timely access to relevant information, mitigate alert fatigue, foster user trust, and ultimately contribute to more informed and effective clinical decision-making processes [68].

Textbox 3. Alert design recommendations.

- The visual presentation of alerts can be improved by using different colors, bullet points, and clear textual guidelines [48].
- Alerts should be triggered at appropriate points within the clinical workflow and should align with real-world practices [50].
- False alarms that can occur when the alert's logic is flawed or not based on updated information must be avoided. In some cases, rigid sensitivity calibrations can result in false alarms [49].
- The presentation of alerts should be determined based on their level of importance; for instance, higher-priority alerts may be presented in a way that interrupts the current workflow [50].
- Habituation pertains to repeated exposure to insignificant alerts. This underscores the importance of reducing the occurrence of false alarms, along with adopting an alarm philosophy aimed at minimizing alert overrides [49].
- Consistent terminology emphasizes the use of standardized and predefined words and expressions. This enhances the ability to locate specific words or data on the screen through visual screening and promotes uniformity in the generated data irrespective of geographic location [96].
- Mental models refer to an individual's interpretation of a specific matter that influences their reaction when an alert is triggered; for instance, the color red typically evokes an immediate association with "STOP" [49].
- The content of the alert—the reason for its activation and potential medical consequences—should be kept concise [97], with additional details accessible through related data links [98].
- Font style and size can be used to convey the importance and prioritization of the alert [51,99].
- Alert visibility is a critical HCI component that should be considered in the design of alerts within the CDSS environment [52]. The alert's dimensions as displayed on the screen (target size), luminosity, background contrast, and typography attributes should be carefully considered to quickly capture the user's attention [100,101].
- The degree of workflow interruption must be proportional to the severity of the medical issue that triggered the alert [51]. For high-priority alerts, it may be necessary to interrupt the workflow to prompt immediate user intervention [52].
- To ensure the proximity of decision-making components, decision support tools must be incorporated within the alert; for example, the alert should include hyperlinks to medical reference websites [53].

Excessive and Unnecessary Alerts

Particularly in specific patient populations or under uncommon circumstances, excessive and unnecessary alerts represent a significant barrier to the effective use of alerts within CDSSs. This obstacle can be resolved by grouping similar alerts into a single notification and tailoring alert thresholds and delivery methods based on patient condition and clinical context [54].

Ease of Use

Ease of use was identified as a principal user concern in 19% (8/43) of the selected papers. This element is foreseeable and represents a standard expectation among users, particularly physicians. In this respect, systems should be designed so that users easily understand how to operate the system. This is referred to as perceived ease of use. A positive perceived ease of use is associated with an increased intention to use (IU) [55].

The concept of consistency will augment a system's ease of use. It can be achieved in 2 distinct areas: jargon-free language and consistent operative patterns. Consistent terminology and operation across all system components minimize user confusion and cognitive load, enabling users to quickly and effectively achieve their goals [59].

XSL•FO
RenderX

In essence, a system that is easy to use enhances learnability because users can understand and remember operational procedures more quickly [102].

In a CDSS environment, ease of use can significantly boost system functionality by ensuring that health care professionals can quickly and without complexity access and apply clinical guidelines and decision aids [58]. In this regard, a key facilitator is automated data fetching, which streamlines the retrieval of relevant information, minimizing complexity and allowing users to focus on patient care [62].

Moreover, goal-directed design is a user-centered approach that prioritizes understanding user needs and goals throughout the design process. By engaging end users throughout the design process, goal-directed design ensures that the system effectively supports their tasks and contexts. This alignment directly contributes to ease of use by streamlining interactions and enhancing UX [61].

Interface

Interface, another important HCI element**,** was addressed in 19% (8/43) of the selected papers, especially between 2015 and 2021. While interface design inherently encompasses various HCI elements, the analyzed papers offer unique insights that extend beyond the scope of other discussed elements. These papers provide specific recommendations for interface improvements that can significantly enhance user interaction by optimizing system design and fostering intuitive use.

The interface of a CDSS directly influences acceptability by determining how intuitively users can access and act on clinical information. When the interface aligns with users' workflows and preferences, it increases their willingness to adopt and use the system effectively [63]. Despite recent advances in computerized technologies, the defective design of graphical UIs in clinical settings may lead to frustration among physicians [10]. In the context of CDSSs, the UI refers to the graphical or visual representation through which users interact with the system to access, input, and interpret information [63]. An effective UI should be intuitive, user-friendly, and tailored to health care professionals' specific needs and workflows [64].

Via integration with EHRs, well-designed interfaces within CDSSs can present a list of possible diagnoses associated with medical symptoms, the compatibility percentage of the patient's current medical status, and the factors contributing to the diagnosed illness [65,103]. In addition, effective data visualization enables quick comprehension of complex information, promoting time efficiency by enabling health care professionals to rapidly interpret data without the need for extensive analysis [66].

A responsive and interaction-enabled UI encompasses 2 distinct features: presentation and placement. In terms of presentation, elements such as simplicity, appropriate font size, meaningful colors, acceptable contrast, and bold text enhance readability and user engagement. Regarding placement, information should occupy a prominent position, be localized for easy access, and use multiple presentation layers to facilitate quick comprehension. Together, these interface features facilitate the seamless flow of essential medical data to decision makers [67].

In the interface realm, the physical layout concept refers to the arrangement and organization of screen objects with which users interact. This layout significantly impacts user control, allowing health care professionals to directly manipulate the screen's objects (such as buttons, sliders, and forms). When users have clear control over screen objects, they can more effectively navigate the system, customize their workflow, and respond to patient needs promptly, ultimately improving overall usability and satisfaction with the CDSS [68].

There are some facilitators and barriers relevant to the interface within CDSS environments. One of them is the content-based facilitator that enhances interface usability by presenting clear, concise, and relevant information. In this respect, tailoring content to meet the health care professionals' specific needs and preferences and providing real-time updates on clinical guidelines will enhance the interface. Conversely, inconsistent content within the data presentation and guidelines, potentially leading to confusion and misinterpretation, has been identified as an interface barrier [69].

One reviewed paper introduced the concept of "heuristic tags" to enhance CDSS interface design [70]. The paper describes a container comprising 14 HCI elements relevant to CDSS environments, referred to as semantic tags [70]. These elements are outlined in Table 2.

XSL•FO
RenderX

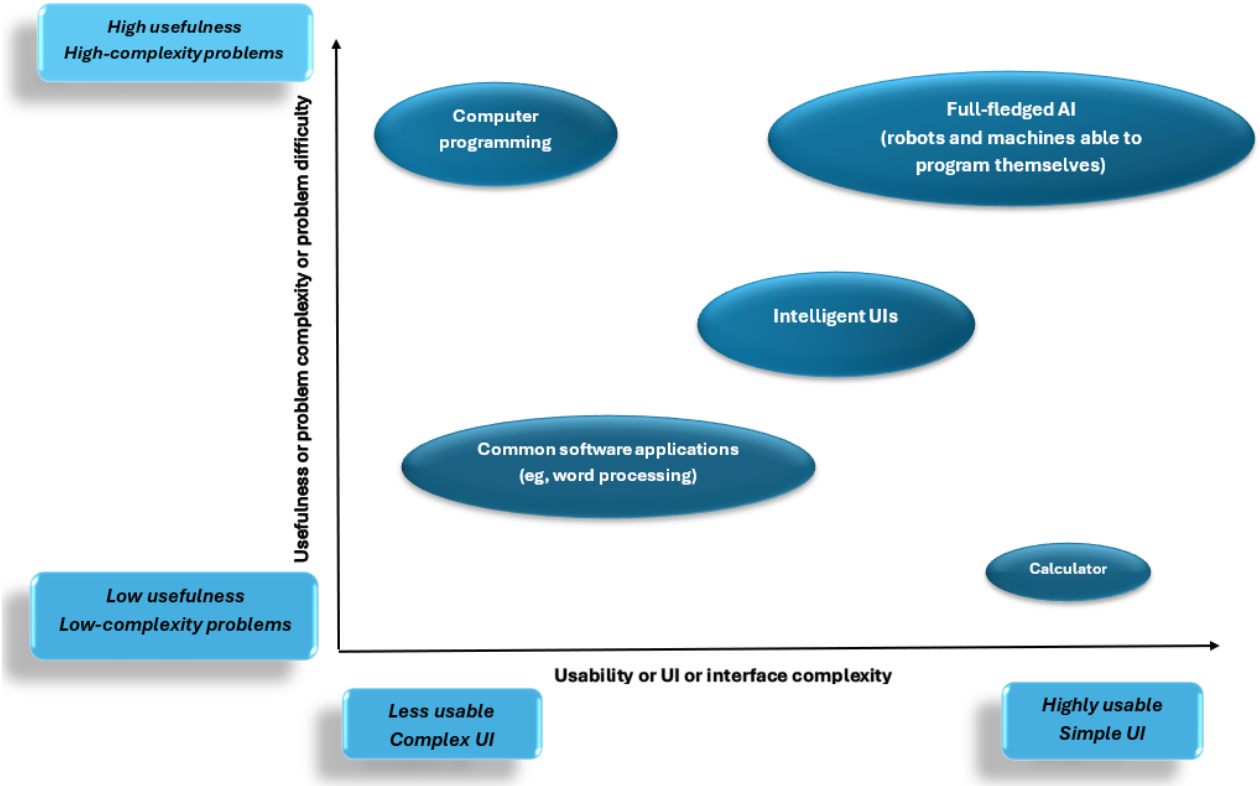
Table 2. Semantic tags.

Tag	Description
Consistency and standards	All system providers throughout the design must adhere to a unified protocol by maintaining consistency in terminology, sequence of actions, and data localization.
Visibility of the system status	Users should be notified of ongoing processes via suitable alerts and feedback mechanisms.
Match between system and world	Users' perceptions of the system should align with their mental models of how the system is expected to function.
Minimalist design	Any unnecessary information should be eliminated because it acts as a distraction and impedes efficiency.
Minimize memory load	Users should not be required to memorize extensive information to perform routine tasks.
Informative feedback	Users must receive informative feedback regarding their activities.
Flexibility and efficiency	The system should provide resiliency so that users can customize settings and expedite their tasks.
Good error messages	Messages should provide sufficient information for users to comprehend the nature of errors, learn from mistakes, and take corrective action.
Prevent errors	The design should deter errors by preventing incorrect actions.
Clear closure	Users must be explicitly informed when a task has been completed.
Reversible actions	Users should be allowed to recover from errors made by them.
Use user's language	The system language must be comprehensible to the targeted users.
Users in control	Users should not feel in control of the system without encountering unforeseen circumstances.
Help and documentation	The system should offer various forms of help, such as contextual assistance, mission-focused guidance, and alphabetically organized (lexicographically arranged) help topics for easier navigation.

Therefore, interface quality will influence the precision of medical decisions by facilitating intuitive access to relevant information and enhancing user interaction.

Visibility

Visibility was addressed in 7% (3/43) of the selected papers, emphasizing that quick access to information requires data to be readily accessible within a short time frame and ensuring that medical data are available at expected locations. This includes the clear and immediate visibility of possible errors or system warnings, allowing users to identify and address issues quickly [71]. Within the treatment cycles pertinent to CDSSs, visibility refers to the clarity and transparency of the workflow stages and progress, meaning that health care providers can easily track and understand the status of the treatment process, including diagnostic tests, medication administration, and patient outcomes [72]. In addition, by visually emphasizing critical information such as high-risk alerts or abnormal laboratory values through color coding, bold text, or other visual cues, clinicians can quickly identify and prioritize important information [73]. As visibility criteria provide a clear and transparent view of the treatment cycle workflow, they enable users to easily monitor the progress of patient care and make informed decisions based on the current stage of treatment, leading to the best possible decision [73].



Simplification

Of the 43 selected papers, 2 (5%) addressed simplification elements. Simplification can be achieved by eliminating unnecessary complexities and providing an optimized workflow congruent with real-world practices [104]. Removing extraneous information and procedures is crucial for achieving this goal [74]. Pantazi et al [75] propounded a theory describing a paradox between simplification a medical system and its usefulness: systems with high usability typically can solve trivial problems, whereas solving intricate problems requires an appropriate level of complexity, which can reduce overall usability.

As shown in Figure 4 [75], some CDSS applications designed for intricate problems have complex UIs with lower usability levels, whereas sections with simpler structures within CDSSs, such as medical calculators, exhibit higher usability levels. Meanwhile, system designers are striving to develop medical AI systems that simultaneously enhance both usability and problem-solving capacity.

XSL•FO
RenderX

Figure 4. The relationship between system complexity and usability. AI: artificial intelligence; UI: user interface.

Nonetheless, while striving for complexity in medical procedures can be inherently beneficial, it is crucial to maintain a balance between usability and necessary intricacy [105]. Striking this balance ensures that procedures are not unnecessarily complex, saves time, and ultimately enables rapid emergency medical decision-making [106,107].

User Satisfaction

User satisfaction was discussed in 7% (3/43) of the selected papers. Recognized as a central focus in HCI research, user satisfaction is paramount to the effectiveness of CDSSs. This concept encompasses aspects such as system acceptability, learnability, memorability, and accessibility [76].

UCD methods are essential for achieving high user satisfaction [108]. By prioritizing the user's needs and perspectives throughout the development process, CDSSs can be tailored to meet their specific requirements [109]. Learnability facilitates users in quickly understanding how to operate the system, which enhances initial engagement [110]. Memorability ensures that the system's functions are easily recalled once learned, reducing the need for repeated training [111]. Accessibility ensures that the required medical information and history are promptly accessible in the system [77]. Incorporating these elements boosts overall user satisfaction, improves efficiency and adoption, and ultimately leads to better patient outcomes in clinical environments.

Conversely, the mismatch between meaningful-use criteria and physicians' expectations represents a significant barrier to user satisfaction within CDSSs. In these cases, the requirements set by system designers do not align with physicians' practical needs and processes, leading to frustration and decreased usability. This misalignment can hinder the effective adoption of CDSSs because physicians may find the systems cumbersome or irrelevant to their clinical workflow. Addressing this gap is essential for improving user satisfaction and ensuring that CDSSs effectively support health care professionals in delivering high-quality patient care [78].

Explainability

Explainability, as identified in 2% (1/43) of the selected papers, is a critical focus in the ongoing discourse surrounding CDSSs and medical AI [112]. Transparency, a cornerstone of explainability, fosters trust between the user and the system [113]. Once the CDSS provides recommendations and solutions, physicians can understand why and how the advice was generated. This understanding augments their clinical expertise and contributes to more informed decision-making over time [79].

Flexibility

Flexibility was articulated in 2% (1/43) of the selected papers. This element requires significantly more attention and could be leveraged to enhance CDSS functionality. Adjustable medical systems typically achieve higher adoption rates, particularly when they meet physicians' need for flexibility [114]. In this context, 3 diverse dimensions related to flexibility concerns have been identified [80]: (1) user tendency to return to previous stages to correct or modify information; (2) data entry in multiple different sequences; and (3) customizable data presentation.

Flexibility is a crucial attribute when designing digital pathways. By aligning flexibility with actual clinical workloads**,** treatment

XSL•FO
RenderX

routes can be tailored to meet physicians' and patients' specific needs and demands [115]. This alignment enhances medical decision accuracy, enhances user satisfaction, and ultimately improves patient outcomes [116].

User Control

User control was addressed in 2% (1/43) of the selected papers, emphasizing the importance of instructions that align with real-world workflows, aiding users in recovering from and preventing errors. Interfaces that are compatible with established practices help users rectify mistakes and reduce the recurrence of common errors, enhancing overall usability and efficiency [81]. In this context, an important framework is the unified theory of acceptance and use of technology (UTAUT). UTAUT is used to predict and understand individuals' acceptance and adoption of new technologies, integrating various factors such as performance expectancy, effort expectancy, social influence, and facilitating conditions. By enabling users to recover from mistakes and easily control their interactions, systems can enhance user satisfaction and increase the likelihood of technology adoption, as predicted by the UTAUT model [117].

Data Entry

Data entry was investigated in 2% (1/43) of the selected papers, with a focus on designing systems that minimize potential user errors [82]. Structured data entry management is fundamental in CDSSs, ensuring organized, standardized, and systematic data input. Emerging technologies such as voice recognition technology and natural language processing have facilitated and improved the data entry aspect in eHealth systems. These advancements minimize errors and inconsistencies, ultimately enhancing the reliability and effectiveness of CDSSs in supporting clinical decision-making [118].

Individuality

Individuality was presented in 2% (1/43) of the selected papers. In this area, Klumpp et al [83] discuss the HCI concept as a theory encompassing 4 key issues that shape individuals' interactions with computerized systems. The first factor is the identification of technology, including all technological features applied to the system [119]. The second factor is the assignment, referring to a defined task where the technology used varies depending on the satisfaction and aims of the task [120]. The third factor is context, which can vary depending on the geographic, corporate, or community conditions, meaning that the recommendations should be customized according to the geographic positions and other local conditions [121]. The fourth factor involves human dimensions, such as population characteristics, cognitive abilities, and the attitudes of individuals [122]. In other words, customizability should be based on the intended populations' approaches, attributes, and desires. Concentrating on system individualization and customization can enhance the accuracy of decision-making in CDSSs [83].

Mental Effort

Mental effort was identified as an HCI element in 2% (1/43) of the selected papers. The Rating Scale Mental Effort (RSME), first proposed by Militello et al [84], is designed to accurately measure perceived mental effort during task completion. In other words, it measures the extent to which individuals feel they have exerted mental effort to complete a task. The RSME can be used to gauge how effectively CDSSs aid medical practitioners without overly complicating their decision-making processes. A low RSME score indicates that the CDSS is well integrated into clinical workflows, and CDSS functionality is enhanced without imposing significant additional cognitive complexity on the user [123].

Discussion

Principal Findings

While several studies have explored HCI elements in CDSS environments, each has focused on specific aspects independently. This has left a research gap regarding a comprehensive analysis and categorization of these effective elements. This study attempts to present a scientific framework for CDSS design by identifying HCI elements that influence CDSS functionality across different dimensions. In this respect, after reviewing 43 selected papers in this SLR, we identified and stratified 12 key HCI elements, thereby distinguishing our investigation from the selected studies, which, although they explored the identification and classification of HCI elements, were experimental in nature, with a limited focus on specific, monitored elements.

A common thread among the selected studies is their focus on HCI elements relevant to CDSS applications, which can substantially influence CDSS functionality and performance. Throughout this SLR, the categorization of studies under specific HCI elements depended on the primary focus of each study. While some studies explicitly investigated a single HCI element, others addressed multiple aspects (such as heuristic semantic tags [70]) or offered broad recommendations. In such cases, the main HCI concern emphasized in the study was the selection criterion. This approach ensured that each study was categorized based on its core usability focus, maintaining consistency and relevance in the analysis.

Throughout this SLR, the categorization of studies under specific HCI elements depended on the primary focus of each study. While some studies explicitly investigated a single HCI element, others addressed multiple aspects (such as heuristic semantic tags [70]) or offered broad recommendations. In such cases, the main HCI concern emphasized in the study was the selection criterion. This approach ensured that each study was categorized based on its core usability focus, maintaining consistency and relevance in the analysis.

The interface is considered a distinct HCI element because it serves as the primary medium for user interaction [124]. Although it encompasses visibility, data presentation, and ease of use, its role transcends these components [125,126]. Indeed, the interface functions as the platform that enables the delivery and experience of these elements, making it a distinct and critical component of the HCI context [127]. This distinction is crucial for CDSS environments, where the interface must accommodate complex clinical workflows and user needs to ensure usability and patient safety. Hence, despite its broad scope, the interface has been examined as an independent HCI element in some

XSL•FO
RenderX

studies, allowing for a more focused and in-depth evaluation of its inherent contributions to UX and decision-making in CDSS environments [128]. Thus, we considered it a separate HCI element in this study.

The relationship between HCI and UI and UX design further underscores the importance of the interface as an independent element. While UI focuses on the visual and interactive components of a system (eg, buttons, menus, and layouts) and UX encompasses the user-centered experience (including usability, accessibility, and emotional satisfaction), the interface concept (within HCI) is the physical manifestation of these principles [129,130]. As Paneru et al [131] explain, the interface is a visual and interactive layer that enables users to interact with digital products. It is the medium through which all other HCI elements are experienced, making it a foundational component of HCI. However, the interface also extends beyond traditional UI and UX design by incorporating considerations such as workflow alignment, cognitive load reduction, and task efficiency, which are central to HCI. By contrast, Motlagh and Safaei [132] emphasized that, rather than relying solely on UI and UX considerations, HCI evaluation in health care systems should prioritize error prevention, cognitive effort, and information recall. This means that HCI elements promote interfaces that support accurate decision-making and clinical workflow integration.

According to ISO 9241-11, usability measures how effectively, efficiently, and satisfactorily users can achieve their goals with a system in a particular context. This highlights the importance of context and task dependency in evaluating usability because the relevance and effectiveness of HCI elements vary across different environments and user needs [133]. The HCI elements identified in this study align with these usability dimensions but manifest differently depending on task requirements and system context. In frequently used systems such as EHRs in busy hospitals, ease of use, simplification, and task efficiency are paramount HCI elements. Clinicians using these systems need interfaces that minimize cognitive load and streamline workflows because even small inefficiencies can accumulate, leading to frustration and errors. In this context, alerts must be designed to be highly visible but nonintrusive so that they support rather than disrupt workflow [48]. In these circumstances, data entry mechanisms should be optimized for speed and accuracy because frequent use requires efficiency. Conversely, in an infrequently used system (such as a specialized diagnostic tool used only occasionally), HCI elements such as explainability become more critical. Users of such systems will need more guidance and contextual support to navigate the interface effectively. Regarding user control and flexibility, although these elements align with the satisfaction component of the ISO 9241-11 standard, their impact is also context dependent. Experienced physicians may prefer more flexible customization to streamline interactions, while novice users benefit from structured interfaces with clear navigation paths and constraints to prevent errors [80,81]. As shown in Table 1, the identified HCI elements were categorized based on their primary usability contributions; nevertheless, their actual significance in improving CDSS usability depends on the task, frequency of use, and clinical environment.

Two closely related but distinct HCI elements—ease of use and simplification (simplification)—play unique roles in enhancing CDSS usability. Ease of use refers to the system's ability to provide an intuitive and seamless interaction experience, minimizing cognitive and physical effort for users. It encompasses aspects such as jargon avoidance, consistency of operations, and efficient task execution, ensuring that clinicians can navigate the system with minimal frustration [56,58-60]. By contrast, simplification focuses on reducing unnecessary complexity within the system, such as streamlining workflows, eliminating redundant steps, and minimizing information overload [74,75]. While ease of use improves UX, simplification optimizes system design by removing obstacles and extraneous procedures that could hinder task completion. Moreover, ease of use is closely tied to user satisfaction and IU. An easy-to-use system facilitates navigation, reduces cognitive efforts, and leads to a more positive UX, ultimately increasing IU and user satisfaction.

This study recognized another prevalent and critical challenge faced by CDSS designers: balancing the paradox between system simplification and maintaining its usefulness in solving complex problems, even if doing so leads to increased complexity. This balance is essential for developing systems with high usability and appeal, ensuring that users can effectively interact with the system without being overwhelmed by its complexity [75]. To reach this equilibrium, designers must adopt a user-centered approach that prioritizes the needs and capabilities of health care professionals. This involves continuous user testing and feedback loops to refine the interface and functionality [59]. In addition, incorporating adaptive interfaces can reduce complexity based on the user's expertise and the specific task to help manage this paradox, resulting in augmented overall satisfaction and higher adoption rates [65].

This study attempted to highlight the HCI elements dedicated to CDSSs, specifically those that address user requirements across various dimensions such as informative notifications [52], aesthetics [61,71], contextual facets [79], unification [70], and psychological aspects [84]. To illuminate all HCI aspects within CDSSs, this study also identified elements that represent challenges in this domain requiring mitigation, such as existing HCI barriers [78], usability flaws [43], user fatigue [7], and the phenomenon of alert override [49]. Although considering the identified HCI aspects is crucial, the final goal is to improve user interaction with the system, enhance ease of use, and anticipate and fulfill user expectations. This approach fosters user satisfaction and promotes a positive UX [74]. This focus on users as major "players" in the design process is now an established principle. Hence, UCD methods are fundamental to the development of CDSSs with high levels of user interaction [134]. Depending on the system's complexity and ease of use, both user interaction with the system and data accuracy can vary, consequently affecting the accuracy of medical decision-making [58].

In summary, this study provides comprehensive insights into the essential HCI elements applicable in the CDSS environment, answering the RQs. It contributes to the field by systematically categorizing these elements and developing a structured

XSL•FO
RenderX

framework aimed at improving usability and medical decision-making outcomes.

Conclusions

Of the 923 papers found in 3 databases (PubMed, Scopus, and Web of Science), 43 (4.7%) met the predefined criteria with regard to addressing HCI elements applicable in CDSS environments. This SLR indicates that attention to HCI elements tailored to CDSSs has increased since 2015. In this study, we identified 12 HCI elements. While elements such as "ease of use," "interface," and "alerts" have consistently garnered attention from experts, others such as "user satisfaction," "visibility," and "explainability" have recently received increased focus. This SLR has answered the RQs regarding the HCI elements that can affect CDSS functionality and described how these elements impact CDSS performance. Moreover, the study categorized the identified aspects according to their context and scientific perspectives.

This study identified a gap in current research: the lack of a comprehensive consideration of HCI elements within CDSS design. By leveraging the findings from this investigation, a set of applicable HCI elements for CDSS environments can be established. Consequently, these findings have the potential to enhance the synergistic effect between medical information systems and CDSSs, ultimately leading to improved overall performance.

This research provides the groundwork for generating more structured and reliable datasets to support medical decision-making. Systems designed with these HCI elements are expected to reduce missing data, minimize data redundancies, and improve data clarity. Accordingly, the accuracy and reliability of medical decisions derived from these systems will be noticeably enhanced. Future studies can leverage this framework to develop and examine CDSS systems that improve user interaction and ensure higher data integrity and precision in medical decision-making. This structured approach will advance medical informatics, leading to more efficient, accurate, and user-friendly CDSS solutions.

Acknowledgments

The authors appreciate all researchers' efforts regarding human-computer interaction concerns, especially within clinical decision support systems. The Spanish Ministry of Science and Innovation partially funded this research through the Analítica Visual y machine learning para toma de decisiones en ecosistemas de Salud (AVisSA; "Visual Analytics and Machine Learning for Decision-Making in Health Ecosystems") project (PID2020-118345RB-I00).

Authors' Contributions

AA and FJG-P contributed to conceptualization, methodology, and validation. AA contributed to formal analysis, investigation fulfillment, visualization, and writing—original draft preparation. FJG-P contributed to project administration and writing—review and editing. Both authors have read and agreed to the published version of the manuscript.

Abstract

Background: Disparities in health equity between metropolitan and rural areas are a global concern, especially in vast countries such as Australia, Canada, and the United States. Virtual care models in health care settings are promising in reducing inequalities, with virtual hospitals (VHs) potentially bridging the gap for isolated or underserved regions. However, evidence-based strategies and the complexities of VH implementation necessitate further research.

Objective: This rapid review aims to examine the role of VHs in enhancing regional and remote health care by focusing on accessibility, patient and health care provider experiences, and implementation barriers and facilitators. It provides tailored recommendations for large-scale implementation in communities with access issues, contributing to the discussion on equitable health care.

Methods: A rapid review was conducted in accordance with the World Health Organization guidelines. A systematic search was performed across PubMed, MEDLINE, CINAHL, and the La Trobe University Library for peer-reviewed articles published between January 2015 and March 2023. Additional gray literature was identified through Google searches and snowballing from relevant web articles. Studies were included if they focused on regional or remote populations and addressed VHs or virtual care. Studies that solely discussed hybrid models of care were excluded. Data were systematically extracted using a customized Microsoft Excel template. A mixed methods thematic analysis was conducted to identify recurring themes, barriers, facilitators, and recommendations related to VH implementation as well as patterns in clinical outcomes and stakeholder perspectives.

Results: A total of 35 articles were included in this review, comprising 23 (66%) peer-reviewed studies and 12 (34%) gray literature sources. Positive clinical outcomes were reported in 9 (26%) articles, highlighting outcomes such as reduced disease transmission, improved patient safety, fewer admissions and readmissions, lower mortality, shorter hospital stays, and better adherence to clinical best practices. Health system outcomes were identified in 15 (43%) articles, including reduced costs, enhanced patient experience and safety, improved care delivery and health care provider support, greater efficiency, broader geographic coverage, and better integration of services. Patient and health care provider perspectives were discussed in 12 (34%) articles, with positive views attributed to convenience, time and cost savings, and improved service quality. Barriers and facilitators were the most frequently discussed themes, appearing in 27 (77%) and 26 (74%) articles, respectively, with challenges and enablers commonly linked to people, processes, technology, and financial sustainability.

Conclusions: VHs have the potential to revolutionize regional and remote health care by overcoming barriers, using facilitators, and following recommended practices, leading to better clinical outcomes and increased satisfaction for patients and health care providers.

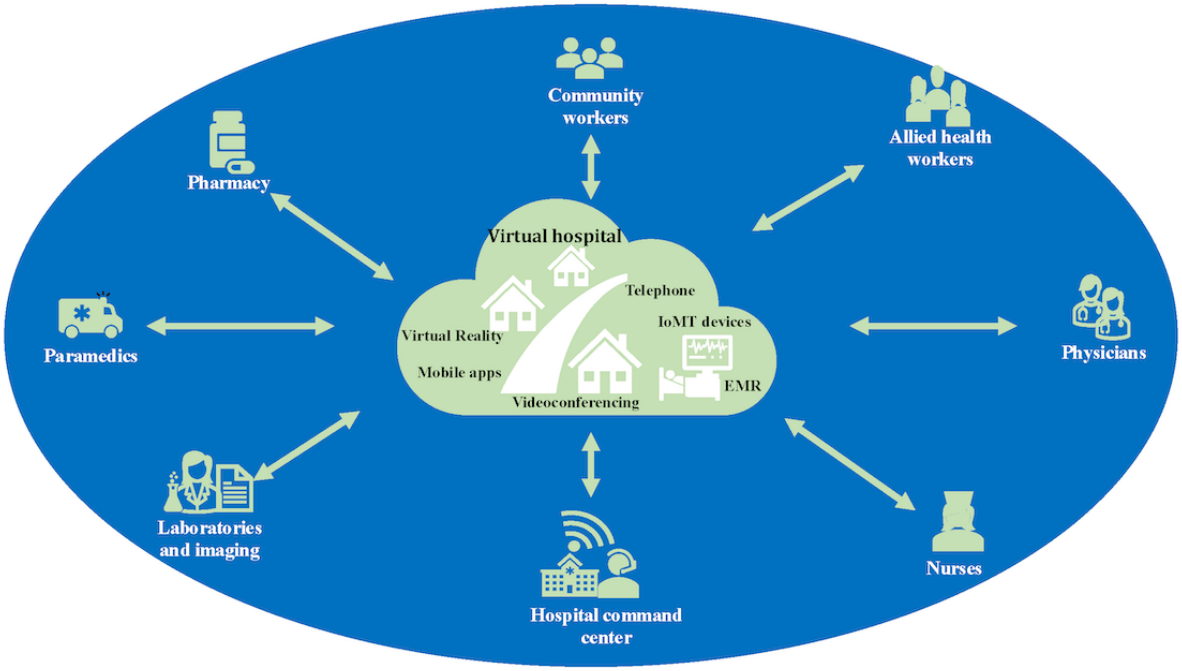
Introduction



Background

Health care disparities between rural and remote regions and urban centers are a global challenge. Countries such as Australia, Canada, and the United States have documented significant disparities in health care access and outcomes [1-3]. Data from the Australian Institute of Health and Welfare reveal a 1.4-fold increased incidence of disease in remote and very remote regions compared to urban cities [2]. Furthermore, in very remote regions, the risk of premature mortality is elevated by 1.3 times for men and 1.5 times for women compared to metropolitan areas. This disparity aligns with findings from the Centers for Disease Control and Prevention, which highlights the challenges faced by rural Americans due to limited access to specialized and emergency health care, ultimately contributing to a higher prevalence of preventable deaths in these communities [4].

Traditional health care models often struggle to provide equitable services in geographically isolated regions due to shortages of medical facilities, specialized professionals, and advanced diagnostic equipment. Consequently, rural and remote populations experience higher rates of preventable diseases, avoidable hospitalizations, and mortality compared to urban counterparts [2,4,5]. In Australia, hospitalization rates for preventable conditions are 2.5 times higher [2]. Similarly, in the United States, rural populations have a 20% higher overall mortality rate compared to urban counterparts, and 1 in 5 rural adults experience multiple chronic conditions, leading to increased rates of preventable hospitalizations and deaths [5].

The emergence of virtual health offers a promising solution to bridge the health care gap in regional and remote locations. Virtual health, driven by digital technologies, has made considerable strides, transforming primary, secondary, and tertiary care services. Health care institutions have embraced virtual health solutions, such as virtual hospitals (VHs), to provide advanced treatments, surgical consultations, multidisciplinary team discussions, and hospital-at-home care, enhancing patient access to complex medical interventions. VHs leverage digital initiatives, such as telehealth and telemedicine technologies, to deliver a comprehensive range of remote health care services, including consultations, diagnostics, treatment plans, and hospital-level care at home [6]. These services are typically delivered through videoconferencing, web platforms, mobile apps, and other digital channels. Figure 1 further illustrates the concept of a VH.

Figure 1. Concept of a virtual hospital. IoMT: Internet of Medical Things; EMR: electronic medical record.

Unlike traditional hospitals with physical infrastructure, VHs operate primarily in the digital realm. Their significance lies in their ability to transcend geographic barriers, enhancing access to health care for patients in remote or underserved areas [7]. It is important to note that while the terms VH, virtual care, hospital at home (virtual wards), and telehealth are sometimes used interchangeably, there are key distinctions between them. Virtual care represents a broad spectrum of health care services delivered remotely, encompassing a range of synchronous and asynchronous technologies and applications. Talevski et al [8] states that virtual care refers to “the integration of digital technologies across the continuum of care to improve patient

XSL•FO
RenderX

outcomes." This definition covers existing health care programs, such as the Victorian Virtual Emergency Department [8], the Ochsner Connected Health Remote Patient Monitoring (RPM) Program [9], and the Cleveland Clinic Express Care Online [10]. Telehealth, on the other hand, is a subset of virtual care that primarily focuses on real-time communication between patients and providers using telecommunication technology [11]. An example of virtual care outside the scope of telehealth is RPM. RPM systems use devices, such as wearables or sensors, to collect and transmit health data, such as heart rate or glucose levels, to health care providers for analysis [12]. This occurs asynchronously, making it distinct from the real-time communication that characterizes telehealth. On the other hand, VH represents a more comprehensive approach to remote health care, offering a wide range of services beyond consultations, including remote diagnostics, treatment plan development, and virtual wards [13]. Hospital-at-home programs, a subset of VH or stand-alone initiatives, provide hospital-level care in the patient's home, incorporating remote monitoring and regular consultations [14].

Digital health technologies form the cornerstone of modern health care delivery systems, including virtual care, telehealth, VHs, and hospital-at-home programs, facilitating remote health care services through diverse technological platforms and applications. According to the World Health Organization [15], digital health encompasses "the field of knowledge and practice associated with the development and use of digital technologies to improve health". This definition encompasses the various terms often used when discussing the design and implementation of technology in health care, including virtual care, telehealth, and VHs. The Healthcare Information and Management Systems Society [12] further characterizes digital health as a comprehensive framework that incorporates various digital technologies, systems, and platforms designed to deliver health care, manage health information, and enhance patient care delivery.

The COVID-19 pandemic accelerated the adoption of VHs as a means to manage health care demands while mitigating infection risks. This rapid expansion led to demonstrated improvements in patient outcomes, including length of stay (LOS) and improved wait times [16-18]. Success stories, such as the Royal Prince Alfred VH [19], the Mayo Clinic Advanced Care at Home program [20], and the Victorian Virtual Emergency Department [21], further exemplify the capability of VHs to deliver effective health care remotely. The experience gained during the pandemic highlights the need for strategic planning and investment in VHs to address health care disparities in rural and remote areas [22,23].

The successful implementation of a VH is a complex endeavor, requiring careful planning, assessment, and integration of digital technologies [24]. Challenges such as inadequate guidance, poor governance, limited technological literacy, and concerns about safety and privacy can hinder the seamless adoption of VHs and related virtual care-from-home solutions [17,18]. To overcome these barriers and successfully implement VHs, evidence-based recommendations must be prioritized [25].

Research Focus and Aims

Despite the potential of VHs to transform health care delivery, there is a notable lack of evidence supporting context-specific and comprehensive implementation strategies of these systems [26]. Existing research often focuses on individual virtual care programs rather than the broader array of integrated health care technologies used in VHs [27]. To effectively deliver VH services, a deeper understanding of how different virtual care technologies contribute to overall patient care is essential. This knowledge is critical for optimizing the design, implementation, and scalability of VH services, particularly in rural and remote regions.

Current evidence highlights the potential of VHs to revolutionize health care delivery by offering improved clinical and health system outcomes, enhanced provider and patient experiences, and increased health care accessibility. However, this evidence is largely limited to the broader health care landscape, with a noticeable gap in understanding the specific application of VHs in regional and rural settings. Existing studies discuss the clinical effectiveness of VHs but primarily address the general population [28,29]. Similarly, research on the barriers, facilitators, and recommendations for implementing VHs does not align with the unique challenges of regional and remote communities, such as limited access to specialists, longer travel distances, and a higher prevalence of preventable conditions [17,18]. This gap in the literature necessitates research focused on tailored recommendations, barriers, and facilitators specific to VH implementation in regional and remote areas, enabling health care systems to fully harness the potential of this innovative approach.

This rapid review aims to synthesize existing evidence on the role of VHs in enhancing health care delivery in regional and remote areas. It seeks to analyze clinical and health system outcomes, explore patient and provider perspectives, identify implementation-related barriers and facilitators, and provide recommendations for its successful implementation. The findings will contribute to evidence-based policy making and decision-making to optimize the use of VHs in addressing health care disparities in challenging geographic settings.

Methods

Overview

This rapid review was conducted to assess the potential of VHs in addressing health care disparities in regional and remote areas. This approach aligns with the need to understand how VHs address health care disparities and improve access for remote and underserved populations in a timely manner. By analyzing a wide range of literature, a rapid review helped to identify the most current evidence and trends, providing a comprehensive overview of the benefits, challenges, and best practices associated with developing VHs to support regional and remote health care.

Using the World Health Organization rapid review guideline [30] and the 2020 PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement [31], a systematically defined, transparent, and concise approach was

XSL•FO
RenderX

used to identify relevant peer-reviewed articles and gray literature, extract relevant information, and synthesize the findings of this review. A completed PRISMA checklist is provided in Multimedia Appendix 1.

Protocol Development

The research protocol for this study was developed using the population, intervention, comparison, and outcome (PICO) framework [32]. The protocol, as presented in Table 1, guided the development of the search strategy (Multimedia Appendix 2). La Trobe librarians also contributed to the development of the protocol and search strategy.

Table 1. Population, intervention, comparison, and outcome protocol development.

Parameter	Description	Keywords
Population	• Patients living in regional and remote areas • Patients having limited access to health care due to distance and a lack of resources	Regional health, rural health, remote health, rural health services, and remote and regional area health
Intervention	• Building VH[a] using telemedicine, telehealth, or eHealth technologies	Virtual hospital, telemedicine, telehealth, telemonitoring, remote consultation, virtual care, virtual health, eHealth, mHealth, and health virtualization
Comparison	• Physical public and private hospitals (traditional health care delivery models) without VHs or digital health technologies	—[b]
Outcome	• Improved health care access, quality of care, patient satisfaction, health care provider satisfaction, and health outcomes and reduced health care costs	Health care delivery, health care access, health planning, hospital strategy, health care accessibility, clinical effectiveness, user experience, implementation, best practices, recommendations, enablers, strategies, benefits, facilitators, challenges, barriers, problems

[a]VH: virtual hospital.

[b]Not applicable.

Search Strategy

We searched for peer-reviewed articles from January 2015 to March 2023 across 3 key databases: PubMed, MEDLINE, and CINAHL. The La Trobe University Library database was also used. The time frame from January 2015 to March 2023 was intentionally chosen to capture the literature spanning both the prepandemic development of VH models and the significant innovations that emerged in response to the COVID-19 pandemic.

Our search strategy was designed to align with the PICO framework, using 2 distinct approaches. The first strategy targeted articles discussing enablers and facilitators of VH implementation, while the second strategy focused on identifying literature addressing barriers, challenges, and limitations. In addition, to ensure quality and minimize bias, both search techniques were reviewed collaboratively by all authors in consultation with La Trobe research librarians.

To identify relevant gray literature, the research topic "advancing regional and remote health care with virtual hospital implementation" was googled, and from the first 4 pages of the search result, policy documents and web articles that discussed the research questions were marked as relevant and selected for further analysis. Furthermore, snowballing was used to screen and select other gray literature cited in relevant web articles [33].

Inclusion and Exclusion Criteria

A set of inclusion and exclusion criteria was developed using the PICO framework (Textbox 1). This review included (1) studies addressing regional or remote populations or populations facing health care access difficulties; (2) studies discussing recommendations, strategies, facilitators, barriers, challenges, or limitations to VH or virtual care-from-home solutions, telehealth, telemedicine, eHealth, mobile health, and remote monitoring for hospital-level care at home; (3) studies discussing clinical or health system outcomes, user experience, and patient perspectives of the innovative technologies used in developing VHs and (4) studies conducted in a country such as Australia or countries with similar geographic landmasses, such as Canada, the United States, or India. Furthermore, only peer-reviewed studies published in English between January 2015 and March 2023 were included.

This review excluded (1) studies addressing urban or suburban population settings with comprehensive and timely health care access and (2) studies solely discussing hybrid models of care.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Population: people of all age groups living in regional or remote regions and people with acute or chronic illness experiencing difficulties in accessing health care due to distance and lack of resources
- Intervention: virtual hospital (VH) or virtual care-from-home implementation; telemonitoring, telehealth, and telemedicine implementation supporting care-from-home services; eHealth or mobile health implementation; remote monitoring; interventions in a country such as Australia or countries with similar health care systems and geographic challenges; studies that discussed recommendations, opportunities, and challenges of implementing health care virtualization; and studies that discussed patient or provider experience or successful VH or virtual care-from-home implementation stories
- Comparison: an optional comparison group including people with no limitations to accessing health care but who preferred virtual consultation
- Outcomes: clinical outcomes of health care virtualization (improvements in health for people living in remote or regional areas or having limited access to resources); improved delivery of services; success strategies (stories) of VH implementation; program user experience (access, engagement, usability, experience, and satisfaction); and changes in health care resourcing
- Studies: published in peer-reviewed journals, conference proceedings, or health care services reports; published in the English language; and published between January 2015 and March 2023

Exclusion criteria

- Population: people living in urban or suburban areas and those having no limitation on health care access
- Intervention: traditional health care delivery models with minimum virtualization and virtualization in urban and suburban geographic regions
- Outcomes: studies discussing only the benefits and challenges of telehealth or telemedicine and studies discussing user perspectives only
- Studies: studies or reports from unverified sources that have not been peer reviewed, published in other languages, and published before January 2015 or after March 2023

Screening and Study Selection

The search results were initially filtered for peer-reviewed articles published in English between January 2015 and March 2023. Following the initial database search, 589 records were retrieved from 4 databases. These records were imported into Covidence Systematic Review Software (Veritas Health Innovation) [34], where 255 (43.29%) duplicate records were eliminated automatically. The remaining 334 (56.71%) articles underwent title and abstract screening based on predefined inclusion and exclusion criteria. This stage resulted in the exclusion of 159 (47.6%) articles. The initial screening was conducted by AAK, with URK verifying a subset of the records to ensure consistency and accuracy in applying the criteria.

The remaining 175 full-text articles were then assessed for eligibility using the same inclusion and exclusion criteria. During this phase, the snowballing technique was also used, where relevant peer-reviewed articles cited within these studies were identified and retrieved from Google Scholar for potential inclusion. After full-text screening and the additional retrieval through snowballing, 23 (13.1%) articles met all eligibility criteria and were included in the final analysis.

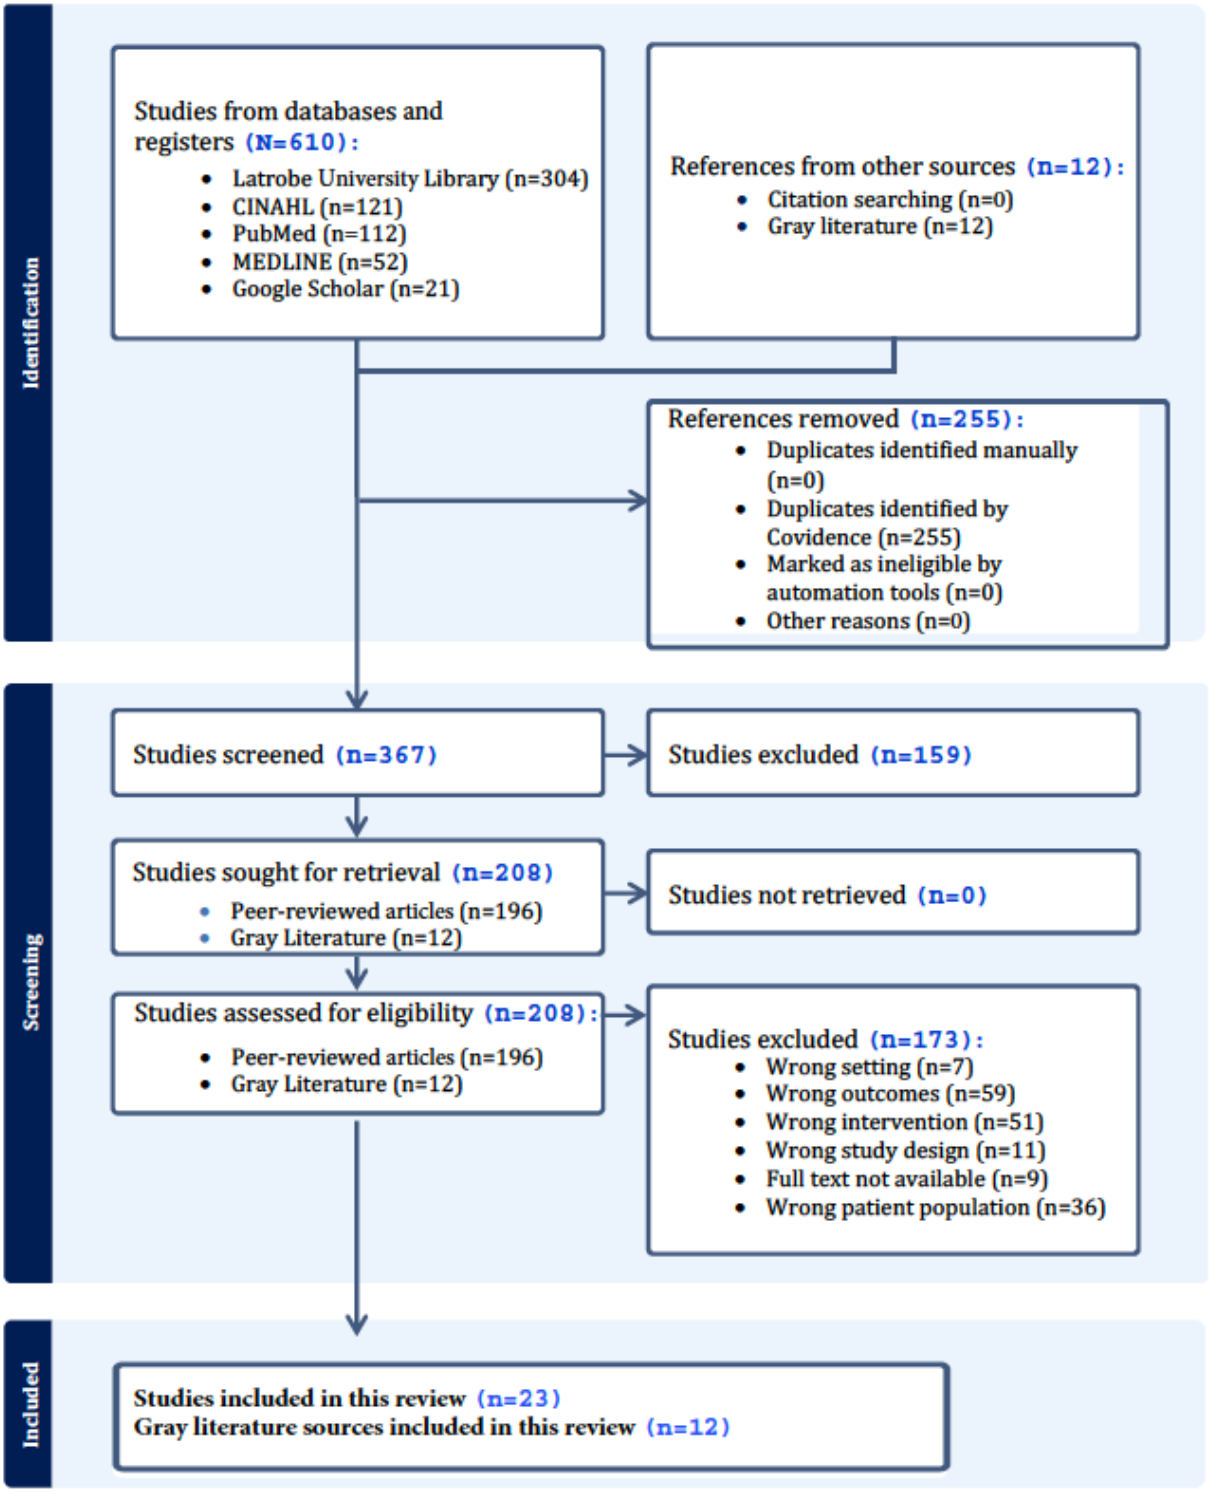
Data Extraction and Knowledge Synthesis

We used the Quality Criteria Checklist (Multimedia Appendix 3 [35]) to develop a Microsoft Excel template for quality assessment because our review included various study designs. This template helped us critically appraise the included studies and assess their potential bias.

In addition, a data extraction template was customized in Microsoft Excel (Multimedia Appendix 4), which was then used to systematically extract and record relevant information from the peer-reviewed studies and gray literature included. The template was prepared based on the extraction variables retrieved from the research question and objectives. Apart from the core characteristics, such as title, abstract, and author, the data extraction template included demographic location, health care conditions addressed, health care services provided virtually, virtual care technology used, health care outcomes, patient satisfaction, provider perspectives, barriers and facilitators, and recommendations and strategies for implementation. This approach helped ensure consistency and accuracy during the data extraction process. In addition, a concept matrix (Multimedia Appendix 5) was constructed to assess the relevance of each study to specific research objectives.

The extracted information from the included studies was then thematically analyzed to identify recurring patterns, emerging trends, and insights into common recommendations for developing VHs and their related barriers and facilitators. Data were also analyzed to identify common themes emerging from clinical and health care system outcomes and patient and provider perspectives. The thematic analysis approach allowed the identification and interpretation of key themes, enabling the synthesis and presentation of findings in a coherent and meaningful manner [36].

Results



Study Characteristics

Overall, 23 peer-reviewed articles and 12 gray literature sources were included in our review. The selection process is summarized in the PRISMA flow diagram (Figure 2). Detailed characteristics of all included peer-reviewed articles and gray literature are presented in Tables 2 and 3. Among the 23 peer-reviewed articles, 12 (52%) focused on telehealth interventions [37-48], 6 (26%) discussed VHs or

XSL•FO
RenderX

hospital-at-home interventions [49-54], 2 (9%) examined telemedicine [55,56], 2 (9%) addressed RPM [57,58], and 1 (4%) evaluated a virtual pharmacy [59]. In the 12 gray literature sources, 8 (67%) discussed virtual care-from-home solutions comprehensively [60-68], while 4 (33%) articles specifically addressed the concept of a VH [62,69-71].

[a]VH: virtual hospital.

The included 23 peer-reviewed articles were from 9 different countries, with 10 (43%) studies from the United States [38-42,47,51-53,55], 7 (30%) studies from Australia [37,43,45,46,48,57,59], 3 (13%) from Canada [44,49,50], and 1 (4%) from India [56]. Moreover, 1 (4%) study analyzed data from both Australia and Canada [58], while 1 (4%) was a multinational study where data were combined from the United Kingdom, the United States, Canada, China, the Netherlands, Ireland, Brazil, and Australia [54]. The 12 items of gray literature included in this review were all from Australia [60-71].

The selected academic articles covered a wide range of health care issues. Of the 23 peer-reviewed articles, 5 (22%) concentrated on general and primary health care [37,44,48,56,58], 3 (13%) addressed COVID-19 [53,54,57], 2 (9%) focused on emergency and inpatient care [47,52], and 2 (9%) discussed mental health [39,42]. In addition to this, there were 2 (9%) studies discussing equitable access to health care services [50,55] and 1 (4%) study each addressing ambulatory practices and triage [41], breast cancer assessment [43], burn care [51], cardiovascular disease [45], lower back pain [49], multiple chronic conditions [38], pelvic health [46], medication use [59], and frontier critical access care [40]. All 12 (100%) of the 12 items of gray literature addressed general health, focusing mainly on providing equitable health care services virtually [60-71].

In terms of digital technology used for VH implementation, most (20/23, 87%) of the peer-reviewed articles explored the use of videoconferencing [37-39,41-45,47-53,55-59], followed by telephone communication [38,40,41,49,50,53-55,58] and wearable sensors [4,39,41,43,44,54,56,57]. In total, 30% (7/23) of the studies focused on the use of online electronic medical record systems [39,40,49,53,54,57,59], 22% (5/23) of the studies described mobile apps [39,41,48,50,57], while 17% (4/23) of the studies highlighted text messaging for virtual care

XSL•FO
RenderX

[41,46,50,57]. Other technologies, such as store and forward (3/23, 13%) [37,43,44], email and chatbot (1/23, 4%) [57], and robotic ultrasonography (1/23, 4%) [44] were also included as supportive VH technologies. Among the 12 gray literature sources, only 2 (17%) reports explicitly addressed virtual care-from-home technologies. Shaw and Wilson [71] discussed the use of videoconferencing, Internet of Medical Things devices, and telephone technology for remote monitoring and directed self-care, while Microsoft News Center [70] concentrated on the use of mixed reality and space technology to support VH implementation. The remaining 10 (83%) gray literature sources holistically discussed the implementation and use of digital care technologies.

Study Design

Among the 23 peer-reviewed studies, 6 (26%) were case studies [38,49,52,53,55,59] and 1 (4%) was a mixed methods study [39]. In addition, there were 8 (35%) qualitative studies [40,42,43,45-48,57], 1 (4%) quantitative study [51], 1 (4%) scoping review [58], 2 (9%) systematic reviews [37,54], and 4 (17%) low-quality commentaries [41,44,50,56]. Among all included articles, only 2 (9%) reported selection bias [51,53]. Among the 12 gray literature sources, there were 2 (17%) national strategies [61,63], 3 (25%) state-level strategy documents [65,66,68], 6 (50%) web reports [60,62,67,69-71], and 1 (8%) telecommunication survey report [64].

Clinical Outcomes

Only 7 (30%) academic studies of the 23 peer-reviewed articles and 2 (17%) of the 12 gray literature sources assessed the clinical outcomes of the VHs or virtual care-from-home models.

Findings from existing literature demonstrated that VHs have contributed toward positive clinical outcomes, including specialist medication advice, better medication knowledge, reduced medication errors [59], reduced disease transmission [53,56], minimized disease exposure to staff [53], improved patient safety [57,59], reduced admission and readmission [52,71], lower mortality, shorter LOS, and maximized adherence to clinical best practices [52,54,69].

According to Allan et al [59], VHs facilitated enhanced medication management by enabling specialists to provide tailored advice based on individual patient needs. This personalized approach improved patient understanding and medication adherence. Furthermore, by facilitating direct communication between health care providers and specialists, VHs could help reduce medication errors because specialists could review prescriptions remotely, identify potential errors, and provide immediate feedback or corrections.

VHs also enabled remote consultations, diagnosis, and monitoring, reducing the need for physical interaction between patients and health care staff [53,56]. This reduced the risk of disease transmission, particularly in cases of infectious diseases. Moreover, by minimizing in-person visits, health care staff were exposed to fewer patients, reducing their risk of contracting contagious diseases.

Gray et al [57] and Allan et al [59] emphasized the role of continuous monitoring and timely interventions in enhancing patient safety. Remote monitoring devices and telemedicine consultations enabled early detection of complications, facilitating prompt medical interventions and reducing the risk of adverse events. Through remote monitoring and timely interventions, VHs could also manage chronic conditions more effectively, thereby reducing the frequency of hospital admissions and readmissions [52,71]. In addition, by providing patients with better access to health care resources and support, VHs could prevent exacerbations of chronic conditions, further reducing hospitalizations.

VHs have demonstrated potential in improving patient outcomes and reducing health care costs. By enabling continuous monitoring and timely interventions, VHs contributed to reduced mortality rates, shorter hospital stays, and lower readmission rates. Vindrola-Padros et al [54] reported that virtual wards for patients with COVID-19 had lower mortality rates, with only 29% admissions to the emergency department and <36% readmission rate. Likewise, Kuperman et al [52] reported that the pilot VH recorded a 6% decrease in patient transfers, a 17% decrease in admissions, and a 3.7% decrease in LOS. Furthermore, Head et al [51] discussed that virtual care-from-home service for patients with burn injury had similar clinical outcomes when compared to in-person care. None (0/23, 0%) of the studies reported negative clinical outcomes for VHs.

Despite diverse health care conditions, studies revealed similar clinical outcomes. For instance, Head et al [51] concentrated on burn care, Kuperman et al [52] discussed emergency and inpatient care, and Shaw and Wilson [71] addressed overall hospital care; however, all reported that VHs reduced admission, readmission, and transfer in their respective studies. Likewise, Gray et al [57], addressing virtual pharmacy, and Allan et al [59], discussing COVID-19, discovered that virtual care-from-home solutions improved patient safety.

Health System Outcomes

A total of 12 (52%) academic studies of the 23 peer-reviewed articles and 3 (25%) of the 12 gray literature sources discussed 9 positive health system outcomes.

The reported outcomes included improved access to care and efficient use of resources [39,52,54,71], reduced patient and health care costs [37,39,48,51,53,56,58], enhanced patient experience and safety [56-58,69], enhanced health care delivery and provider support through trusted workflow and virtual relocation [53,54,58,59], improved process outcomes and enhanced compliance [37,52,54,58,71], enhanced geographic coverage, and better integration of health care services [67,71].

VHs used telemedicine technologies to provide remote health care services, enabling patients to access health care professionals without physical travel and enhancing access to care in underserved areas [39,52,54,71]. Similarly, VHs enhanced health care efficiency by streamlining delivery processes, reallocating resources toward virtual care platforms, reducing physical infrastructure requirements, and resulting in cost savings and improved service delivery.

VHs also lowered patient and health care costs by minimizing the need for in-person visits, hospitalizations, and associated travel expenses. Telemedicine consultations and remote

XSL•FO
RenderX

monitoring enabled timely interventions, preventing costly complications and reducing the overall health care expenditure for patients and health care providers. According to Head et al [51], virtual visits resulted in significant savings, including an average reduction of 130 miles in travel distance, 164 minutes of travel time, US $104 in travel costs, and US $81 in forgone wages due to the time saved from not having to travel. None (0/23, 0%) of the articles highlighted negative health care system outcomes.

Furthermore, VHs could offer convenient and personalized health care experiences tailored to patients' needs because remote consultations and digital health tools empowered patients to actively participate in their care, leading to greater satisfaction and engagement [56-58,69]. In addition, virtual care models prioritized patient safety by minimizing exposure to health care–associated infections and promoting adherence to evidence-based practices. Similarly, by leveraging technology to optimize health care delivery processes and support health care providers in delivering high-quality care, VH facilitators had managed to enable seamless coordination among multidisciplinary teams, improving communication, collaboration, and patient outcomes [53,54,58,59]. The virtual support systems also enhanced provider efficiency and job satisfaction, ultimately enhancing the overall quality of care delivery.

Findings from the literature also revealed that VHs improved health care by standardizing workflows, promoting clinical adherence, and facilitating efficient data management [37,52,54,58,71]. The use of digital health solutions helped improve care coordination and patient outcomes while ensuring regulatory compliance and quality standards in health care delivery.

The findings were consistent across different health care conditions. While Head et al [51], DeHart et al [39], Kuperman et al [52], Shaw and Wilson [71], and Vindrola-Padros et al [54] focused on burn care, mental health, emergency and inpatient, general hospital care, and COVID-19, respectively, their studies collectively highlighted that health care virtualization significantly improved access to care. Furthermore, the Australian-based Royal Prince Alfred VH received positive feedback from patients for the convenience and stress-reducing benefits of receiving care from home [71].

In addition, Hardy et al [67] and Shaw and Wilson [71] reported that VHs offered health care services beyond traditional boundaries, improving accessibility and enabling broader geographic coverage. Telemedicine and remote monitoring enabled patients to have specialized care, reducing disparities in access. This care model also facilitated better integration of health care services by fostering collaboration among providers, improving care transitions, and promoting continuity of care across different settings.

Patient Perspectives

A total of 8 (35%) of the 23 peer-reviewed articles and 1 (8%) web report of the 12 gray literature sources examined patient perspectives regarding the implementation of VHs and virtual care-from-home solutions.

Allan et al [59] and Correale et al [49] highlighted high patient acceptance and satisfaction with virtual care-from-home services. Similarly, DeHart et al [39] noted increased satisfaction due to time, cost, and travel savings from telehealth services for rural patients. Likewise, Giroux et al [50] disclosed that quality virtual care-from-home enhanced empowerment, improved self-management, and expanded access to culturally appropriate care locally.

Patient involvement in remote care is associated with improved outcomes and satisfaction, as suggested by Vindrola-Padros et al [54]. VHs provided patients with the convenience of receiving treatment locally rather than having to relocate to a secondary care hospital, thus leading to an increased level of satisfaction, as highlighted by Gray et al [57] and Kuperman et al [52]. While none (0/23, 0%) of the studies discussed the negative patient perspectives, LeBlanc et al [58] stated that patient satisfaction was highly dependent on technological proficiency, health care provider readiness, and the quality of care provided virtually.

Health Care Provider Perspectives

A total of 8 (35%) of the 23 peer-reviewed articles and 1 (8%) of the 12 gray literature sources discussed the provider perspectives on the implementation of VHs and virtual care-from-home solutions.

Positive health care provider perspectives included increased provider satisfaction [43,59], enhanced service delivery [43,59], better collaboration and teamwork [39,49,50,60], and increased efficiency and accessibility [52,56,58,60]. Providers reported that VHs and hospital-in-the-home solutions offered them more flexibility in delivering care and managing their workload. They could engage in telemedicine consultations, remote monitoring, and virtual care delivery, which led to reduced burnout and increased job satisfaction. The convenience and efficiency of virtual care platforms contributed to a more satisfying work environment for health care professionals. Both peer-reviewed articles and gray literature also highlighted that providers reported that VHs improved health care delivery by enabling telemedicine consultations and remote monitoring, thus allowing them to reach a wider patient population, deliver timely interventions, and offer continuous support. Furthermore, the providers stated that the integration of digital health tools allowed for enhanced service quality, accessibility, and patient outcomes.

In addition, health care providers expressed that virtual care platforms allowed them to facilitate collaboration and communication among health care team members, regardless of their physical location [52,56,58,60]. Rural providers could easily consult with specialists, share patient information, and coordinate care plans in real time, promoting interdisciplinary collaboration and teamwork. This seamless exchange of information enhanced care coordination and improved patient outcomes.

Studies by Allan et al [59] and Johnston et al [43] indicated that enhanced service timeliness, greater accessibility, and reduced provider travel time increased provider satisfaction. They also stated that improved workflows and clinic processes and better

XSL•FO
RenderX

medication management further contributed to enhanced service delivery.

No patients or health care providers reported negative views of the results.

Barriers to VH Implementation

Barriers to VH implementation were reported in 21 (91%) of the 23 peer-reviewed articles and 6 (50%) web reports of the 12 gray literature sources.

Poor digital literacy and language barriers among rural patients emerged as significant obstacles, hindering successful VH adoption. Language barriers and a lack of digital skills presented challenges in connecting remote patients with virtual care solutions, contributing to a digital gap [48,50,53,58,71]. The lack of digital skills also presented a substantial obstacle in connecting remote patients with virtual care-from-home solutions [39,57,71]. Poor digital literacy and language barriers among patients often deterred them from engaging in virtual care services [57] and led to a lack of patient commitment to continue using virtual care-from-home services [39]. Furthermore, health care providers' low adoption and lack of provider knowledge or skills were reported, resulting in resistance to change and workforce constraints, indicating a need for targeted strategies to address these issues [37-40,44,48,53,68,71].

Technological barriers, such as poor technical infrastructure and connectivity [41,45,48-51,53,56,58,64,67,68], limited technical support [39,46,50,57,58,60,68,71], restricted access to digital equipment [38,43,46,49,53,57,60], and legacy and outdated technologies [47,68,71], were also identified as significant barriers to VH implementation for regional and remote communities.

In remote and rural areas, inadequate technical infrastructure and connectivity hindered the effective deployment of VH services [41,45,48-51,53,56,58,64,67,68]. Without reliable internet access and robust communication networks, health care providers and patients faced challenges in accessing telemedicine consultations, remote monitoring, and digital health platforms.

Similarly, the absence of adequate technical support exacerbated challenges associated with VH implementation [39,46,50,57,58,60,68,71]. Health care providers and patients encountered difficulties in troubleshooting technical issues, configuring digital devices, or navigating telemedicine platforms.

Another major technological barrier faced by individuals in remote and underserved communities was the lack of access to digital devices, such as tablets, webcams, or computers, which were essential for participating in virtual care consultations [38,43,46,49,53,57,60]. The digital divide exacerbated disparities in health care access and highlighted the need for initiatives aimed at providing digital equipment to marginalized populations.

Moreover, the presence of legacy and outdated technologies impeded the adoption and effectiveness of VH solutions [47,68,71]. Incompatible systems, outdated software, and obsolete hardware hindered interoperability, data exchange, and user experience.

Several studies reported barriers related to processes of coordination and communication among stakeholders [38,58], cultural neglect for rural communities [66,68], absence of robust governance and effective leadership [42,43,59,68,71], data privacy and security concerns [38,48,49,56,58,69], organizational challenges in relation to resource planning [54,59], operational processes [38,42,60], and limited policies supporting rural community inclusion [45,48,54,57].

According to Davis et al [38] and LeBlanc et al [58], effective coordination and communication among stakeholders were essential for the successful implementation of VHs. Barriers within these processes, such as fragmented communication channels or a lack of standardized protocols, impeded the seamless delivery of care and collaboration among health care providers, patients, and support staff.

In addition, the cultural neglect of rural communities highlighted disparities in health care access and delivery. Policies and initiatives that failed to consider the unique cultural, social, and geographic factors of rural populations exacerbated health care inequities [66,68]. Recognizing and addressing cultural diversity and rural-specific health care needs were essential for ensuring inclusive and patient-centered VH services.

Furthermore, inadequate governance frameworks and leadership support led to ambiguity, resistance to change, and lack of accountability, hindering progress and sustainability [42,43,59,68,71]. Strong leadership and governance mechanisms were essential for guiding strategic planning, resource allocation, and decision-making processes in VH initiatives, and these were fundamental for driving organizational change and ensuring the successful implementation of VHs.

Another critical consideration for VH implementation was data privacy and security concerns, particularly regarding the storage, transmission, and sharing of sensitive patient information [38,48,49,56,58,69]. Failure to address these concerns could impact patient trust, compromise confidentiality, and expose health care organizations to legal and regulatory risks. Robust data privacy policies, secure information systems, and adherence to industry standards were considered essential for safeguarding patient data and maintaining confidentiality.

Organizational challenges, such as inadequate resource planning and inefficient operational processes, impeded the scalability and sustainability of VHs [54,59]. Limited resources, workforce shortages, and inefficient workflows hindered the delivery of timely and quality care, affecting patient outcomes and satisfaction. Strategic resource allocation, process optimization, and continuous quality improvement were necessary for overcoming organizational barriers and enhancing operational efficiency in VHs.

In addition, limited policies supporting rural community inclusion also affected the implementation of equitable VH services [45,48,54,57]. The absence of supportive policies may have limited funding opportunities, regulatory incentives, and infrastructure development for VHs in rural areas. Advocacy for policies that prioritized rural community inclusion, addressed

XSL•FO
RenderX

health care disparities, and incentivized VH adoption were essential for promoting equitable access to health care services.

Furthermore, a few (4/35, 11%) studies identified financial sustainability challenges [47,57,60,69] and the unfair distribution of funds among different health care settings [42,47,57].

Facilitators of VH Initiatives

Facilitators for the successful implementation of VHs were identified in 19 (83%) of the 23 peer-reviewed articles and 7 (58%) web reports of the 12 gray literature sources.

The literature strongly suggested that key facilitators included clinical leadership and advocacy [37,48,71] together with staff and patient enrichment and training [40,42,43,46,47,52,54,59,71], emphasizing the importance of enhancing patient and provider capabilities for successful VH implementation. The Australian federal and state governments are investing in digital literacy upskilling programs to empower patients to self-manage symptoms and navigate VHs confidently [67,68].

Few other facilitators were recognized as a way to mitigate barriers such as collaboration and partnerships [43,48,57,59,71], effective communication [48,49,52,65], purposeful planning and development [37,60,65,71], a comprehensive governance structure [60,65,71], optimized organizational structure [38,43,49,53], iterative system implementation [59,65,71], and supportive government policies [37,51,67,69].

Collaboration and partnerships among stakeholders, including health care providers, government agencies, technology vendors, and community organizations, were instrumental in overcoming barriers and driving the adoption of VHs [43,48,57,59,71]. By fostering collaboration, organizations could leverage collective expertise, resources, and networks to address challenges; share best practices; and promote innovation in virtual care delivery. Likewise, effective communication strategies were essential for ensuring clear understanding, alignment, and engagement among stakeholders involved in VH implementation. Open and transparent communication channels facilitated knowledge sharing, stakeholder engagement, and problem-solving, enabling organizations to address concerns, manage expectations, and drive consensus toward common goals [48,49,52,65].

Purposeful planning and development also incorporated strategic initiatives aimed at designing, implementing, and optimizing VHs [37,60,65,71]. By adopting a systematic approach to planning, organizations could anticipate challenges, identify opportunities, and develop robust strategies for addressing barriers and achieving desired outcomes in virtual care delivery. Similarly, a comprehensive governance structure provided the framework for guiding decision-making, accountability, and oversight in VH initiatives [60,65,71]. Clear governance mechanisms, policies, and procedures ensured alignment with organizational goals, regulatory requirements, and industry standards while also promoting transparency, efficiency, and stakeholder engagement.

In addition, an optimized organizational structure will align roles, responsibilities, and workflows to support the effective delivery of VH services [38,43,49,53]. By streamlining processes, clarifying responsibilities, and fostering collaboration, organizations can enhance efficiency, agility, and responsiveness in virtual care delivery, ultimately improving patient outcomes and satisfaction. Likewise, iterative system implementation will involve continuous assessment, refinement, and optimization of VH services and processes. By adopting an iterative approach, organizations can adapt to evolving needs, address emerging challenges, and incorporate feedback from stakeholders, thereby enhancing the effectiveness, usability, and sustainability of virtual care solutions [59,65,71].

Moreover, supportive government policies created an enabling environment for VH implementation by providing regulatory intelligibility, funding support, and incentives for innovation. Policies that promoted telemedicine reimbursement, infrastructure development, workforce training, and data privacy enhanced the viability and scalability of virtual care initiatives while also fostering collaboration and alignment among stakeholders across the health care ecosystem [37,51,67,69].

These facilitators highlighted the importance of strategic planning, clear communication, and collaborative efforts involving various stakeholders to overcome process-related challenges and ensure successful VH deployment.

Investment in *technical infrastructure* [59,60,65,67,68,70], quality, user-friendly and affordable technology [53,59,60,67,68], and technical outreach and support services [43,58,68] were noted as enablers for VH initiatives.

Robust technical infrastructure formed the foundation for VHs, facilitating seamless communication, data exchange, and service delivery [59,60,65,67,68,70]. Hence, investment in infrastructure, such as high-speed internet connectivity, secure data storage, and interoperable systems, was essential for ensuring reliable and efficient virtual care delivery. Without adequate infrastructure, VHs would face connectivity issues, data security risks, and operational inefficiencies, hindering their effectiveness in reaching and serving rural patients.

Furthermore, access to quality, user-friendly, and affordable technology was critical for enhancing the accessibility and usability of VHs [53,59,60,67,68]. User-friendly interfaces, intuitive design, and affordability ensured that health care providers and patients could easily navigate and use virtual care platforms. Quality technology solutions also contributed to positive user experiences, engagement, and satisfaction, ultimately improving the effectiveness and adoption of VHs.

Similarly, technical outreach and support services played a vital role in assisting health care providers and patients in navigating and troubleshooting virtual care technology services [43,58,68]. These services might include training programs, help desks, and technical assistance teams that provide guidance, education, and troubleshooting support. By offering ongoing technical support, organizations could empower users to effectively use VH platforms, address technical issues, and maximize the benefits of remote care delivery.

These facilitators emphasized the importance of a robust technical foundation, user-friendly interfaces, and support services to overcome technological challenges and enhance the acceptance of VHs within regional and remote communities.

XSL•FO
RenderX

Sustainable financing also emerged as a crucial facilitator, emphasizing the importance of permanent insurance reimbursement solutions and grant funding to support and expand the reach of VH services [38,47,53].

Discussion

Principal Findings

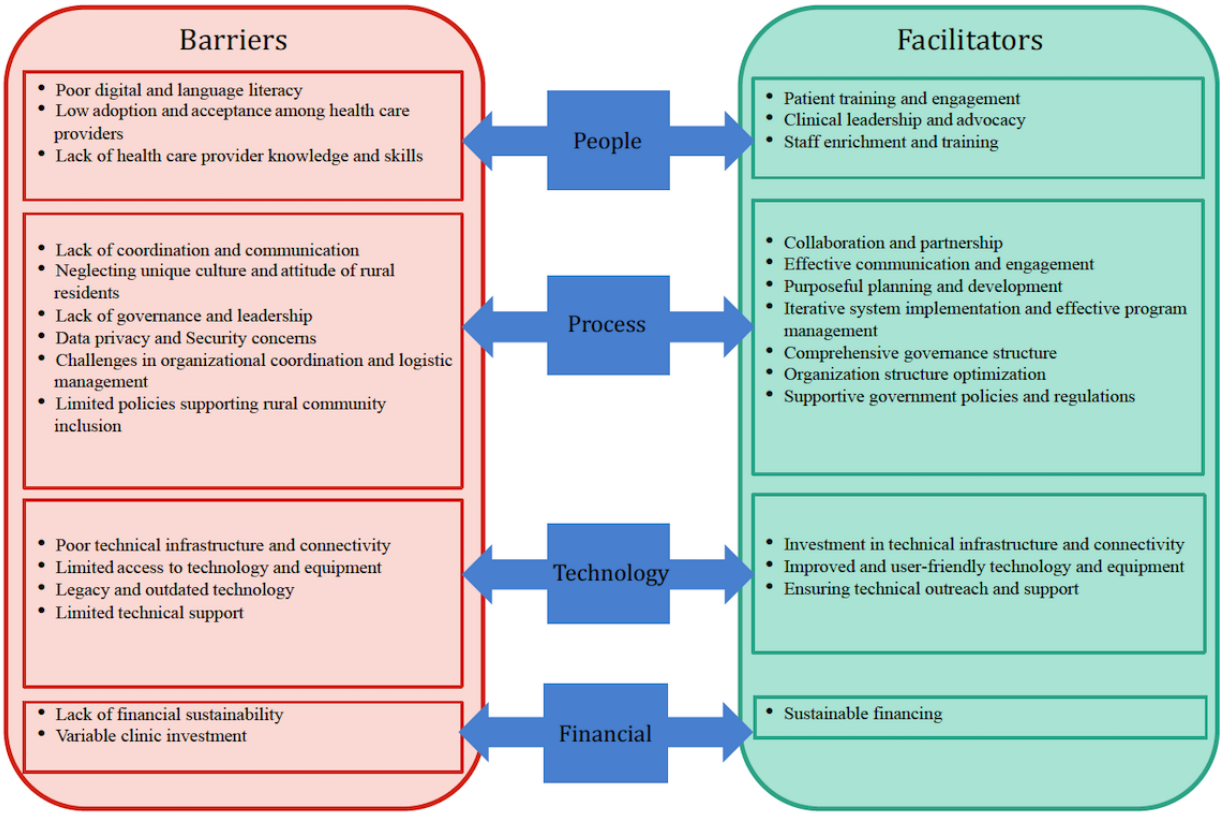
This review demonstrated clinical and health system outcomes of VHs in remote and rural health settings. It addresses the current evidence gap regarding the impact of VHs for regional and rural populations on clinical, health system, patient, and provider outcomes, indicating that VHs significantly enhance clinical effectiveness, regardless of population demographics.

In terms of clinical effectiveness, this review reported positive outcomes against key indicators commonly used to evaluate health care interventions, such as mortality rates, readmission rates, LOS, and improvement in clinical indicators [71]. These findings are consistent with those of Norman et al [17], who reported similar benefits from hospital-at-home care for older individuals, such as shorter LOS and reduced readmission rates. However, it should be noted that this review does not examine the impact of VHs on chronic condition management, a critical area for evaluating the overall effectiveness of VHs. Further research is needed to explore how VHs can better support chronic disease management and improve long-term health outcomes.

Furthermore, this study highlights the health system benefits of VHs, noting their potential to reduce patient and health care expenditures for various conditions, including general health, mental health, burn care, and infectious diseases such as COVID-19. The analysis correlates with key metrics such as quality care, equitable access, cost management, and population health improvement, affirming that VHs significantly enhance health system outcomes in regional and remote communities.

Moreover, the health system outcomes identified in this review align with those observed in urban populations, as reported by Bidoli et al [13] and Snoswell et al [72]. Evidence indicates that VHs positively impact health system outcomes by improving efficiency, accessibility, and resource management, thus proving to be a valuable addition to contemporary health care delivery.

The findings also reveal that positive patient and provider perspectives are contingent on adequate internet connectivity, user-friendly technology, sufficient training, and enhanced collaboration between urban and rural health care providers. A comparison with the studies by Denny and Hill [73], who evaluated patient and health care worker perspectives of virtual care delivery for patients with cystic fibrosis in a suburban setting, and Babaei et al [18], who assessed barriers to and facilitators of virtual care, revealed similar findings. Both studies support the argument that high patient and provider satisfaction heavily depends on adequate internet connectivity, effective technology, and robust technical support systems.



Beyond the findings of this study, it is worth noting that VHs also have the transformative potential in mitigating climate change while maintaining effective patient care. King et al [74] revealed a 99.37% reduction in carbon emissions per appointment compared to in-person visits. Likewise, Thiel et al [75] demonstrated that telemedicine reduced greenhouse gas emissions by nearly 17,000 metric tons in 2021, equivalent to the annual energy use of 2100 homes, by replacing in-person visits with virtual appointments.

Despite the numerous benefits of VHs for rural and remote health care, their implementation often faces significant challenges. These challenges can be categorized into 4 main themes: people, process, technology, and finance (Figure 3). Effectively addressing barriers in these areas requires a multifaceted approach, including digital literacy and enrichment, stakeholder collaboration, a patient-centered approach, sustainable funding structures, and the application of smart technologies. By implementing these strategies, regional and remote communities can gain better access to quality health care, potentially improving clinical and health system outcomes and enhancing satisfaction among rural patients and providers.

Addressing these multifaceted challenges is crucial for the successful implementation of VHs in regional and remote health care settings. The identified facilitators provide a road map for strategic interventions and investments to overcome barriers, thereby enhancing the effectiveness of VHs in improving health care accessibility and delivery in underserved areas.

XSL•FO
RenderX

Figure 3. Barriers to and facilitators of virtual hospital initiatives.

Recommendations for Developing VHs

The synthesis of studies on the development of VHs in regional and remote areas has led to 4 key recommendations. First, successful VH implementation relies heavily on stakeholder collaboration and patient-centered approaches. Engaging a diverse range of stakeholders, including community members and health care providers, ensures that VHs align with the needs and preferences of all involved. Key elements include collaborative engagement, health care professional advocacy, seamless communication policies, patient-centered design, and culturally responsive models. These strategies foster trust, improve coordination, and ensure inclusivity among and respect for diverse populations.

Second, achieving digital equity and securing sustainable funding are critical for the success of VHs. Implementing robust governance structures and advisory committees to oversee VH operations ensures coordination, safety, and quality standards. Policy-driven organizational transformation enables VHs to adapt to evolving health care needs while leveraging government grants to provide essential financial support, addressing infrastructure needs and operational deficits.

Third, investing in sustainable infrastructure and advancing health care technology are vital for enhancing VH services. Recommendations include developing resilient infrastructure to support VH technology, advancing integrated health care systems, empowering remote care staff with the necessary tools and training, building robust digital foundations through iterative development, and implementing stringent privacy and security measures to protect patient data.

Finally, enhancing digital literacy among health care providers and patients is crucial for the seamless implementation of VHs. Continuous training and involvement of health care providers build trust and competence in using new technologies, while educating patients about virtual care technologies improves acceptance and engagement.

Overall, successful VH implementation in regional and remote regions requires a holistic approach that considers stakeholder collaboration, a patient-centered approach, digital equity, smart technology application, and digital literacy enhancement. These recommendations provide a comprehensive framework for developing and sustaining VHs in regional and remote health care settings.

Limitations and Future Research Direction

This review encountered several limitations. First, the restricted search period, which concluded in March 2023, limited the capture of more recent developments and emerging insights. However, the unique focus on the remote and rural context offers timeless relevance to the baseline understanding of regional and remote VH implementation globally during the COVID-19 pandemic. This study provides a valuable foundation for future comparative research on VH implementation across rural and urban settings. Second, the absence of studies reporting negative outcomes restricts our understanding of the potential risks and drawbacks associated with the development of VHs for remote and regional communities. This lack of balanced reporting may lead to an overly optimistic view of VH implementation. In addition, as a rapid review, this study faced typical limitations, such as a constrained time frame and reliance on English language sources, potentially excluding relevant

XSL•FO
RenderX

studies and resulting in a less comprehensive literature search. While efficient, the rapid review methodology offers less depth compared to systematic reviews, potentially limiting the robustness of conclusions. Finally, this review insufficiently emphasized the broader environmental implications of VHs, particularly their demonstrated potential to reduce carbon emissions through decreased patient travel and resource consumption. This oversight limits the discussion of their potential as a tool for environmental sustainability. Finally, despite the authors' efforts to avoid using region-specific terms in the gray literature search, it is important to note that the use of the Google search engine in this study may have contributed to geographic bias, leading to an emphasis on Australian-focused gray literature sources.

Future research should focus on evaluating both positive and negative outcomes of VHs compared to inpatient care, using robust methodologies, such as randomized controlled trials or matched cohort studies. Such research would provide a comprehensive evaluation of the clinical and health system outcomes of VHs, facilitating direct comparisons to traditional inpatient care. Moreover, there is a pressing need for qualitative research involving interviews with key stakeholders engaged in successful VH projects. Analyzing these interviews would yield valuable insights into the challenges, successes, and lessons learned from specific projects, enabling the development of well-informed recommendations for future VH initiatives. In addition, research should investigate how implementing VH services in rural and remote areas could contribute to climate change mitigation through reduced health care–related travel and resource consumption.

Conclusions

Research into VHs is continuously evolving due to developments in regulations, digital advancements, communication tools, and remote monitoring capabilities. By bringing together information across different disciplines, including health care, technology, and policies, this evidence-based rapid review aids in effectively strategizing VH deployment so that the benefits can be realized by regional and remote communities.

This review suggests that VHs provide a promising solution to bridge health care gaps in regional and remote communities by enhancing clinical effectiveness, improving health system outcomes, and increasing patient and provider satisfaction. This review also supports the positive contribution of VHs on equitable health care access and addresses the existing evidence gap within the context of regional and rural health care.

To sum up, this rapid review highlights the barriers, mitigating facilitators, and recommendations that can serve as key strategic pillars to developing VHs so that clinical outcomes, health system performance, and satisfaction among patients and health care providers are enhanced within regional and remote communities.

Acknowledgments

The authors would like to thank Fiona Sturt and Umer Nisar for their guidance in directing this research. Their valuable time and advice made a huge contribution to this study, and the authors would like to thank them for this opportunity.

Abstract

Background: As information and communication technologies and artificial intelligence (AI) become deeply integrated into daily life, the focus on users' digital well-being has grown across academic and industrial fields. However, fragmented perspectives and approaches to digital well-being in AI-powered systems hinder a holistic understanding, leaving researchers and practitioners struggling to design truly human-centered AI systems.

Objective: This paper aims to address the fragmentation by synthesizing diverse perspectives and approaches to digital well-being through a systematic literature review. Using the stimulus-organism-response framework as a guiding lens, this study aims to develop a comprehensive model for designing human-centered AI systems that promote digital well-being.

Methods: A systematic review of 240 multidisciplinary publications was conducted to explore the intersection of AI, digital well-being, and human-centered design. The analysis involved identifying key themes, frameworks, and approaches, with the stimulus-organism-response model serving as an overarching perspective to organize findings and inform the model development.

Results: The review led to the development of a human-centered artificial intelligence model for digital well-being, a conceptual framework that consolidates current knowledge on designing AI systems to support digital well-being and positively influence human behavior. The proposed model integrates insights from cross-disciplinary research, providing a structured understanding of how AI system features (stimuli) affect users' internal states such as perceptions and emotions (organisms) and lead to attitudinal or behavioral changes (responses). Additionally, this paper highlights emerging challenges and opportunities, including ethical considerations, scalability, and practical guidelines for applying the model in long-term research and practice.

Conclusions: This study contributes to advancing the field by presenting an overarching framework for fostering digital well-being through human-centered AI systems. By addressing gaps in the fragmented literature and proposing a unifying model, the findings offer insights for researchers and practitioners. The human-centered artificial intelligence for digital well-being model serves as a foundation for future exploration and practical application in creating intelligent computing systems that improve users' digital well-being in everyday life.

Introduction

Digital well-being is a concept that describes the impact of information and communication technologies (ICTs) on people's physical and mental well-being in general [1-3]. Researchers and practitioners in many relevant fields, including computer science, health care, human-computer interaction (HCI), psychology, cognitive science, and data science, have emphasized that there are plenty of opportunities to leverage everyday ICTs in users' daily HCIs [4-14]. In this regard, daily intelligent computing systems have been developed and

XSL•FO
RenderX

investigated mainly with a focus on people's higher level of involvement in technology used to enhance their well-being and behavioral design [2,15].

Existing literature has provided diverse methods and approaches for building ICT-based computing systems that support users' daily quality of life by promoting users' positive attitudinal and behavioral changes [16]. For the past decade, the trend of increasing computing systems' complexity and interactivity has stimulated the introduction of a variety of artificial intelligence (AI) technologies (eg, chatbots, voice assistants, self-driving vehicles, or recommendation systems) that have penetrated far into people's everyday lives [17,18]. The application areas of these intelligent systems include (1) consumer applications such as recommender systems and social media platforms, (2) consequential applications in medical, legal, environmental, or financial systems, and (3) life-critical applications such as those in cars, airplanes, or military systems [19]. Furthermore, the previous COVID-19 pandemic has accelerated the use and adoption of these AI-powered intelligent systems in people's lifestyles [20]. For example, the social distancing restrictions in everyday life during the pandemic have increased the demand for AI-powered services and noncontact operations such as driverless delivery services, pre-entry wellness checking systems, or autonomous cleaning solutions [21,22].

However, several studies have pointed out negative aspects of prior approaches and perspectives that maximize users' engagement with these computing systems by attracting their attention and encouraging them to interact with the systems more frequently [1,23-26]. In this regard, large global technology companies, such as Google, Apple, Microsoft, and Meta, have reframed the meaning of digital well-being and have incorporated digital well-being into their business models. They have introduced various design and system features to help users manage their interactions with these computing systems and address these users' challenges in terms of being overloaded and distracted by the systems [27]. Many of these features have been developed as personal informatics tools (PITs) or digital self-control tools. With an emphasis on an instant and short-term well-being–enhancing intervention, these tools have mainly allowed users to monitor and reflect on their technology use with digital timers, usage dashboards, or lock-out features [16,25].

The concept of digital well-being has been interpreted in a broad sense among relevant fields with a strong consideration of daily HCI and recent human-AI interaction [28]. However, as aforementioned, several researchers and practitioners have also construed in a limited sense of the term by sharing a consensus that "excessive" and "frequent" use of systems could result in physical or mental health problems for users [11,29-34]. Despite this perspective gap, there is still a lack of studies that systematically reframe the concept of digital well-being with AI-powered computing systems. Further, the varying approaches developed in the related disciplines tend to focus on domain-, device-, or context-specific and fragmented aspects of human experience and interactions with computing systems, which can be limiting for researchers and practitioners as they search for a holistic understanding of digital well-being in daily HCIs and human-AI interactions [2,15,25,35,36].

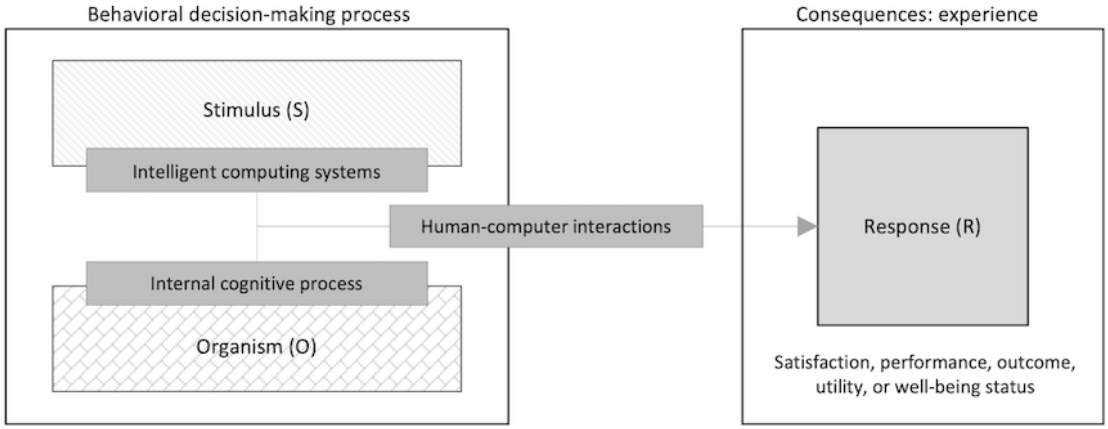
In response, this paper sees the value in consolidating diverse but scattered initiatives regarding designing human-centered AI systems for users' digital well-being to support effective implementation by researchers and practitioners. More specifically, this paper addresses the research question as follows: "How can existing research on digital well-being with intelligent computing systems be reframed and synthesized toward an overarching model for human-centered AI?"

As part of the effort to develop such a cumulative body of knowledge, this paper conducts a multidisciplinary systematic literature review on intelligent computing systems for users' daily digital well-being with a consideration of user- and human-centered perspectives. The findings from the review serve as a conceptual foundation for the development of an overarching model: human-centered artificial intelligence for digital well-being (HCAI-DW) model. The results from this consolidation are also expected to enrich the current understanding of digital well-being in daily HCIs for further implementation of designing human-centered computing systems.

Methods

Theoretical Framework: The Stimulus-Organism-Response Model

To address the current knowledge gaps, this study developed an initial conceptual model of human-centered computing for digital well-being. In this process, this paper incorporated the stimulus-organism-response (SOR) model. According to the SOR model [37,38], an individual's responses to a stimulus are the result of a behavioral decision-making process that reflects interplay between internal aspects (eg, preference, personality, ability, motivation, etc) and external aspects of the specific context (eg, time, money, weather, etc). The SOR model states that either context or environment could be understood as a stimulus (S), which consists of a set of designed or nondesigned interactions that causes an internal cognitive process in individuals (O) and produces a response (R) [39,40].



The SOR model has allowed researchers and practitioners in various fields to investigate how humans interact with nonhuman objects broadly and comprehensively [39]. In this regard, many have incorporated the model because of its broader range of possibilities for human behavior and objects and its structured way of focusing on behavioral mechanisms instead of behavioral consequences (eg, satisfaction, performance, outcome, utility, or increased well-being status). For this reason, this paper seeks to bridge the existing perspective gaps by using the basic SOR model, with complementary points of view for digital well-being and human-centered AI computing systems.

Through incorporating the SOR model as an initial viewpoint, it is expected that this study can investigate multilayered aspects of digital well-being with intelligent computing systems (Figure 1). Most previous perspectives on digital well-being in relevant fields mainly paid attention to the "consequences" of experiences, instead of focusing on the different ways people make behavioral decisions and their divergent experiential processes with intelligent systems and technologies. Researchers

XSL•FO
RenderX

and practitioners should consider behavioral decision-making mechanisms as well as a specific behavioral result targeted by designed interactions, including interface and system features. However, a systematic understanding of the multidimensional aspects of the behavioral decision-making process within the research boundary of design for digital well-being with intelligent computing systems is still lacking. Therefore, from the perspective of the SOR model, this study concentrates on individuals' behavioral decision-making mechanisms as a core concept for the unified conceptualization of digital well-being with intelligent computing systems.

Figure 1. Overarching viewpoint of digital well-being with intelligent computing systems.

Data Collection

Overview

This study uses a systematic literature review to gain a structured understanding of diverse perspectives on digital well-being within intelligent computing systems. Systematic literature reviews are recognized as rigorous and transparent methods for synthesizing existing evidence and addressing emerging interdisciplinary issues [41]. This review was guided by 2 complementary methodological frameworks: the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [42] (Multimedia Appendix 1) and the approach developed by Tranfield et al (2003) [43], which is widely adopted in evidence-informed management research. Following these frameworks, the review was conducted in four phases: (1) searching existing research, (2) screening relevant studies and approaches, (3) reviewing and evaluating focal studies on digital well-being with intelligent computing systems, and (4) conducting supplementary backward and forward searching.

In the initial phase, 4 primary databases—Web of Science, EBSCO, PubMed, and the Association for Computing Machinery (ACM) Digital Library—were used to identify relevant studies. The first publication search was conducted on August 15, 2022, with the final literature list updated on May 20, 2025, to ensure the inclusion of up-to-date studies.

The search strategy was designed by analyzing prior research and examining terminology used in the relevant scientific papers, which were critically reviewed in this paper's initial scoping review phase. For the searching process, the initial keyword string was designed to focus on the intersection of technology and well-being across multidisciplinary fields by constructing a query that combined multiple thematic dimensions:

- Core concepts: the query incorporated terms related to well-being, such as "wellbeing" and "well-being," to capture diverse terminology used across disciplines.
- Technological scope: keywords such as "system," "interface," "computer," and "technology" were included to ensure relevance to studies that involve digital and computational systems.
- Intelligence and interactivity: to refine the focus on intelligent and adaptive technologies, terms such as "artificial intelligence," "AI," "intelligent," "interactive," "smart," "autonomous," and "digital" were included.

Data Collection From the Web of Science

The Web of Science was chosen as the primary database for conducting a systematic literature search due to its comprehensive coverage of high-impact journals, conference proceedings, and other scholarly publications. The final query was adapted as follows:

TS=("wellbeing" OR "well-being") AND TS=("system" OR "interface" OR "computer" OR "technology") AND TS=("artificial intelligence" OR "AI" OR "intelligent" OR "interactive" OR "smart" OR "autonomous" OR "digital")

Boolean operators and wildcards were applied to broaden the search and accommodate variations in terminology. Advanced search filters were also used to focus on peer-reviewed publications, including journal papers, conference proceedings, and review papers. The systematic search yielded an initial pool of 5424 papers.

XSL•FO
RenderX

Data Collection From the EBSCO

The EBSCO database was used to conduct a comprehensive literature search, leveraging its extensive collection of resources spanning a wide array of academic disciplines. EBSCO was chosen for its strong interdisciplinary coverage, particularly in areas related to social sciences, computer science, and HCI, making it well-suited for exploring the digital aspects of well-being. The search string mirrored that of other databases:

("wellbeing" OR "well-being") AND ("system" OR "interface" OR "computer" OR "technology") AND ("artificial intelligence" OR "AI" OR "intelligent" OR "interactive" OR "smart" OR "autonomous" OR "digital")

The search was limited to peer-reviewed publications to ensure that only high-quality scholarly work was included. Additionally, in EBSCO, the search was restricted to the abstracts of papers to focus on studies that explicitly address the targeted themes. The initial query yielded a total of 6433 papers, encompassing a wide range of studies related to the HCI and digital well-being domains.

Data Collection From the PubMed

The PubMed database was chosen as a key resource for exploring studies at the intersection of digital well-being and intelligent systems due to its focus on digital health, biomedical research, and related fields. To align with the overarching research goals, the following search query was constructed to capture a wide range of relevant studies:

(("wellbeing" OR "well-being") AND ("system" OR "interface" OR "computer" OR "technology") AND ("artificial intelligence" OR "AI" OR "intelligent" OR "interactive" OR "smart" OR "autonomous" OR "digital"))

The initial query yielded 4073 papers. This output reflects the strength of PubMed in identifying multidisciplinary research that links intelligent systems with digital well-being, particularly within the contexts of health care and user interaction.

Data Collection From the ACM Digital Library

Finally, the ACM Digital Library was selected for its specialized focus on computing and information technology research, encompassing both theoretical advancements and practical insights from academia and industry. Given its prominence in the field of computing, the ACM Digital Library was anticipated to offer unique and highly relevant contributions to understanding the intersection of digital well-being and intelligent systems. The search was designed to explore themes of digital well-being, particularly in the context of HCI. To capture a broad range of studies, the following search query was used:

AllField:("wellbeing" OR "well-being" OR "digital wellbeing" OR "digital well-being")

To ensure high relevance and quality, 1 advanced filter was applied to limit the results to research papers published under the ACM SIGCHI (Special Interest Group on Computer-Human Interaction). SIGCHI represents a core community in HCI research, making it a critical source for studies at the nexus of well-being and intelligent systems. The initial search yielded a total of 5669 papers. This comprehensive set of results highlights the breadth of research contributions in the ACM Digital Library, particularly within the SIGCHI community, which has long been at the forefront of exploring the relationship between human-centered design (HCD), interaction, and user well-being.

Final Literature Sample and Data Exploration

From the initial search, a total of 21,599 papers were identified. These papers were manually screened by the researcher based on their titles, abstracts, and index keywords, resulting in a reduced set of 218 papers. The manual screening process was guided by 5 predefined inclusion criteria (Textbox 1), which ensured consistency and relevance in the selection process.

Textbox 1. The eligibility criteria for selecting the papers for the final review process.

- The paper should be related to the targeted research areas and topics of this study.
- The paper should be peer-reviewed and categorized as an academic paper.
- The paper should have well-defined research purposes to tackle the issue of design for digital well-being with intelligent computing systems in everyday contexts.
- The paper should point out the importance of investigating interactions between users and intelligent computing systems in their everyday behavioral decision-making contexts.
- The paper should contain practical aspects to create or evaluate the designed interactions for supporting users' digital well-being.

Subsequently, the remaining papers were reviewed in full. During this phase, backward and forward citation searches were conducted, yielding 12 additional papers. To further enhance the comprehensiveness and objectivity of the review, 10 relevant papers were also identified through consultations with external researchers and practitioners with expertise in HCI. These external consultations provided valuable third-party perspectives and helped mitigate potential bias in paper selection. After the review process, a total of 240 papers were selected for the final literature sample.

After the data collection and screening process, an inductive qualitative coding approach was conducted to systematically analyze the full text of each selected publication. The coding process was guided by the SOR model, which served as a conceptual lens to identify and organize how each paper addressed the roles of stimulus (ie, technology or system-level factors), organism (ie, user-level individual and contextual factors), and response (ie, behavioral outcomes or digital well-being effects). A coding scheme was iteratively developed and refined during this process to capture the range of constructs

XSL•FO
RenderX

and considerations described in the literature. Particularly, each paper was coded based on its entire content, allowing for the extraction of both explicit concepts and latent themes. The codes derived from this process were then used in an affinity diagramming procedure, wherein related codes were grouped and clustered to surface patterns across the corpus. This bottom-up synthesis approach enabled the researcher to identify conceptual similarities, contradictions, and gaps across the diverse literature on AI systems and digital well-being.

Through the affinity diagramming process [44], codes organically clustered into 3 major thematic areas. The first cluster focused on implementation domains of intelligent computing systems, capturing how technologies were designed to support overall well-being, facilitate behavior or habit change, or serve as behavioral intervention tools. The second cluster highlighted conceptualizations of human autonomy, including autonomy as supported through technology and autonomy from human control. The third cluster reflected each paper's approaches to system design and evaluation, with codes centering on the need to incorporate contextual adaptation (stimulus), individual differences (organism), and outcome-specific tailoring (response) into the development and assessment of AI-driven digital well-being interventions.

These 3 clusters, developed through iterative coding and visual grouping via affinity diagramming, provided the conceptual foundation for a model of human-centered AI computing systems for digital well-being presented in this study. All selected papers and their coding outcomes are described in the attached Multimedia Appendix 2, which is a review of 240 publications from 2008 to 2024.

Results

Sample Data Description

The review of 240 publications between 2008 and 2024 reveals an evolving landscape in which digital well-being and intelligent computing systems have become central themes of inquiry across multiple disciplines (Figure 2). The temporal distribution of studies demonstrates a marked increase in scholarly attention, with the number of relevant publications growing from just 2 papers in 2008 to 43 in 2024. This acceleration reflects the growing urgency—both academic and societal—to understand how intelligent systems can be designed and evaluated to support human well-being in digital contexts. Figure 3 illustrates the data collection process.

During the initial period from 2008 to 2016, research primarily focused on early digital interfaces and the psychological impact of technologies such as smartphones, social media, and ubiquitous computing platforms. These studies were largely rooted in exploratory research, with conceptual frameworks drawn from subjective well-being and affective computing. The dominant focus was on describing emotional and behavioral responses to digital engagement, often framed in terms of stress, distraction, or mood regulation. The technological systems under study were mostly nonadaptive and nonintelligent, and user autonomy was often treated as a passive construct.

An inflection point emerged in 2017. This period marked a transition from exploratory inquiries into more normative and design-oriented investigations. Triggered by public discourse around technology addiction, ethical technology, and digital detox movements, scholars began reframing digital well-being as a design goal rather than merely a behavioral outcome. This era coincided with a surge in industry initiatives (eg, Apple's Screen Time and Google's Digital Wellbeing suite), and research began to reflect growing societal concern about how technologies could undermine or support flourishing. Tools such as digital self-control tools and PITs became common subjects of investigation, signaling a broader shift toward proactive design strategies for well-being.

From 2022 onward, there was a notable rise in publications proposing frameworks, systems, and user studies that examined the role of human-centered AI in supporting digital well-being. Interdisciplinary contributions expanded, including papers from HCI, health informatics, behavioral science, and even management science. Concepts such as autonomy, persuasive design, ethical nudging, and emotion-aware interfaces were increasingly investigated through user-centered lenses. Many of these studies moved from simple heuristics to formal models, measurement tools, and empirical evaluations of intervention efficacy.

By 2024, the scope of the literature had broadened further to include the intersection of digital well-being with AI. This more recent body of work introduced sophisticated technologies, including generative AI, adaptive learning systems, hybrid human-AI collaboration platforms, and emotion recognition interfaces. These systems increasingly relied on real-time user data to personalize feedback and optimize interventions.

Overall, the sample data reinforces the need for design frameworks that synthesize empirical insights, respect user autonomy, and adapt to contextual and personal differences. As explored in the following findings and the model development section, the coding analysis helped identify key pain points and opportunities across system implementation, user experience (UX), and evaluation design.

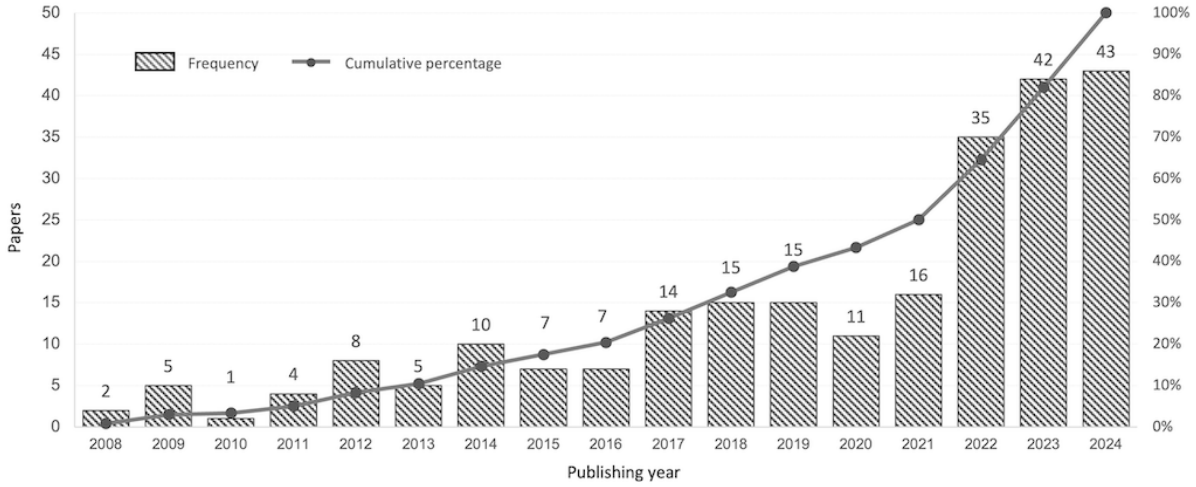

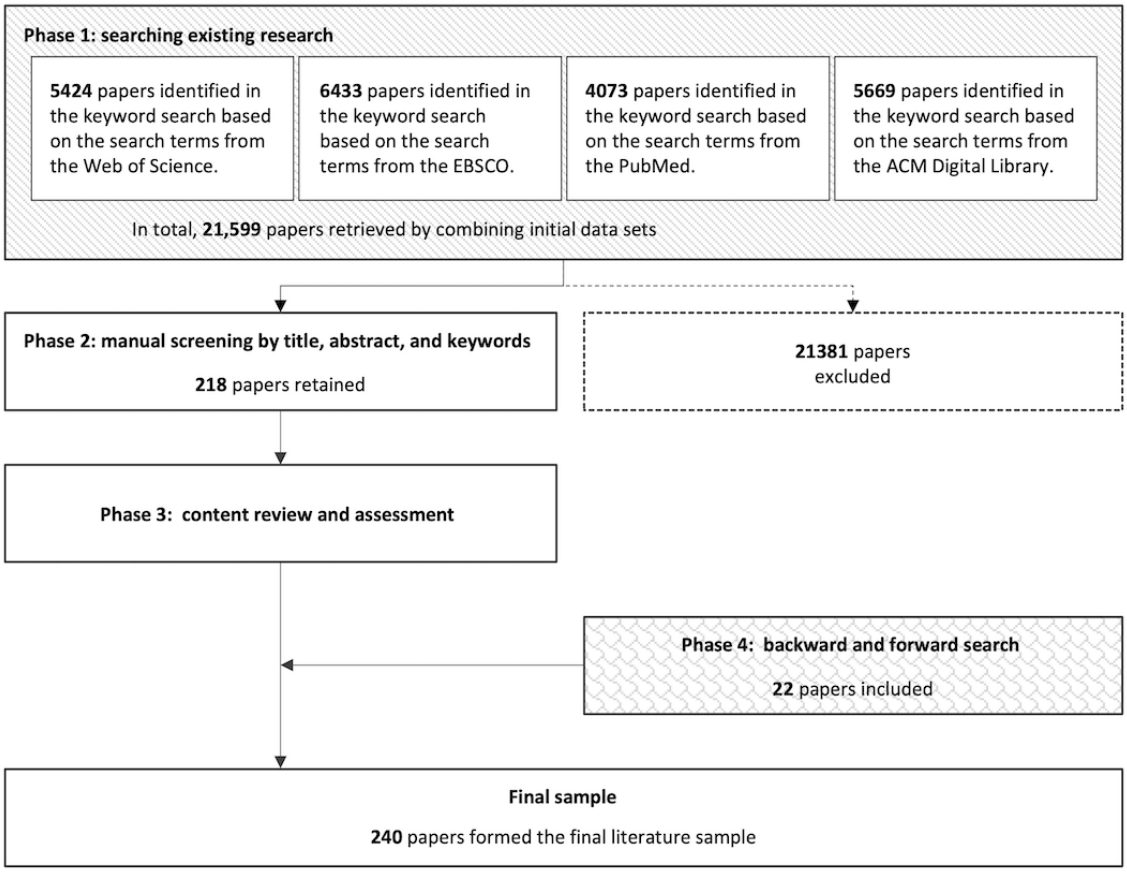

Figure 3. Overview of the data collection process. Databases: Web of Science, EBSCO, PubMed, and the Association for Computing Machinery (ACM) Digital Library.

Emerging Perspectives on Digital Well-Being and Intelligent Systems

Overview

From the in-depth analysis with the affinity diagramming process, 3 emerging perspectives were clustered, which can be incorporated into the development of a model of human-centered AI computing systems for digital well-being.

Finding 1. Three Implementation Areas of Intelligent Computing Systems for Digital Well-Being

As summarized in Table 1, the dataset revealed 3 major implementation areas—daily well-being in HCIs, design for behavioral change, and behavioral intervention technologies (BITs)—that form the basis for findings 1-3 in this study.

XSL•FO
RenderX

Table 1. Summary of 3 implementation areas in intelligent computing systems for digital well-being.

Implementation area	Description	Papers, n	Common theories or approaches	Key limitations
Daily well-being in HCIs[a]	Broad framing of well-being as a design goal, often informed by psychological theories	114	Self-determination theory and hedonic experience	Conceptual vagueness and limited operationalization
Design for behavioral change	Focus on changing user behaviors or habits via persuasive or adaptive systems	71	Dual-process theory, habit theory, and goal-setting theory	Lack of long-term efficacy and inconsistent success metrics
Behavioral intervention technology	Systematic approaches rooted in clinical settings using adaptive, data-driven interventions	55	BITs[b] and personal informatics	Limited practical integration and focus on high-income populations

[a]HCI: human-computer interaction.

[b]BIT: behavioral intervention technology.

Daily Well-Being in HCI

First, well-being in daily interactions with computing systems has been studied through a variety of lenses (ie, digital health, technology for mental health, or digital medicine) and under diverse human behavioral contexts over the past 2 decades. Among these various perspectives, "well-being in HCIs" is the broadest for considering technology as a tool for human flourishing and well-being [3]. Most related works aim to improve a user's psychological and subjective well-being by developing interactive design and technology interventions along 2 pathways. The first pathway involves formulating system design principles by using relevant theories from psychology, such as self-determination theory and hedonic experience [3,45,46]. The second pathway involves investigating certain well-being determinants derived from these theories—such as autonomy, competence, and relatedness—which typically serve as both intentions for computing system design and as criteria for evaluations in technology development processes [3].

The review of 240 papers confirmed that this conceptualization is foundational: 114 (48%) studies in the dataset treat well-being as a core design or evaluative objective. Many of these adopt an HCI-centric viewpoint, emphasizing positive emotional experiences, mental health, or life satisfaction as outcomes of well-designed user interactions. However, despite shared theoretical anchors—especially self-determination theory—there remains significant inconsistency in how well-being is defined, operationalized, and measured across studies. Most of the papers in this category relied on self-report measures (eg, user satisfaction surveys and qualitative feedback) to evaluate well-being outcomes. These findings reveal a methodological gap between theoretical aspiration and empirical implementation.

Previous studies have attempted to suggest tools for system design and development practices by grounding them in rigorous and evidence-based empirical research. However, the major criticism of the well-being perspective in HCIs has been the fragmented and unstructured nature of its implementation [3,47]. Furthermore, the notion of well-being is often used as a descriptive umbrella for current lifestyle trends or invoked conceptually to justify a human-centric design ethos, especially in discussions focused on the outcomes of system design [32]. As a result, many studies frame well-being as an aspirational goal but lack the definitional clarity or structured methodology required for robust evaluation.

Still, the literature reflects an evolution in the treatment of well-being. In earlier studies—particularly those published before 2016—the dominant approach was reactive: minimizing digital harms (eg, mitigating distraction, reducing screen time, or addressing smartphone addiction). More recent contributions, however, embrace a proactive stance. Instead of merely limiting technology's negative impacts, intelligent systems are now increasingly designed to scaffold reflection, self-regulation, emotional resilience, and long-term behavior change.

Despite these promising developments, the field still lacks integrative models that bridge disciplinary boundaries and connect technological features to measurable well-being determinants. Moreover, the challenge of balancing persuasive design with respect for user autonomy remains unresolved, as detailed in finding 2. While the well-being domain continues to expand in scope and influence, future research must prioritize the development of validated, multidimensional frameworks that align well-being theory with empirical evidence and real-world system design practices.

Design for Behavioral Changes

Second, the topic of design for behavioral change has been explored from a more defined and targeted angle by focusing on both short-term and long-term changes in users' behaviors [48]. In the context of digital well-being, designing for behavior change often involves addressing complex, subjective aspects of human experiences—elements that are inherently difficult to operationalize and quantify [49]. To address these challenges, researchers and practitioners have drawn extensively from behavioral science, using empirically validated frameworks that explain how human attitudes, cognitive patterns, and routines can be shaped through deliberate system design [28]. These behavioral foundations have been used to develop intelligent systems that aim to promote health-related behaviors and improve users' overall well-being.

The systematic review of 240 papers identified 71 (30%) studies that explicitly frame their system design objectives around catalyzing behavioral or habitual changes through intelligent computing. These studies span a wide range of behavioral domains, including digital overuse, emotional regulation, sleep

XSL•FO
RenderX

hygiene, and physical activity. What distinguishes this subset is its methodological rigor and theoretical alignment. Most of these studies ground their design logic in well-established behavioral science models, such as dual-process theory, habit formation theory, and implementation intentions. These theories provide a robust framework for creating interventions that influence users' decision-making processes across varying contexts and levels of awareness.

More recently, research and practice in this domain have shifted toward exploring the long-term consequences of technology-mediated behavior and its cumulative impact on well-being. For example, several studies [50,51] have sought to move beyond optimizing discrete moments of interaction (eg, interface usability and prompt timing) to designing systems that encourage enduring lifestyle changes. As a result, the field is beginning to transition from a narrow focus on behavior change to a more expansive framing around habit change. The review indicates a growing number of studies—particularly those integrating machine learning models—that aim to detect recurring behavior patterns and trigger interventions based on behavior-specific cues [52]. These approaches reflect a deeper ambition: to influence not only immediate choices but also the broader cognitive scaffolding that sustains long-term habits.

The growing interest in habit change has been accompanied by a series of conceptual and practical challenges. Niedderer et al [53] provided a macrolevel overview of behavior change design practices and noted major gaps in shared understanding, terminology, and implementation standards across sectors. This fragmentation is especially evident when comparing health-based interventions with HCI-focused strategies. For instance, while health researchers often emphasize measurable outcomes such as physical activity levels or sleep duration, HCI researchers tend to focus on experiential metrics such as emotional resonance or usability satisfaction. This inconsistency complicates the evaluation of intervention efficacy and limits the generalizability of findings.

Pinder et al [54] similarly noted the heterogeneity in how the concept of habit change is interpreted and operationalized across disciplines. In response, they proposed the "habit alternation model," which integrates 3 dominant theories—dual-process theory, modern habit theory, and goal-setting theory—into a single explanatory framework. This model has proven influential in reconciling divergent approaches and in guiding the design of more cohesive and context-sensitive interventions.

In parallel, a growing number of behavioral scientists have emphasized the importance of integrating HCD into behavior change systems [55]. HCD techniques—particularly participatory design methods—are increasingly used to ensure that interventions align with users' lived experiences, values, and goals. By involving users directly in the design and refinement process, these approaches seek to address the limitations of top-down, expert-driven interventions that may overlook individual motivation, digital literacy, or environmental constraints.

However, despite the growing sophistication of these approaches, the literature reveals several persistent issues. Chief among them is the challenge of sustaining user engagement over the long term and producing consistent results across diverse user populations [44,56,57]. While personalization features—such as content adaptation, feedback customization, and dynamic goal-setting—are widely used, the findings indicate that tailoring alone is insufficient. Systems that fail to account for users' deeper cognitive and emotional processes—such as internal motivation, self-regulation, and reflective goal alignment—often achieve only short-term success before engagement tapers off.

Another persistent concern is the lack of standardization in how success is measured. Some studies report efficacies in terms of quantitative behavior change (eg, reduced screen time and increased steps per day), while others emphasize qualitative improvements (eg, enhanced focus, better mood, or increased self-awareness). This lack of convergence around evaluative criteria undermines the comparability of results and highlights the need for more unified, theory-driven frameworks for assessing intervention outcomes.

In this regard, the literature points toward the need for deeper integration of behavioral theory with longitudinal user evaluation. The most promising studies combine short-term intervention efficacy with sustained reflection and feedback loops that help users internalize new behaviors. For example, systems that facilitate reflective journaling, goal adjustment, or feedback calibration were more likely to show lasting impact. These findings underscore the value of designing for not only behavioral compliance but also behavioral understanding and transformation.

In summary, the design for behavioral changes in the context of intelligent systems represents a maturing area of research—one that is increasingly grounded in theory, enriched by participatory methods, and informed by both real-time data and long-term evaluation. While notable progress has been made in creating adaptive, user-centered systems, the next frontier will require more holistic approaches that synthesize behavioral theory, co-design practices, and robust measurement strategies to enable durable and meaningful improvements in users' digital well-being.

About BIT

Third, the recent rise of BITs marks a significant and structured subdomain within the broader discourse of digital well-being, especially in health care and clinical settings. Defined by Mohr et al (2014) [58] as "the application of behavioral and psychological intervention strategies by using technological features to target behavioral, cognitive, and affective context and environment that support physical, behavioral, and mental health," BITs have gained traction through the development of computing systems designed to support health-related behavior change. This growth has enabled behavioral scientists to generate new empirical insights on how digital tools can promote physical, emotional, and psychological well-being [36,58,59].

The review of 240 papers revealed that 55 (23%) studies explicitly focus on BIT development and evaluation, making it one of the most clinically grounded areas in the literature. These systems typically emerge from interdisciplinary collaborations among behavioral scientists, HCI researchers, and system

XSL•FO
RenderX

developers, often underpinned by robust theoretical foundations. Common targets of BITs include mental health symptom reduction [60], emotional regulation, and adherence to behavioral protocols.

In recent years, BITs have evolved to incorporate technologies categorized under PITs and digital medicine. Several systems in this group exemplify the practical application of such theories through adaptive interfaces that personalize nudges, prompts, or feedback mechanisms in real time. These include systems that leverage decision science and data science to personalize interventions based on user behavior and preference data [24,61,62]. For instance, the deployment of Just-In-Time Adaptive Interventions (JITAIs)—where prompts are delivered based on biometric signals, app usage data, or behavioral cues—has become a dominant trend [63-66]. These JITAI-based systems aim to maximize user engagement by intervening at moments of high receptivity, demonstrating significant promise in both user satisfaction and short-term efficacy.

Despite their strengths, BITs continue to face several limitations. Traditionally, these technologies have been developed and evaluated within clinical contexts, emphasizing short-term efficacy over broader UX or long-term impact [67]. Researchers and practitioners have highlighted several persistent issues: (1) limited theoretical grounding in some system designs, (2) insufficient models for evaluating user interaction and engagement, (3) accessibility challenges and associated costs, (4) inconsistent user adherence, and (5) poor integration into broader health delivery infrastructures [48].

Moreover, there is a notable lack of diversity in the populations studied. Most BITs have been designed and tested in high-income settings, raising concerns about their generalizability and inclusivity. Addressing this gap, recent work has begun to explore the use of generative AI and low-cost sensing technologies to extend the reach of BITs in underserved or resource-constrained environments.

In response to these limitations, behavioral scientists have called for a shift toward more ethically grounded and human-centered BIT development. This includes integrating fragmented design perspectives into cohesive theoretical frameworks and emphasizing transparency, adaptability, and co-design practices [68]. Features such as explainable AI, user override functions, and participatory evaluation have been proposed to mitigate ethical concerns related to manipulation, autonomy, and privacy.

Synthesizing insights from BITs and broader literature on intelligent computing systems for digital well-being, 3 key observations emerge. First, much of the prior research has focused on the outcomes of behavioral decision-making without adequately considering the diversity of users. There is now increasing emphasis on individual differences—such as psychological profiles, health status, and behavioral tendencies—to inform more effective and equitable system design [53,69]. Second, while earlier work emphasized generic system usability, recent studies highlight the importance of well-structured, personalized interventions that account for contextual variables, such as environment and time of use [36,59,62,70]. Third, as AI technologies become more pervasive, researchers and practitioners are increasingly grappling with how to reconcile advancements in human autonomy research with digital well-being initiatives—particularly concerning personalized UXs and human-centered AI system design [3,67,68].

Finding 2. Conceptual Diversity on Human Autonomy With AI-Powered Intelligent Systems

The review results revealed that as AI-powered computing systems become increasingly integrated into our daily life—supporting decision-making, automating routine tasks, and influencing behavioral patterns—the concept of autonomy has emerged as a central design value [19,27,71]. However, the interpretation of autonomy varies widely across disciplines, leading to conceptual ambiguity and design inconsistencies. From the perspective of psychology and behavioral science, the concept of human autonomy is considered one of the basic psychological needs, particularly within the framework of self-determination theory, which views autonomy as freedom from external control or influence—including from other people and environmental factors [72]. From this perspective, psychologists and behavioral scientists have focused on behavioral interventions to change people's attitudes and behaviors in positive ways by investigating the relationship between human autonomy and the behavioral decision-making process [47].

The analysis of 240 papers found that 147 (61%) studies engaged directly with autonomy-related issues, with 2 dominant and sometimes competing perspectives emerging: (1) technological autonomy from human control and (2) human autonomy through technology.

The first perspective, technological autonomy from human control, is most prevalent in the fields of computer science and engineering. In this framing, autonomy refers primarily to the capabilities of AI systems themselves—their ability to function independently, adapt dynamically to changing conditions, and minimize the need for continuous human input [27,73]. This notion is often associated with intelligent automation, self-regulating algorithms, and predictive systems that optimize for performance and reduce cognitive load for users. Forty-six (19%) studies aligned with this perspective, emphasizing the design of systems that learn and act autonomously, such as context-aware recommendation engines, automated productivity tools, and self-adjusting health monitors. However, while this approach offers efficiency and scalability, it also raises concerns about diminishing user control, consent, and interpretability. Systems designed for technological autonomy may inadvertently undermine user agency by prioritizing automation over transparency or flexibility—especially when users are not able to understand, override, or adapt the system's decisions.

In contrast, the second and more human-centered perspective, human autonomy through technology, is emphasized in the disciplines of management, HCI, and HCD. This framing views technology not as a substitute for human agency but as an enabler of it—providing tools that amplify users' capacity to make intentional, informed, and self-endorsed decisions [61,74]. In total, 102 (43%) studies in the dataset foregrounded this approach, suggesting that AI systems should support user autonomy by offering decision-support dashboards, intelligent

XSL•FO
RenderX

filtering mechanisms, PITs, and customizable experiences [27,75,76]. In this view, autonomy is not merely preserved in the face of automation but is actively cultivated through interactions that respect the user's goals, values, and contexts. Systems aligned with this perspective often use noncoercive prompts, user-configurable settings, and ethical nudging strategies to support reflection and volition rather than compliance or behavioral control [61,74]. This divergence in perspectives is summarized in Table 2.

Table 2. Conceptualizations of human autonomy in AI[a] systems.

Autonomy perspective	Disciplinary origin	Papers, n	Core ideas	Key example use cases
Technological autonomy from human control	Computer science and engineering	46	AI systems operate independently, reducing user input	Predictive automation and context-aware recommender systems
Human autonomy through technology	Management, HCI[b], and HCD[c]	102	AI enhances user capacity and supports informed and volitional action	Personal informatics, decision-support interfaces, and nudging tools

[a]AI: artificial intelligence.

[b]HCI: human-computer interaction.

[c]HCD: human-centered design.

Despite widespread efforts to embed autonomy-supportive features into intelligent systems, many researchers and practitioners continue to struggle with translating these abstract values into coherent design strategies [17,71]. The conceptual gap between the system-centered and user-centered views of autonomy contributes to ongoing tensions in system development, particularly when trying to balance the benefits of automation with the preservation of user agency.

A recurring issue highlighted in the literature is the persuasion-autonomy dilemma, where AI systems intended to assist or influence behavior (eg, through nudges or reminders) risk being perceived as overly controlling, opaque, or misaligned with users' intentions. In practice, users often appreciate automation that reduces effort but become frustrated or resistant when systems overstep—such as enforcing goals that feel inappropriate, invasive, or difficult to override. For example, the review identified cases where health-monitoring applications encouraged physical activity without sensitivity to context (eg, illness), or algorithmic management systems in gig work environments reduced perceived autonomy and flexibility—prompting resistance among users [41,77].

These examples illustrate that perceived fairness, transparency, and reversibility often matter more to users than algorithmic sophistication alone. The review underscores that user trust and acceptance are closely linked to how much control and interpretability a system allows. In response to these concerns, a promising development is the emergence of "repairable AI"—systems that embed mechanisms for user revision, feedback, or override. These systems transform autonomy from a static feature into a relational and dynamic property, allowing users to negotiate control over time.

For instance, the TypeOut system by Xu et al [78], implemented self-affirmation prompts that allowed users to reflect on their values and motivations when trying to reduce smartphone overuse. This approach supported users' autonomy by reinforcing self-directed action rather than imposing strict limitations. Similarly, several studies explored hybrid intelligence systems that combine algorithmic recommendations with human coaching or collaborative decision-making. These systems demonstrated higher user satisfaction, engagement, and personalization, as they allowed users to maintain interpretive authority while benefiting from intelligent assistance.

Across the dataset, the most effective systems for supporting autonomy shared several characteristics: they offered clear explanations of system behavior, allowed users to customize settings or feedback modalities, and supported decision-making rather than unilateral automation. Autonomy was thus conceptualized not as a binary variable but as a continuum that must be calibrated to the user's needs, task context, and preferences.

In summary, the review suggests that autonomy in AI-powered systems should be approached as a relational, context-sensitive construct shaped through the dynamic interplay of system design, user interaction, and ethical affordances. While technological autonomy from human control may offer performance benefits, the long-term sustainability of human-centered AI depends on the extent to which these systems preserve and enhance human autonomy through technology. Future research and development should prioritize design practices that support transparency, reversibility, and participatory engagement, ensuring that users retain meaningful agency in an increasingly intelligent world.

Finding 3. Developing and Evaluating Process for Digital Well-Being With AI Systems

As AI systems become increasingly embedded in everyday life, the challenge of ensuring that these technologies genuinely support digital well-being has taken on new urgency. Existing initiatives have repeatedly highlighted a persistent gap between high-level theoretical ideals and the actionable methodologies required to guide the development and evaluation of human-centered AI systems. Two practical and recurring questions have emerged from these efforts: (1) How can researchers and practitioners identify applicable strategies for designing AI systems that enhance digital well-being? (2) How can they rigorously evaluate whether these systems are effective in achieving that goal?

Despite a growing body of literature advocating for human-centered values in AI, the systematic review of 240 papers revealed that few studies translate these values into

XSL•FO
RenderX

structured, repeatable design and assessment strategies. Instead, the current landscape remains fragmented—often disconnected from both theoretical frameworks and real-world user needs. In response to this problem, this paper synthesizes prior work through the lens of the SOR model, which offers a practical and conceptual bridge between research, design, and evaluation in the context of digital well-being.

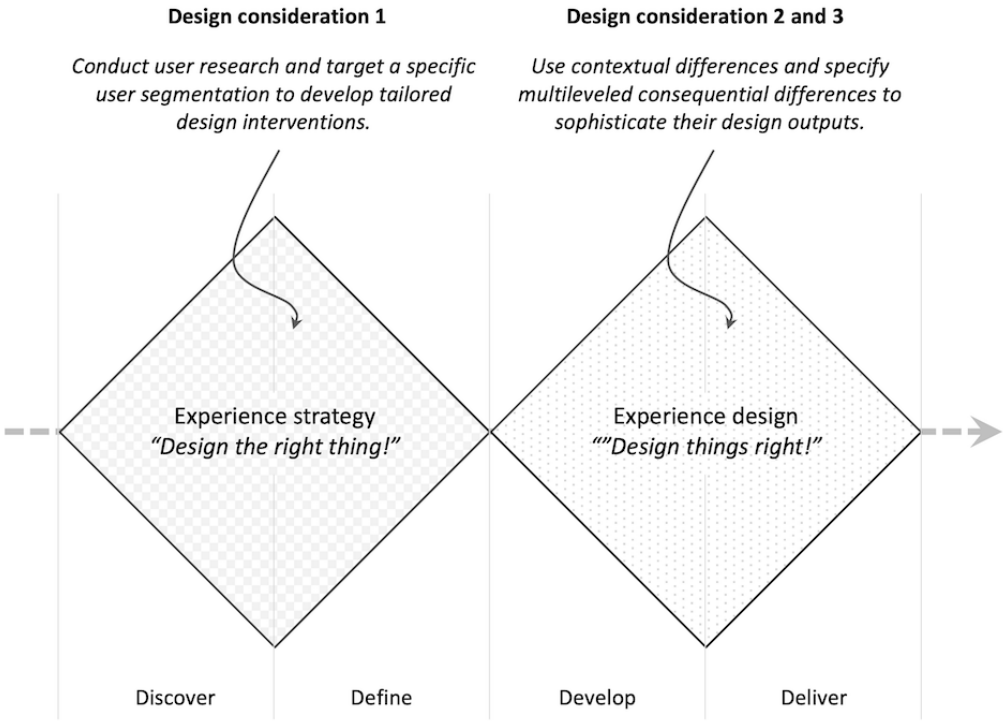
As summarized in Table 3, the SOR-based framework articulates three key considerations for guiding human-centered AI system development: (1) using contextual differences for the stimulus component, (2) accounting for individual differences in the organism component, and (3) specifying consequential differences in the response and outcome components.

Table 3. Methodological focus in developing AI[a] systems for digital well-being.

SOR[b] component	Key research concerns	Papers, n	Representative methods	Challenges identified
Contextual difference (stimulus)	Leveraging real-time sensing and situational awareness	94	Wearables and ambient sensing	Reliability of context-detection
Individual differences (organism)	How to adapt systems to personal traits and contexts	79	Profiling, personalization, and HCD[c]	Often, surface-level traits are used only
Consequential difference (response and outcome)	Long-term changes in well-being and reflection processes	140	Multimodal evaluation and journaling tools	Rarely includes holistic well-being metrics

[a]AI: artificial intelligence.

[b]SOR: stimulus-organism-response.



[c]HCD: human-centered design.

The SOR framework was well-reflected across the dataset. Ninety-four (39%) papers focused on the integration of contextual data into system design, leveraging information from wearable devices, mobile sensors, and behavioral logs to deliver personalized and context-aware interventions. These findings align with growing interest in BITs and JITAIs that respond dynamically to real-world environments and user states. Additionally, 79 (33%) papers emphasized the importance of addressing individual variability in AI systems for digital well-being. These studies adopted approaches such as adaptive personalization, participatory design, and segmentation based on psychological traits, user preferences, or digital literacy levels. Systems that integrated this type of individual profiling were consistently associated with higher levels of user engagement, perceived relevance, and intervention efficacy. However, the third design consideration—specifying consequential outcomes—remains underdeveloped across the literature. While 140 (58%) papers discussed the interaction between context, individual traits, and well-being outcomes, many stopped short of evaluating long-term psychological or behavioral change. Instead, outcome assessments often relied on narrow usability metrics (eg, user satisfaction or screen time reduction) or short-term behavioral proxies (eg, frequency of feature use), without considering deeper indicators such as habit formation, digital resilience, or emotional regulation.

Building on these insights, the development of digital well-being interventions through AI can be conceptualized in two phases, aligned with the revamped double diamond design model [79]: (1) experience strategy—designing the right thing, and (2) experience design—designing things right (Figure 4). In the experience strategy phase, researchers and practitioners conduct user research to understand core challenges and motivations. Here, individual differences (SOR: organism) are identified through profiling and segmentation—considering factors such as personality, digital habits, emotional needs, and cognitive preferences. These insights help define targeted user groups and establish design priorities.

XSL•FO
RenderX

Figure 4. The developing process for digital well-being with AI systems. AI: artificial intelligence.

The experience design phase focuses on implementation—developing system features that respond to both individual and contextual variation (SOR: stimulus). This includes creating adaptive interfaces, intelligent feedback loops, and multimodal interventions that nudge users toward meaningful behaviors. As part of this phase, teams are encouraged to define consequential outcomes (SOR: response and outcome) not just in terms of app usage or time-on-task, but through broader and more enduring metrics such as user autonomy, emotional well-being, and sustainable habit change.

Despite the clear utility of this model, the review found that many studies continued to rely on simplistic evaluation strategies, such as postuse surveys or single-time-point measurements. While these can offer useful feedback, they often fail to capture the temporal and emotional dynamics that characterize digital well-being. For instance, AI systems intended to reduce screen time were rarely evaluated for their effects on users' perceived autonomy or cognitive fatigue. Likewise, productivity tools often neglect to measure whether increased efficiency was accompanied by psychological strain or decision exhaustion.

Additionally, promising developments were observed in systems that integrate generative AI for personalized support in mindfulness, reflection, and journaling tasks. These tools showed early evidence of enhancing emotional regulation and user engagement. However, consistent frameworks for evaluating their effects—particularly on user autonomy and mental energy—remain lacking. Furthermore, despite increased technical sophistication, emotion recognition algorithms still struggle with reliability, and few studies incorporated robust longitudinal evaluations. Equity concerns also surfaced across the dataset. Very few evaluation frameworks accounted for variables such as socioeconomic status, neurodiversity, or differential access to digital tools, raising concerns that certain AI interventions may inadvertently reinforce existing disparities rather than reduce them.

In conclusion, the development and evaluation of AI systems for digital well-being must move beyond high-level rhetoric and toward deeply contextualized, empirically grounded processes. By applying frameworks such as the SOR model and drawing from findings in interdisciplinary literature, researchers and practitioners can more effectively align design goals with meaningful, measurable, and user-centered outcomes. The field's advancement depends not only on technical innovation but also on a more nuanced understanding of how intelligent systems intersect with users' daily decisions, emotional states, and broader societal contexts.

Development of HCAI-DW Model

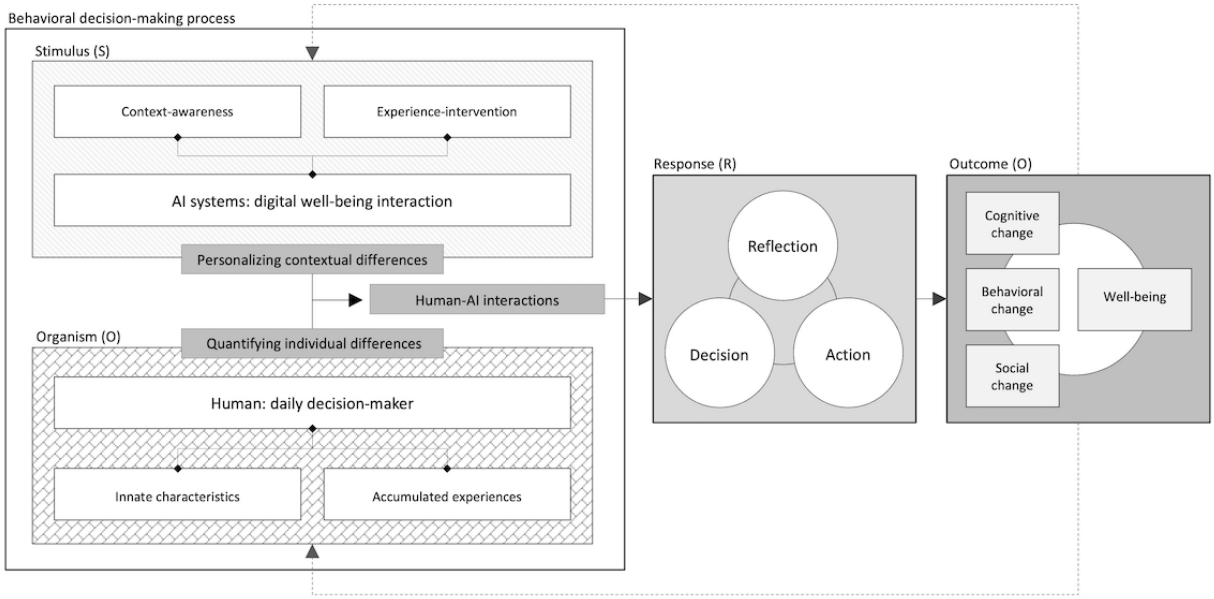
Background

The preceding 3 findings collectively underscore a fragmented but evolving landscape in the design and evaluation of intelligent systems for digital well-being. First, implementation efforts tend to cluster around 3 key domains—supporting well-being in daily HCIs, designing for behavioral and habit change, and deploying BITs—but each varies in conceptual clarity, theoretical grounding, and methodological rigor. Second, the value of user autonomy is widely recognized, but interpreted through different disciplinary lenses, leading to tensions between automation and agency. Third, despite strong calls for human-centered development, the field still lacks coherent, actionable methodologies for designing and assessing AI systems that meaningfully support users' emotional, behavioral, and cognitive well-being.

In response to these interrelated challenges, this study proposes an integrative framework: the HCAI-DW model. Developed to

XSL•FO
RenderX

bridge the persistent gaps between conceptual ideals and real-world implementation, the HCAI-DW model synthesizes insights from empirical findings, behavioral theory, and interdisciplinary practice. It offers a structured lens to guide researchers and practitioners in designing, deploying, and evaluating AI-powered systems that promote human flourishing in digital environments.



The model was developed through an iterative, participatory process that combined the systematic review of 240 research papers with expert feedback from 5 professors and 17 graduate students in HCI and HCD. These structured review sessions—conducted at both early and final stages of the modeling process—played a critical role in refining the model's conceptual clarity, usability, and relevance to current challenges. The goal was not only to reflect the state of the field but to cocreate a framework that is both theoretically robust and practically applicable.

A key insight that emerged throughout this process is that digital well-being is inherently multidimensional, shaped by the complex interplay of individual psychological traits, system-level design interventions, users' behavioral responses, and broader social or environmental outcomes. To capture this interplay, the HCAI-DW model adapts and extends the SOR model, a well-established paradigm in behavioral science, and reframes it for the context of human-AI interaction. This adaptation provides a structured but flexible blueprint for understanding how intelligent systems can shape and support digital well-being in everyday life.

Overview

As illustrated in Figure 5, the HCAI-DW model describes 4 essential and interrelated components that shape human-centered AI system development for digital well-being: (1) the organism component, which views users as daily behavioral decision makers; (2) the stimulus component, which frames AI system features as intentional behavioral interventions; (3) the response component, which introduces a cyclical model of user engagement involving decision, action, and reflection; and (4) the outcome component, which emphasizes a layered understanding of cognitive, behavioral, and social transformations. Together, these components offer a comprehensive pathway for designing intelligent systems that promote digital well-being in nuanced, personalized, and sustainable ways.

Figure 5. HCAI-DW Model. AI: artificial intelligence; HCAI-DW: human-centered artificial intelligence for digital well-being.

Organism: Daily Decision Makers

The organism component foregrounds the diversity of individual characteristics that influence how people interact with AI-powered systems. In the HCAI-DW model, these differences—including traits such as motivation, digital literacy, emotional state, and decision-making tendencies—are recognized as critical design inputs for tailoring interactions. As past research has demonstrated, individuals tend to make behavioral decisions based on their innate characteristics or accumulated experiences. Profiling user preferences and behaviors allows AI systems to deliver personalized support that is more effective and meaningful in fostering digital well-being [36,59]. The reviewed literature shows that most existing studies emphasized the importance of personalization, though only a fraction deployed adaptive systems that responded to individual differences in real time. By leveraging machine learning and deep learning algorithms, intelligent systems can move beyond generalized models to provide highly contextualized and evolving interventions [59,80,81]. This model suggests treating AI systems not merely as tools for behavior modification but as coregulatory agents that continuously adapt to users as they navigate complex decision-making environments. For this reason, the HCAI-DW model posits that seeing users as "daily behavioral decision makers" is essential for designing effective AI systems that address the nuances of digital well-being.

XSL•FO
RenderX

Stimulus: Digital Well-Being Interactions

The stimulus component redefines AI system features as intentional behavioral interventions that can promote or hinder digital well-being. While many previous initiatives have explored user interaction with AI as a design theme or an evaluation component [3,82], the HCAI-DW model differentiates between 2 interrelated stimulus phases: the context-awareness phase and the experience-intervention phase.

The context-awareness phase is derived from the quantified-self and personal informatics movements [59]. In this phase, AI systems track and interpret user data—including time, location, physical state, and social context—to deliver interventions that are sensitive to situational dynamics. Of the 240 reviewed studies, 94 specifically focused on the integration of such contextual variables into design. Wearable sensors, app usage logs, and mood-tracking tools were among the techniques used to improve the precision of interventions. The experience-intervention phase draws from BIT literature [70,83]. In this phase, AI systems deliver tailored and systematized interactions that aim to encourage behavioral shifts and preserve user autonomy. These interventions include nudges, reminders, content recommendations, and interface adjustments. Rather than enforcing a one-size-fits-all approach, the HCAI-DW model supports dynamic and transparent adaptation to individual feedback, reducing the risk of perceived manipulation or coercion.

Together, these 2 stimulus phases highlight the dual nature of AI system design: sensing and acting. Systems that only track without intervening, or intervene without contextual sensitivity, risk ineffectiveness or user resistance. The HCAI-DW model provides a roadmap for designing stimulus mechanisms that are integrated, adaptive, and user-centric.

Response: Decision-Action-Reflection Loop

The response component expands the understanding of user engagement beyond simplistic stimulus-response paradigms to include a full cycle of decision, action, and reflection. This loop is crucial for supporting sustainable behavior change and deeper cognitive engagement. Most previous studies have treated user responses as fixed behavioral outputs (eg, goal achievement and app usage). However, this approach overlooks the underlying reflective processes that support long-term well-being [16,36]. In contrast, the HCAI-DW model emphasizes the temporal and cyclical nature of engagement. AI systems should facilitate not only behavioral outcomes but also opportunities for users to reflect on their choices, understand system recommendations, and adjust their goals over time [17,19,53]. Such features are underdeveloped in the current literature; only few studies described systems that supported ongoing reflective practice, and even fewer implemented adaptive feedback based on longitudinal user behavior. Examples of effective reflective design include journaling prompts, feedback dashboards, and generative content that encourages users to process their experiences emotionally and cognitively. These elements help close the loop between system recommendation and user transformation, offering pathways for deeper and more enduring engagement.

Outcome: From Cognitive Change to Social Change

The outcome component identifies and categorizes the types of changes users experience after interacting with AI-powered systems [4,71]. Based on an analysis of prior research, the HCAI-DW model distinguishes 3 levels of outcome: cognitive change (eg, increased awareness and motivation), behavioral change (eg, reduced screen time and improved sleep), and social change (eg, enhanced family communication and digital equity). While many previous approaches target a single optimized outcome (eg, productivity or screen-time reduction), the HCAI-DW model encourages consideration of multilayered and user-defined metrics. It also addresses a common limitation of models such as Motivation, Engagement, and Thriving in User Experience model [27], which, despite offering a comprehensive structure for evaluating technology-mediated experience, struggle with implementation due to insufficient differentiation between experience levels and limited guidance on design implications.

This model fills that gap by suggesting a framework for systematically specifying consequential differences—that is, the variations in outcomes that result from users' unique behavioral decisions and reflective processes. Many prior interventions have focused on training or instructing users to modify their behavior [4,35] but have not always aligned these goals with users' lived experiences, values, or autonomy. The HCAI-DW model enables researchers and practitioners to avoid these pitfalls by distinguishing between process (decision-making) and product (outcome) and ensuring that both are addressed in a human-centered, contextualized manner.

In sum, the HCAI-DW model offers a synthesized and actionable framework that integrates the diverse findings of this review and provides a comprehensive guide for the design, development, and evaluation of intelligent systems that prioritize digital well-being. Its structure—rooted in the SOR model and refined through interdisciplinary and participatory input—reflects a growing need in the field for models that are not only conceptually rigorous but also practically useful. By highlighting individual differences, incorporating contextual adaptation, supporting reflective engagement, and mapping layered outcomes, the model promotes a vision of AI that respects human agency while optimizing support. As AI technologies become increasingly embedded in everyday life, models such as HCAI-DW will be critical in guiding their ethical, effective, and human-centered development.

Discussion

Principal Findings

This paper developed the HCAI-DW model to conceptualize how AI systems can support individuals' behavioral decision-making and foster behavioral changes that enhance their daily digital well-being. Grounded in evidence-based academic literature and established perspectives from relevant practical domains, this model reflects a human-centered approach to AI systems aimed at improving digital well-being. The HCAI-DW model is expected to enhance existing technology development practices by offering a systematic framework to encode and use core factors that drive digital

XSL•FO
RenderX

well-being in AI computing systems. Furthermore, the model was purposefully designed for intuitive and practical use, addressing the emerging needs of researchers and practitioners seeking to apply theoretical insights and design approaches to shape human experiences. As such, the model enables the creation of more effective AI system interactions by tailoring them to individual and contextual differences, particularly those associated with decision-making processes.

Limitations

This paper offers a timely investigation into human-centered AI systems designed to support users' digital well-being, incorporating insights from a systematic literature review. To provide a comprehensive and multidisciplinary overview of the most relevant research, 4 academic databases were used as the primary sources for data collection. This approach aimed to ensure the inclusion of diverse scholarly contributions from computing, design, behavioral science, and information systems. However, a key limitation lies in the fragmented nature of existing studies in this domain. Many initiatives related to digital well-being and intelligent computing systems are published under varied terminologies and conceptual framings. To address this, the initial phase of data collection used broadly defined search terms to capture a wide scope of literature. Despite this inclusive strategy, there is a possibility that some relevant studies—particularly those published under domain-specific or alternative terminologies—were not included. For example, literature from niche fields or interdisciplinary collaborations may have described similar phenomena without explicitly using the terms "digital well-being" or "AI systems."

Additionally, while the topic has gained increasing attention in both academic and industrial contexts, the number of studies explicitly integrating the concepts of AI and digital well-being remains relatively limited. This restricts the ability to generalize findings across all potential applications or use cases of AI systems designed for human well-being. Future systematic reviews should aim to capture these additional perspectives by refining search protocols and expanding the inclusion criteria to account for heterogeneity in terminologies, research methods, design strategies, usage contexts, and evaluative outcomes.

Furthermore, the HCAI-DW model proposed in this study should be understood as a preliminary step rather than a finalized theoretical framework. The model synthesizes key themes and design considerations from the existing body of work to propose an integrated perspective on designing for digital well-being with AI. However, the model has not yet been empirically validated, and its applicability across different cultural, technological, or organizational contexts remains uncertain. This limitation suggests that further empirical research—particularly studies conducted in real-world design and development settings—is necessary to test and refine the model's relevance, accuracy, and usability.

In summary, while this paper contributes a foundational understanding of how human-centered AI systems can support digital well-being, the evolving and interdisciplinary nature of the field calls for continued theoretical expansion and empirical validation. Follow-up works should also explore additional stakeholder perspectives and context-specific requirements to enhance the robustness and applicability of the HCAI-DW framework.

Future Directions

Overview

This study provides a foundation for advancing both theoretical and practical efforts in designing AI systems that promote digital well-being in daily HCIs. Based on insights from the systematic literature review, three key challenges emerge for future research and practice: (1) developing new evaluation methods for digital well-being in AI contexts, (2) addressing ethical considerations in AI-powered technology interventions, and (3) designing for hyper-personalization by accounting for individual decision-making contexts. The following sections elaborate on each of these challenges and outline opportunities to enrich the body of knowledge in this domain.

New Evaluation Methods for Digital Well-Being in AI Systems

Several studies have highlighted the limitations of existing evaluation tools for measuring subjective experiences of well-being in technology use. In particular, concerns have been raised regarding the reliability and validity of commonly used instruments [35,83]. From the perspective of the HCAI-DW model, digital well-being outcomes are shaped by a complex interplay of daily behavioral decisions and interactions with AI systems. However, a major challenge remains: there is a lack of well-validated and universally applicable measurement tools that can accurately assess the short-term and long-term effects of AI-based interventions.

Current tools are often adapted from adjacent domains and may not reflect the nuances of digital well-being in AI-enhanced contexts. As a result, the evaluation of AI system effectiveness remains inconsistent and difficult to standardize [84]. There is an urgent need to develop novel, context-sensitive evaluation methods that can capture the dynamic and individualized nature of well-being outcomes. These tools should account for both objective indicators and subjective experiences to ensure that the impact of AI systems on users' digital well-being can be meaningfully assessed.

Ethical Considerations in AI-Powered Interventions

While digital well-being aims to enhance users' lives through technology, intervention through AI systems must be approached with caution. Interventions, though potentially beneficial, are inherently value-neutral and may be used in manipulative or unethical ways [85]. For example, leveraging behavioral decision-making mechanisms could enable governments or corporations to influence individuals' choices in ways that serve organizational goals rather than personal well-being [54]. This raises significant ethical concerns, including the risk of undermining users' autonomy or reinforcing harmful behavioral patterns [86].

The HCAI-DW model calls for AI systems that are sensitive to individual needs and contexts. However, achieving this level of personalization often requires collecting sensitive behavioral data, which brings digital privacy into focus. Ethical design practices must address questions of informed consent, data

XSL•FO
RenderX

transparency, and user agency. Researchers and practitioners should ensure that AI interventions prioritize individual rights and safeguard against potential misuse or harm. Privacy-by-design principles and responsible data governance should be core components of future development strategies.

Designing for Hyper-Personalization Based on Individual Decision-Making Contexts

The advent of AI has fueled a growing trend toward hyper-personalization—tailoring content, services, and experiences to individual users based on real-time data and behavioral histories [17,18,62]. Although hyper-personalization holds promise for promoting sustained engagement and behavioral change, few studies have explored its implementation through the lens of digital well-being and human-centered AI [17,53,74].

The HCAI-DW model offers a conceptual foundation for understanding how personalization can support well-being by considering users' individual, contextual, and behavioral differences. It emphasizes that design should not only respond to users' past behaviors but also anticipate their goals, motivations, and environmental conditions. To fully realize the potential of hyper-personalization in AI systems, future research should identify actionable design principles that align AI-driven personalization with users' well-being outcomes. This includes developing frameworks for adaptive and context-aware personalization that respect user boundaries and preferences. By doing so, designers can increase the impact of AI systems on sustained behavioral change and help users make informed decisions that enhance their overall digital well-being.

Conclusions

This paper identifies everyday behavioral decision-making as a foundational concept for designing AI systems that enhance digital well-being. By synthesizing fragmented and often inconsistent perspectives from prior research, the study introduces the HCAI-DW model. This model offers a conceptual framework that links individual behaviors, AI system interactions, and well-being outcomes in everyday life. Through this model, this paper demonstrates how AI systems can be intentionally designed to support users' behavioral decisions in ways that promote meaningful and sustained improvements in digital well-being. Rather than treating digital well-being as an abstract or isolated construct, the HCAI-DW model emphasizes its dynamic and context-dependent nature, highlighting the critical role of personalized, ethical, and adaptive AI design. Ultimately, this work encourages researchers and practitioners to reconsider the evolving relationship between humans and AI in everyday contexts. It invites further exploration into what it means to be a "new type of human"—one whose daily life and well-being are increasingly mediated by intelligent technologies.

Abstract

Background: Endometriosis is a chronic disease that affects 1 in 10 women worldwide. The disease affects patients' daily life at physical, psychological, and social levels. In recent years, the management of this disease has evolved, thanks in particular to the emergence of digital technologies and associated interventions. However, despite their growing use, there seems to be no systematic review of their development, design, and efficacy.

Objective: A systematic review was conducted with the aim of characterizing the development process, design, and effectiveness of interventions using a digital tool for endometriosis.

Methods: A total of 7 databases (MEDLINE, APA PsycArticles, Academic Search Premier, Psychology and Behavioral Sciences Collection, APA PsycInfo, SocINDEX, and SPORTDiscus) were searched to identify relevant articles published between 2010 and 2024. The articles selected were analyzed using a methodological framework specific to the development of digital health interventions (Design and Evaluation of Digital Health Interventions [DEDHI]), consisting of 4 phases: preparation (phase 1, specific to application development), optimization (phase 2, dedicated to identifying the best intervention configurations), evaluation (phase 3, aiming to confirm the effectiveness of the intervention), and implementation (phase 4, implementing and updating the intervention on a large scale).

Results: A selection of 10 articles was made from the 381 studies retrieved from the databases. Among these 10 studies, 6 distinct digital health interventions were identified. The interventions based on digital devices produced physical and psychological benefits. Analysis using the DEDHI framework showed (1) a disparity in the responses to the different phases (ie, 9/10, 90% of studies responding to phase 1; 3/10, 30% to phase 2; 4/10, 40% to phase 3; and 2/10, 20% to phase 4) and (2) a variability in the completion of the evaluation criteria ranging from 10% (1/10) to 80% (8/10) in phase 1, 0% (0/13) to 77% (10/13) in phase 2, 0% (0/10) to 80% (8/10) in phase 3, and finally 0% (0/13) to 77% (10/13) in phase 4. The objectives of these digital interventions were to support pain management (5/6, 83%), to provide information about the disease and strategies for managing it (4/6, 67%), and to provide psychosocial support (2/6, 33%).

Conclusions: This systematic review highlights an emerging literature, limited regarding the use of digital technology in the management of endometriosis, and heterogeneous concerning the methodologies used. This variability limits the generalizability of the results and requires a nuanced interpretation of the available data. However, the results of this review have demonstrated the value of digital technology–based interventions to support endometriosis, while highlighting the importance of a methodological framework to structure their development to optimize patient support.

endometriosis; digital health interventions; technological intervention; endometriosis care; development framework; systematic review

Introduction

Endometriosis is a chronic disease characterized by the abnormal presence of an epithelium, stroma, or both, histologically similar to the endometrium, located outside the endometrium and myometrium, and frequently associated with an inflammatory state [1,2]. Its prevalence is estimated at around 10%; that is, approximately 190 million women of childbearing age worldwide [3]. Endometriosis is currently presented by major organizations such as the WHO, the European Parliament, the Office on Women's Health, and the scientific community as a major public health problem [4]. Although responsible for significant morbidity, endometriosis is a disease for which there is as yet no effective treatment [5].

Lack of treatment has a deleterious impact on patients' quality of life [6]. Thus, numerous physical constraints, such as chronic pelvic pain [7]; associated symptoms such as dysmenorrhea, dysuria, dyschezia, and dyspareunia [8]; and a greater predisposition to the risk of comorbidities [9] arise from this disease. As well as these physical impacts, endometriosis can also cause anxiety or depression [10], psychosomatic disorders [11], reduced self-esteem [12], or a negative perception of one's body [13]. Finally, endometriosis can also affect these women's social relationships, as it severely restricts their daily and professional lives [14], causes difficulties in their relationships and sexuality [15,16], and can, in some cases, lead to isolation [17]. The diversity of these symptoms and their varying degrees of severity in each woman can make universal management difficult. It is, therefore, important that the support offered to patients is based on a personalized approach (ie, a care pathway tailored to each patient), multidisciplinary (ie, close collaboration between different health care professionals), and multimodal (ie, several types and sources of support) [18].

Chronic disease support is embedded in a global context, where digital technology is playing an increasingly important role in health care [19]. Especially since the COVID-19 pandemic, digital technologies are receiving more and more attention as a relevant solution to improve chronic disease management [20,21]. Digital technologies can involve a wide range of aspects such as telemedicine, mobile health apps, internet, websites, virtual reality, artificial intelligence, distance education, etc [22-24]. The growth of these technologies offers new possibilities for digital interventions designed to support the development of knowledge, behavioral changes, etc [25]. For chronic disease, a dominant approach is to use these technologies to increase patients' autonomy in managing their symptoms [26]. They can be used to improve patients' quality of life [27,28] and allow them to be in charge of certain aspects of their health, such as symptom management [29].

Endometriosis has not escaped this digital wave, as several countries, including the Australian and French governments, have already introduced national plans based on these technologies to combat the disease. These plans aim to develop interventions to enhance the quality of life for women with endometriosis through the use of digital technology, both to raise awareness and to improve patient care. According to Giudice et al [30], there is an urgent need to invest in digital technologies (eg, mobile apps) dedicated to the management of endometriosis. Digital technologies can help to prevent the risks associated with the disease, involve different professionals in the care pathway, and adapt the care offered to the needs of each patient. Since 2013, enthusiasm for digital technologies addressing endometriosis has grown, with at least 26 health applications on platforms like the Apple iTunes Store or Google Play. These applications are designed to help patients manage their symptoms, provide information on diagnosis and treatment, act as a social network, and allow them to share their experiences or keep a health diary [31]. Although there is strong interest among researchers, politicians, and developers in interventions that use digital technologies to support chronic conditions, such as endometriosis [30,32,33], there is also evidence showing that these technologies do not necessarily deliver the expected positive health outcomes [34]. A lack of specific guidelines dedicated to the development and evaluation of technologies could explain this inefficiency [35,36]. Thus, methodological frameworks such as the iterative Design and Evaluation of Digital Health Interventions (DEDHI) [37] have been developed to support the long-term implementation of a digital technological innovation dedicated to health. Nevertheless, this type of framework still seems to have limited use [38,39], although it can be useful for guiding the development of innovations dedicated to newly studied pathologies, as is the case for endometriosis [4,37].

Scientists, politicians, and decision-makers are tending to promote the use of digital technologies, and applications dedicated to endometriosis are multiplying. However, to the authors' knowledge, there is no systematic review on digital and technological interventions to support the management (ie, pain, mental health, knowledge, behavior, etc) of endometriosis. This systematic review aims to examine how digital health interventions (DHIs) targeting endometriosis have been developed and designed and to evaluate their effectiveness, with a particular focus on the use of a structured methodological framework and reported outcomes related to physical and psychological health.

Methods

Protocol

This systematic review followed the recommendations of the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) checklist (Multimedia Appendix 1) [40,41]. The protocol of this review has been registered in the

XSL•FO
RenderX

International Prospective Register of Systematic Reviews (PROSPERO CRD42023461263).

Inclusion Criteria

The inclusion criteria for the studies are as follows: (1) participants must have endometriosis, (2) use digital technology solutions to manage endometriosis, (3) take place between 2010 and 2024, to reflect current technological development [42], and (4) be written in French or English.

Search Strategy

The following computer databases were searched: Academic Search Premier, MEDLINE, APA PsycArticles, Psychology and Behavioral Sciences Collection, APA PsycInfo, SocINDEX, and SPORTDiscus. A total of 3 filters were used when searching the databases: years (2010-2024), peer-reviewed academic journals, and the terms appearing in the title or abstract. In order to make the research equation as exhaustive as possible, particularly with regard to digital tools, it was decided to draw on equations from recent research specifically on technological and digital interventions in the field of mental health [23]. These databases were examined using the following search equation: “endometriosis” AND (websites OR “smartphone app*” OR wearable OR “virtual reality” OR “augmented reality” OR “immersive technology” OR platform OR mhealth OR “mobile health” OR ehealth OR “e-mental health” OR e-health OR internet OR mail OR chat OR SMS OR text message OR digital intervention OR technological intervention) NOT (systematic review or meta analysis or scoping review or literature review or umbrella review). Databases were searched using the same equation through the Rennes 2 University library portal, which provides access to a wide range of bibliographic resources. In July 2024, the search equation was run for the first time and identified 5 articles in the final selection. In line with best practice for systematic reviews (eg, see chapter 4 of the Cochrane Handbook) [43], which recommends rerunning the search before final analysis to capture all newly published studies, the same search equation was rerun in November 2024 before submission. This update ensured the completeness and timeliness of the review before submission. The updated search identified a further 5 articles.

Study Selection

As proposed by the PRISMA methodology [41], the screening stages were followed. Zotero software (Digital Scholar) [44] was used to extract references from databases. Rayyan software (developed by Ouzzani et al [45]) was used for the first selection steps, that is, duplicate identification and selection by title and abstract [46].

After removing duplicates, the titles and abstracts of all identified articles were examined for eligibility. Articles were excluded if (1) endometriosis was not mentioned, (2) participants were not ill, (3) it was a systematic review, exploratory review, or meta-analysis, (4) it did not mobilize digital technology or focus on an intervention mobilizing digital technology, (5) it was a research protocol, (6) it was written in a language other than French or English, and (7) it was written before 2010.

Potentially eligible articles were retrieved, and if the text was not available, the authors were contacted. All the texts retrieved were then examined by 2 reviewers (TP and KN). Any disagreements were resolved by discussion with a third author (GC).

Risk of Bias

The risk of bias of each study included in this review was assessed with the Mixed Methods Assessment Tool (MMAT) [47]. A percentage was calculated for each study as proposed by Pluye et al [48] using the following formula: (number of “yes” responses divided by the number of “relevant criteria”) × 100. “Yes” indicates that an item is satisfied. A higher score indicates a lower risk of bias. The risk of bias was analyzed by 2 reviewers. A general intraclass correlation coefficient was calculated to determine interrater reliability. As recommended by Hong et al [47], no study, not even one of low methodological quality, was excluded. Interjudge agreement was satisfactory (0.98, 95% CI 0.82-0.99). Percentage scores are reported in Table 1.

[c]RCT: randomized controlled trial.

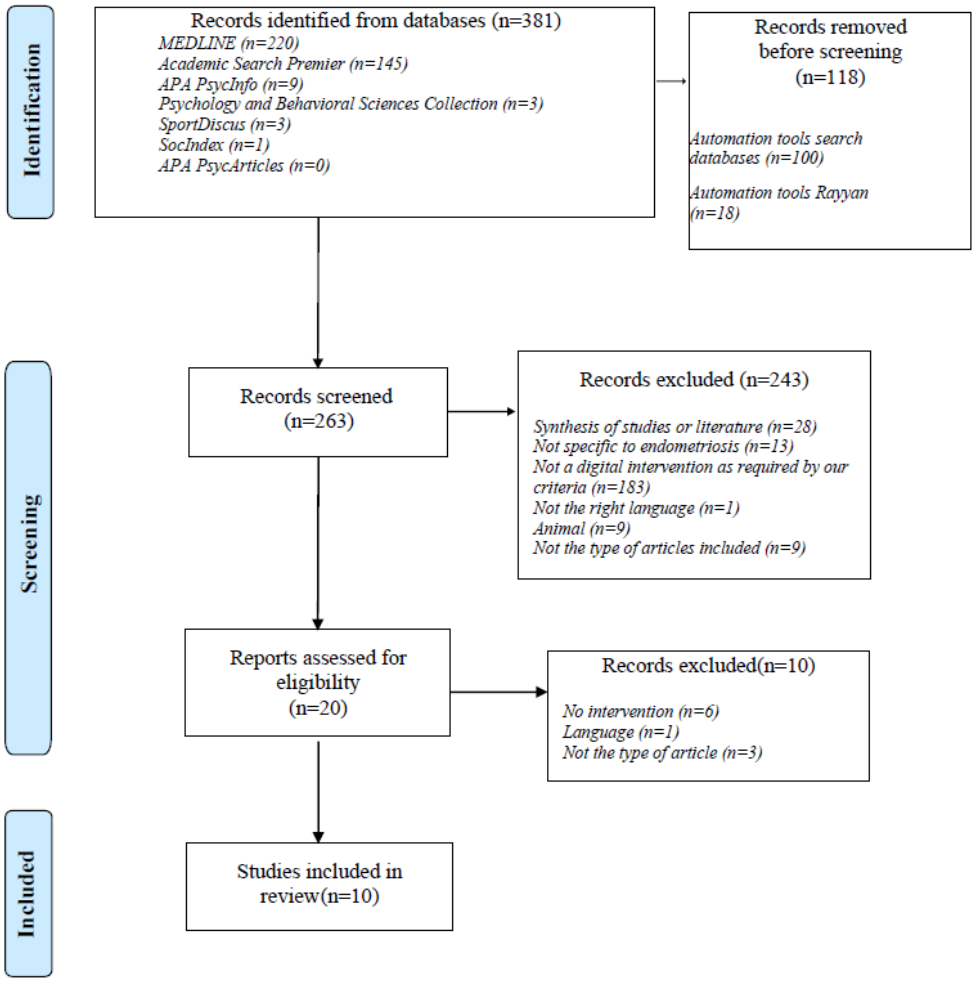
[d]VR: virtual reality.

[e]MRI: magnetic resonance imaging.

[f]DTx: digital therapeutics.

[g]DiGa: digital health applications.

Analysis of Articles Using the Framework for Designing and Evaluating DHIs



The DEDHI framework [37] was used to characterize the overall development process of digital technology–based interventions proposed in the studies of this corpus. Indeed, this framework seems particularly appropriate for the development of interventions based on digital technologies, specific guidelines dedicated to the design, and large-scale implementation of health-related innovations [59,60]. This framework proposes four stages: (1) the "preparation phase" describes the design phases of the innovation—review of the knowledge justifying an intervention, development of a conceptual model, and feasibility or acceptability study to test new components of the health intervention while identifying the optimization criterion offering the best result. This phase, therefore, requires a prototype offering the basic functionalities. (2) The "optimization phase" suggests building an optimized health care intervention using microtrials to identify the best configuration for the innovation, while respecting the optimization criteria. This phase requires a prototype offering all the functionalities set out in the conceptual model. (3) The "evaluation phase" is used to confirm the effectiveness of a health intervention, in particular, by carrying out a randomized controlled trial. At this stage, the prototype must be fully functional. And (4) the "implementation phase" offers a guide for the large-scale implementation and maintenance of an effective health intervention. For each phase, different criteria need to be addressed in order to optimize the long-term use of health innovations and recommended levels of technological maturity. They are organized according to 3 axes into each phase: goals and tasks (from 1 to 4 criteria, eg, feasibility and acceptability in the first phase), technical maturity (1 criterion, eg, elaborated research prototype in phase 2), and evaluation (from 5 to 10 criteria, eg, adherence, safety, and personalization). The 2 reviewers (TP and KN) independently examined the presence or absence of each criterion in the articles, and a third reviewer (GC) was called in in the event of disagreement. This made it possible to calculate a percentage of completion for each phase, determined by the ratio between the number of criteria present and the total number of criteria expected for that phase.

Results

Figure 1 illustrates the screening stages in the PRISMA flow diagram.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.

Studies Design

Of the 10 studies included, 3 (30%) used mixed methods [49,57], one of which was a pilot randomized controlled trial [58]. One study was based on a qualitative analysis [56], and 5 (50%) studies were solely based on quantitative analyses [51-55], 4 of which were randomized controlled trials [51-53,55]. Finally, a study on the development of a methodology for designing a digital tool was based on a case study of endometriosis [50]. For this reason, due to its general methodology, this article will not be included in the following results sections: Sample Size, Age, and Participants.

Studies Characteristics

Sample Size

Among the 9 included studies, the smallest reported sample size was 10 [56] and the largest was 225 [58]. In quantitative studies, the number of participants ranged from 19 [51] to 122 [55]. In the mixed methods studies, the minimum number of participants was 12 [49] and the maximum was 225 [58]. Over the 9 studies, the average sample size was 73.1 (SD 72.4) individuals.

Age

Age is reported with varying degrees of accuracy depending on the methodologies used. The minimum age reported is 16 years [56], and the maximum is 63 years [49]. Based on the average ages reported by the studies [49,51-55,57,58], the total average age is 31.43 (SD 3.89) years.

Participants

The majority of studies (7/9, 78%) were based on samples of women diagnosed with endometriosis [51-56,58]. One study involved patients with a self-reported diagnosis [57], and one involved patients with a suspected diagnosis [49].

Countries

All the articles selected come from Western countries. Of these, the majority (5/10, 50%) were conducted in Europe, including 2 in France [52,53] and 3 in Germany [54-56]. Additionally, 4 studies took place in Australia [50,51,57,58]. Finally, 1 study has been carried out in Canada [49].

Types of DHIs

Of the 10 studies selected, the analysis revealed six distinct DHIs: (1) via a website [49], (2) health information recommendation features within web-based health applications [50], (3) an autonomous physical activity session using virtual reality video games for pain management [51], (4) a second intervention uses virtual reality and sensory stimuli for relaxation purposes to support patients in pain management (eg, Endocare) [52,53], (5) via a mobile application (ie, Endo-APP) [54-56], and (6) an SMS text messaging intervention (ie, EndoSMS) [57,58]. The first 3 DHIs were the subject of a single

XSL•FO
RenderX

publication [49-51]. The DHI proposed by Abdulai et al [49] is a website that aims to provide information on dyspareunia and its management (eg, treatment) and to combat the stigma associated with sexual pain. The DHI of Li et al [50] aims to propose personalized disease management strategies (eg, therapy or solutions to manage pain, dietary information, etc) based on symptoms (ie, reported in an initial questionnaire) and an algorithm. The third DHI [51] aims to reduce pelvic pain through physical activity performed either autonomously through virtual reality or supervised by telehealth in comparison with a control group.

The other 3 have been the subject of several studies and publications [52-58]. Of these last 3 DHIs, the first concerns a virtual reality device (ie, Endocare) compared with a 2D version, which was tested in the laboratory [52] and then autonomously at home in a second study [53]. The second DHI is a mobile app called Endo-APP, which was used in 3 studies [54-56]. Two of these studies were conducted by the same research team, although they did not cite each other [54,55]. This can be explained by the fact that the manuscript for the first study [54] was submitted in 2022 but accepted in 2024. The third study [56], which used Endo-APP, is a qualitative study focusing on patient experience following the prescription of this app by a health care professional. Finally, the third DHI was based on sending SMS text messages (ie, EndoSMS) and includes 2 studies [57,58]. Sherman et al [58] evaluated the acceptance and feasibility of a 3-month SMS text messaging intervention designed in a previous study [57].

Objectives, Interfaces, and Functionalities of the 6 DHIs Studied

The specific objectives pursued by these 6 DHIs vary from study to study. A total of 5 (83%) DHIs aimed to help manage pain or painful symptoms [49-56]. Among these 5 DHIs, 2 were based on a website but differ in their functionalities, with specific sections (eg, information on endometriosis, causes and treatments available for dyspareunia, and frequently asked questions) for Abdulai et al [49] and suggestions (eg, relaxation methods and dietary advice) based on initial responses to a questionnaire [50]. The other 2 DHIs used virtual reality but do not rely on the same functionalities. In the case of Lutfi et al [51], the interface and functionalities of the DHI depended on the participants' choices (eg, relaxation application and video games). For Merlot et al [52,53], Endocare's immersive intervention included auditory stimulation (ie, alpha and theta binaural beats and sounds inspired by nature) and visual stimulation by moving a laterally moving sphere. Finally, the Endo-APP mobile app was designed to help with this management. It features modules for monitoring symptoms, disease management (eg, educational content with articles and videos, exercise guides, and psychosocial support), or a personalized emergency plan for dealing with episodes of intense pain [54-56].

Overall, 4 (67%) DHIs aimed to provide information about endometriosis and strategies for managing the disease. They include the DHI proposed by Abdulai et al [49], that of Li et al [50], and the Endo-APP mobile app [54-56]. Another DHI targets this objective by being based on a unidirectional SMS text messaging broadcast, that is, with no possible response. The functionalities include the sending of 4 SMS text messages per week covering a variety of themes (eg, emotional health, social support, and information about the disease), and for some women, the possibility of adding a reminder to follow treatment. These authors also specify that this intervention can be personalized (ie, first name and time of receipt of messages) [57,58].

Furthermore, 2 (33%) interventions were intended to provide emotional and psychosocial support (ie, Endo-APP and EndoSMS). Finally, only the intervention proposed by Abdulai et al [49] sought to address the stigma associated with sexual pain. This information is summarized in Multimedia Appendix 2.

Patient Feedback on DHI Design and Deployment

Of the 6 DHIs studied in this systematic review, 3 were developed with the support of women with endometriosis [49,50,57]. For the other 3 DHIs (ie, the virtual reality and telehealth interventions of Lutfi et al, Endocare, and Endo-APP), the articles do not mention patient involvement during development. However, 4 DHIs studied in 5 articles [49,50,56-58] were evaluated by women with endometriosis. These were the 3 DHIs developed with patients [49,50,57,58] and 1 DHI evaluated after it was approved for prescribing to patients [56]. Overall, 3 DHIs were evaluated with quantitative analysis [49,50,57,58] and 3 were analyzed with qualitative analysis [49,56-58]. More precisely, the DHI proposed by Abdulai et al [49] was evaluated both quantitatively and qualitatively, as was the DHI EndoSMS [57,58]. Endo-APP was evaluated qualitatively in the study by Zugaj et al [56] and the DHI by Li et al [50] quantitatively. The other DHIs (ie, Endocare and Lutfi et al DHI) do not seem to have been evaluated by the participants.

Quantitative evaluations allow objectifying patients' user experience. A total of 3 DHIs were evaluated using this method. For example, the website proposed by Abdulai et al [49] is perceived as easy to use. Similarly, the study of Li et al [50] indicates that a quantitative evaluation of each proposed content was carried out. The details of each content are not reported. However, these authors noted a good user experience, although the number of returns was lower than expected. Similarly, Sherman et al [57] reported that the information provided in SMS text messages was useful and accessible to the majority of women with endometriosis, and so on. The same is true of the evaluation of this DHI under real-life conditions in terms of feasibility (eg, low attrition rate and few unsubscribes) and content acceptance [58].

Qualitative analysis identifies the limitations and potential for improvement of DHIs. A total of 3 DHIs were assessed using this methodology. For example, the study by Abdulai et al [49] enabled the research team to identify some minor problems (eg, comprehension of certain content such as graphics and icons), as well as features to be added (eg, search bar) or improved (eg, visibility of information on the home page). The study of Sherman et al [58] was positive overall, but some patients highlighted improvements (eg, disease information considered too general) and a greater need for personalization of the

XSL•FO
RenderX

intervention (eg, content, frequency of SMS text messages, etc). Similarly, although positive, the study by Zugaj et al [56] highlights some limitations of the app, its content, or functionality (eg, time required for correct and regular use, concerns about security and data use, and content deemed redundant). They also pointed out missing functionalities (eg, possibility of exchanging information with peers) and made suggestions for improvement (eg, integration of information on diseases concomitant with endometriosis). Other DHIs have not been evaluated in terms of their development. However, the study by Merlot et al [53] showed that patients who received the intervention were significantly more satisfied than women in the control group.

Efficiency to Manage Endometriosis

This systematic review highlights different types of benefits, such as physical, psychosocial, and self-management. A total of 5 studies [51-53,55,56] involving 3 different DHIs (ie, virtual reality and teleconsultation, Endocare, and Endo-APP) reported physical benefits. Regarding fatigue, the results are not homogeneous. Studies using the Endo-APP app [55] reported a significant reduction in fatigue compared to a control group. A DHI based on virtual reality (ie, Endocare) led to a reduction in fatigue, but there was no significant difference between the groups [53]. Finally, the other studies did not report any benefits in terms of fatigue. With regard to pain, these 5 studies reported a reduction in pain [51-53,55,56], regardless of the DHI used. It therefore seems that apps and virtual reality are relevant devices for managing physical symptoms, and specifically pain.

Regarding psychosocial benefits, 6 studies have reported benefits in this field. An improvement in quality of life was reported in 3 studies [53-55] based on 2 distinct DHIs (Endocare and Endo-APP). In the Endocare study (ie, virtual reality), there were no significant differences between the groups [53]. The other 2 studies reported significant improvements in Endo-APP users compared to the control group [54,55]. An improvement in self-efficacy in managing the disease and its symptoms was reported in 2 studies [55,56] involving a DHI (ie, Endo-APP). One study showed that patients found the website nonstigmatizing despite the subject matter [49]. Stress reduction was reported in 1 study [53] with no significant difference between groups, and 1 DHI has encouraged the adoption of active coping strategies [58]. Depressive symptoms were significantly reduced in 1 study [55], and an improvement in mood was reported in another [58]. A reduction in the nocebo effects associated with internet searches was observed in 1 study [56]. Better acceptance of the disease by certain women was reported in 1 study [56]. The same applies to the reduction of certain fears [56]. One study [58] reported a reduction in feelings of isolation and loneliness. The same applies to the increase in self-compassion [58].

In terms of the benefits of self-management, 3 studies report benefits, and 3 studies report on medication management. Overall, 3 types of DHIs (mobile app with personalized advice, EndoSMS, and Endo-APP) make it easier to access relevant information about the disease and change patients' perceptions of it [50,56,58]. Studies about medication management all report beneficial effects, whatever the DHI (ie, Endo-APP, Endocare, and EndoSMS), related to the use of analgesics, for example [53,55], or to remembering to take treatment [58]. This information is summarized in Multimedia Appendix 2.

Analysis of Selected Studies Based on the DEDHI Framework

Phase 1: Preparation

With the exception of Zugaj et al [56], all the studies mentioned at least 1 criterion corresponding to this first phase. However, there are major disparities between studies, with the criteria being met in 10%, with 1 in 10 criteria (eg, Rohloff et al [54]) to 80%, with 8 in 10 criteria (eg, Abdulai et al [49]) of cases. Among the criteria, a review of existing justificatory knowledge and feasibility were the most frequently reported in the studies. In contrast, criteria such as safety, privacy, and security were rarely reported.

Phase 2: Optimization

A total of 3 studies [50,51,54] reported criteria for the second phase. Li et al [50] and Rohloff et al [54] reported 54% (7/13) of the criteria, while the last study [51] reported 77% (10/13) of them. Criteria such as effectiveness, perceived benefits, and content quality were consistently reported. In contrast, perceived enjoyment was never mentioned, and criteria such as service quality, safety, privacy, and security were rarely taken into account. The other 7 studies [49,52,53,55-58] do not mention any elements relating to this second phase.

Phase 3: Evaluation

A total of 4 studies reported between 60% (6/10) and 80% (8/10) of the criteria for this third phase [50,52,53,55]. The other 6 studies [49,51,54,56-58] do not mention any of the criteria relating to this third phase of the DEDHI framework. As far as the evaluation criteria are concerned, effectiveness and perceived benefits are reported by all those meeting the criteria for this phase. Personalization was reported by only 1 of the 4 studies [50]. Moreover, privacy and security are rarely considered, as is the quality of service.

Phase 4: Implementation

A total of 2 articles met 77% (10/13) [50] and 62% (8/13) [56] of the criteria for the implementation phase of the DEDHI framework. The other 8 studies [49,51-55,57,58] did not mention any of the criteria for this phase. In these 2 studies, safety and service quality criteria are never mentioned. However, criteria such as personalization, perceived benefits, and content quality are the most regularly mentioned by studies responding to criteria from this fourth phase. The results of this section are summarized in Table 2.

[e]DHI: digital health intervention.

Discussion

Overview

The aim of this systematic review was to characterize the design, quality, and efficiency of the digital technologies used to support women with endometriosis. This review highlights four important points: (1) the literature on this topic is at an early stage, although it is developing rapidly, as is the case for other chronic diseases; (2) digital interventions show physical, psychological, and self-management benefits, but the small number of studies and methodological variability limit the reliability of current evidence; (3) few studies mobilized a methodological framework to develop their intervention; and (4) analysis of the corpus using the DEDHI framework revealed that the majority of the studies essentially reported criteria relating to the first phase (development), leaving the later phases as yet unexplored.

Results of this systematic review highlight recent literature that is embedded in the growth of digital technology. Indeed, the least recent article selected in this corpus was published in 2022. In addition, the studies are mainly based in Western countries that have implemented policies to address this disease (eg, France [61], Canada [62], and Australia [63]), for instance, by supporting the funding of targeted research projects. This geographical focus may be linked to the fact that the disease has received increasing media coverage in recent years [64]. This geographical disparity may therefore contribute to the lack of international literature. This may result in an incomplete understanding of patient needs on a global scale. At the same time, the recent increase in DHIs and related publications follows the trend observed in endometriosis research, which has been steadily increasing since 2017 [65]. Finally, as reported in the results section, most of the studies conducted and the DHIs designed have been developed by the same research teams, which may result in some limitations of the literature on the subject. This literature is also the result of the evolution in the recommendations concerning the management of the negative effects of illness [4,5,66,67]. These recommendations were aimed, in particular, at improving the operational efficiency (eg, time management) of health care professionals [32,68] and the optimization of care and the quality of service provided to patients [69]. A growing trend is the use of digital health technology to enable patients with chronic illness to manage their disease over a long period of time [70], while developing their disease management skills [71]. These technologies are regularly used because of the freedom they offer (eg, use at home, at any time, or on any day) [72], both for the practitioner providing the care and for the patients benefiting from it. This systematic review illustrates precisely this point, since a number of applications and technologies (eg, websites, mobile apps, SMS text messaging, and virtual reality) are being used to optimize support for endometriosis. The use of digital technology for this disease is part of a wider movement concerning chronic pathologies, reflecting a paradigm shift in which patients become the central actors in their own care [73]. Several studies in this review indicate that patients were involved from the tool's design stage [49,50,57,58] or during the evaluation phases of the tool designed to support them [49,50,56-58]. These studies show just how valuable it can be to involve patients from the earliest stages of device development—for example, to increase patient satisfaction [74]. The results of this study suggest that digital technologies can be useful in the treatment of endometriosis. However, they do not appear to be sufficient on their own to meet patients' needs and could even have deleterious effects. Indeed, many women already report a sense of isolation and lack of recognition, both socially and within the health care system [10,75], which could be accentuated through digital technology. In this context, DHI could be seen as a complement to traditional care as part of a hybrid care model. This approach would exploit the advantages

XSL•FO
RenderX

of digital tools while preserving the essential human dimension of care [76].

Studies in this systematic review reported physical, psychological, and self-management benefits of endometriosis. Indeed, some of the digital interventions in this corpus using digital technology [51-55] reported a reduction in pain, the main symptom of endometriosis [77]. Reduced pain can improve patients' overall quality of life [78] and, therefore, has beneficial repercussions on other areas of patients' lives, such as absenteeism from work [14] and social relationships [79]. Some studies in this corpus [54,55] reported a more global improvement in physical quality of life (eg, reduction in chronic pain) and psychological quality of life (eg, increased emotional well-being), while 1 study reported a reduction in feelings of loneliness and isolation [58]. Studies [53,55,58] have also shown a reduction in the use of analgesics. This could reduce treatment costs, which is particularly important in the context of endometriosis [80]. The DHIs presented in this systematic review seem to respond to the main challenges posed by endometriosis, whether related to the management of the disease or to its main consequences on physical, psychological, and social health, among others [81,82]. Furthermore, the articles reported an increase in patients' feeling of being able to manage their symptoms [55,56]. Yet, self-efficacy is a key variable, having been shown in the literature to be an important determinant of the adoption and maintenance of health-enhancing behaviors (eg, health belief model) [83,84]. Indeed, a person with a high degree of self-efficacy will be more inclined to respond to a perceived threat [85] and to adopt relevant strategies to manage the symptoms of endometriosis. For example, the patient will be more likely to adopt health behaviors that improve her quality of life, such as physical activity [86] or a balanced diet [87]. To promote behavior change and management of this disease, future DHIs could draw on psychological and behavioral theories. Self-determination theory [88], the transtheoretical model of change [89], and the taxonomy of behavior change techniques developed by Michie et al [90] could offer valuable leads for the design of DHIs. Such models can help identify motivating factors, stages of change, and techniques adapted to users' needs. Integrating these theoretical frameworks could improve the effectiveness and reproducibility of interventions. Finally, they provide a better understanding of the mechanisms of action underlying long-term user commitment and adherence. For instance, self-determination theory emphasizes autonomy, competence, and relationship as essential components of sustained motivation [91]. The transtheoretical model enables content to be adapted to the user's stage of change. In this way, each individual could have a personalized intervention [92], as requested by some patients (eg, [58]). Using the taxonomy of behavior change techniques would enable a structured approach to the selection and presentation of behavioral strategies.

Despite these advantages, a number of limitations need to be recognized. Most of the interventions examined were of short duration (up to 12 weeks [55]). It is therefore difficult to assess the durability of beneficial effects or the stability of user engagement over time. However, these elements appear to be crucial in understanding chronic diseases, such as endometriosis [93]. In addition, several studies [50,54-58] have proposed that intervention should be holistic, encompassing several dimensions of patient well-being (eg, dietary monitoring, stress management, and physical activity). While such an approach is recommended in the literature [94], this does not allow for the identification of the specific part played by the use of digital technology. Finally, as reported by Zugaj et al [56], the use of digital technologies does not seem to be suitable for all patients. This is why it seems necessary to pay particular attention to the personalization of devices [37,95] and take advantage of the variety of care modalities available in order to offer optimal support to each patient [94].

Among all the included studies and the 6 identified DHIs, 3 DHIs were developed with patient involvement [49,50,57]. Of these, only 2 articles [49,50] reported using a methodological framework to guide the development of a digital intervention and progressed to large-scale deployment. Nevertheless, 1 study [57] drew on various theories from social psychology (eg, theory of planned behavior [96]) to construct part of its intervention. After analyzing the studies using the DEDHI framework, it appears that almost all of them (9/10) focused on the criteria of phase 1 (preparation), leaving the subsequent phases unexplored. Furthermore, a detailed analysis of the phases revealed wide disparities in the way the criteria were addressed, particularly in this first phase. Thus, in the first phase, the criterion most often reported was the use of a literature review to justify technological choices and their positive effects on chronic pathologies. For example, Merlot et al [52] considered various meta-analyses on the use of virtual reality for chronic pain management in different pathologies, and Rohloff et al [54,55] did the same for the use of smartphones in pathologies with chronic pain. Nevertheless, even if the use of literature reviews is an essential step to support the development of intervention devices, it remains insufficient if criteria such as acceptability and acceptance of these devices are not taken into account because, as recommended by the DEDHI framework [37], they make it possible to adjust the intervention to the real expectations and needs of users. Moreover, considering "individual acceptability" would enable the adoption of a particular support strategy depending on the individual's specific relationship with the technology [97]. On the other hand, the studies do not seem to have adapted their tools to the various standards and regulations in force concerning the use of digital technology in health (eg, General Data Protection Regulation). One explanation may lie in the fact that the research teams are more often than not made up of health care professionals and do not always include specialists in the development and implementation of these digital tools (eg, engineering research teams, lawyers, psychologists, and ergonomists). Yet, interdisciplinarity is generally considered to be one of the essential elements in medical innovation, particularly to meet the different needs of the market [98]. The ever-increasing call for research into health care innovations [99] may lead research teams to neglect certain essential stages of development (eg, optimization, evaluation, and implementation), which can compromise the ownership and sustainability of the intervention device and associated benefits [37]. Li et al [50], who highlight the advantages of mobilizing a clearly defined methodological framework to think through the implementation of a technology

XSL•FO
RenderX

with potential users, support this view. Yet, some of the included studies collected patient perceptions during the development or trial phases of DHIs. For example, 3 studies [49,56,58] have highlighted that patient satisfaction and engagement were linked to perceptions of ease of navigation, clarity of content, and perceived credibility of information. Conversely, problems such as excessive text content [49], poor section visibility [50], or a lack of personalization [58] were seen as potential barriers to engagement with the intervention or continued use. These results, therefore, underline the need to systematically involve the various stakeholders in the development process. In addition, they also highlight the importance of user testing in order to limit identified obstacles and support potential long-term use.

Strengths and Limitations of This Review

This systematic review has 4 main strengths. First, the PRISMA methodology and its stages were applied [41]. Second, the quality of each study was assessed with an adjusted evaluation of the risk of bias according to the experimental design used [100]. Third, each article was evaluated by several researchers, a discussion was organized to harmonize assessments, and an intraclass correlation coefficient calculation [101] was performed for the risk of bias. Fourth, several databases were mobilized to improve the comprehensiveness of the search [100].

Several limitations can also be identified. First, a meta-analysis could not be carried out due to the heterogeneity of experimental designs implemented, the measurements performed, and the results observed in the review analysis [102]. This methodological variability has limited the possibility of producing a quantitative synthesis of results or drawing definitive conclusions about the effectiveness of specific digital interventions. Thus, future systematic reviews or meta-analyses on the effects of digital interventions will need to be conducted, particularly on variables of interest in the context of endometriosis (eg, perceived pain, quality of life, and anxiety). Second, the published literature often reports positive and significant results [103], and there is not always a control group to put the results into perspective. This bias may have influenced the overall impression of the effectiveness or feasibility of the DHIs presented in this review. As a result, these findings may provide an overestimated picture of the actual benefits or readiness of these tools for wider implementation, while underrepresenting the difficulties or limitations encountered in practice. Third, the growing interest in digital and associated technologies is such that the search equation used may not have identified some articles mobilizing terminologies different from ours [104]. Fourth, following the selection process, 10 studies were retained out of the 381 articles identified. While this highlights the current state of research, it also limits the scope of the conclusions of this systematic review and the generalizability of the results. However, the recent increase in the number of studies on the subject calls for clarification of the methodological framework used to develop interventions and the associated digital tools, which should help to improve the reproducibility of interventions. Finally, the studies in this review were mainly conducted in Western countries, which raises questions about the transferability of the results, particularly given the difficulties of accessing and using DHIs linked to cultural, economic, and physical factors [105]. It is possible that in some parts of the world, access to this type of technology and the internet is more limited, which could reduce the reach of these digital solutions. For example, without the support of health authorities, the financial cost of accessing these digital resources may be too high and restrict access. Unequal access to digital resources may also hinder the development of digital literacy (ie, digital skills and the skills to understand and use content available on the internet [106]). These elements are identified as potential barriers to the use of DHIs [107]. It therefore seems necessary for international research teams to focus on the development of digital health devices. The approach could be to develop or adapt existing frameworks to the cultural and contextual specificities of their implementation to ensure greater accessibility and usability for diverse groups.

Research Implications

In light of these challenges, future research could potentially focus on several key priorities. First, longitudinal studies appear necessary to better understand the mechanisms underlying the sustained use of digital health tools [94]. Second, more rigorous and interdisciplinary research (eg, randomized controlled trials) with larger samples and standardized outcome measures would also appear to be relevant. Carried out in this way, they would ensure reproducibility while strengthening the evidence base for the effectiveness of digital interventions. Third, qualitative studies exploring patients' experiences, expectations, and perceptions of digital health technologies could be carried out. This could complement the results of quantitative evaluations of content or user experience [108]. Fourth, cross-cultural studies could be conducted to assess the transferability of these interventions for different patient profiles (eg, age, sociodemographics, and digital literacy), as well as for different cultural, geographical, and socioeconomic contexts [109]. Fifth, future studies could explore hybrid models of care to better meet patients' needs and evaluate the effectiveness of this type of support. Sixth, future studies could be based on the study of behavior change theories or on the identification of behavior change techniques used by DHI. Finally, future studies should systematically apply methodological frameworks, such as DEDHI, to frame the development and implementation process. All relevant phases and criteria would then be transparently reported in their publications.

Conclusion

This systematic review highlights the current interest in using digital technology to support patients with endometriosis. It appears promising and offers advantages in terms of patient care. However, the development of digital devices is rarely based on a methodological framework that would direct each stage of development to maximize patient involvement and, ultimately, improve their overall quality of life.

Overall, this systematic review has highlighted a number of elements for the development of digital devices for the management of endometriosis, from the initial design phases through to market implementation and appropriation by patients. Three points seem crucial to develop interventions mobilizing digital technology and encourage patients with endometriosis

XSL•FO
RenderX

to appropriate these tools: (1) mobilizing a methodological framework tailored to the context and specific to the development of support with digital devices, (2) relying on a multidisciplinary team (ie, doctors, engineers, ergonomic psychologists, and lawyers) capable of addressing every aspect of the development of the digital device, and (3) involving all stakeholders in the management of endometriosis (ie, patients, algologists, gynecologists, psychologists, and physiotherapists) in the design. These few points could serve as a guideline for outlining the contours of a global research reflection on the development of interventions using digital tools in the context of endometriosis, aimed at improving the quality of patient care. Developed using this approach, these digital tools place patients at the heart of the interventions by offering them not only concrete tools to better manage their health but also a space to share their experiences with other patients concerned. These elements help to foster health empowerment and, ultimately, pain management [110]. These digital tools can help to change the way patients are supported, moving away from "traditional medical care" to "holistic care," which takes into account all the dimensions of a patient's health—physical, mental, and social.

Abstract

Background: With the rising global adoption of telemedicine, there is a crucial need to address inefficiencies and challenges in current service systems. This case study focused on enhancing the telemedicine service system of a traditional Chinese medicine clinic.

Objective: The primary objective was to identify and address pain points and inefficiencies in the existing telemedicine system with the aim of streamlining service operations for the benefit of both patients and service providers.

Methods: Through comprehensive service design analysis, including the creation of a customer journey map and a service blueprint, key areas for improvement were identified, and the service process was redesigned accordingly. A user-friendly web application was developed and evaluated using usability testing and satisfaction assessments. Participants took part voluntarily. Task testing was conducted using real-world scenarios, with index of item-objective congruence values ranging from 0.84 to 1.00. Participants were assigned role-specific tasks as either patients or service providers in a step-by-step format, followed by role-specific paper-based questionnaires.

Results: The redesigned system successfully streamlined operations by automating processes and reducing task complexity, resulting in improved time efficiency for both user groups. Participants included 6 patients (aged 23 - 54 years) and 7 service providers from various departments. Usability testing revealed a task success rate of 100% for all tasks among patients, coordinators, physicians, and finance personnel as well as 83.33% among pharmacists. Satisfaction outcomes were positive: patients reported a net promoter score of 67, whereas service providers reported a mean System Usability Scale score of 71.4 (SD 20.76).

Conclusions: This study highlights the transformative potential of telemedicine in health care delivery. For patients, consolidating services into a single digital platform improved accessibility and ease of use. For service providers, the system reduced repetitive tasks and facilitated more efficient task completion. These findings demonstrate the effectiveness of service design methodologies in enhancing telemedicine systems, ultimately contributing to improved health care quality and patient outcomes.

KEYWORDS

digital transformation; efficiency improvement; service design; telemedicine; traditional Chinese medicine

Introduction

Telemedicine, also known as telehealth or eHealth, was introduced in the 1970s as a means of delivering health care services over long distances using telecommunication and IT tools [1,2]. These tools include voice and video calls, SMS text messaging, remote monitoring, and virtual consultations [3]. The US Centers for Disease Control and Prevention has defined telemedicine as “healing at a distance” [4]. Today, telemedicine is used for a wide range of services, including diagnosis of common illnesses, follow-up consultations, psychotherapy, and chronic disease management [5].

The benefits of telemedicine are widely recognized. These include cost savings [6], improved access for patients with mobility limitations [7], and enhanced continuity of care while minimizing exposure during the COVID-19 pandemic [8,9]. The global health crisis in 2020 accelerated the adoption of telemedicine as health care systems sought to reduce viral transmission and maintain service continuity [4,10]. In the United States, telehealth visits increased by 50% in the first

XSL•FO
RenderX

quarter of 2020 compared to the same period in 2019 and surged by 154% by week 13 of 2020 [11]. Despite this rapid uptake, much of the telemedicine infrastructure at the time was still in its early stages of implementation, hindered by limited understanding of the virus and system unpreparedness [12].

While the urgency of the pandemic necessitated swift development and deployment of telemedicine platforms, numerous challenges persist. These include concerns about patient-provider relationships, digital literacy, technical reliability, privacy and data confidentiality, reimbursement policies, physical examination limitations, and acceptability among special populations [3,13,14].

This study focused on the development and improvement of a telemedicine system within a traditional Chinese medicine (TCM) clinic in Bangkok, Thailand. The clinic serves approximately 5000 patients monthly and presents unique service characteristics distinct from conventional modern medicine. TCM diagnostics rely on observation of the patient's physical appearance, vocal quality, pulse palpation, and tongue examination, whereas treatments often involve custom herbal preparations. These distinctive diagnostic and therapeutic practices introduce additional complexity in adapting telemedicine systems for TCM settings.

The clinic initially launched telemedicine services via telephone in April 2020, expanding to video consultations in March 2022. According to internal records, the number of telemedicine visits more than doubled from 1955 in 2020 to 3972 in 2021, with the age group from 41 to 50 years representing the largest proportion of users. Despite the growth, both patients and service providers reported difficulties. Patients experienced confusion regarding appointment scheduling and status updates, whereas staff encountered challenges related to fragmented communication channels, repetitive manual tasks, and workflow inefficiencies.

Given the known advantages of telemedicine [7] and the increasing demand for remote TCM services, this study aimed to systematically identify pain points in the existing telemedicine service system and redesign it to improve efficiency and user experience for both patients and service providers.

Methods

Investigation of Current Service Operation

Overview

The telemedicine service was investigated from both patient and service provider perspectives. Two hypothetical workflows were developed to visualize the end-to-end service interaction: a *customer journey map* representing the patient experience [15,16] and a *service blueprint* illustrating the provider-side operations [16,17]. These workflows were constructed using data collected from direct observations of the service operations, content review of the clinic's website, and semistructured interviews with service providers.

The purpose of these visual tools was to map the sequence of interactions between patients and the service system, as well as among service providers, to identify pain points and service gaps [18]. The preliminary workflows were subsequently validated through in-depth interviews: 4 current telemedicine patients validated the customer journey map, and representatives from each relevant department (eg, registration, consultation, and pharmacy) reviewed and confirmed the accuracy of the service blueprint.

Barriers From the Patient Perspective

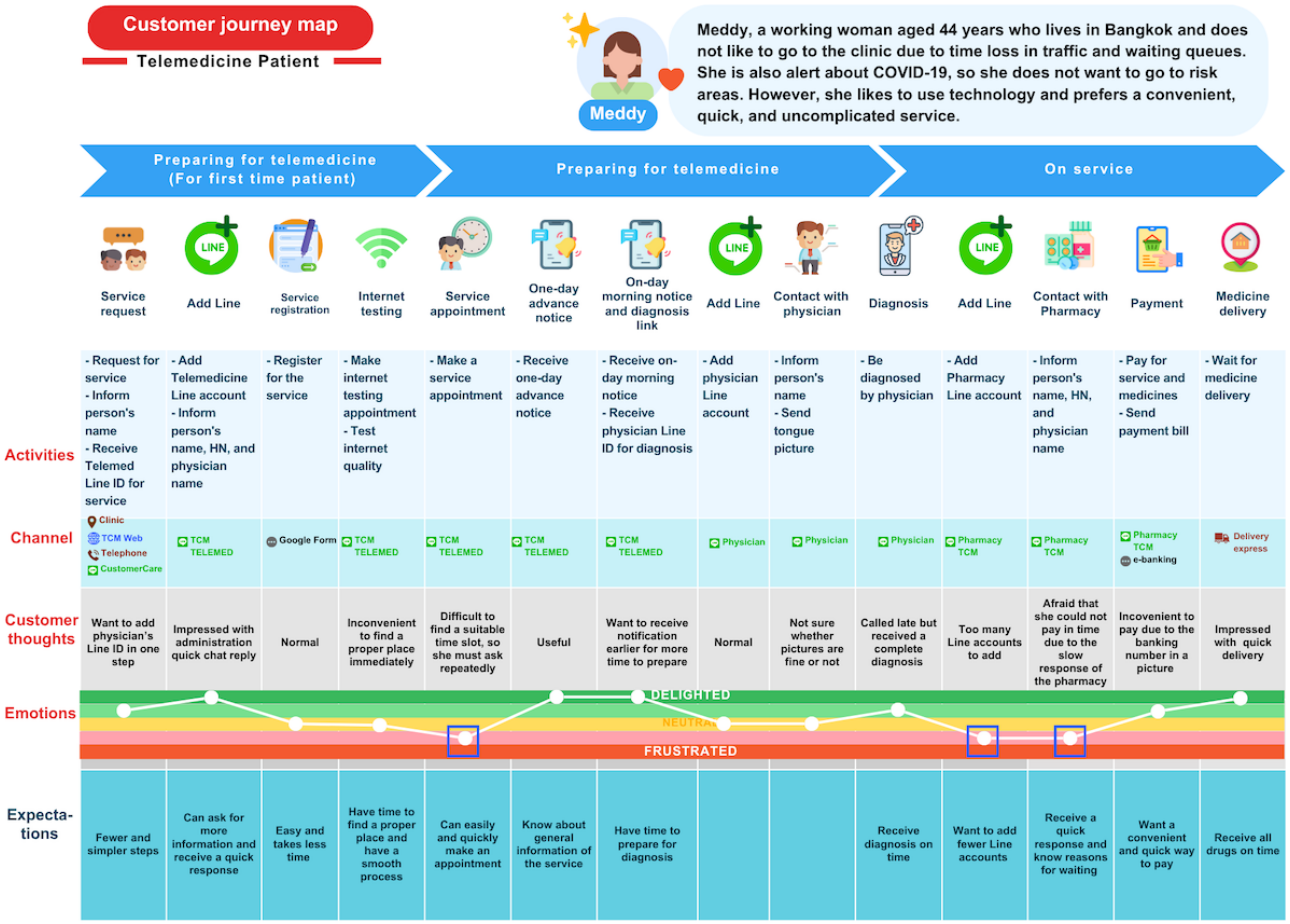

Figure 1 presents the validated customer journey map from the patients' point of view. The analysis revealed 3 key barriers that contributed to user dissatisfaction, indicated by negative emotional states on the emotion-tracking row of the map.

First, patients experienced difficulty in scheduling appointments. As shown in the "Customer thoughts" row in Figure 1, many users had to engage in multiple rounds of communication with the clinic to secure a suitable time slot, some reporting up to 5 separate calls. This resulted in excessive human effort and a high interaction cost. Patients expressed a clear expectation for a simplified and more efficient appointment scheduling process.

Second, the current system required patients to interact with multiple communication channels. Specifically, they had to register with 4 separate Line messaging accounts (CustomerCare TCM, TCM TELEMED, the physician's personal account, and Pharmacy TCM) to complete a single telemedicine session. This fragmentation added significant complexity and increased the interaction burden on patients. Many expressed the desire to minimize the number of communication accounts required for service access.

XSL•FO
RenderX

Figure 1. Customer journey map of the current telemedicine service (patient perspective). HN: health number; TCM: traditional Chinese medicine.

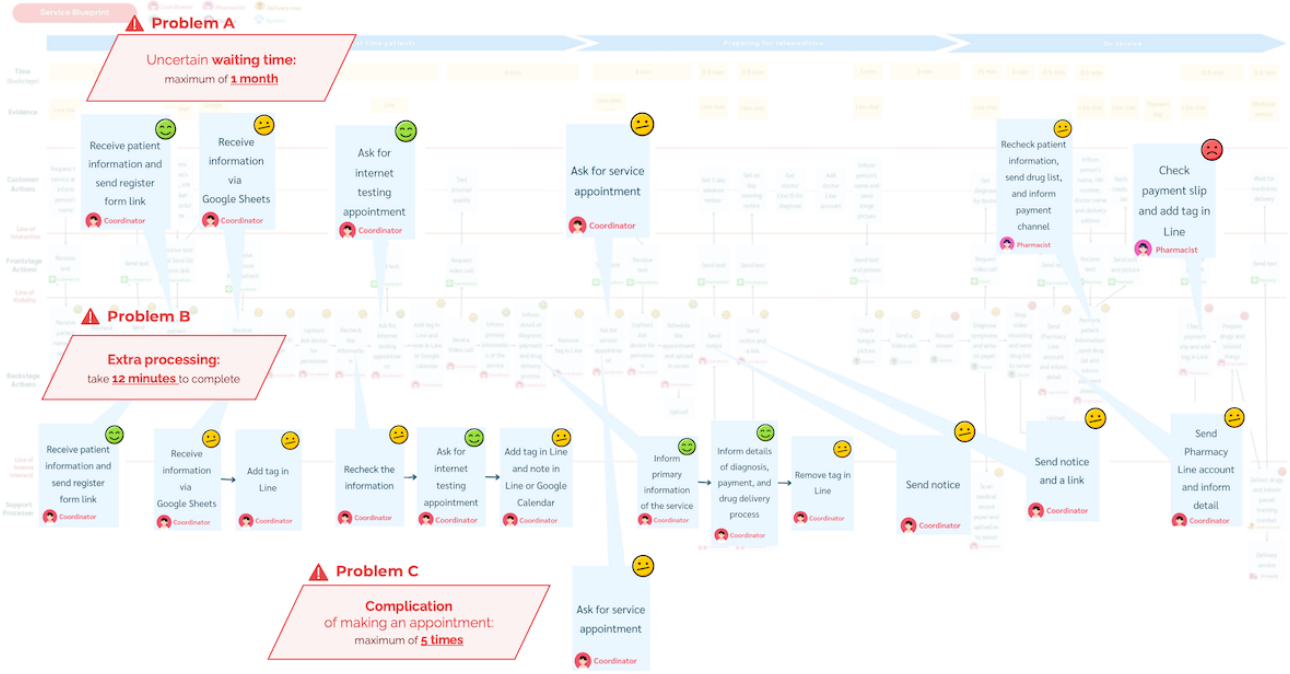
Third, there was a lack of transparency regarding service response times. Patients were not informed of estimated wait times for replies from service providers. Data logs revealed a wide variation in response time, ranging from 5 minutes to as long as 3 hours, with an average of 30 minutes. This uncertainty undermined patient confidence and satisfaction. Participants emphasized the need for real-time service tracking and automated notifications to improve the overall user experience.

Collectively, these issues of excessive communication effort, fragmented service channels, and uncertain wait times indicate critical inefficiencies in the current telemedicine system. From the patient perspective, three areas for improvement were identified: (1) simplification of the service process, (2) consolidation of communication channels, and (3) visibility and predictability of service status and wait times. Addressing these pain points through streamlined service design is expected to enhance patient satisfaction, reduce interaction costs, and improve the overall usability and efficiency of the telemedicine service.

Barriers From the Service Provider Perspective

Figure 2 presents the current service blueprint for the TCM telemedicine operation, highlighting 3 primary barriers reported by service providers.

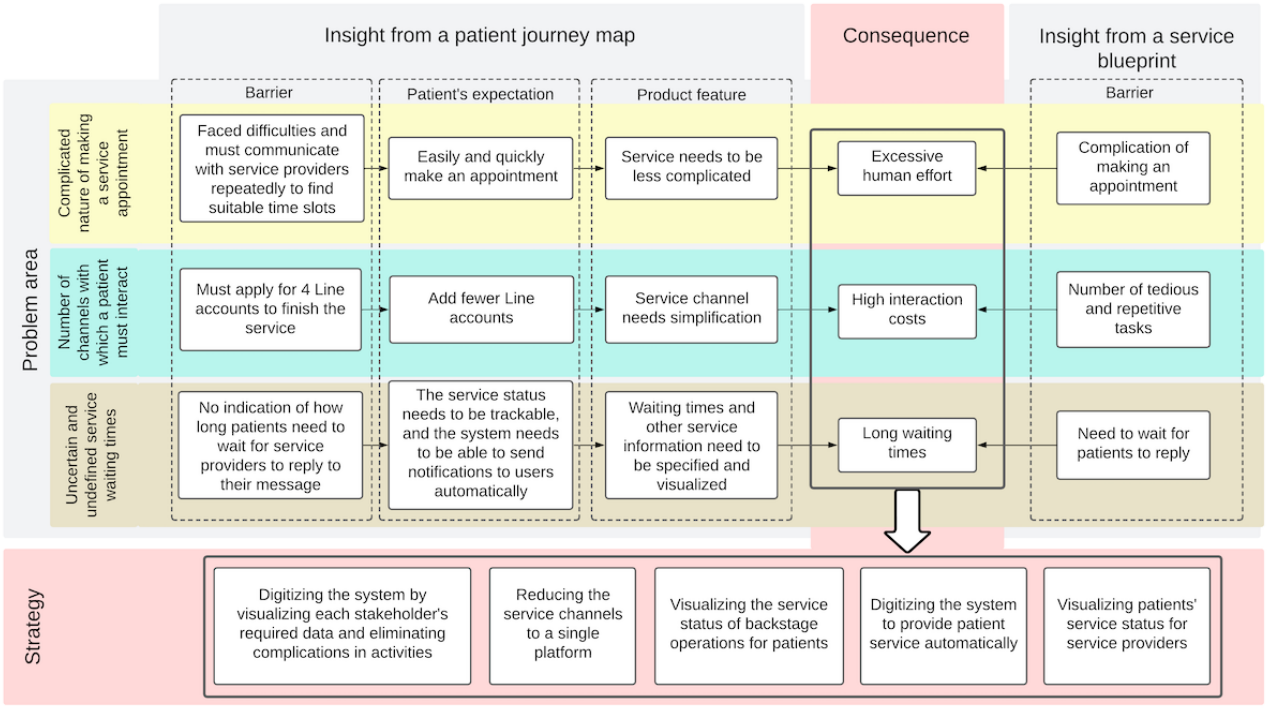
First, providers faced challenges due to uncertain waiting times. They were required to monitor patient responses closely and ensure timely replies to maintain patient satisfaction (problem A in Figure 2). Patient response times varied widely, ranging from as little as 10 minutes to as long as 1 month, with an average of 2 days. This unpredictability increased provider workload and disrupted workflow. Digitizing the system to automate follow-up communication would mitigate this issue.



Second, service providers were burdened by numerous repetitive administrative tasks (problem B in Figure 2). These included sending registration forms, checking for completeness, updating status tags, issuing notifications, and sharing Line contact details. Collectively, these tasks consumed approximately 12 minutes per patient, representing wasted time and avoidable effort. Automating these processes could substantially reduce inefficiency.

Third, appointment scheduling was unnecessarily complicated (problem C in Figure 2). Providers often engaged in repeated communication with patients (up to 5 exchanges to finalize a booking due to mismatched availability). This process increased provider effort and interaction costs, diverting attention from more value-adding clinical activities.

Overall, these barriers illustrate inefficiencies that compromise the effectiveness and stability of the telemedicine service. From the provider perspective, three key areas required improvement: (1) reducing waiting times, (2) eliminating repetitive administrative tasks, and (3) simplifying the appointment scheduling process.



XSL•FO
RenderX

Figure 2. Service blueprint of the current traditional Chinese medicine telemedicine service (provider perspectives).

When considered alongside patient-reported barriers, a common set of challenges emerged for both groups: (1) excessive human effort, (2) high interaction costs, and (3) long or uncertain waiting times. As shown in Figure 3, addressing these problem areas is essential to improving operational efficiency and ensuring a better overall telemedicine experience for both patients and service providers.

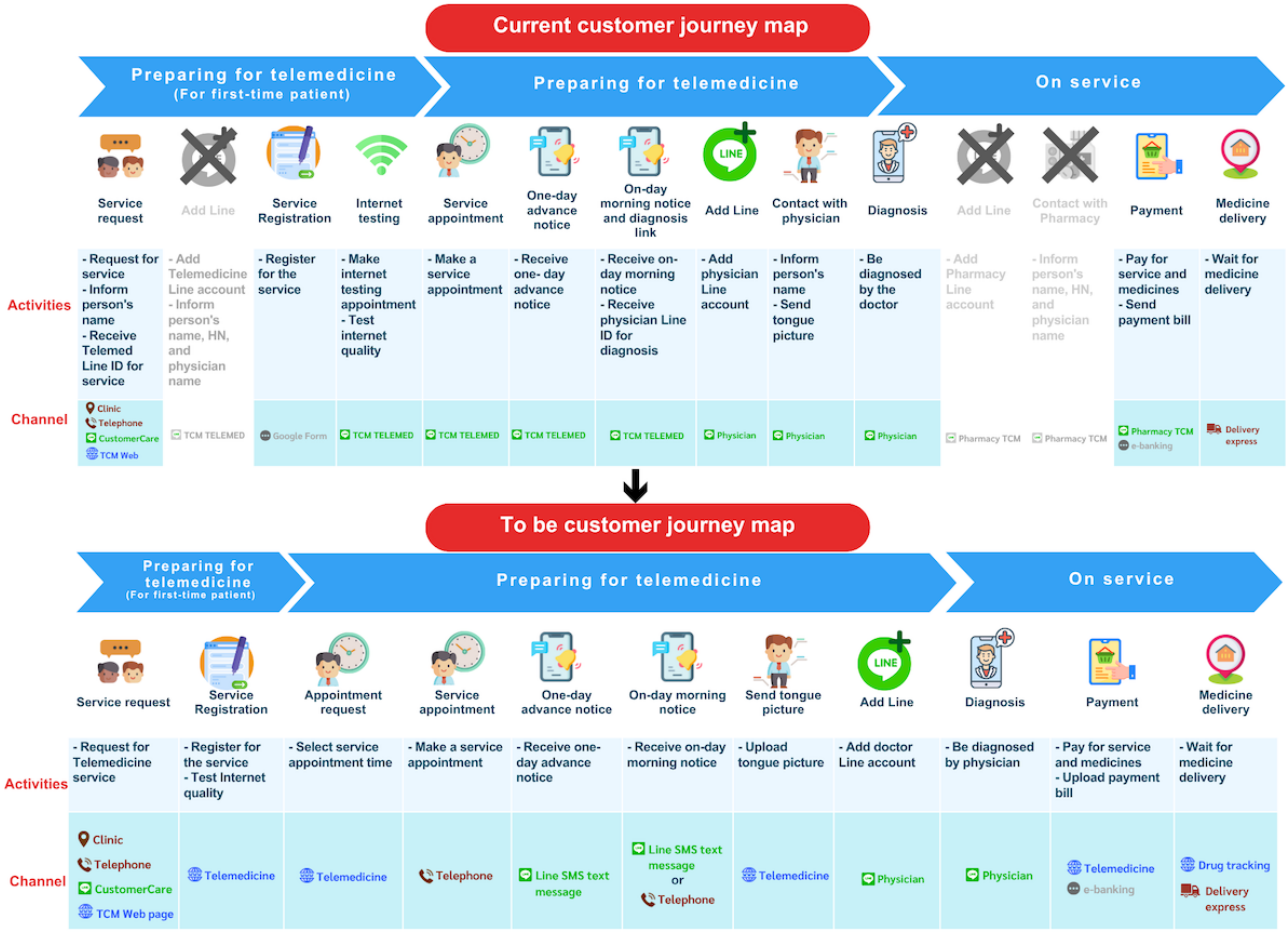
Figure 3. Common problems and improvement strategies for patients and providers.

System Design

Redesigning Service Operations

Following the identification of barriers in the current service system, solutions were designed to eliminate inefficiencies and enhance user experience. A digital transformation strategy was adopted integrating information, computing, communication, and connectivity technologies [19,20]. This approach aimed to strengthen the telemedicine service's capabilities and address issues such as repetitive tasks and the difficulty of sharing real-time information between patients and providers. For example, dissatisfaction arising from uncertain waiting times could be mitigated by providing estimated wait times and visualizing them for users [21].

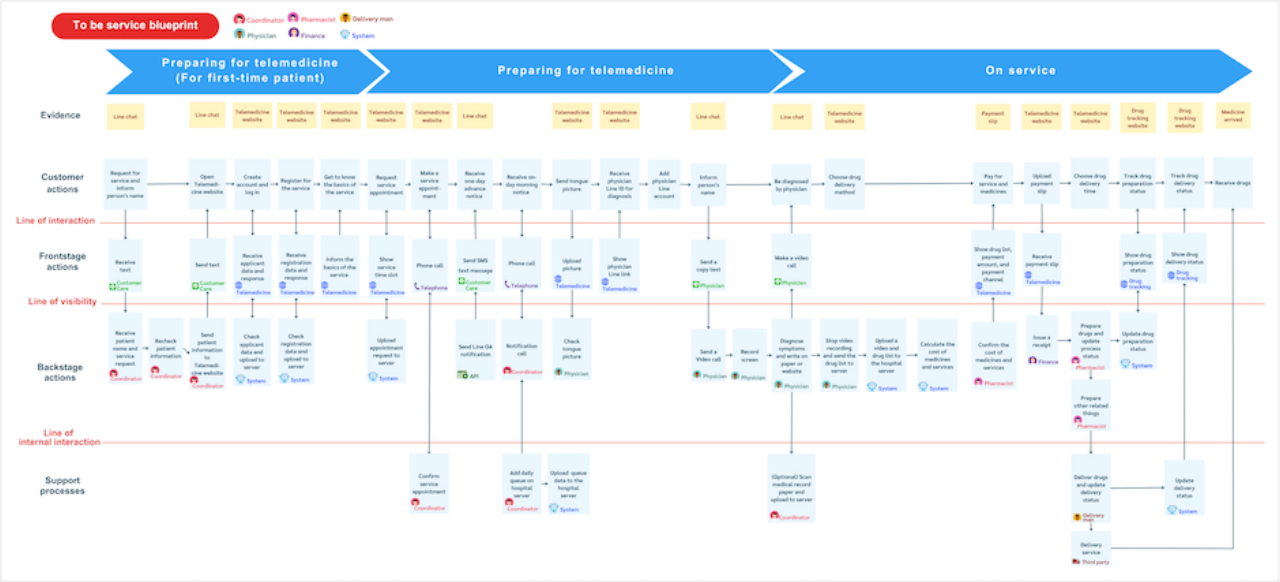
XSL•FO
RenderX



The success of such digital interventions also depended on staff skills and competencies. Therefore, comprehensive training for all system users was considered essential to ensure effective adoption of the redesigned processes.

To guide implementation, a "to be" customer journey map was developed (Figure 4) illustrating three major strategies: (1) *channel consolidation* (consolidating multiple service channels into a single integrated platform that supported all service activities, thereby lowering patient interaction costs), (2) *system digitization* (streamlining complex activities such as appointment scheduling by digitizing workflows and visualizing the required data for each stakeholder), and (3) *service status visualization* (providing patients with real-time updates on backstage operations to reduce uncertainty and dissatisfaction caused by undefined waiting times [22]).

In summary, the redesigned service model focused on consolidating communication channels, digitizing processes, and visualizing service status—strategies aimed at streamlining operations, improving efficiency, and delivering a more seamless telemedicine experience.



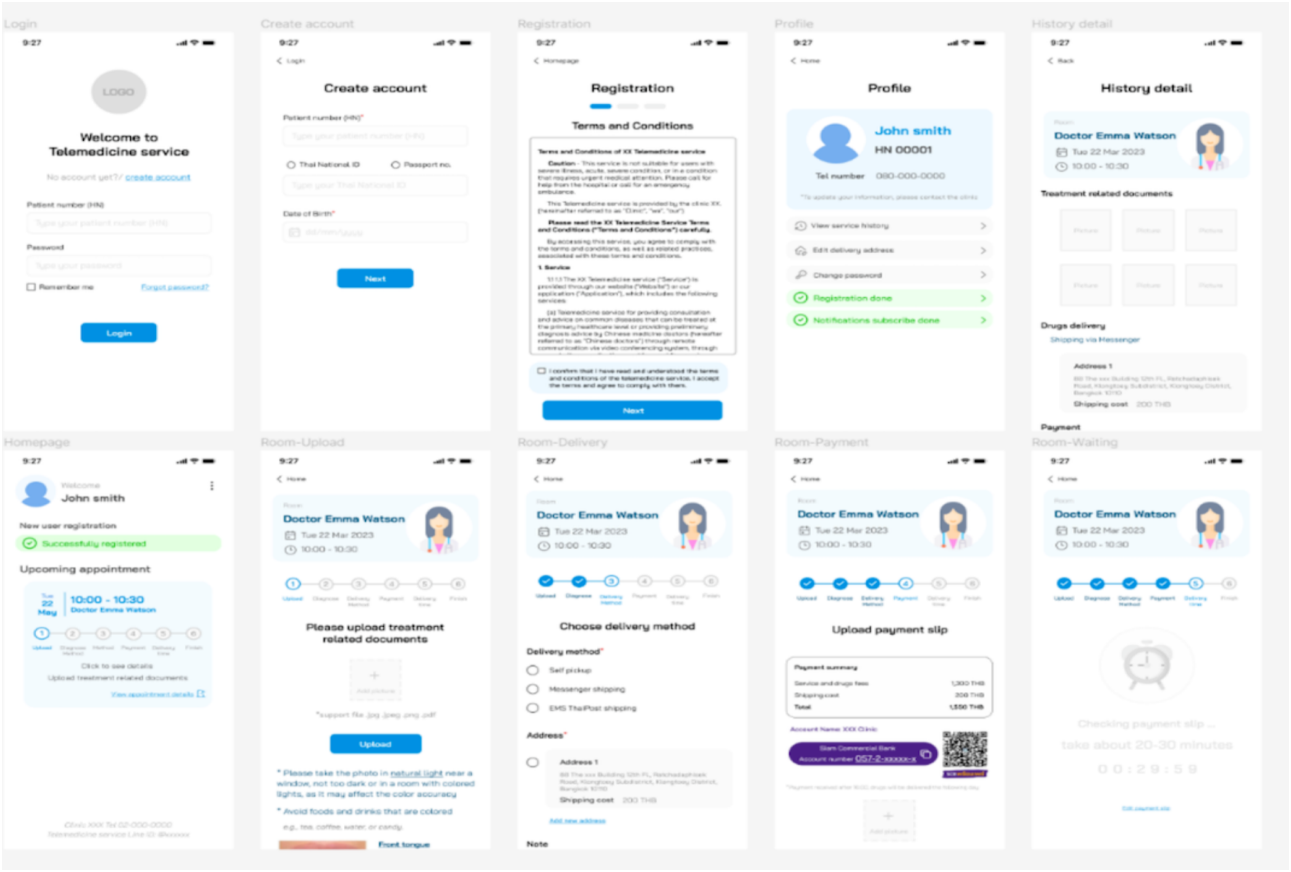
Moreover, a "to be" service blueprint was developed to enhance the service provider experience (Figure 5, or see the enlarged image in Multimedia Appendix 1). This blueprint emphasized 2 key strategies. First, the system was digitalized to automate patient-facing processes, thereby reducing provider workload associated with repetitive administrative tasks and ongoing patient follow-up. Automation also eliminated complex tasks such as appointment scheduling. Second, the blueprint introduced service status visualization for providers accompanied by automated notification alerts when action was required. This functionality helped reduce uncertainty during patient response delays and minimized the need for providers to manually review patient messages. In summary, streamlining provider operations was achieved through 2 strategies: system digitalization and visualization of service status.

Figure 4. "To be" customer journey map of the redesigned telemedicine service (patient perspective). TCM: traditional Chinese medicine.

XSL•FO
RenderX

Figure 5. "To be" service blueprint of the redesigned telemedicine service (provider perspective). API: application programming interface; OA: official account.

System Interface



The system interface is a critical component of service improvement, functioning as the primary channel of interaction between patients and health care providers. To guide interface design, a use case diagram of the redesigned telemedicine web application was developed to define user roles and their corresponding system functions. For example, users with system authentication privileges could manage log-in and log-out processes, change account passwords, create new patient accounts, and edit other user accounts.

Interfaces for each role were prototyped using Figma, a digital design platform that enables realistic mock-ups and supports iterative development [23]. Interactive buttons and workflows were tested during the prototyping stage, and feedback from trial users was collected to refine the design through iterative improvement cycles.

The final interface was divided into 2 dedicated websites: one for patients and one for service providers. The patient website was optimized for mobile devices and designed to support all essential patient tasks, including log-in, registration, profile management, and appointment booking (Figure 6, or see the enlarged image in Multimedia Appendix 2). In contrast, the provider website was optimized for desktop use to reflect providers' routine work patterns. This platform supported role-specific functions for physicians, coordinators, pharmacists, and finance staff, facilitating streamlined management of patient services and system operations.

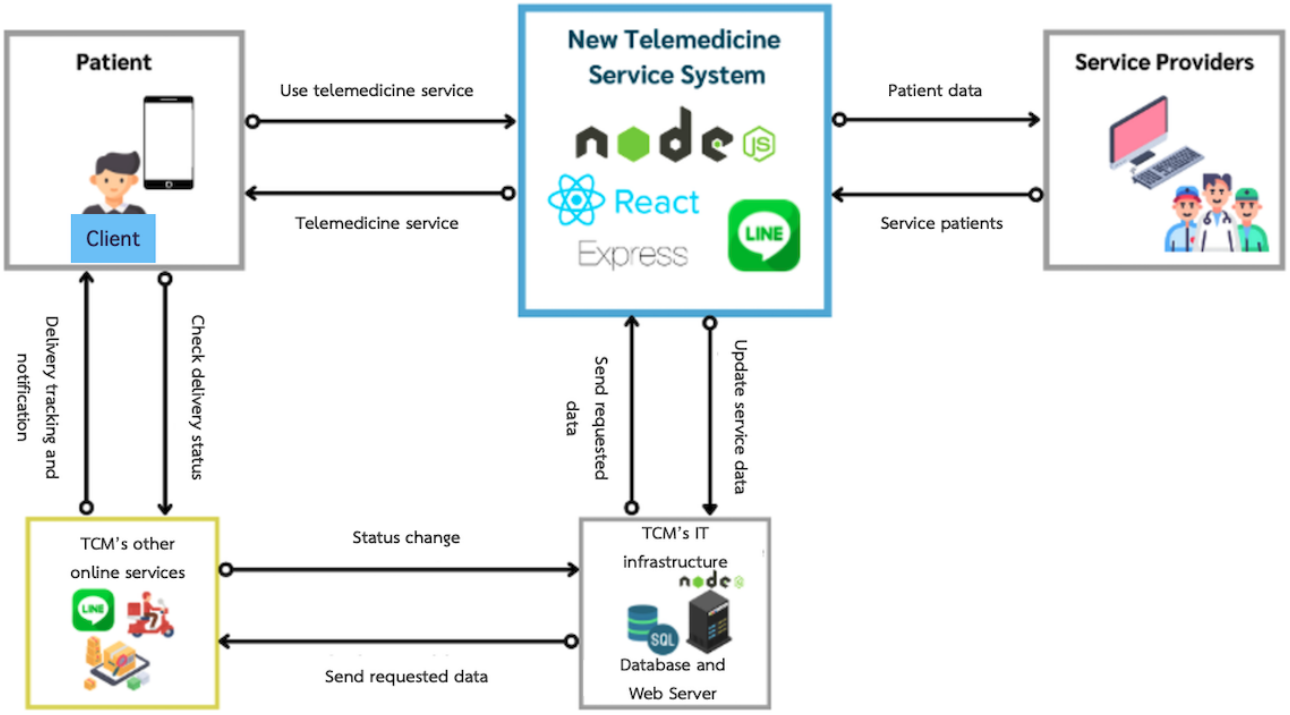
XSL•FO
RenderX

Figure 6. The patient web application interface optimized for mobile devices.

System Implementation

Following the design phase, the next step was the implementation of the new telemedicine web application system. This stage involved translating the design concepts into a functional system accessible to both patients and service providers. An overview of the telemedicine service system is shown in Figure 7.

To support implementation, an entity-relationship diagram was developed to represent the database structure and the relationships between its entities [24]. The entity-relationship diagram served as a blueprint for database design, ensuring that data were logically organized and efficiently structured to support the system's core functionalities.



In developing the TCM clinic's telemedicine service system, the web applications described in the System Interface section were implemented using Node.js (version 10; OpenJS Foundation), a widely adopted runtime environment for web development. The system interfaces were designed to be dynamic and responsive, ensuring low latency and a positive user experience.

The implementation integrated several JavaScript libraries and packages. The front end was built using React (version 17), compatible with Node.js version 10, alongside additional libraries such as SweetAlert and Fortawesome to enhance interactivity and usability. For the back end, Express.js (OpenJS Foundation) served as the primary framework for building application programming interfaces that adhered to the Representational State Transfer architectural style, enabling communication between users and the clinic's Microsoft SQL Server 2000 database. Supporting packages included *mssql* for database connectivity, *cors* to enable cross-origin requests, *express-fileupload* for image uploading, *bcrypt* for secure password encryption, and *line/bot-sdk* for integrating notification services through the Line app.

System interactions followed a client-server architecture: users engaged with the front-end interface, which transmitted data requests to the back-end system. The back end processed the data, executed the required operations, and returned results to the front end for user display.

XSL•FO
RenderX

Figure 7. Overview of the redesigned telemedicine service system. TCM: traditional Chinese medicine.

Although the real-time communication module was developed independently from the back end, seamless integration allowed for direct connection between the web application and physicians' Line accounts. Furthermore, the new telemedicine service system was linked with the clinic's existing automated alert system, prescription tracking system [25], and medicine delivery service [26], ensuring compatibility with established workflows and continuity of care.

System Validation

A system validation process was conducted to ensure that the redesigned telemedicine platform met the requirements of both patients and service providers and to evaluate user satisfaction with its performance and functionality.

Participants

Two participant groups were recruited: patients and service providers. Recruitment flyers were posted on noticeboards throughout the hospital where the TCM clinic is located. The flyers included details of the study objectives, experimental procedures, and eligibility criteria for both groups. Interested individuals self-screened for eligibility and contacted the research team via telephone to register.

A purposive sampling strategy was used to allow for in-depth understanding of user experiences [27]. Initial eligibility interviews were conducted by 2 web application developers from the author team. Participants were intentionally selected based on criteria relevant to the research objectives. To avoid bias, the remaining author team members who conducted the data analysis were blinded to the recruitment process.

Tasks

Overview

Task testing was conducted using simulated real-world scenarios designed to cover all key functions that patients and service providers would perform within the system. Separate test scenarios were developed for each role to ensure that all system features were evaluated comprehensively.

Content validity of the test scenarios was assessed by 3 domain experts, with each task receiving an index of item-objective congruence score between 0.84 and 1.00, indicating strong validity and suitability for use [28].

Tasks for the Patient Role

The patient scenarios were designed to address challenges commonly faced by individuals visiting the TCM clinic in person, particularly those who lived at a distance and found travel burdensome. Six scenarios were developed to validate the telemedicine functions from the patient perspective:

1. Registration: creating a telemedicine account and completing a 2-step registration process, including agreement to the telemedicine service terms and opting in for service notifications
2. Appointment booking: requesting a telemedicine consultation by selecting a specific date and time and choosing a physician from the provider list
3. Telemedicine consultation: completing the end-to-end telemedicine process, including uploading treatment-related documents (eg, tongue photos), joining the scheduled consultation, selecting a medicine delivery method, making payment, and choosing a delivery time
4. Address entry: adding a medicine delivery address with complete details (street address, district, province, and postcode)
5. Service history: viewing consultation history, including appointment details, physician information, diagnosis, payment records, and medicine delivery status
6. Password reset: resetting the telemedicine account password if forgotten

XSL•FO
RenderX

Collectively, these scenarios ensured validation of all core patient-facing functions in the telemedicine system.

Tasks for the Coordinator Role

The coordinator role scenarios reflected coordinators' primary responsibilities, including reviewing service requests, managing appointments, and monitoring daily schedules. Four scenarios were developed to evaluate system functionality from the coordinators' perspective:

1. Appointment creation: reviewing patient appointment requests, confirming the appointment with the patient via phone, and creating the appointment record in the system
2. Daily schedule review: viewing all patient service appointments scheduled for the day, including health number, name, phone number, date, time, and attending physician
3. Service status review: entering a patient's health number in the search bar to access the profile page and view the current service status
4. Provider information management: editing a physician's information in the system, such as Line ID and Line URL

Tasks for the Physician Role

The physician role scenarios represented physicians' key responsibilities in reviewing patient appointments and treatment-related materials. Two scenarios were simulated:

1. Document reupload request: reviewing patient appointment details and treatment-related documents submitted via the system and then requesting patients to reupload documents when necessary
2. Service history review: accessing a patient's historical records by entering the health number in the search bar to view profile information and past service data.

Tasks for the Pharmacist Role

Three scenarios were developed to evaluate the pharmacist role, which primarily involved managing patient medication and related communications:

1. Expense notification: viewing the patient's health number, name, and delivery method and then entering service, medication, and shipping costs to inform the patient
2. Delivery detail review: accessing patient records to confirm delivery method and scheduled delivery time, including health number, name, phone number, and delivery type and time
3. Service status review: entering the patient's health number in the search bar to access the profile page and review the current service status

Tasks for the Finance Personnel Role

Two scenarios were created to reflect the finance personnel's responsibilities regarding payment verification and follow-up:

1. Payment reupload request: reviewing the "waiting for payment confirmation" list, assessing uploaded payment bills, and notifying patients when resubmission was required
2. Review of patients with unpaid consultations: viewing details of patients with unpaid consultations, including health number, name, phone number, and service date and time

Measurement

Three quantitative usability metrics were used to evaluate task performance: success rate, number of interactions, and time on task. The success rate measured the effectiveness of the system and represented the ultimate outcome of usability testing. The number of interactions was used to evaluate efficiency by capturing the steps required for task completion. Time on task measured the time needed to complete each task and served as a primary indicator of efficiency [29]. Together, these metrics provided a comprehensive assessment of task effectiveness and overall system usability.

User satisfaction was assessed through 2 role-specific paper-based questionnaires. The patient questionnaire consisted of 4 sections: understanding of service procedures, ease of service completion, overall satisfaction, and net promoter score (NPS). The NPS, first introduced in 2003, measures customer loyalty by asking participants how likely they are to recommend a service to others, with scores ranging from –100 to +100 [30]. All patient questionnaire items were rated on a scale from 0 to 10, with higher scores indicating greater satisfaction.

The service provider questionnaire consisted of 10 items adapted from the System Usability Scale (SUS) [31]. The SUS includes statements about system usability rated on a 5-point Likert scale from "strongly disagree" (1) to "strongly agree" (5). Scores were converted to a percentile scale ranging from 0 to 100, with higher scores indicating better usability [31].

Procedure

Testing was conducted using the provided mobile phone (participants could select either iOS or Android). Participants were given a scenario and a step-by-step list of tasks to complete, whereas their interactions with the interface were recorded. The focus of this study was to evaluate the usability of the telemedicine application, not the participants' skills or knowledge.

Upon completing all scenarios and tasks, participants filled out a role-specific satisfaction questionnaire reflecting their experience with the telemedicine system. Finally, participants were thanked for their involvement and dismissed.

Ethical Considerations

Ethics approval for this study was obtained from the Burapha University Ethics Committee for Human Research (approval HS 100/2567). All participants were comprehensively briefed in person regarding the procedural details and the data protection protocols implemented to ensure anonymity and subsequently provided informed consent before testing. The consent form stated that no personally identifiable information would be collected, testing would take approximately 30 minutes, and participants retained the right to withdraw at any time. It was explicitly communicated to participants that they retained the right to withdraw from the experiments at any moment without adverse consequences. Furthermore, participation was voluntary, with no compensation offered.

XSL•FO
RenderX

Results

System Design

One of the major advantages of the redesigned telemedicine system was its enhanced operational efficiency, achieved by applying insights from the customer journey map and service blueprint during the redesign process. By automating processes and reducing the number of required steps, the new system streamlined service operations and optimized task completion time for both patients and service providers.

From the patient perspective, the number of steps required to register for telemedicine services decreased from 3 to 1 (a 67% reduction). Similarly, the number of interactions required to book an appointment, make a payment, and enter delivery details decreased from 9 to 5 (a 44% reduction).

From the service provider perspective, efficiency gains were even more substantial. The number of steps required to register a patient, order testing online, and provide service details was reduced from 14 to 2 steps (an 86% reduction), saving approximately 10 minutes per patient. In addition, the number of steps required to schedule an appointment and prepare a patient for diagnosis decreased from 5 to 4 (a 20% reduction). The system also eliminated redundant tasks, such as adding patient tag statuses and sharing Line contact details of physicians, pharmacists, and finance personnel.

Collectively, these reductions enabled service providers to process requests more quickly and allocate more time to higher-value clinical tasks. Table 1 presents a comparison of interaction steps before and after system redesign from both the patient and provider perspectives.

Table . Improvement in interaction steps between users and the telemedicine system after redesign.

Tasks	Improvement in interaction steps		Reduction (%)
	Before redesign	After redesign	
Patient perspective			
Registering for telemedicine service	3	1	67
Communicating with the service provider during the pre- and postservice stages	9	5	44
Service provider perspective			
Registering, internet testing, and informing the patient of service details	14	2	86
Scheduling an appointment and preparing a patient for diagnosis	5	4	20
Adding the tag status of a patient in the system and sending the Line contacts of all stakeholders	5	0	100

System Validation

A comprehensive validation process was conducted to evaluate the usability of the redesigned telemedicine service system. Usability was defined as “the extent to which a product or service can be used by specified users to achieve specified goals with effectiveness, efficiency, and satisfaction in a specified context of use” [32].

Three categories of quantitative usability metrics were assessed: effectiveness (success rate), efficiency (time on task), and satisfaction (overall satisfaction rating, NPS, and SUS score). As suggested by Eysenbach [33], validation encompassed both task performance and subjective evaluation. Figure 8 summarizes the number of participants in each role, along with details of their engagement, including assigned scenarios, completion of paper-based questionnaires, and the measurement metrics.

A total of 13 participants were involved in this study. The patient group comprised 6 individuals (n=5, 83% female and n=1, 17% male), with an age range from 23 to 54 years (mean 36.5, SD 9.95 years). The service provider group consisted of 7 individuals representing various departments involved in the telemedicine service system: 1 (14%) female coordinator, 2 (29%) physicians (n=1, 50% male and n=1, 50% female), 2 (29%) female pharmacists, and 2 (29%) female finance personnel.

During the usability testing phase, all participants completed role-specific tasks using the redesigned telemedicine web application. The tasks were designed to cover all functional aspects of the system. Six participants evaluated the patient-facing web application, whereas 7 participants evaluated the provider-facing management platform. Descriptive statistics from the usability testing are shown in Table 2 (patient usability) and Table 3 (service provider usability).

XSL•FO
RenderX

Figure 8. Number of participants in each role and details on their engagement. NPS: net promoter score; SUS: System Usability Scale.

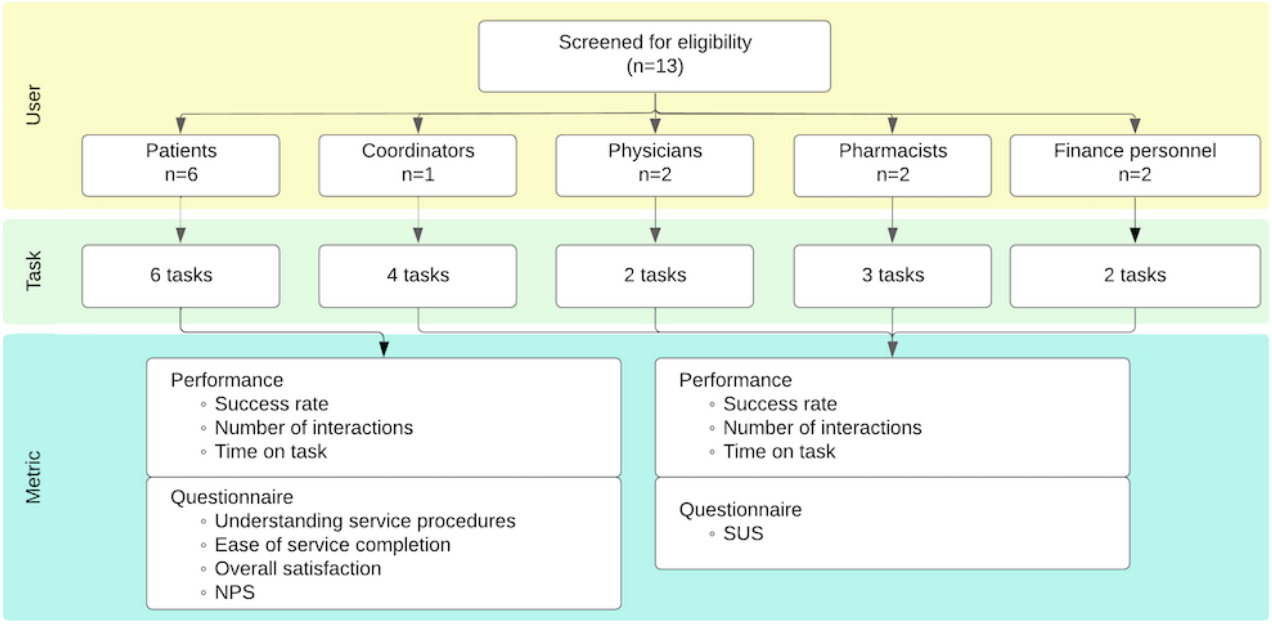


Table . Patient statistical usability testing results (N=6).

Scenarios	Number of interactions		Time on task (s)		Task completion						Success rate (%)
	Mean (SD)	Range	Mean (SD)	Range	Participants						
					#1	#2	#3	#4	#5	#6	
Registration	33.70 (0.52)	33 - 34	203.00 (61.96)	135 - 285	Pass	Pass	Pass	Pass	Pass	Pass	100
Appointment booking	4.00 (0.00)	4 - 4	30.20 (3.76)	27 - 37	Pass	Pass	Pass	Pass	Pass	Pass	100
Telemedicine consultation	21.20 (1.94)	20 - 25	204.80 (69.44)	107 - 294	Pass	Pass	Pass	Pass	Pass	Pass	100
Address entry	5.80 (1.33)	5 - 8	14.80 (6.82)	9 - 26	Pass	Pass	Pass	Pass	Pass	Pass	100
Service history	3.00 (0.00)	3 - 3	17.00 (10.18)	7 - 30	Pass	Pass	Pass	Pass	Pass	Pass	100
Password reset	6.70 (0.82)	6 - 8	115.20 (36.89)	72 - 155	Pass	Pass	Pass	Pass	Pass	Pass	100

For the patient-facing telemedicine web application, all patient participants successfully completed the full complement of six tasks. Variability was observed in the number of interactions and task completion times, which may reflect individual differences in participants' technological proficiency.

For the provider-facing telemedicine management platform, task success rates were similarly high, with 100% completion for most roles. The exception was the pharmacist role, which achieved a task success rate of 83.33%. The number of interactions and task completion times was not recorded for providers as the redesigned system allowed most tasks to be completed within a very short time. Variability in the pharmacist results may be attributed to individual differences in interface familiarity or task complexity (Table 3). Overall, the findings demonstrate that the provider platform was highly usable for most staff roles.

User satisfaction data are shown in Table 4. Among patients, the NPS was 67 based on feedback from 6 participants: 4 (67%) promoters, 2 (33%) passives, and no detractors. The mean satisfaction score was 9.2/10, indicating excellent user experience. For service providers, usability was evaluated using the SUS. The mean SUS score was 71.4 (SD 20.76) based on feedback from 7 participants, placing the system in the above-average usability range [34].

Item		Score, mean (SD)	Score, median (IQR)	Score range
Patients (n=6)				
	Knew the procedure well	8.7 (1.51)	8 (7.25 - 10)	7 - 10
	Completing the service felt easy	8.8 (0.98)	8 (8 - 9.75)	8 - 10
	Overall satisfaction with the service	9.2 (0.75)	9 (9 - 9.75)	8 - 10
Service providers (n=7)				
	SUS	71.4 (20.76)	65 (55 - 86.25)	52.5 - 100

Discussion

Principal Findings

This study developed and validated a new telemedicine service system for a TCM clinic centered on separate patient- and provider-facing web applications. The redesign was guided by service design tools, customer journey mapping, and service blueprinting that revealed inefficiencies in the legacy system, including fragmented communication channels, redundant steps, and undefined waiting times.

By reconfiguring these workflows into a logically harmonized digital design, the new system integrated patient-facing processes with provider operations in a coherent manner. Automation eliminated repetitive administrative tasks, communication was consolidated, and service notifications connected actions across roles. These features not only simplified the patient journey but also aligned provider tasks with patient needs in real time, reflecting a deliberate harmonization of activities across the digital service process.

Usability testing with 13 participants (n=6, 46% patients and n=7, 54% providers) demonstrated the effectiveness of this design. Patients achieved a 100% task success rate, with completion times within acceptable ranges, supporting learnability and intuitive system use [35,36]. Providers achieved similarly high success rates, with the exception of pharmacists (83.33%), whose tasks were inherently more complex. The observed errors were categorized as slips [37,38], suggesting that the design was fundamentally sound but required refinement in more information-intensive workflows, such as those for pharmacy.

The logically harmonized design also translated into high user satisfaction. Patients reported an average satisfaction score of 9.2/10 and an NPS of 67, both indicating excellent performance and strong acceptability [30,39,40]. This suggests that patients not only found the system easy to use but were also motivated

XSL•FO
RenderX

to recommend it, an important marker of adoption in digital health.

Among providers, the average SUS score was 71.4 (SD 20.76), above the average usability benchmark [34]. The variability in provider scores reflected differing levels of familiarity and adaptation to the new workflows. Importantly, this underscores a central challenge of digital transformation: harmonizing not only technical systems but also user practices and mindsets. With training and support tools (eg, video tutorials, workflow guides, and quick-reference materials) [35,36], providers can adapt to the harmonized processes more readily, leading to even higher usability and acceptance.

A distinctive contribution of this study is the introduction of service notifications as an orchestration mechanism in the harmonized design. Patients received automated alerts about next steps (eg, physician availability, payment confirmation, and delivery status), whereas providers were notified when specific actions were required (eg, reviewing documents, issuing receipts, and preparing medication). These notifications bridged the frontstage and backstage operations, ensuring that both patients and providers had a shared, transparent view of the service process. This alignment reduced uncertainty, supported timely action, and reinforced the logically harmonized structure of the digital service.

Patients highlighted improvements in convenience and accessibility, particularly for those with travel barriers, whereas providers reported efficiency gains from reduced redundant tasks and better cross-role coordination. Together, these results illustrate that harmonization of digital workflows not only improves efficiency but also strengthens the interconnectedness of patient and provider experiences in telemedicine.

This study contributes to the broader discourse on digital transformation in health care by demonstrating that success lies not only in digitizing existing processes but also in logically harmonizing them across all stakeholders. The integration of customer journey maps and service blueprints provided a structured pathway to identify misalignments and redesign them into a unified digital flow.

While service design tools remain underused in TCM and telemedicine contexts [41,42], our findings show that they can be instrumental in achieving harmonized digital transformation. The resulting framework could serve as a TCM telemedicine service design model or as guidelines for telehealth service design more broadly. By bridging service design thinking with digital health practice, this study highlights how logically harmonized design enables patient-centered care, reduces provider burden, and strengthens overall health care efficiency.

Limitations

This study faced several limitations. First, the case study clinic's IT infrastructure constrained the technical development of the web application. For example, while Node.js supported the system backbone, the integration of Web Real-Time Communication was limited due to the complexity of configuring Traversal Using Relays Around Network Address Translators and Session Traversal Utilities for Network Address Translators servers. These challenges affected the implementation of smooth real-time communication features.

Second, the patient sample (n=6) included participants aged 23 to 54 years, which does not fully represent the broader adult population typically served by the clinic, particularly older adults (with those aged 41-50 years being the most common age group in clinic data). As older adults are likely to benefit most from remote care solutions, future telemedicine research should prioritize this demographic, focusing on usability and accessibility tailored to older users.

Future Work

One of the distinctive challenges in TCM telehealth is the reliance on visual tongue examination for diagnosis. The current system addressed this by enabling patients to upload tongue photographs for physicians to review, as well as request resubmission if necessary. Future research could extend this by integrating machine learning and artificial intelligence to automate initial screening of tongue images. Automated feedback on image quality could reduce wasted time, decrease physician workload, and further improve diagnostic efficiency.

Beyond the TCM context, the system could be adapted for other traditional medical practices, such as Ayurveda. Although attempts to implement telemedicine in Ayurveda have been reported, barriers remain due to limited physician awareness and acceptability [43]. Applying the service design approach demonstrated in this study may support the integration of such services, particularly where workflows require specialized or customized patient data.

Finally, the use of service design tools (customer journey maps and service blueprints) in this study provides a replicable methodology for integrating new digital technologies into health care services. These tools can guide the redesign of service processes to optimize delivery, improve user experiences, and enhance both patient satisfaction and provider efficiency.

Conclusions

This study implemented strategies for both patients and service providers to improve the telemedicine service system and streamline its operations, with a focus on reducing human effort, interaction costs, and waiting times.

For patients, 3 strategies were central: consolidating service channels into a single platform, digitizing processes through web applications, and visualizing service status. These interventions lowered interaction costs by providing an all-in-one, easily accessible platform. Visualization of service status reduced dissatisfaction from undefined waiting times and improved patient understanding of service steps. Usability testing confirmed the positive effects of these improvements, with patients reporting an NPS of 67 and an average satisfaction score of 9.2, reflecting excellent performance.

For service providers, 2 strategies were central: digitizing tasks and visualizing service status. This reduces repetitive administrative work, facilitating tracking of patient responses and supporting more efficient communication across roles. While the system markedly reduced provider workload, structured training at the start of implementation is

XSL•FO
RenderX

recommended to support adoption, build confidence, and promote trust in the system.

Collectively, the results demonstrate that a logically harmonized digital transformation informed by service design methodologies can enhance telemedicine effectiveness and efficiency. By aligning redesigned workflows with patient and provider needs, the system improved usability and satisfaction while contributing to higher-quality health care delivery.

Abstract

Background: Antimicrobial resistances pose significant challenges in health care systems. Clinical decision support systems (CDSSs) represent a potential strategy for promoting a more targeted and guideline-based use of antibiotics. The integration of artificial intelligence (AI) into these systems has the potential to support physicians in selecting the most effective drug therapy for a given patient.

Objective: This study aimed to analyze the feasibility of an AI-based CDSS pilot version for antibiotic therapy in sepsis patients and identify facilitating and inhibiting conditions for its implementation in intensive care medicine.

Methods: The evaluation was conducted in 2 steps, using a qualitative methodology. Initially, expert interviews were conducted, in which intensive care physicians were asked to assess the AI-based recommendations for antibiotic therapy in terms of plausibility, layout, and design. Subsequently, focus group interviews were conducted to examine the technology acceptance of the AI-based CDSS. The interviews were anonymized and evaluated using content analysis.

Results: In terms of the feasibility, barriers included variability in previous antibiotic administration practices, which affected the predictive ability of AI recommendations, and the increased effort required to justify deviations from these recommendations. Physicians' confidence in accepting or rejecting recommendations depended on their level of professional experience. The ability to re-evaluate CDSS recommendations and an intuitive, user-friendly system design were identified as factors that enhanced acceptance and usability. Overall, barriers included low levels of digitization in clinical practice, limited availability of cross-sectoral data, and negative previous experiences with CDSSs. Conversely, facilitators to CDSS implementation were potential time savings, physicians' openness to adopting new technologies, and positive previous experiences.

Conclusions: Early integration of users is beneficial for both the identification of relevant context factors and the further development of an effective CDSS. Overall, the potential of AI-based CDSSs is offset by inhibiting contextual conditions that impede its acceptance and implementation. The advancement of AI-based CDSSs and the mitigation of these inhibiting conditions are crucial for the realization of its full potential.

Introduction

Sepsis infections caused by pathogens with antimicrobial resistance (AMR) represent a significant global challenge in health care [1,2]. In 2017, there were 48.9 million new cases of sepsis and 11 million deaths related to sepsis, accounting for 19.7% of all global deaths [3]. In Germany, sepsis incidence increased by an average of 5.7% per year, from 280 cases in 2010 to 370 cases in 2015 per 100,000 individuals [4]. A recent meta-analysis indicated that the 30-day mortality rate for sepsis in Germany was estimated to be 26.5%, which is consistent with the observed rates in North America and Europe [5]. Furthermore, over 1.27 million deaths per year are attributed to AMR worldwide. In 2019, there were 9650 deaths attributable to AMR (mortality rate of 5 per 100,000) and 45,700 deaths associated with AMR (mortality rate of 22 per 100,000) in Germany [6]. Recent data from Germany show heterogeneous trends in AMR proportions of infected patients underscoring the urgent need for enhanced infection prevention measures to limit AMR spread [7]. Inappropriate antibiotic prescribing represents a significant contributing factor [8]. In particular, the prolonged or improper use of nonspecific, broad-spectrum antibiotics is highly problematic, as these antibiotics provide symptomatic relief but also facilitate the development of resistance in other bacteria [9,10].

Clinical decision support systems (CDSSs) provide a solution for promoting targeted and guideline-based antibiotic prescribing [11-13]. CDSSs adopt a variety of forms and are integrated into routine practice. Despite their diverse nature, they share a common objective: to assist medical professionals in identifying the most appropriate form of therapy for each patient, based on existing data and established guidelines, through the use of programmed algorithms or artificial intelligence (AI) [14,15]. In the context of CDSSs, previous studies have demonstrated a decrease in antibiotic prescription rates, more rapid initiation of appropriate antibiotic therapy for patients, and improved clinical outcomes, such as reduced mortality, increased antibiotic-free days, and fewer medical complications [16-19]. However, CDSSs do not always improve clinical practice [20]. For example, there is still insufficient evidence to conclusively show positive effects on therapy duration, dosage, or adherence to clinical guidelines [11,16,21].

Despite the growing body of research on AI-based CDSSs in intensive care units (ICUs) [22,23], there is a notable gap in the implementation of AI tools in routine care in general [24] and the availability of AI-based CDSSs for sepsis in the German health care system. The KINBIOTICS (translated as “AI-based decision support for antibiotic therapy”) project, funded by the German Federal Ministry of Health, aimed to train AI-based algorithms and improve the prediction of suitable antibiotics for sepsis infections on the basis of a comprehensive data set. In addition to the development of an AI-based CDSS, a cross-sectoral resistance observatory and a new rapid test for sequencing the antibiotic genome were developed [25].

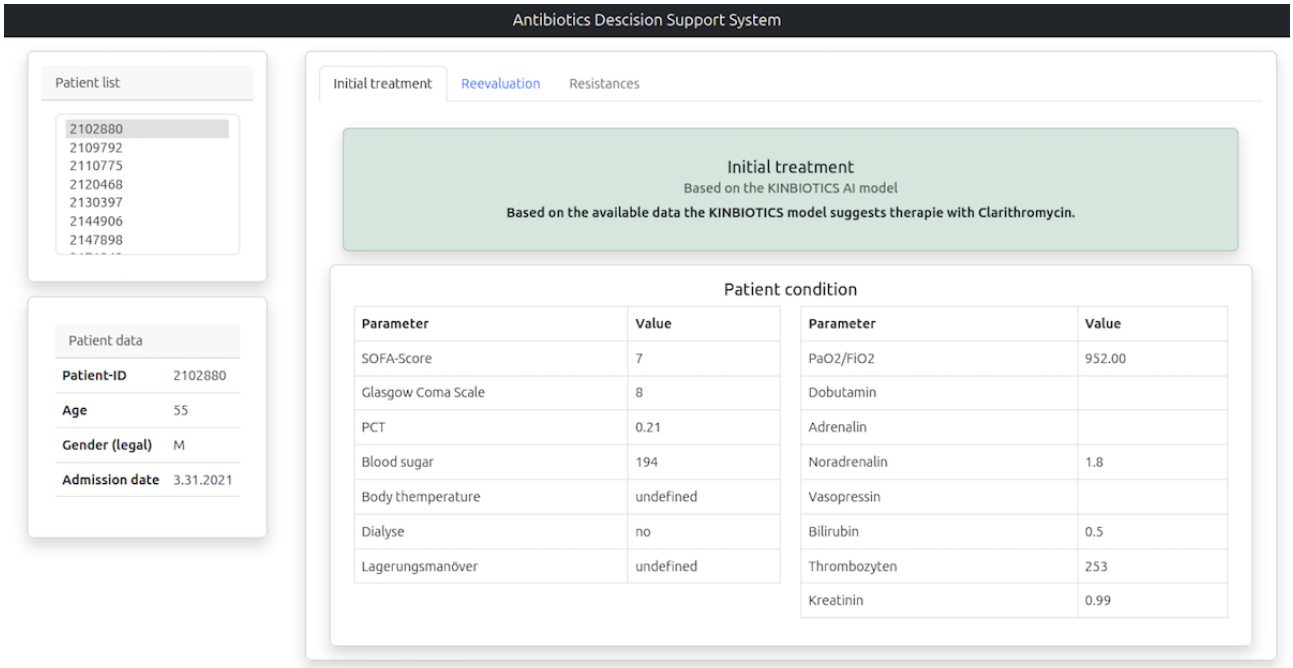
Engaging clinicians in the design and development of CDSSs is often suggested as a strategy to enhance the alignment between the system and the needs of its users [26-28]. Interviews and expert groups are approaches used for preimplementation clinician involvement [29]. Insights into clinicians’ views provide valuable information on the barriers and facilitators that affect their willingness to adopt and use CDSSs in practice [30]. By examining clinicians’ perceptions, the study seeks to inform targeted strategies to improve the CDSS’s design, usability, and relevance, thereby promoting more effective and widespread adoption in clinical practice.

This study aimed to perform a use case analysis of a pilot version of the AI-based CDSS within an ICU setting. The objective was to analyze the clinical decision-making processes, and adopt a more comprehensive perspective on the factors that facilitate or hinder the future implementation of such a system.

Methods

Reporting is based on the Standards for Reporting Qualitative Research (SRQR) [31]. The SRQR checklist is provided in Multimedia Appendix 1.

Study Design and Setting



A 2-stage base model (random forest at both stages) was developed for the initial therapy using patient data, laboratory data, and clinical data. Subsequently, the model was optimized using a variety of parameters, including the number of decision trees and tree depth (the model specifications and results will be published separately once the AI-based CDSS model has been finalized). The developed model was trained and tested on data from 1 of the 3 participating clinics and then evaluated for robustness using data from a second clinic. Although the performance of the underlying AI model was insufficient in terms of accuracy, specificity and sensitivity at the time of the evaluation, it was crucial at this time to gain insights into the decision-making mechanisms of the physicians. This was undertaken in order to scrutinize the variables included in the initial model and, where necessary, to supplement or adjust them. Accordingly, the preliminary prototype was not modified during the interview phase. However, subsequent to the interviews, the model underwent alterations and is still under development.

The pilot version of the AI-based CDSS was evaluated in a 2-stage semistructured qualitative process [32]. With regard to feasibility, physicians were each shown 5 exemplary sepsis patient cases in a desktop version of the CDSS. Cases were selected randomly from the evaluation dataset and were identical for each interviewee. In addition to basic patient information, this contained relevant vital parameters, and the treatment recommendation determined by the AI-based CDSS (Figure 1). This antibiotic therapy recommendation was presented to the physicians both for the admission situation to the ICU (initial treatment; the start of antibiotic therapy) and for a possible therapy correction at the time the microbiological findings were available (re-evaluation; usually 48-72 hours after start of antibiotic therapy). The physicians were informed during the individual interviews that the CDSS is still in a pilot status and that the recommendations are likely not yet reliable. The physicians were asked to assess and evaluate the intensive care situation at both time points as well as the AI-based model

XSL•FO
RenderX

recommendation for antibiotic therapy. In addition to the plausibility of the content of the therapy recommendations, the design and layout of the pilot version were evaluated.

Figure 1. Screenshot of the pilot version of the artificial intelligence–based clinical decision support system.

Following the individual interviews, physicians from each clinic were interviewed again as part of a focus group interview. The theoretical focus here was on technology acceptance of AI-based CDSSs and the identification of challenges and conductive conditions with regard to future implementation.

Expert Selection

Expert interviews were conducted with intensive care physicians from the 3 clinical centers involved in the project at the University Medical Center East Westphalia-Lippe. The interviews were conducted on a voluntary basis and the potential participants were selected by the respective project partners in the 3 clinical centers.

Data Collection

Between October and November 2023, the face-to-face expert interviews and focus groups were conducted. The interview guideline (Textbox 1) for the focus group interviews was developed on the basis of the extended Unified Theory of Acceptance and Use of Technology (UTAUT 2) [33,34]. The UTAUT has recently being used to explain technology adoption among health care practitioners' intention to use AI-based CDSSs [35].

Textbox 1. Interview guideline for the focus groups (based on the Unified Theory of Acceptance and Use of Technology 2).

- Opening question
- What were the objectives of today's meeting?
- Questions about the tool
- Please describe your impressions of the KINBIOTICS user interface.
- What information may have been lacking in your medical decision-making process that led to the prescription of antibiotics?
- Please indicate which aspects you consider to be beneficial for a potential application.
- What additional functions would be beneficial to include in the KINBIOTICS user interface to ensure effective utilization in routine clinical practice?
- Questions regarding the use of artificial intelligence (AI) in general
- To what extent do digital tools contribute to the processes undertaken in your day-to-day work?
- Please indicate which digital applications you currently use in your professional activities.
- Please indicate which digital health applications you use in your private life.
- Please indicate your opinion on the utilization of AI, and provide your expectations regarding the implementation of AI in healthcare, both in general and on your ward.
- Please describe your previous experience of contact with AI and clinical decision support systems.
- What is the prevailing attitude in your clinical setting, on the ward and among your professional colleagues with regard to the utilization of artificial intelligence in everyday medical procedures?
- In the hypothetical scenario of utilizing such a tool like KINBIOTICS in tomorrow's clinical decision-making process, what potential challenges might be identified?
- Questions about future utilization of a clinical decision support system
- Please describe the benefits you perceive in the utilization of AI and clinical decision support systems in your everyday professional practice.
- In order to apply such a system in medical decision-making, what prerequisites must be met?
- Please indicate whether you identify any additional aspects that should be addressed for use in everyday clinical practice.

The interviews were recorded by audio and subsequently transcribed. After complete transcription, the audio recordings were irrevocably deleted in accordance with the data protection policy.

Data Analysis

The data analysis of the transcribed interview material was conducted deductively and inductively based on categories according to Kuckartz (2018) [36]. The procedure for the individual interviews primarily followed evaluative content analysis, while the focus groups were analyzed in terms of content structure. To gain as much knowledge as possible, the transcripts of the individual interviews were also analyzed with regard to possible content-structuring findings. The transcripts were analyzed anonymously using the qualitative analysis software MAXQDA (version 2022, VERBI) [37]. The interview analyses and category assignment were carried out independently by 2 researchers (JAD and MK). In the case of discrepancies, a third researcher (DL) was consulted. Categories were adapted or reformulated by the interdisciplinary research team (JAD, MK, DL, SE, and WG).

Ethical Considerations

Informed consent was obtained before the interviews. A positive ethics vote (November 22, 2021) from the ethics committee of the Medical Association of Westphalia-Lippe and the Westphalian Wilhelms University of Münster was received for the entire project (No. 2021-699-f-S). The interview transcripts were anonymized. The interviewees did not receive any compensation; participation was on a voluntary basis.

Results

Sample

A total of 19 individual interviews and 3 focus group interviews were conducted. The distribution of respondents with regard to gender, age, and professional experience was relatively balanced, with 10 (53%) of the respondents identifying as male. In each case, 7 (37%) respondents were aged 30-40 years, and 40-50 years. In total, 5 (26%) respondents had less than 5 years or 11 - 20 years of professional experience, 4 (21%) had between 5 and 10 years, and 3 (16%) respondents indicated that they had more than 20 years of professional medical experience. The duration of the expert interviews ranged from 17 to 43

XSL•FO
RenderX

minutes, while the average duration of the focus group interviews was 1 hour.

Feasibility of the AI-Based Clinical Decision Support System

The approval or rejection of the AI-based antibiotic recommendations was heterogeneous and primarily dependent on 2 factors: first, the plausibility of the AI-based individual therapy (change) recommendations (refer to quotes 1 and 2). It should be noted that not every detailed recommendation was already plausible or medically advisable due to the pilot status of the CDSS respective example cases.

> ***Quote 1:****The system now suggests piperacillin/tazobactam. Of course, this is a very far-fetched suggestion for primary antibiotics when it comes to designing a calculated antibiotic therapy. For me, this would not be the first drug of choice for patients who arrive at the hospital as primary patients, who have been treatment-naïve so far and have not yet received antibiotic therapy [...].* [Expert 5, Clinical Center 3]

> ***Quote 2:****So, [piperacillin/tazobactam]. Well, difficult [...] with a completely normal PCT [Procalcitonin], I would find it difficult [...] to start directly with such a broad antibiotic.* [Expert 8, Clinical Center 2]

> ***Quote 3:****[...] So, [...] such a recommendation, I'm very sure, will be malpractice in the next three to five years [...]. This reflects the reality, but this is the worst thing that can happen, to treat a Staphylococcus aureus bacteremia with [piperacillin/tazobactam], that is an absolute no-go.* [Expert 4, Clinical Center 1]

Second, the evaluation of the recommendations is dependent upon the level of professional experience (quote 3). Accordingly, the more advanced the professional experience, the more confident a recommendation was to be approved or rejected. However, the data indicate that the majority of respondents expressed consensus regarding the CDSS recommendation in each case study (Table 1).

Table . Assessments of the experts surveyed on the feasibility of the pilot version of the artificial intelligence–based clinical decision support system (N=19).

	CDSS recommendation for initial treatment		CDSS recommendation for re-evaluation	
	Agreeing with the recommendation, n (%)	Rejecting the recommendation, n (%)	Agreeing with the recommendation, n (%)	Rejecting the recommendation, n (%)
Use case 1	14 (78)	4 (22)	12 (67)	6 (33)
Use case 2	11 (61)	7 (39)	1 (5)	18 (95)
Use case 3	3 (16)	16 (84)	2 (11)	16 (89)
Use case 4	15 (83)	3 (17)	14 (78)	4 (22)
Use case 5	13 (76)	4 (24)	12 (71)	5 (29)

A suggestion was made that the pilot CDSS should be expanded to include the integration of combination therapies. The vital parameters and patient information should be included as variables in the statistical model for predicting therapy to include the suspected focus of infection. In addition, it was noted that the data provided for the development of the model and the case studies in the pilot version were incomplete in many instances (Table 1). The physicians encountered significant challenges in evaluating the CDSS recommendation when the fields for data that could be viewed in the application were left empty (quote 4).

> ***Quote 4:****Here again the PCT [Procalcitonin] is missing, that would make it easier for us. We only have [...] indirect information that we have an infection here [...] measured by the thrombocytopenia, and then [...] I can get along with actually using piperacillin and tazobactam primarily here when it comes to the calculated antibiotic therapy [...].* [Expert 5, Clinical Center 3]

> ***Quote 5:****The [application] is more explanatory than my phone. So, everything is fine in that respect.* [Expert 3, Clinical Center 3]

From the physicians' perspective, the primary factor influencing the acceptance of the AI-based CDSS was the time required for completion of the process. If the system is able to produce an evident medication recommendation in a shorter time than the physicians can achieve, a high willingness to use it was reported. There was unanimous feedback that the design and layout of the CDSS are pleasant and easy to understand (quote 5). Furthermore, the majority of respondents indicated a preference for a mobile version of the system for use in everyday clinical practice. This preference was again justified by the availability of digital resources.

Facilitating and Inhibiting Factors for the Implementation of an AI-Based Clinical Decision Support Systems

The focus group interviews showed that while there is already strong foundational support for digital tools and applications in diagnostics and therapy as part of routine clinical practice, the use of more advanced applications, especially those based on AI, was limited to isolated cases and primarily on a project basis. Previous experiences with CDSSs had a significant impact on expectations regarding the quality of the CDSS, the effort required for integration into everyday medical practice, and the intention to potentially use such a system (quotes 6 and 7).

> ***Quote 6:****I'm thinking about the echocardiography, [...] where the AI has become so good that we let it*

XSL•FO
RenderX

take over. We do the examination ourselves. And yet the module helps us with that. That's how I imagine it [here] too. [Expert 2, focus group 2]

Quote 7:*Yes, for the colonoscopy [...] we once had [a CDSS]. But the human was faster than the AI. So in that respect [...] rather not.* [Expert 3, focus group 3]

Nevertheless, the majority of respondents indicated a high level of willingness to adopt AI-based CDSSs (quotes 8 and 9). The option of re-evaluation included in the application was considered to be particularly beneficial.

Quote 8:*I actually found the idea compelling. Because in the early days of my clinical work, even more so than now, the question always arises: am I doing it right now?* [Expert 1, focus group 2]

Quote 9:*[T]he field is so complex [...] that's why I think a support tool that works well is very helpful.* [Expert 3, focus group 1]

As previously noted, the acceptance and implementation of digital solutions is largely dependent on the amount of time available. In addition, the majority of respondents indicated that they are consistently seeking tools that facilitate efficient support in routine clinical practice. Consequently, the respondents exhibited an intrinsic motivation to use CDSSs, which was observed across all age groups and genders, but was particularly pronounced in the "30 - 40 years" and "40 - 50 years" age groups.

In contrast with the physician's technology openness as a beneficial factor, the level of digitization in the clinics was found to be heterogeneous. Furthermore, the physicians' assessment indicated that there was significant potential for improvement in all 3 hospitals (quote 10). The statements indicated that the level of digital infrastructure, including stable internet coverage, exhibited considerable variation not only between the clinics but also between individual wards within the clinics. Overall, there was a consensus that better equipment in terms of digital devices and applications was needed (quote 11). The lack of comprehensive digital and cross-sectoral availability of relevant patient health information was also identified as a barrier to the implementation of AI-based CDSSs and efficient medical treatment in general. This demonstrated that the degree of digitization in everyday clinical practice affects the perceived feasibility of implementing the CDSS and is the most significant barrier to the beneficial factors.

Quote 10:*So, it's really funny that you can still secure good pens. Because we do so much paper based.* [Expert 2, focus group 2]

Quote 11:*The problem is that there are far too many individual components that all [...] communicate with each other via interfaces. And in the process, values are lost or the data transfer doesn't work. And then you end up standing there and yes, the computer hangs.* [Expert 4, focus group 2]

Furthermore, the existing data basis for the AI-based CDSS model was identified as a significant challenge. The participants were aware that, in addition to the aforementioned lack of digitized patient information, the heterogeneous quality of previous antibiotic administration practice also had an influence on the predictive ability of the recommendation from the CDSS. Furthermore, an increased documentation and justification effort in the event of potential deviation from the CDSS recommendation was also seen as a barrier. However, all participants were aware that such a system would be implemented as a supportive and not a replacement measure, and this was not criticized.

Two relevant recommendations for improvement were derived from the interviews. First, the majority of respondents indicated that applicable guidelines on antibiotic therapy should be incorporated into the specification of the underlying statistical models. Second, there was a recurring suggestion that, alongside the further development of the presented system, the capability to diagnose sepsis infections should also be integrated into a CDSS. Once again, the time to correct diagnosis and subsequent appropriate treatment was identified as the main driver. Suggestions for adapting the tested CDSS comprised the inclusion of quantities and suggestions for the duration of antibiotic administration, in addition to the therapeutic agents themselves (quote 12).

Quote 12:*So, in an ideal world, [...] [AI] can be a huge step forward as a decision-making tool. But [A] the right information has to flow in. And [B] the decisive recommendation [...] is already anticipated here [...]. So, the first step: can this be sepsis? That is an important step. [...] In the second step, a recommendation for initial therapy is helpful [...], yes.* [Expert 4, focus group 1]

Discussion

Principal Findings

Overall, this use case analysis shows various barriers and facilitators for the implementation of AI-based CDSSs for antibiotic therapy in sepsis (Textbox 2). The findings of the expert and focus group interviews indicate that the potential of digitization and, in particular, AI-based tools is expected and viewed in a favorable light by the majority of the physicians. This finding is in line with other research which indicates that clinicians have a predominantly positive perception of AI systems [38-40]. Similarly, the willingness to use these tools is high [41]. In this context, the plausibility of the prediction and the potential time savings are of particular importance. It is evident that the existing contextual conditions represent the most significant obstacle to future implementation. In addition to the basic technical equipment in the clinics, other factors, such as a stable, comprehensive internet supply and the necessary digital availability of data, were also identified as potential barriers to future implementation. Accordingly, the question arises as to what extent clinics are equipped with the digital infrastructure to fully leverage the benefits of AI-based CDSSs. At this point it has to be noted that the digital maturity of German hospitals appears to be comparatively limited [42]. This can be attributed, at least in part, to a lack of financial resources [24,43]. It remains to be seen to what extent hospitals use the transformation fund provided by the German Hospital

XSL•FO
RenderX

Future Act and how this can enhance the conditions for the implementation of AI systems.

Textbox 2. Summary of barriers, facilitators, and recommendations for artificial intelligence–based clinical decision support systems' feasibility and implementation.

Barriers

- Overall
- Low degree of digitization in everyday clinical practice.
- Lack of comprehensive digital and cross-sectoral data availability.
- Negative previous experiences with clinical decision support systems.
- Use Cases
- Heterogeneous quality of previous antibiotic administration practice limits predictive ability of the artificial intelligence–based recommendations.
- Increased effort to document and justify potential deviations from the clinical decision support system's recommendation.
- The confidence to approve or reject artificial intelligence–based antibiotic recommendations depends on the level of professional experience.

Facilitators

- Overall
- Potential time savings.
- Physician's technology openness or intrinsic motivation.
- Positive previous experiences with clinical decision support systems.
- Use Cases
- Re-evaluation of clinical decision support system recommendations is considered to be particularly beneficial.
- Pleasant design and layout of the clinical decision support system (easy to understand).

Recommendations

- Incorporation of guidelines on antibiotic therapy into the specification of the statistical models.
- Clinical decision support systems should include the integration of combination therapies.
- Statistical model for predicting antibiotic recommendations should include vital parameters and further patient information to identify the suspected focus of infection.
- Besides sepsis treatment, the capability to diagnose sepsis infections should also be integrated into a clinical decision support system.
- Preference for a mobile version of the clinical decision support system.

The medication recommendations by the CDSS were not yet perceived as reliable due to the limited and biased data available for training the AI system. Often, a very broad standard therapy (piperacillin/tazobactam) was recommended. This was mainly due to the fact that this medication occurred considerably more frequently within the learning data set than all other antibiotics. According to the experts, this approach is not absolutely mandatory and sometimes maybe counterproductive in terms of calculated antibiotic therapy. Younger physicians in particular tended to agree with the recommendations. This is a sign that a CDSS for the most common "standard medication" might not be beneficial if not detrimental. This can be confirmed by the physicians' statements that they would like decision support primarily for medication combinations and for rare antibiotic agents or rare sources of infection. In view of the goal of avoiding the development of resistance by reducing the use of broad-spectrum antibiotics, the current pilot version of the AI system would possibly even promote this risk of further resistance. To avoid this, current guidelines should be incorporated into the model design in addition to retrospective primary data.

The respondents' call for the upstream integration of sepsis diagnostics in addition to the further development of the existing CDSS appears to be purposeful. A recent study has confirmed initial successes in this regard [44]. Although no clear correlations between sociodemographic characteristics and the willingness to use CDSSs were found in the present evaluation, differences in the approval or rejection of the AI-based CDSS recommendations depending on professional experience were identified. This finding is supported by Lambert et al [45]. It is recommended that future studies investigate the degree to which professional experience and other sociodemographic variables exert an influence on technology acceptance and the willingness to use CDSSs. In this regard, using the UTAUT would be appreciated [35].

XSL•FO
RenderX

Generally, the following challenges associated with the use of AI in health care should not be overlooked. For example, automation bias, in which health care providers may develop an overreliance on AI recommendations, potentially reducing their clinical vigilance and leading to oversights in patient care, needs to be considered [46]. Furthermore, AI-driven CDSSs may unintentionally propagate biases present in training datasets, resulting in discriminatory recommendations that may disadvantage certain demographic groups [47]. Another key concern is the ambiguity and complexity of liability; it remains unclear who is legally responsible if an AI-influenced decision contributes to a negative patient outcome [48]. Furthermore, previous research has highlighted the potential negative impact of a lack of user involvement in the development of CDSSs on the willingness to use them, even when the system quality is optimal [26]. One of the key strengths of the study is the early involvement of future users. The participatory approach highlights the need for involvement. Consequently, given the significant lack of engagement with CDSS interventions reported within the literature [49], future studies should consider the involvement of users from the earliest stages of development [26,28,50]. The findings of the present study confirm that in addition to personal factors, the plausibility of the recommendations is the most decisive factor determining the willingness to use the tool [51]. Further development of the pilot version or similar systems is therefore crucial for implementing and exploiting the potential benefits of AI. Furthermore, the feedback from the physicians participating in this study provided valuable insights into additional variables that were subsequently integrated into the further development of the CDSS, following the completion of the interviews.

Limitations

Several limitations must be acknowledged in the evaluation of the use case presented in this study. First, the efficacy of the CDSS was clearly limited due to the rather small amount of data used for training. The findings suggest that the CDSS may offer less benefit for physicians during the initial therapy phase compared with its use in the context of therapy re-evaluation. At this stage, it was not feasible to accurately predict the most appropriate antibiotic, one that would minimize treatment changes and side effects, based on the currently available data. The acceptance of AI-based interventions heavily depends on the plausibility and relevance of therapy recommendations, which ultimately impacts their efficacy. Therefore, further development and refinement of AI-based CDSSs are essential, along with an expansion of the digital data infrastructure.

In addition, it is important to consider that the evaluation was based on a qualitative interview study, which comes with inherent limitations. The voluntary nature of participation may introduce self-selection bias, potentially leading to an overestimation of the participants' openness to technology and their acceptance of AI-based CDSSs. This limitation suggests that the findings may not be fully generalizable to the broader population of health care professionals.

Conclusion

This pilot study of an AI-based CDSS indicates that further development is needed to achieve the original goals of minimizing switches in antibiotic prescriptions and reducing the reliance on broad-spectrum antibiotics. Relying solely on retrospective data from past care practices does not seem to be an effective strategy for meeting these objectives. In addition, it is essential to address the key challenges identified in this study to enable the successful integration of AI into clinical settings. While the respondents generally showed a positive attitude toward the use of AI-based CDSSs, a more comprehensive evaluation of technology acceptance among health care professionals can only be conducted when a version with realistic, guideline-compliant recommendations is available. Early engagement of users in the development process proves beneficial, not only for refining the CDSS but also for fostering acceptance among medical practitioners.

Acknowledgments

The authors would like to thank all members of the KINBIOTICS project and in particular the contact persons at the 3 hospitals (Evangelisches Klinikum Bethel, Klinikum Bielefeld Mitte, and Klinikum Lippe) for their support in conducting the interviews. Special thanks go to all the physicians who took part in the interviews and to Inga Heißenberg, who helped to prepare and conduct the interviews. Furthermore, we would like to thank Dr Timothy Mc Call for his support in translating the original quotations. The KINBIOTICS project was funded by the German Federal Ministry of Health (grant ZMVI1-2520DAT930). The funding organization was not involved in the data collection, evaluation, analysis, or writing of the manuscript.

Abstract

Background: The integration of collaborative robots (cobots) in industrial settings has the potential to enhance worker safety and efficiency by improving postural control and reducing biomechanical risk. Understanding the specific impacts of varying levels of human-robot collaboration on these factors is crucial for optimizing cobot use.

Objective: This study aims to investigate the biomechanical effects of different levels of human-robot collaboration on postural stability and control during simulated working tasks.

Methods: A total of 14 participants performed simulated cashier working activities under 4 different collaboration modalities, with increasing levels of cobot assistance: full (Fu), half robot touch (HRT), half robot (HRb), and full robot (FRb). Center of pressure trajectories were extracted from 2 force plates' data to calculate 4 posturography parameters—mean distance (MDIST), mean velocity (MVELO), 95% confidence ellipse area (AREA-CE), and sway area (AREA-SW)—which were analyzed to assess the impact of cobot intervention on postural control.

Results: Nonparametric tests showed significance in the effect of the collaboration modalities on the 4 analyzed parameters. Post hoc tests revealed that FRb modality led to the greatest enhancement in postural stability, with a reduction in MDIST (4.2, SD 1.3 cm in Fu vs 1.6, SD 0.5 cm in FRb) and MVELO (16.3, SD 5.2 cm/s in Fu vs 7.9, SD 1.1 cm/s in FRb). AREA-CE and AREA-SW also decreased significantly with higher levels of cobot assistance (AREA-CE: 134, SD 91 cm^2 in Fu vs 22, SD 12 cm^2 in FRb; AREA-SW: 16.2, SD 8.4 cm^2/s in Fu vs 4.0, SD 1.6 cm^2/s in FRb). Complete assistance of the cobot significantly reduced interindividual variability of all center of pressure parameters. In FRb modality, as compared with all other conditions, removing the weight of the object during loading or unloading phases caused a significant decrease in all parameter values.

Conclusions: Increased cobot assistance significantly enhances postural stability and reduces biomechanical load on workers during simulated tasks. Full assistance from cobots, in particular, minimizes postural displacements, indicating more consistent postural control improvements across individuals. However, high levels of cobot intervention also reduced the natural variation in how people balanced themselves. This could potentially lead to discomfort in the long run. Midlevel cobot assistance modalities can thus be considered as a good compromise in reducing biomechanical risks associated with postural stability at the same time granting a satisfactory level of user control.

human-robot collaboration; cobot assistance; postural control; biomechanical risk; ergonomics; collaborative robot

Introduction

Industrial manufacturing is transitioning from well-established production procedures toward more flexible and intelligent manufacturing systems (Industry 4.0, as initially described by Kagermann et al [1]). This evolution aims to develop innovative, sustainable solutions that create new business models, improve working conditions, increase plant productivity, and enhance product quality [2]. Robotics plays a crucial role in this context, with industrial robots being widely adopted due to their ability to relieve humans from repetitive, unhealthy, or dangerous tasks [3]. The field of robotics has evolved to not only allow humans to share the same workspace with robots but also use them as assistants, thereby enhancing human-robot collaboration (HRC) [4].

Collaborative robots (cobots) are at the forefront of this revolution, offering increased productivity, flexibility, versatility, and safety compared with traditional industrial robots. Cobots are designed to work alongside humans, sharing the same workspace without the need for safety cages and

XSL•FO
RenderX

providing greater mobility and flexibility [5]. The integration of cobots in industrial environments has been shown to significantly enhance operational efficiency [6] and worker satisfaction by enabling safer and more ergonomic working conditions [7,8]. However, the integration of cobots impacts various human factors, which include psychological aspects [9], emotions [10], and biomechanical effects [11]. Consequently, it is important to consider both cognitive ergonomics and biomechanical safety to optimize the overall effectiveness and well-being of human workers [12]. For instance, Gualtieri et al [13] have investigated the cognitive elements involved in human interaction with cobots, revealing significant insights into how mental workload and task complexity can affect worker performance and satisfaction [14]. Similarly, improper collaboration with cobots can expose workers to biomechanical risks, even though these robots are intended to alleviate heavy and tedious tasks. Previous research studies [15,16] emphasized the importance of ergonomic considerations in HRC to prevent musculoskeletal disorders (MSDs) among workers.

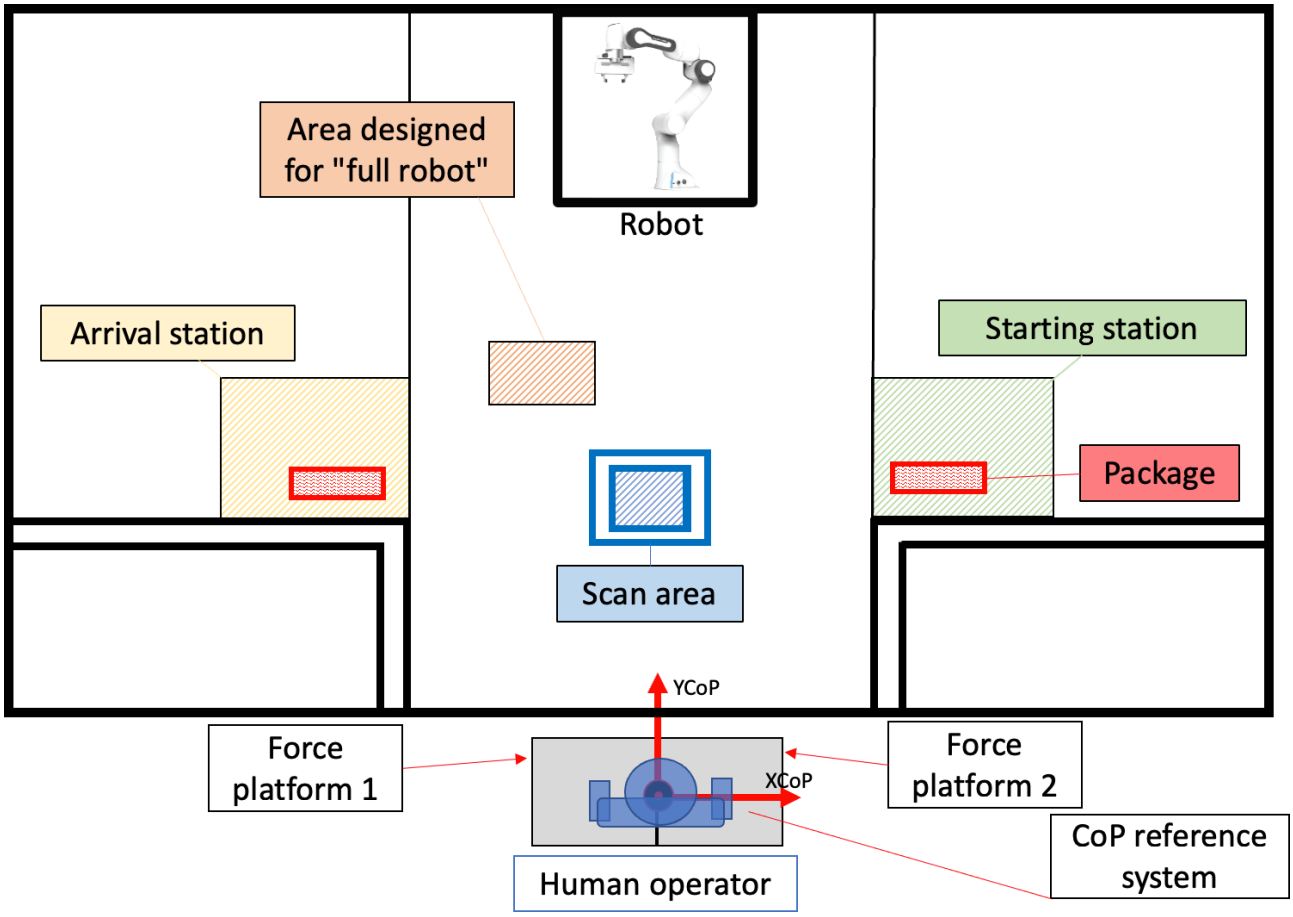
Thus, the right choice of cobot collaboration modality can reduce biomechanical overload on workers, ensuring their safety.

Recent advancements in sensor technology and data analytics have enabled detailed assessments of human biomechanics during HRC [17,18]. Studies have shown that real-time monitoring and analysis of physiological data can provide valuable insights into the physical strain experienced by workers and help in optimizing collaborative processes [19]. For example, the use of wearable sensors and motion capture systems could effectively measure and analyze the biomechanical load on workers during different collaborative tasks with robots [20]. Other recent studies investigated the effects of different HRC modalities on physiological human parameters such as trunk oscillations [21] and muscle coactivation [22,23]. Such studies can also be profitably taken into consideration for the optimization of workplace design and task allocation.

When work tasks are performed in quasi-static conditions, direct measures of posture could reveal insights into the stability and balance of workers and can thus be used to improve ergonomics during HRC, as they can help identify postural adjustments and biomechanical loads, providing a more comprehensive understanding of HRC ergonomic impact [24].

Following this principle, this study will evaluate and analyze posturography data to assess the biomechanical risks in HRC working contexts where cobots are used in different modalities. Through this evaluation, the study seeks to determine whether cobot assistance can effectively reduce biomechanical risks: by examining how different collaborative modalities influence workers' stability and balance, thus providing insights into the effects of cobot assistance on postural control, as this latter one indirectly reflects safety, efficiency, and ergonomic well-being of human workers in collaborative environments.

Methods



Experimental Setup

Overview

The setup was designed to compare a simulated work activity performed with and without cobot assistance. A specific workbench was created by positioning the cobot on one of the longer sides of a 2 × 1 m table, with the operator standing upright on the opposite side (Figure 1). The operator's standing position was fixed relative to the edge of the table, defined by the position of his or her feet and the projection onto the ground of the long side of the table. A starting station (ie, the initial position to the right of the operator) and an arrival station (ie, the final position to the left) were defined, each 1m apart from the other and 30 cm away from the operator in the direction of the cobot. A scanning area was defined in the center of the table in front of the operator. This workbench arrangement allowed the operator to perform all the activities (or part of them) independently, while the cobot could collaborate on some or none of the tasks without interfering with the operator's movements. This configuration was defined to minimize possible hindering of the operator's movements.

XSL•FO
RenderX

Figure 1. Experimental setup dimensioning for the simulation of load-moving activities on a workbench. CoP: center of pressure.

The activities involved the handling and relocating of rectangular packages, each measuring 14 × 12 × 5 cm and weighing 1 kg, bearing a QR code on one side.

The tests were conducted with a group of 14 male volunteers aged between 25 and 48 years (weight: 79, SD 7 kg; height: 180, SD 5 cm). All volunteers were healthy and had no evident or declared mobility issues. Moreover, given the design of the setup, only right-handed subjects have been involved in the tests. Participants were instructed to (1) grasp the packages from the starting station, (2) identify the QR code and scan it (ie, facing the QR code to the scan area) in the central area, and then (3) place the package in the arrival station. Different levels of collaboration were implemented by removing the first part of these activities (ie, grasping the package and bringing it to the center of the table) when in partial assistance, and removing also the last part (ie, bringing the package to the arrival station) when in full cobot assistance. Each participant was asked to perform the task as naturally as possible. This task was designed to simulate the work activity of a cashier in a supermarket, a highly relevant example in terms of strenuous activity [25], where an increase in the level of cobot assistance is hypothesized to reduce the associated biomechanical risk.

In the test, each participant performed consecutive repetitions of the same task, for a 5-minute duration, with different levels of cobot assistance.

The frequency of processing (packages per minute [PPM]) to be handled was not defined a priori, and participants were allowed to choose their own pace in performing all the activities. When collaborating with the cobot, the PPM frequency was however influenced by the cobot's package handling activity, as described below.

Each participant was asked to perform the described activity under 4 different collaboration modalities, performed in random order, with a 5-minute break between each test.

Full (Fu)

In this baseline scenario, the operator performs the tasks independently, without cobot collaboration. The operator picks up the package from the starting station with the right hand, examines it with both hands to locate the QR code, brings it close to the scanner simulation area, and finally places the package in the arrival station with the left hand. The processing rate was freely self-selected by each participant.

Half Robot Touch (HRT)

In this condition, the cobot task is to pick up the package from the starting station and wait for the operator to extend their right arm toward the same area, and to touch it to start. When touched, the cobot moves bringing the package in front of the operator who grabs and examines it with both hands to locate the QR code. The operator then brings it close to the scanner simulation area and finally places the package in the arrival station with the left hand. The task is kinematically like the "Full" case, but there is no lifting of the package from the starting station toward the scanning area. Moreover, the operator drives the activation of the cobot with a touch, and therefore the number of PPM is decided by everyone, taking into account the cobot speed.

XSL•FO
RenderX

Half Robot (HRb)

In this modality, the cobot's task is to pick up the package from the starting station and autonomously transport it in front of the operator, who grabs and examines it with both hands to locate the QR code. The operator then brings it close to the scanner simulation area and finally places the package in the arrival station with the left hand. The operator is not required to initially reach the right arm toward the starting station to ask the cobot for help, so the task is different in terms of kinematic features compared with the previous cases. Packages are moved continuously by the cobot while the operator is performing the required tasks, therefore, the cobot determines the number of PPM.

Full Robot (FRb)

In this condition, the cobot's task is to pick up the package from the starting station and autonomously transport it continuously in front of the operator, who grabs and examines it with both hands to locate the QR code. The operator then brings it close to the scanner simulation area and finally places the package in a closer area with respect to the arrival station (Figure 1). Meanwhile, the cobot picks up the package left by the operator and takes it to the arrival station. The cobot intervenes significantly, fully collaborating in the activity. However, the time taken by the cobot to move the packages always exceeds the time that the operator needs to perform the activity. Therefore, the operator must wait for the cobot, and the motor activity is discontinuous, with the number of PPM defined by the cobot kinematics.

Ethical Considerations

The experimental protocol was approved by the Commissione Etica dell'Università degli Studi Roma Tre (BRIC2019-BRISK approval r.01-10/06/2021). Informed consent was obtained from all participants prior to their inclusion in the study, and they were informed of their right to withdraw at any time without consequences. All data collected were anonymized to protect participants' privacy and confidentiality. No personally identifiable information was retained, and strict security measures were implemented to safeguard the data. Participants did not receive any financial or material compensation for their involvement in this study.

Data Acquisition and Processing

To assess the dynamic interaction of the operator with the ground, two 6-component force platforms (BTS P-6000) were positioned under the participants' feet. These platforms allow for measuring the ground reaction of each participant's lower limbs (force and moment components), from which the center of pressure (CoP) position of each foot is extracted during the execution of performed tasks. Data were acquired from force platforms using a sampling frequency of 500Hz (fixed by the HW system). An optoelectronic system (SMART DX 6000, 8 infrared cameras, 2 Mpixel@300 Hz) was employed to segment and identify each task repetition, and each phase of the repetition. Data from the optoelectronic system were acquired using a sampling frequency of 250Hz. Force platforms data were undersampled at 250 Hz to synchronize those with the optoelectronic system ones.

Dynamic Parameters Extraction

Trajectories of the CoP for each of the lower limbs (ie, CoP-right and CoP-left) during the execution of each task were extracted from the force plates data [26]. The total CoP is obtained as the weighted average between CoP-right and CoP-left and its displacement is defined by both the medial-lateral and the anterior-posterior coordinates with respect to a reference system centered between the 2 force plates (Figure 1).

Four CoP-derived parameters were calculated to evaluate the postural stability of the operator and quantify alterations in balance: for each of the collaboration modalities, the mean distance (MDIST), mean velocity (MVELO), 95% confidence ellipse area (AREA-CE), and sway area (AREA-SW) were calculated, according to the definitions reported in [27], for each cycle of the task repetition. For each parameter, mean values (as a measure of central tendency) and SD across repetitions (as a measure of intraindividual variability) were also calculated and underwent inferential statistics.

Cycles were identified using data extracted from motion capture data, which were synchronized with force plate data: in particular, the time location of the maximum excursion to the left in the medio-lateral direction of the marker placed on the right wrist was used to segment each cycle, as it corresponds to the instant when each repetition finishes.

Statistical Analysis

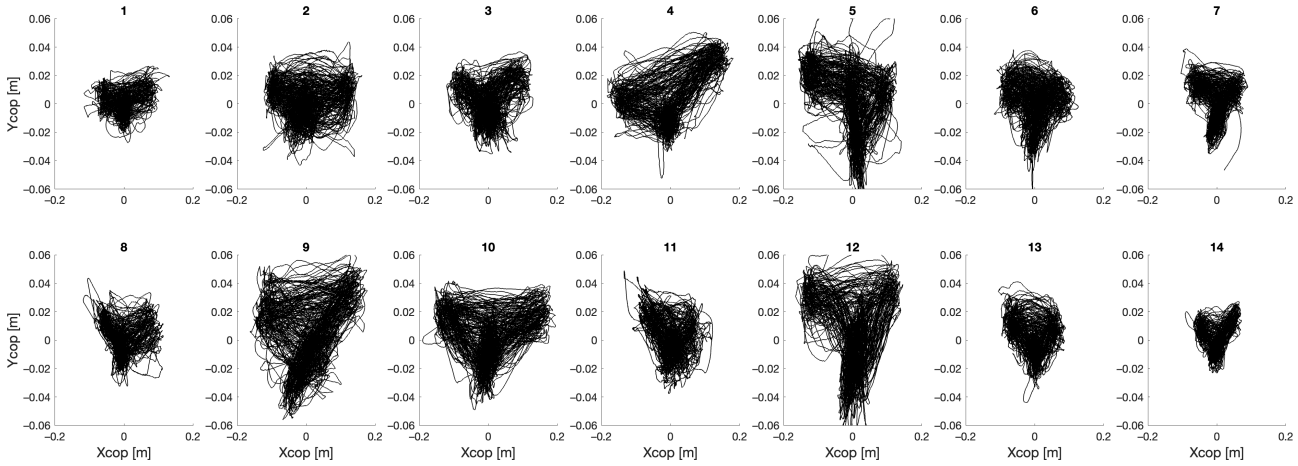
For each CoP-derived parameter thus obtained, the normality of the data, using the Shapiro-Wilk test, was assessed. When all distributions were normal, the homogeneity of the variances was checked with the Leneve test. If these conditions were not satisfied, the Kruskal-Wallis nonparametric test was applied to examine the effect of the collaboration modality. When significant, a post hoc test with a Bonferroni correction was conducted to investigate the differences among the 4 examined collaboration modalities. The α level was set to .05 and .01 (denoted by * and **, respectively).

Results

Rate of Package Processing

The average rate of package processing chosen by the operators in the absence of cobot assistance (Fu) was 15 (IQR 14-16) PPM. The different cobot collaboration modalities yielded median rates of 8 (IQR 7-8.5) for PPM for half robot touch (HRT), 12 (IQR 11.5-13) PPM for half robot (HRb), and 4 (IQR 3.9-4.1) PPM for full robot (FRb).

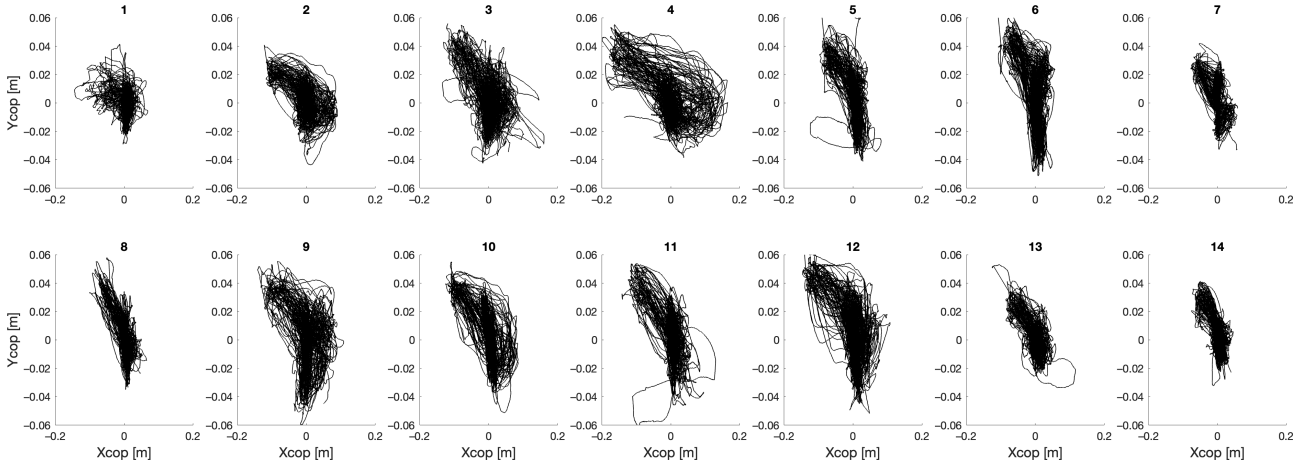
CoP Trajectories



In the following, the different trajectories of the CoP, for all 14 participants and for the 4 different collaboration modalities (ie, full [Fu], HRB, HRb, and FRb) are shown, with Xcop and Ycop denoting respectively the medium-lateral and the antero-posterior coordinate.

Considering the Fu modality (Figure 2), observed CoP paths can be classified into 2 main groups: participants (1,2,3,6,7,8,11,13,14) displayed a compact size of the CoP path, spread in both anterior-posterior (AP) and medial-lateral (ML)

XSL•FO
RenderX



directions, while participants (4,5,9,10,12) drew wider areas, with a remarkable trajectory from the central backward position to the right forward position. However, all the CoP paths present quite diverse behavior, with no visible common aspects. Negative values for Ycop denote backward displacements.

Figure 2. Center of pressure (cop) trajectories for each participant during the full collaboration modality.

Considering the HRT collaboration modality (Figure 3), CoP path can be classified into 2 main groups also in this case: participants (1,2,7,8,13,14) maintained a compact size of the CoP path, more spread along the AP direction, while participants (3,4,5,6,9,10,11,12) drew a wider area of the CoP path. In this case, all CoP trajectories denoted a bias from the central backward position to the left forward position. Displayed CoP paths still exhibit rather diverse behavior, but with more commonalities as compared with Fu modality.

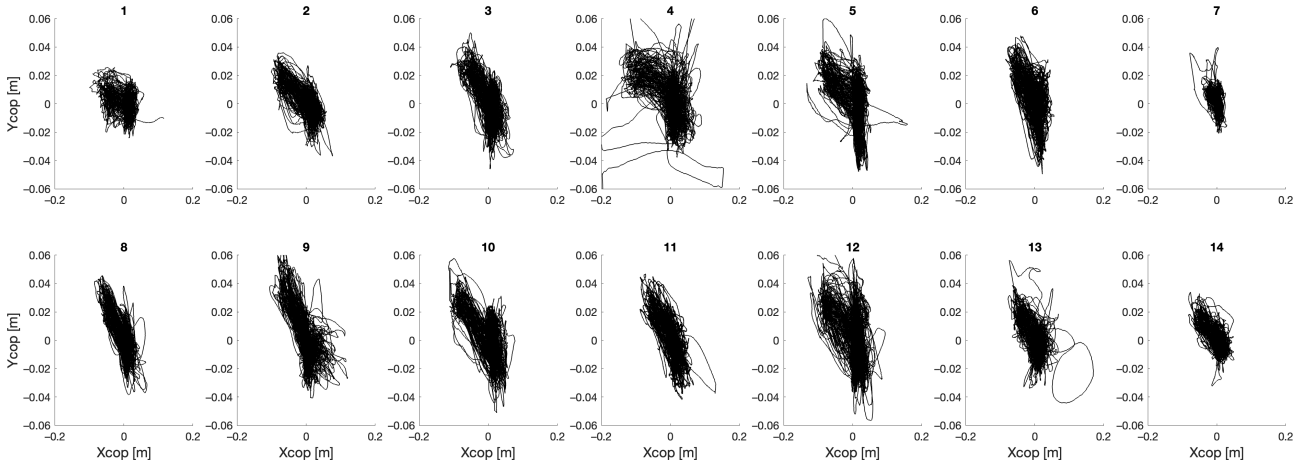


Figure 3. Center of pressure (cop) trajectories for each participant during the half robot touch collaboration modality.

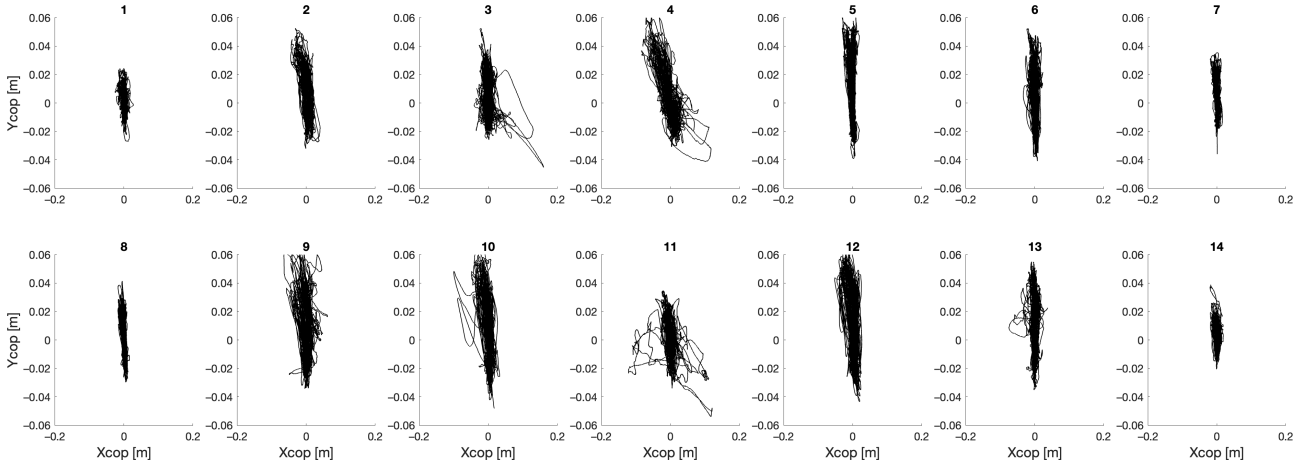
For the HRb collaboration modality (Figure 4), also in this case CoP path can be classified into 2 main groups: for participants (1,2,7,13,14) CoP path was maintained compact, differently from participants (3,4,5,6,8,9,10,11,12), especially considering the AP coordinate. Common behavior of CoP excursion across subjects was instead present along the ML coordinate, while the CoP bias from the central backward position to the left forward position observed in the HRT case is less evident.



XSL•FO
RenderX

Figure 4. Center of pressure (cop) trajectories for each participant under the half robot collaboration modality.

In the FRb collaboration modality (Figure 5), commonalities of CoP behavior are more relevant. While some participants still display lower excursions along the AP direction, the characteristics of CoP trajectories are mostly similar, with no bias both in the right and left forward positions. The amount of excursion in the ML direction is similar across participants.

Figure 5. Center of pressure (cop) trajectories for each participant during the full robot collaboration modality.

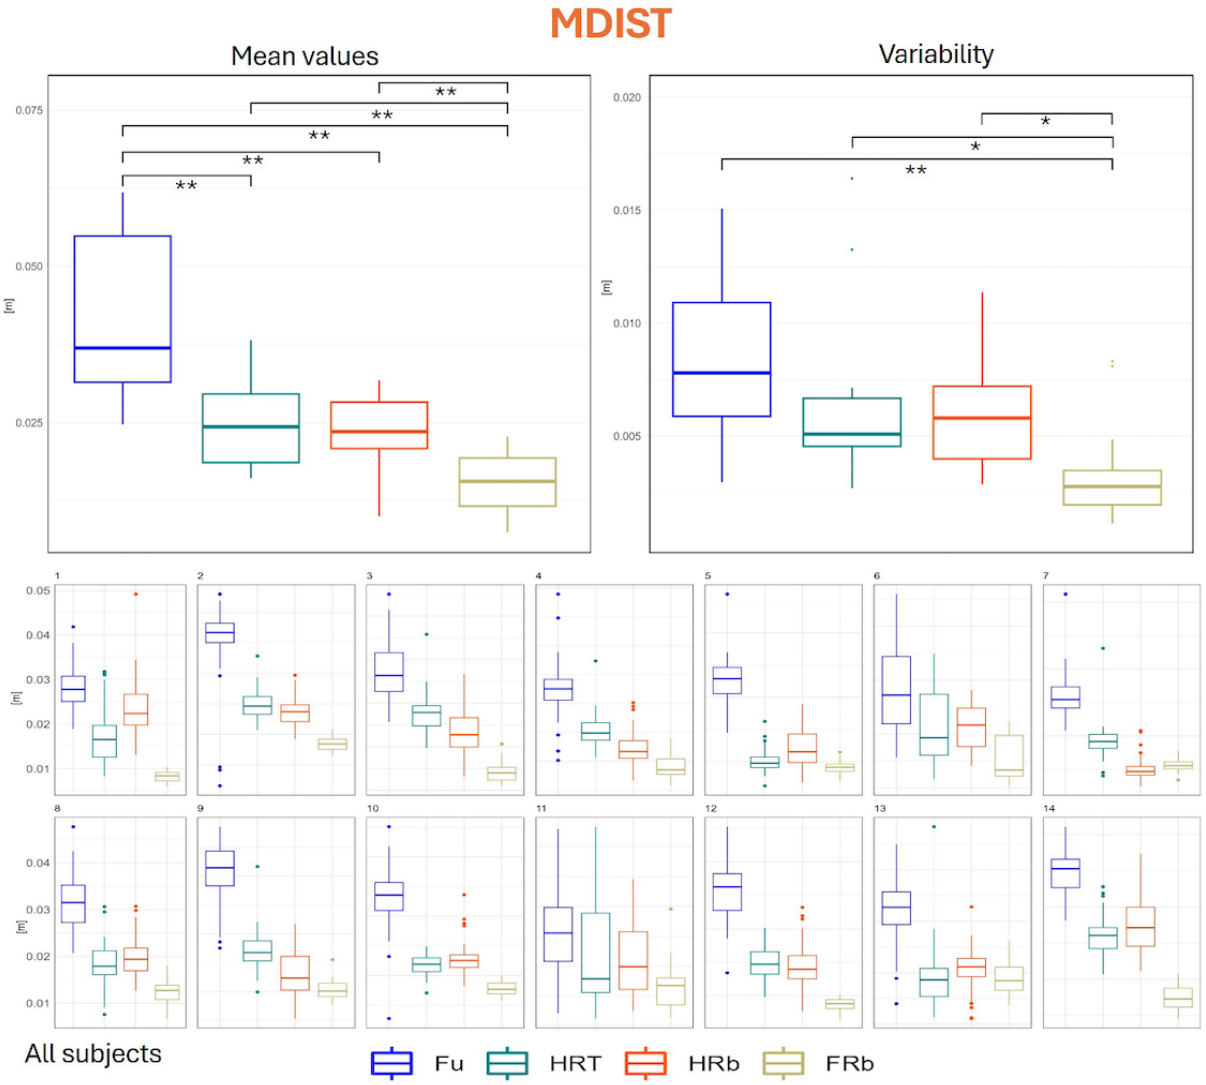
Normality Tests

The Shapiro-Wilk test indicated that some conditions of the parameters did not follow a normal distribution. For the MDIST values, a *P* value <.05, indicating rejection of the null hypothesis of normal distribution, was observed for the Fu condition (*P*=.048). In contrast, a normal distribution (*P* value >.05) was found for all the other conditions (HRT: *P*=.44; HRb: *P*=.57; FRb: *P*=.60).

Similar results were obtained for both the AREA-CE and AREA-SW parameters. The Fu condition showed a nonnormal distribution (*P*=.02 for AREA-CE and *P*=.04 for AREA-SW), while all other conditions were normally distributed (for AREA-CE: HRT, *P*=.18; HRb, *P*=.25; FRb, *P*=.33; for AREA-SW: HRT, *P*=.08; HRb, *P*=.86; FRb, *P*=.25).

Since at least 1 of the distributions for each parameter was not normal, nonparametric statistical analyses were applied.

For the MVELO parameter, data were normally distributed across all conditions. However, Levene test revealed that the variances among the different conditions were not homogeneous (*P* value <.05). Consequently, a nonparametric test was also used for this parameter.



CoP-Derived Parameters

Descriptive statistics at the individual level, and descriptive and inferential statistics at the group level for MDIST, MVELO, AREA-CE, and AREA-SW, as obtained across the 4 collaboration modalities, are given in the following figures.

MDIST, an overall measure of excursion of the CoP from its equilibrium position, was clearly and significantly higher in Fu condition (4.21, SD 1.30 cm) than in all other conditions, and this was confirmed also at the individual level for almost every participant. In addition, as shown in Figure 6, FRb condition caused significantly lower values (1.55, SD 0.50 cm) than both HRT (2.50, SD 0.67 cm) and HRb (2.38, SD 0.59 cm), and this appeared also in all individuals but 2. No significant difference was observed between HRT and HRb conditions, as the result of different behavior across participants. Regarding intraindividual variability, we observed a reduced variability of MDIST across most participants in FRb condition (0.34, SD 0.22 cm) as compared with HRb (0.59, SD 0.23 cm), HRT (0.65, SD 0.37 cm), and Fu (0.85, SD 0.36 cm).

XSL•FO
RenderX

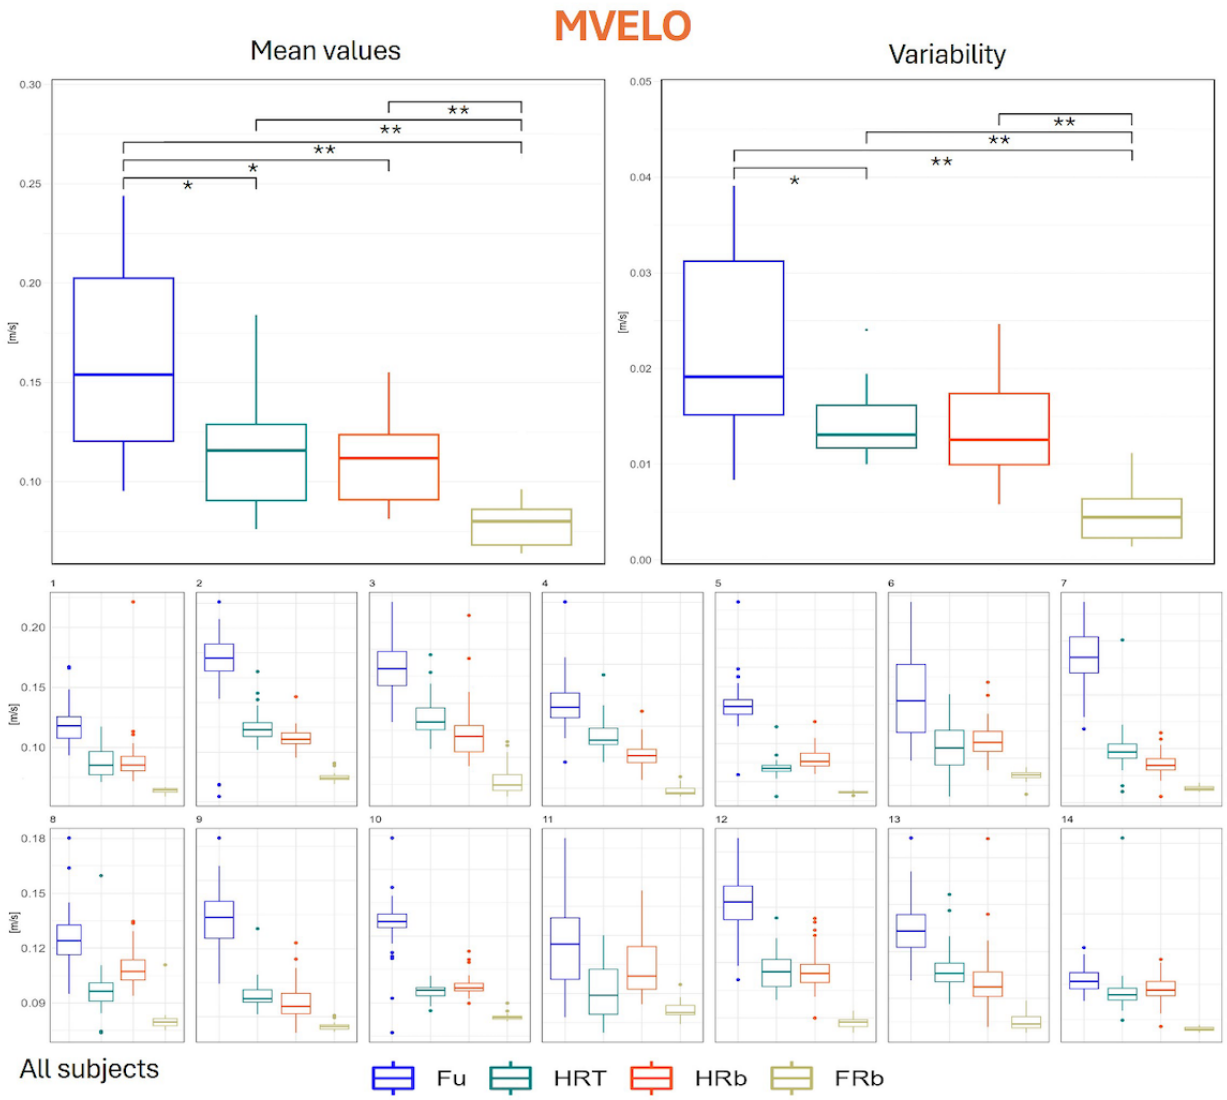


Figure 6. Distribution of MDIST values. Upper panel, left: group mean values across the 4 collaboration modalities; upper panel, right: distribution of intraindividual variability (SD across repetitions); lower panels: distribution of values for each participant. * denotes $P<.05$ as obtained from inferential statistics; ** denotes $P<.01$ as obtained from inferential statistics. FRb: full robot; Fu: full; HRb: half robot; HRT: half robot touch; MDIST: mean distance.

MVELO, an indicator of the amount of movement described by the CoP trajectory, in general confirms what already reported for MDIST: Fu condition determined higher values (16.3, SD 5.2 cm/s) than all other collaboration conditions, and in FRb, MVELO was significantly lower (7.9, SD 1.1 cm/s) than in all other conditions (11.1, SD 2.2 cm/s for HRb; 11.3, SD 2.9 cm/s for HRT). As depicted in Figure 7, these figures were confirmed also at the individual level for all but 2 participants. In terms of variability, while we observed that it was mostly reduced in the FRb condition (0.5, SD 0.3 cm/s) as compared with all the other conditions (2.3, SD 1.0 cm/s for Fu; 1.4, SD 0.5 cm/s for HRb), a significant decrease of the variability was present also when moving from Fu to HRT (1.4, SD 0.4 cm/s). Other variations were not significant at the group level.

XSL•FO
RenderX

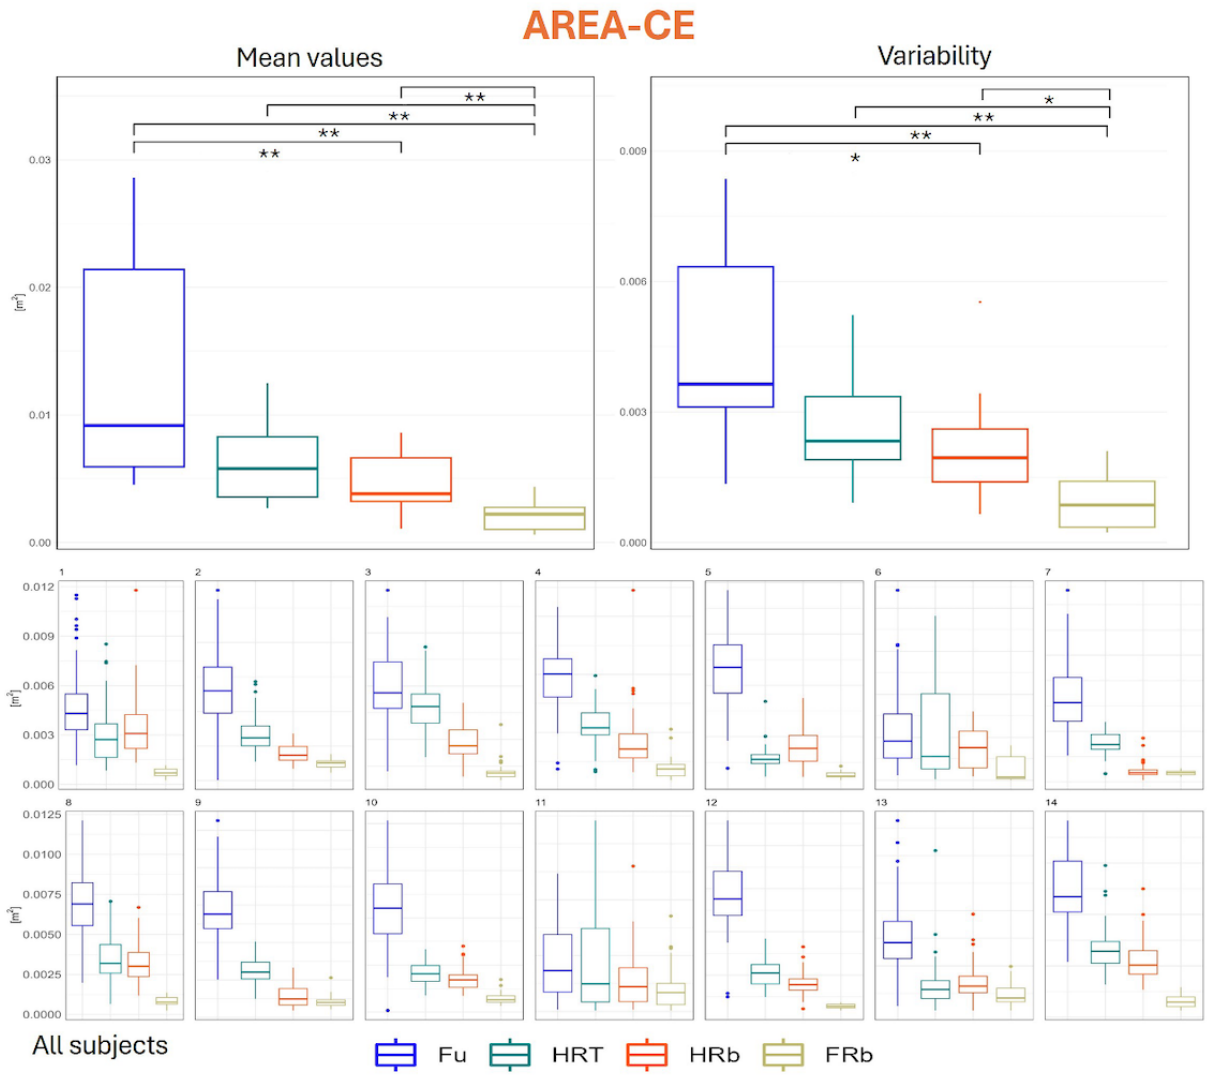

Figure 7. Distribution of MVELO values. Upper panel, left: group mean values across the 4 collaboration modalities; upper panel, right: distribution of intraindividual variability (SD across repetitions); lower panels: distribution of values for each participant. * denotes *P*<.05 as obtained from inferential statistics; ** denotes *P*<.01 as obtained from inferential statistics. FRb: full robot; Fu: full; HRb: half robot; HRT: half robot touch; MVELO: mean velocity.

AREA-CE, which quantifies the planar extent of coverage of the CoP, displayed a behavior similar to what was seen for MVELO: values resulted significantly higher in Fu (134, SD 91 cm²), and lower in FRb (22, SD 12 cm²) than in all the other conditions (64, SD 32 cm² for HRT; 47, SD 24 cm² for HRb), respectively (Figure 8). Again, FRb intraindividual variability was lower in FRb (10, SD 7 cm²) than in all other conditions, and we saw a reduced variability when passing from Fu (45, SD 23 cm²) to HRb (21, SD 12 cm²).

XSL•FO
RenderX

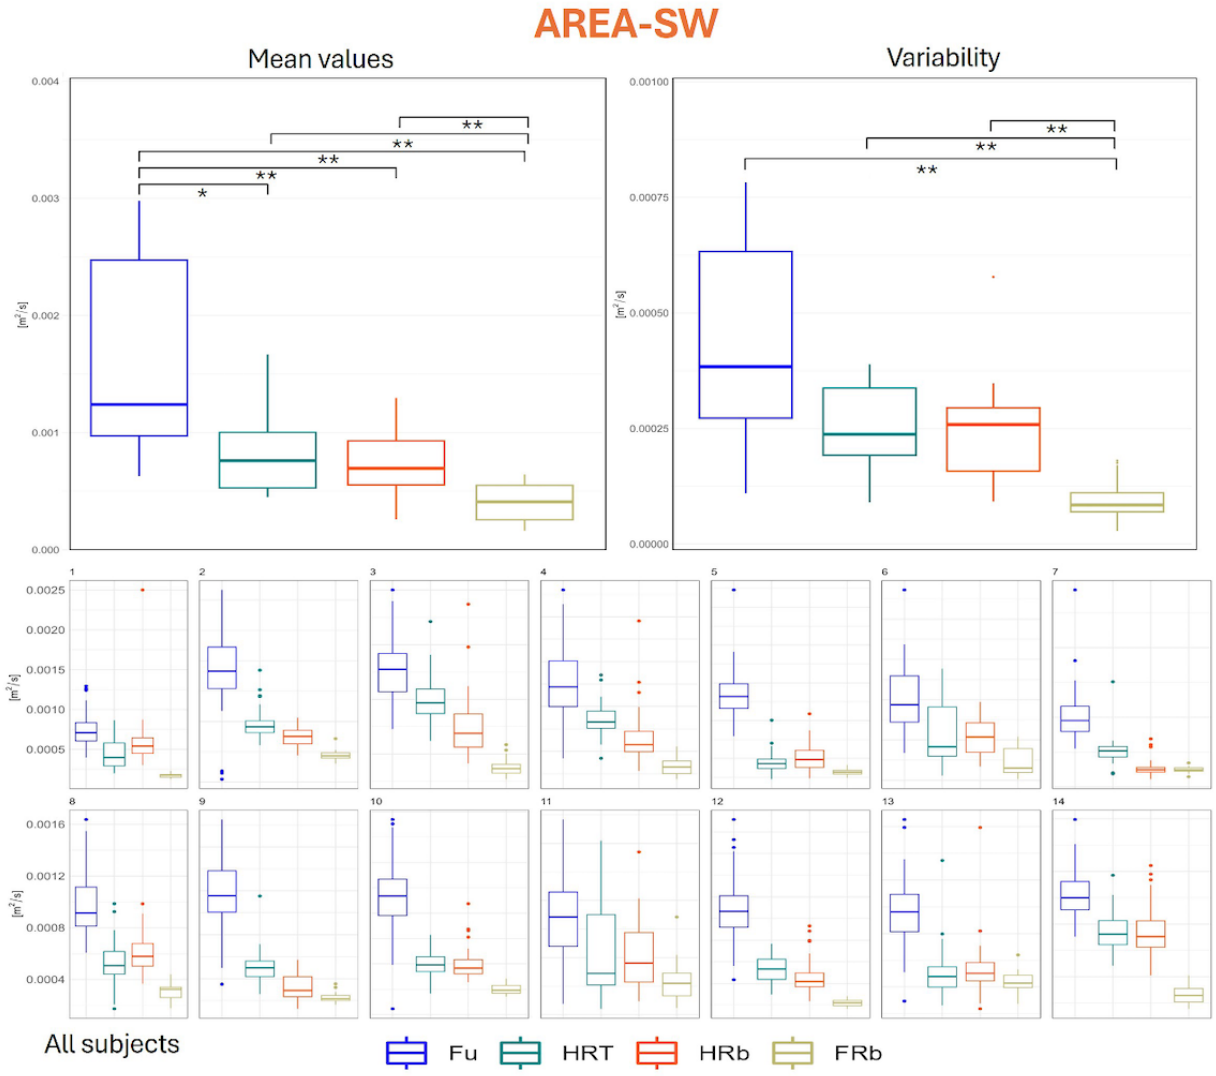

Figure 8. Distribution of AREA-CE values. Upper panel, left: group mean values across the 4 collaboration modalities; upper panel, right: distribution of intraindividual variability (SD across repetitions); lower panels: distribution of values for each participant. * denotes *P*<.05 as obtained from inferential statistics; ** denotes *P*<.01 as obtained from inferential statistics. AREA-CE: confidence ellipse area; FRb: full robot; Fu: full; HRb: half robot; HRT: half robot touch.

Finally, AREA-SW, a planar measure that combines CoP extension and velocity, displayed behavior similar to what obtained with MDIST: Fu caused significantly higher AREA-SW values (16.2, SD 8.4 cm²/s) than all the other conditions (8.4, SD 3.7 cm²/s and 7.3, SD 2.8 cm²/s for HRT and HRb, respectively), and again FRb brought to values lower (4.0, SD 1.6 cm²/s) than all the other collaboration modalities (Figure 9). Both these results were reflected at the individual level for all participants but one. Intraindividual variability of AREA-SW was significantly lower in FRb (0.9, SD 0.4 cm²/s) than in all other conditions (4.4, SD 2.2 cm²/s; 2.5, SD 0.8 cm²/s; and 2.5, SD 1.2 cm²/s for Fu, HRT, and HRb, respectively).

Upper panel, left: group mean values across the 4 collaboration modalities; upper panel, right: distribution of intraindividual variability (SD across repetitions); lower panels: distribution of values for each participant. * denotes *P*<.05 as obtained from inferential statistics; ** denotes *P*<.01 as obtained from inferential statistics. AREA-SW: sway area; FRb: full robot; Fu: full; HRb: half robot; HRT: half robot touch.

Discussion

Principal Findings

The analysis of the CoP trajectories shows that considering data obtained in tests going from the absence of cobot intervention (Fu) to the ones with maximum cobot assistance (FRb), the area of the CoP trajectory significantly decreases, thus possibly indicating a lower amount of oscillations of the body when the cobot intervenes.

As a general consideration, CoP trajectories, when no action of the cobot is present, tend to show greater intensity toward the loading area, indicating a higher amount of sway. This suggests that lifting affects balance control strategies. On the other hand, in both tests involving partial cooperation with the cobot, the CoP draws trajectories mainly toward the arrival station, even in the HRT modality, where the participant's arm moves toward the starting station direction to ask the cobot for help. This aspect suggests that the movement of the arm while carrying the load notably influences the CoP trajectory, while the arm movement, required to ask the cobot for help occurring in the HRT condition, does not produce a significant influence on the CoP trajectory, as compared with the modality where the cobot independently carries the load to the scanning zone (ie, HRb collaboration modality).

Regarding the detailed analysis of the specific CoP trajectories of all subjects and for all test types, results show that during tasks performed alone, CoP paths can be classified into two types: (1) concentrated with symmetrical movements toward both the starting and arrival stations (right and left), and (2) more scattered with a tendency to oscillate between the central rest zone and the arrival station (left). The variability of CoP trajectories across individuals may confirm the adoption of different independent control strategies, as also identified by the 2 types listed before. When instead maximum assistance by the cobot is present, areas drawn by CoP are smaller, and with a reduced interindividual variability. This homogenization effect can be explained by the fact that the cobot sets the activity's pace, causing the subject to adopt a more uniform behavior and timing. This is both apparent at the individual level (ie, each

XSL•FO
RenderX

subject tends to maintain a more uniform CoP trajectory across repetitions), and at the group level.

Results coming from the qualitative description of CoP trajectories were also confirmed by statistical analysis of CoP-derived parameters: specifically, CoP tends to travel more (MVELO and, to a certain extent, AREA-SW) and further (MDIST and AREA-CE) if the level of intervention from the cobot increases. In general, smaller excursions can be associated with improved balance: this means a higher tendency to remain in a smaller (and generally more stable) area during task repetitions. A possible interpretation is that while the cobot influences task execution, it also makes the operator move less with reduced postural oscillation. This aspect is relevant as an increased excursion from the equilibrium position and increased movement of the CoP are associated with an increased risk of falling [28], and incorrect postures in the working scenario are agreed to lead to the development of MSDs [29]. As seen from this perspective only, the modality of full assistance by the cobot brings to the lowest risk, as it clearly leads to minimal excursions and movements of the body.

However, we also observed a marked reduction of intraindividual variability of these parameters when full assistance from the cobot is present: one hypothesis for this evidence is that the presence of the cobot reduces autonomy in task execution and may thus impose a control strategy which is not necessarily beneficial (or chosen) by the operator. If a reduction of variability of such parameters from the baseline condition may be seen as an indicator of long-term discomfort, this needs to be appropriately considered when designing the most beneficial collaboration modalities. In this regard, intermediate collaboration modalities seem to incorporate a tradeoff between the advantages in the carrying task compensation given by the cobot on the load and the possibility of granting autonomy to the operator during the task execution.

Regarding the 2 collaboration modalities that maintain a material operator intervention, statistical analysis at the group level was rather inconclusive: in excursion-based CoP parameters, no difference was found, and this is counterintuitive, considering that one of the modalities required participants to raise the arm and kinematically reach out to ask for assistance. This was not reflected in most CoP-derived parameters, and the possible explanation for this absence of differences may be ascribed to the inherent nature of the CoP variable: it is only indirectly associated with whole body movement: coming from the ground reaction forces, it is a measure of where the foot pressure is concentrated [30]. In static conditions, CoP basically tracks the body barycenter projection to the ground (and dynamically overtakes it in specific conditions) to counteract balance disequilibrium. According to the inverted pendulum hypothesis, the body barycenter projection is thus a filtered version of the CoP trajectory. However, with self-initiated body part movements, the central nervous system is able to predict future whole-body excursions [31], and the position of the CoP may not necessarily reflect the excursions of the body barycenter. If this were the case, activation of the relevant muscles (typically, tibialis anterior) would appear in anticipation of the upper limb movement.

Regarding the inconclusive results appearing between the 2 modalities where collaboration was midlevel (ie, HRb and HRT), we tend to ascribe this process to a rather diverse behavior observed at the individual level: decreases of measures of CoP excursion and movement were in some individuals clear when decreasing the amount of user intervention (ie, passing from HRT to HRb), however this effect disappears in a nonnegligible share of individuals; as it was apparent from the qualitative description of CoP trajectories, 2 different group behaviors seemed to emerge: in one group, CoP is maintained compact despite the lesser level of cobot intervention as compared with FRb, while the second group displays higher amounts of excursion and movement. We were not able to ascribe this phenomenon to specific individual characteristics; whole body kinematics and electromyography activity analysis may help shed light on this, in particular, to check if this evidence might be associated with task role-taking, which may be a key factor in HRC activities [32].

Reduced postural variability, as evidenced by the decreased CoP trajectory area and reduced inter and intraindividual differences under maximum cobot assistance, can have significant long-term implications for musculoskeletal health. A prolonged state of limited variability in posture and movement, while potentially stabilizing in the short term, may contribute to the development of MSDs over time. This is because variability in postural strategies allows the redistribution of mechanical loads across different tissues and joints, reducing the risk of overuse injuries or chronic strain on specific musculoskeletal structures. Conversely, homogenized and repetitive postures imposed by external systems, such as cobots, may lead to localized fatigue, reduced muscular engagement, and impaired adaptability of the neuromuscular system. Consequently, these factors can heighten the susceptibility to cumulative trauma disorders, particularly in dynamic occupational scenarios. These findings highlight the importance of designing collaborative robotic systems that balance task support with opportunities for natural and varied movement patterns to mitigate potential long-term health risks for operators.

The implications of these findings for industrial settings may be interesting. The integration of cobots can significantly enhance worker safety and productivity by reducing physical strain and improving postural control. By enabling safer and more ergonomic working conditions, cobots can play a crucial role in creating healthier work environments, reducing the incidence of work-related MSDs, and improving worker satisfaction.

In general, referring to the obtained results, it must be remarked that the tasks analyzed were simulated rather than conducted in real-world contexts, so further analysis could be conducted to generalize the findings. However, the tests conducted in this study, even if simulating a cashier task, represent real work tasks themselves, and this supports the hypothesis that similar results can be obtained in the real world. Additionally, the sample consisted exclusively of young male participants, so a direct validation on female subjects and older ones was not conducted. Rather than a limit, this might be seen as a validation for the examined population, although it can be extended to other worker categories.

Conclusions

This study investigated the biomechanical impact of various levels of HRC on postural control during working tasks while standing, providing substantial insights into the benefits of cobot assistance for workers' safety and ergonomics. Through an analysis of CoP trajectories and related parameters, it was found that higher levels of cobot collaboration, particularly in the HRT, HRb, and FRb modalities, significantly improved postural stability and reduced biomechanical load on workers. These findings suggest a decreased risk of MSDs, as evidenced by lower values in CoP-derived parameters when cobot assistance increases. The study also highlighted that the intraindividual variability of CoP parameters diminished when levels of cobot involvement were increased: this indicates on one side that cobot integration promotes more uniform ergonomic benefits across different individuals, but at the same time it may tend to impose a similar behavior in balance control which can lead subjects to adopt less ecological strategies.

Moreover, while participants can set autonomously their repetition pace, HRC activities will determine an increased homogenization of repetition rhythm (or parts of it) across workers, and this may potentially lead to decrease ergonomics, as subjects can feel forced to perform the required tasks based on timings dictated by HRC. Intermediate collaboration modalities, such as HRT, can provide both advantages in terms of reduction of CoP-derived parameters—that can be indirectly associated with a reduced biomechanical risk—with the possibility of selecting a more comfortable rhythm in executing tasks.

However, further research is needed to explore the long-term effects of cobot assistance on worker health and productivity. In particular, future studies should include other sensing technologies, able to capture the neuromechanics of HRC. In addition, application to diverse populations and real-world industrial settings to generalize the results and provide a more comprehensive understanding of the benefits and potential challenges of cobot integration. Additionally, exploring the psychological and social impacts of working with cobots on employees would provide a holistic view of the implications of collaborating scenarios in industrial environments: if properly integrated into working environments cobots can potentially revolutionize industrial work by enhancing safety, efficiency, and ergonomic well-being, facilitating the development of more intelligent and flexible workrooms and working conditions.

Abstract

Background: Biofeedback is an established treatment principle for migraine, but home-based therapy with proven efficacy is not available.

Objective: This study aims to assess the feasibility, usability, and safety of 12 weeks of daily use of a novel medical device (Cerebri; Nordic Brain Tech AS) for therapist-independent multimodal biofeedback preventative treatment in adults with episodic migraine.

Methods: In this open-label, one-armed trial, 20 adult participants with episodic migraine used Cerebri for 12 weeks. The primary outcome was the feasibility of the Cerebri system, measured by the level of adherence to daily biofeedback and electronic headache diary (eDiary) entries. Secondary outcomes were safety, usability, and efficacy.

Results: Initial adherence to biofeedback was high (16/20, 80% in weeks 1 - 4), declining to 20% (4/20) by weeks 9 - 12. eDiary adherence remained high (15/20, 75% in weeks 9 - 12). Reduction in migraine days was not significant (–0.6, 95% CI –2.4 to 1.1 days; *P*=.47). App usability was impacted by software issues. No safety concerns were reported.

Conclusions: Cerebri demonstrates potential in self-managed migraine treatment, with strong initial engagement and high safety. Usability issues, including technical bugs, were identified as the most important modifiable cause for the decline in adherence. This highlights the need for further app refinement to sustain user engagement.

Introduction

Migraine is a complex and multifactorial disease and includes autonomic dysregulation and alterations in stress-related behavior [1-3]. Notably, patients with both chronic and episodic migraine have reduced heart rate variability (HRV) in comparison to healthy controls [4,5]. Biofeedback uses technology to monitor physiological processes that are typically modulated unconsciously [6-8]. Humans can learn to modulate these physiological processes by receiving continuous feedback from them [6-8]. Biofeedback training has been linked to a range of positive health effects, including reduced severity of migraine symptom burden [7,9]. A recent study has shown biofeedback's ability to alter HRV in a migraine population [10], and meta-analytical evidence suggests that biofeedback-based interventions are effective in the prophylaxis of migraine [11]. However, despite its efficacy, biofeedback is not widely used. An observational study from a specialized headache care center found that patients with migraine referred for biofeedback therapy face various obstacles to pursuing treatment, including issues related to time constraints, financial obstacles (including, but not limited to, health care insurance), and limited provider availability [12]. Traditional biofeedback training requires a trained therapist and costly and cumbersome equipment, thus limiting use to specialized clinics. Digital therapeutics and mobile health (mHealth) provide great potential for increased access to self-administered nonpharmacological treatments [13,14]. Despite this potential, we are not aware of any market-available, therapist-independent migraine biofeedback treatment with proven efficacy [15].

To fill this gap, we have developed a multimodal biofeedback system for independent home-based use. Two development and usability studies on progenitor versions of the system have already been published, but with short test periods (4 and 2 wk home testing) [16,17]. A small sham-controlled trial in adolescents tested a previous version of the medical device for 8 weeks [18]. The trial was prematurely halted due to the COVID-19 pandemic and included only 16 participants (4 sham). Poor adherence (40% in wk 5 - 8) hampered the interpretation of the trial results. The purpose of this study is to assess the feasibility, usability, and safety of 12 weeks of daily use of a home-based biofeedback system as a preventative in adults with episodic migraine. The findings of the study are intended to lead to refinements in the feasibility and usability of Cerebri (version 0.1.0; Nordic Brain Tech AS) and guide study design choices for a future randomized controlled trial.

Methods

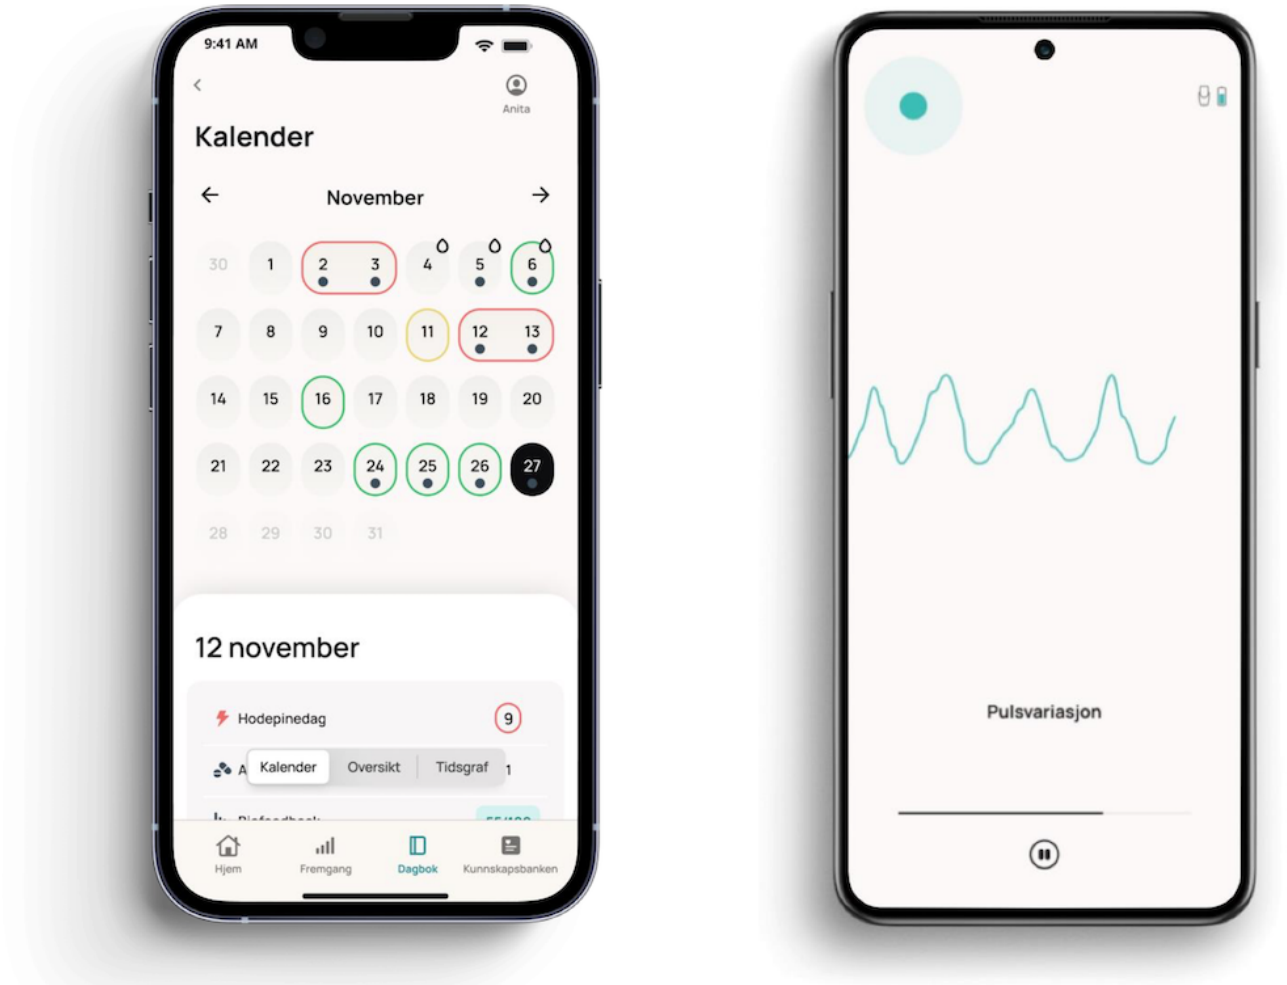
Study Design and Participants

The study was a single-center, open-label, one-armed interventional trial conducted at St. Olav's University Hospital in Trondheim, Norway, from May 2022 to September 2022. The target population was adults with episodic migraine from all of Norway. The total duration of study participation for each participant was 12 weeks.

Inclusion criteria were (1) 18 years of age or older, (2) episodic migraine with or without aura diagnosed by a neurologist or physician per the International Classification of Headache Disorders, Third Edition, (3) having kept a headache diary with at least 80% adherence as part of routine clinical care in the last 28-days prior to inclusion, (4) 4 to 14 migraine attacks per 28-day period in the 3 months prior to screening, (5) at least three months of experience with smartphone and access to an iOS or Android phone at home, (6) onset of migraine before the age of 50 years, and (7) signed written informed consent.

Exclusion criteria were (1) having a continuous background headache that never disappears completely; (2) more than 14 days of headache (all types) per 28-day period; (3) participants diagnosed with trigeminal autonomic cephalalgias and neuralgias or (4) secondary headache conditions including medication overuse headache according to the International Classification of Headache Disorders 3rd edition; (5) participants with pathologies that inhibit use of the device according to the instructions for use (eg, blindness and deafness); (6) participants currently using migraine prophylaxis (pharmacological or nonpharmacological); (7) participants who have previously failed 3 prophylactic pharmacological treatments; (8) opioid use (>3 d per month) or use of barbiturates at time of screening; (9) alcohol overuse according to The International Classification of Diseases, Tenth Revision, Clinical Modification Code F10.1 or illicit drug use; (10) participation in another clinical investigation; and (11) participants unlikely to follow Clinical Investigation Plan or where treatment seems futile in the opinion of the Investigator or have demonstrated an inability to sufficiently adhere to headache diary entries (<80%).

Interventions



The medical device tested in this study is a therapist-independent biofeedback system (Cerebri) consisting of a smartphone app (Figure 1) and 2 noninvasive wireless sensors (Figure 2). One sensor measures neck muscle tension as surface electromyographic (EMG) voltage from the skin over the upper trapezius muscle. The other sensor is placed on one index finger to measure HRV by photoplethysmography and peripheral skin temperature. As part of the product development, validation of sensor performance showed agreement with simultaneous control measurements made with stationary neurophysiological equipment [19]. The 12-week treatment phase with Cerebri consisted of daily biofeedback therapy sessions of a minimum of 10 minutes duration each.

Since the device is intended for independent use without the need for any supervision, no instructional sessions were offered upon receipt of the device or during the course of the study. A limited, written step-by-step on-screen guidance was provided to onboard the participant prior to the first 3 biofeedback sessions. The participants were introduced to 3 biofeedback modalities with real-time on-screen feedback: temperature biofeedback during the first session, HRV biofeedback in the second session, and EMG biofeedback in the third session. During the remaining sessions, the participants could freely alternate between the 3 modalities at their own discretion. Additional user instructions were provided in a user manual and in a library in the app, where the users could read more about biofeedback and relaxation techniques. During the

XSL•FO
RenderX

biofeedback sessions, an adjustable breathing pacer was accessible to users.

Study Follow-Up

All study visits were conducted remotely, and the sensor kit was sent by postal service. Participants accessed the app through a unique link provided via email, compatible with both Android and iOS devices. The app required an initial internet connection for download, but could subsequently operate without an active internet connection. Follow-up included 2 video consultations with a neurologist (IGW) at inclusion and the 12-week final visit; and 3 telephone follow-ups (wk 2, 4, and 8) with a study nurse. Participants were required to keep the daily eDiary integrated with the smartphone app throughout the study participation. Notifications for performing daily biofeedback sessions and diary entries were available for iPhone users, but did not work for Android users in the trial. Android users were therefore encouraged by study personnel to add a reminder manually in the integrated phone calendar to ensure this. The issue was persistent throughout the trial. Although participants were asked to register daily, the eDiary allowed registration within a 3-day interval (present day, and the 2 previous days). eDiary users were first asked if they had a headache or not. If a headache was reported, the app prompted the participant to answer additional questions about the type of headache (migraine or other), as well as the duration, intensity, and medication use. Questionnaires regarding usability and efficacy were collected via Helsenorge.

Outcome Measures

Overview

The primary objective of this study was to investigate the feasibility of the Cerebri biofeedback system as a preventative treatment in adults with episodic migraine. Key secondary objectives were to (1) assess usability, (2) assess the user experience, (3) assess the safety and tolerability, and (4) evaluate data on the efficacy of the intervention, recognizing that the study was not specifically designed or powered for an efficacy analysis.

Assessment of Primary Outcome

The feasibility of Cerebri was evaluated by assessing the level of adherence to daily biofeedback sessions and daily eDiary entries. Adherence was defined as the percentage of completed sessions and eDiary entries per 28-day period. On a given day, adherence was defined as the completion of a 10-minute biofeedback session or a completed eDiary entry, respectively.

Assessment of Secondary Outcomes

Usability, satisfaction, and ease of use of the device were assessed using a Norwegian translation of the mHealth App Usability Questionnaire (MAUQ) [20]. Questionnaires were collected at weeks 1 and 12. The MAUQ contains 18 items distributed across three subscales: (1) ease of use (5 items), (2) interface and satisfaction (7 items), and (3) usefulness (6 items). Responses for each item were recorded on a 7-point scale, ranging from 1=disagree to 7=agree, with higher scores indicating better usability. Users were allowed to select the option “not applicable” for each item. Such answers were considered missing data and excluded from the analysis.

Semistructured usability interviews in a subset of participants were used to gather qualitative data about the user experience of Cerebri for product development purposes. All study participants were asked if they wished to be considered for the interview, and 5 participants declined. From a pool of 15 potential participants, 6 individuals were selected based on a set of predefined criteria (Multimedia Appendix 1). Interviews were conducted midway (at wk 6) and upon completion of the study (at wk 12).

Data on adverse events (AEs) and device deficiencies were collected at phone consultations and the final visit. All treatment-emergent AE were collected throughout study participation.

Treatment efficacy was assessed using self-reported migraine and headache days that were collected prospectively in the integrated eDiary. The number of days in each 28-day period was compared to that collected from the past 28 days prior to inclusion.

Change in self-reported, migraine-related disability was measured using the Migraine-Specific Quality of Life Questionnaire version 2.1 (MSQ) from before treatment to end-of-treatment [21]. The questionnaire contains 14 items that measure the quality of life impacts of migraine in 3 domains: “role function-restrictive,” “role function-preventive,” and “emotional function.” Participants rate their experiences on a scale of 1=none of the time to 6=all of the time. The scores for each domain in the MSQ were calculated in accordance with the license holder’s instructions, with each domain receiving a score out of 100, where a higher score indicates more favorable functioning.

The participants’ perceived change in overall health was measured by the Patient Global Impression of Change (PGI-C) at weeks 4, 8, and 12. Participants were asked to rate their current condition compared to their condition before receiving the treatment intervention on a 7-point scale, ranging from a score of 1=very much improved to a score of 7=very much worse. For descriptive purposes, participants may be classified into 4 categories: much improved (score of 1 or 2), minimally improved (score of 3), unchanged (score of 4) or disease deterioration (score of 5, 6, or 7).

Data Analytic Strategies

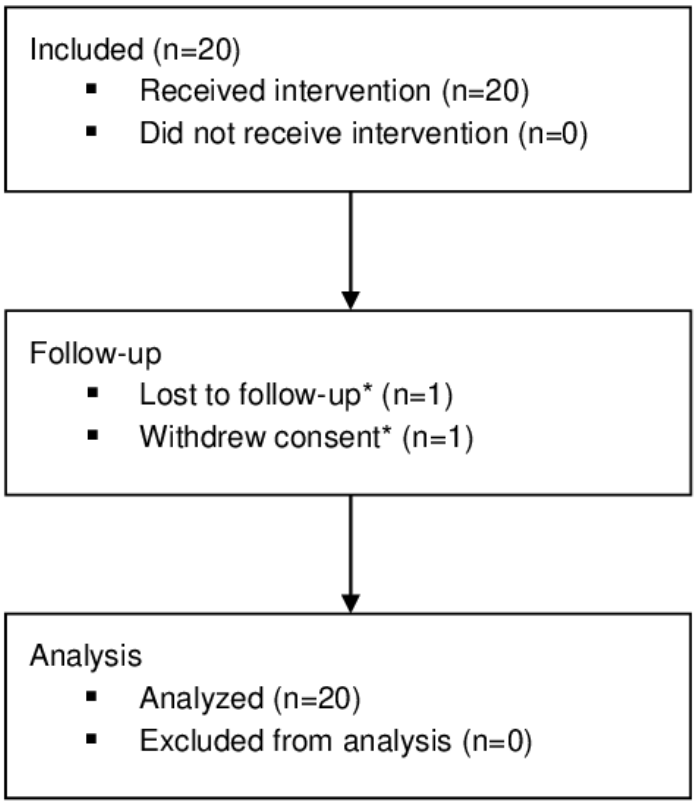
Descriptive data were summarized as means with SDs or medians with IQRs according to normality distributions. Assessment of normality was based on visual inspection of histograms. Adherence rates to the eDiary and biofeedback program were calculated for each 28-day period separately. Summary statistics for MAUQ were calculated for weeks 1 and 12. Changes in the number of days with migraine and headache in each 28-day period compared to the last 28 days prior to inclusion were analyzed with a mixed logistic regression model with participant ID included as a random variable. The model estimated the odds ratio for each 28-day period. This odds ratio represented the estimated daily odds of migraine or headache in each 28-day period compared to the baseline period. The estimated number of migraines or headaches in each 28-day period and the difference from baseline were calculated based

XSL•FO
RenderX

on the regression coefficients using the nlcom command in Stata (version 17.0; StataCorp LLC). The use of a mixed logistic regression model allowed the inclusion of all available daily data, also from participants who had not completed all eDiary entries during each 28-day period. The change in MSQ domain scores was analyzed using mixed linear regression models with the mean change in each domain score estimated from these models.

Semistructured interviews were held through video or phone and recorded. Transcripts were stored on the Miro (RealtimeBoard Inc) platform during analysis, where they were grouped, mixed, and sorted in several rounds to identify patterns of themes that were relevant to the usability experience.

Ethical Considerations



The study was approved by the regional ethics committee (457654) and the Norwegian Medical Products Agency (NoMA; 22/04658 - 4; Eudamed: CIV-NO-22-03-039126), and registered at ClinicalTrials.gov (NCT05454319) prior to initiation. Trial information was disseminated via multiple communication channels. Interested parties made contact by email. All participants received written information via email prior to the first study visit. Eligibility assessment and a review of the study information were performed by a consultant neurologist (IGW) with headache expertise in a video meeting. If eligible, consent was collected by digital signature via the national government-operated electronic data entry application Helsenorge (Norsk helsenett SF). Data collection for the study was initiated after electronic consent. Data were deidentified through pseudonymization. No payment was made to the study participants for their participation.

Results

Overview

A total of 20 participants were enrolled in the study intervention. All 20 participants contributed to the evaluation of the feasibility of the Cerebri biofeedback system. One participant withdrew consent, and one was lost to follow-up (Figure 3). The majority of participants were female and in full-time employment, with a mean of 6.7 (SD 2.8) migraine days per month (Table 1). One participant was pregnant during the entire study period.

Figure 3. CONSORT flow diagram. Intervention: Cerebri biofeedback treatment. *Data collected from participants who withdrew or were lost to follow-up were included in the analysis. CONSORT: Consolidated Standards of Reporting Trials.

Full-time (≥100%) paid employment	15 (75)
Part-time (<100%) paid employment	1 (5)
Partial sick or medical leave	1 (5)
Sick or medical leave (100%)	1 (5)
Work assessment allowance	2 (10)
Previous use of preventive medication	4 (20)
Propranolol	1 (5)
Candesartan	1 (5)
Amitriptyline	2 (10)

[a]Participants all kept a headache diary for a minimum of 28 days prior to inclusion.

[b]One participant reported both full-time paid employment and "other governmental benefits" (parental leave). The student also received work assessment allowance and is thus registered twice.

Primary Outcome: Feasibility

Out of 20 participants, the majority continued to regularly record information in the daily eDiary throughout the study period, with 15 (75%) participants still recording information on at least 70% of days (20 d) in weeks 9 to 12 (Table 2). The proportion of participants completing at least 70% of biofeedback sessions decreased throughout the study, with 16 (80%) participants during weeks 1 to 4, and 4 (20%) participants during the final 4 weeks (Table 2).

XSL•FO
RenderX

Table . Adherence to eDiary[a] and biofeedback in the 3 intervals, respectively[b].

Period	Mean (SD)	Median (IQR)	Proportion with ≥20 days recorded of all included (N=20), n (%)
eDiary			
Day 1 - 28 (n=20)[c]	25.7 (3.8)	27 (15 - 28)	18 (90)
Day 29 - 56 (n=19)	25.5 (4.3)	27 (10 - 28)	18 (90)

[a]eDiary: electronic headache diary.

[b]The proportion of participants with adherence to intervention (eDiary and biofeedback, respectively) >20 days (=70% adherence) per 28-day period includes all participants (N=20).

[c]n is the number of participants in each period

Usability

The Cerebri app received favorable user perceptions, with MAUQ summary score for the ease of use subscale at week 1 (median score 6.2, IQR 5.6-6.6) and at week 12 (median score 6.0, IQR 5.2-6.8; Figure 4). Summary scores for the interface and satisfaction and usefulness subscales were 6.1 (IQR 5.7-6.7) and 5.0 (IQR 4.2-5.6) at week 1, and 5.8 (IQR 5.3-6.6) and 4.8 (IQR 3.5-5.2) at week 12, respectively.

XSL•FO
RenderX

Figure 4. MAUQ weeks 1 (n=19) and 12 (n=17). Median scores and IQRs from each question (1-18) with median summary scores for each of the 3 domains are presented. N is the number of responses to the question, the response “not applicable” is excluded. MAUQ: mHealth App Usability Questionnaire; mHealth: mobile health.

XSL•FO
RenderX

The app was regarded as both easy to learn and to use (questions 1 - 5), with stable median scores of 6 or 7 for almost all of these questions at both weeks 1 and 12. The exception was a notable decline in median scores from 6 (IQR 4-7) at week 1 to 4 (IQR 2.5-7) at week 12 for participants' ability to recover after having made a mistake using the app (question 5).

MAUQ questions concerning the app's interface and user satisfaction (questions 6 - 12) also received favorable scores. However, there was a noticeable decline in the median score from 7 (IQR 6-7) at week 1 to 5 (IQR 5-7) at week 12 for question 11, which assessed users' likelihood of using the app again. Nevertheless, overall satisfaction with the app (question 12) remained high with a median score of 7 (IQR 6-7) at week 1, and 6 (IQR 6-7) at week 12.

Furthermore, the scores for MAUQ question 13, which assessed the app's perceived usefulness for health and well-being, remained consistently high with a median score of 6 (IQR 4-7) and 6 (IQR 4-6) at weeks 1 and 12, respectively. Meanwhile, MAUQ question 18, which evaluated whether the app provides an acceptable way to receive health care services, showed a median score of 5.5 (IQR 4-6) at week 1, decreasing slightly to 5 (IQR 4-6) by week 12.

MAUQ question 17, which addressed whether the app could be used without or with a poor internet connection, maintained a median score of 4 (IQR 4-6) at week 1 and 4 (IQR 3-5) at week 12. Notably, this item had fewer respondents compared to other questions, with 9 participants responding at week 1 and 11 participants at week 12, suggesting that not all users encountered situations where the app's functionality under these conditions was tested.

Usability Experience

A total of 6 participants were recruited to participate in the semistructured interviews. Five midway user interviews were completed in total. Three of these interviewees also partook in the final user interview. All interviewees reported that Cerebri was easy to both learn and use. Finding time for daily training sessions and implementing this as a daily routine activity seemed to be the most challenging part. However, despite this challenge, interviewees expressed a sense of satisfaction in being able to dedicate 10 minutes to achieving a state of complete relaxation, which they found rewarding in itself.

A concern was identified that the app focused excessively on achievements and earning high scores. Participants feared that they might not experience the intended treatment effects unless they attained the top achievements. When probed further about their reasoning, participants attributed significance to such score achievements, assuming a correlation between achieving them and experiencing a reduction in migraine symptoms.

The finger temperature parameter was reported to be preferred among users, as it was the easiest to understand whilst also providing the most concrete goal during biofeedback sessions. Output user data from all completed biofeedback sessions from all study participants identified the same preference, with a total collective screen time of 75 hours used within the finger temperature modality across a total of 132 hours in 795 sessions. In comparison, 22 and 35 hours were used in the EMG and HRV modalities, respectively. The EMG parameter appeared to provide little feedback for participants to observe and improve upon, except for one individual who reported having tense muscles and experiencing a strong connection between muscle tension and migraines. All 5 participants expressed difficulties understanding the goal of HRV measurement, how to achieve it, or both.

Several bugs in the app occurred during the second half of the study, resulting in difficulties launching the app or starting biofeedback sessions. Notably, all iPhone users were involuntarily logged out of the app at one point due to these issues. All 3 participants partaking in the final user interview mentioned bugs as a reason for reduced motivation. In total, 13 unique bugs were reported by one or more participants during the study (not limited to the interviewees). These were perceived as disruptive to the user experience and led to disruptions in use patterns, ultimately impacting user motivation and compliance. The degree to which the 3 participants experienced a drop in motivation due to technical errors was not quantified specifically during the interview, but addressed for the entire population in questions 4 and 5 in the MAQU questionnaire.

Safety and Tolerability

Three AEs were recorded during the trial period (Multimedia Appendix 2). All AEs were assessed as nonrelated to the medical device. Thus, no adverse device effects and no serious adverse events occurred. One participant was pregnant during trial participation. No AE were registered for that participant, and the child was born healthy at term.

Exploratory Data on Efficacy

We observed a statistically nonsignificant reduction in the number of migraine days compared to baseline in all three 28-day periods, but no clear change in the number of headache days (Table 3). At all timepoints, approximately 50% (8/16) of participants described overall health conditions as "unchanged" on the PGI-C questionnaire (Figure 5). However, 22% (4/18) and 24% (4/17) of participants described their condition as "much improved" in week 8 and 12, respectively. No reports of worsening conditions were reported after week 4. There was a trend toward improvements in all MSQ domains throughout the study, reaching statistical significance for the domain "role function-restrictive" in week 4 and the domain "emotional function" in week 12 (Table 4).

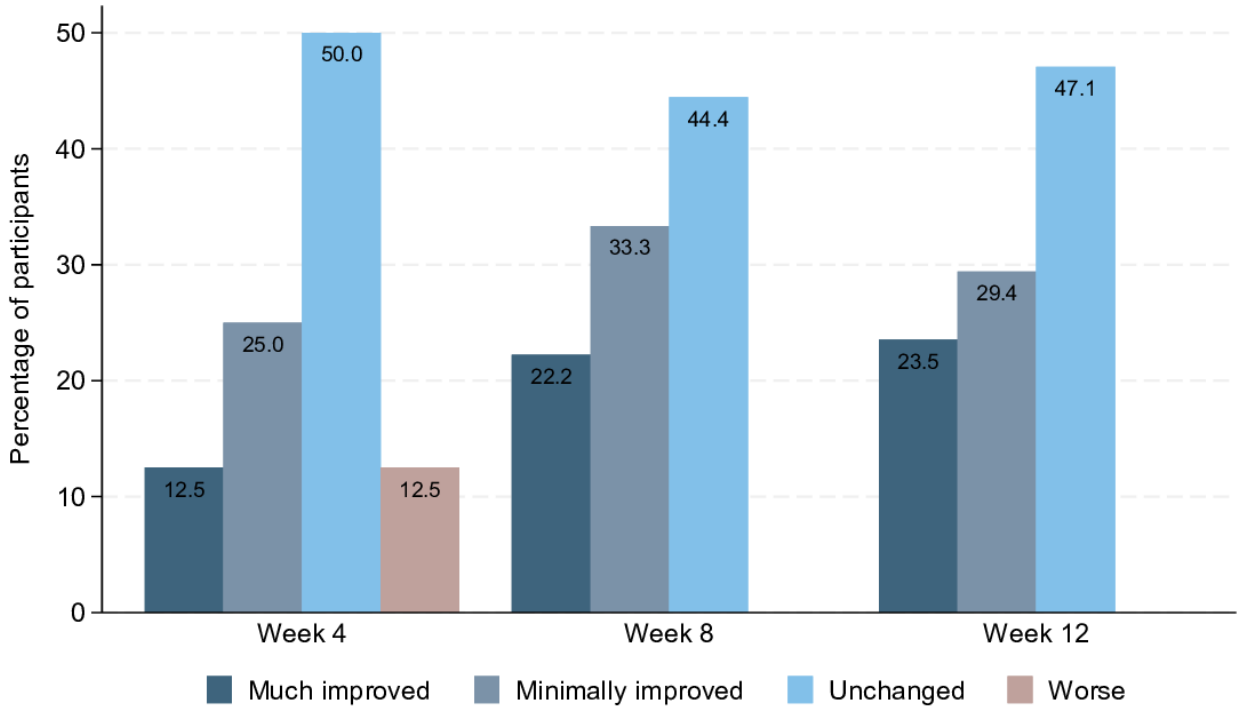
Baseline (n=20)	6.7 (2.8)	reference	6.2 (5.1 to 7.4)	reference	N/A[d]
Week 1 - 4 (n=20)	5.7 (4.5)	0.80	5.2 (3.4 to 7.0)	–1.0 (–2.3 to 0.3)	.13
Week 5 - 8 (n=19)	5.3 (4.0)	0.80	5.2 (3.4 to 7.1)	–1.0 (–3.0 to 0.9)	.31
Week 9 - 12 (n=18)	5.9 (4.2)	0.87	5.6 (3.8 to 7.4)	–0.6 (–2.4 to 1.1)	.47
Headache days					
Baseline (n=20)	7.7 (2.7)	reference	7.5 (6.3 to 8.7)	reference	N/A
Week 1 - 4 (n=20)	8.1 (4.2)	1.07	7.9 (6.1 to 9.6)	0.4 (–0.9 to 1.6)	.58
Week 5 - 8 (n=19)	8.0 (4.1)	1.04	7.7 (5.9 to 9.6)	0.2 (–1.7 to 2.2)	.81
Week 9 - 12 (n=18)	7.4 (4.1)	0.97	7.3 (5.5 to 9.1)	0.2 (–2.1 to 1.7)	.85



[a]Mean number of days based on available information in each 28-day period. For participants who did not complete the headache diary on all 28 days, the number of migraine or headache days was divided by the number of days with complete headache diary entries multiplied by 28 to obtain the number of days the participant would have been expected to have a migraine or headache.

[b]OR: odds ratio.

[c]A mixed logistic regression model was used to estimate the OR for each 28-day period. This OR represented the estimate OR compared to the daily odds of migraine and headache for each 28-days period. The estimated 28-day migraine and headache differences was calculated based on the regression coefficients and using the nlcom command in Stata.

[d]Not applicable.

Figure 5. Distribution of responses to the PGI-C question at weeks 4 (n=16), 8 (n=18), and 12 (n=17). The corresponding average (SD) for weeks 4, 8, and 12 were 3.6 (0.9), 3.2 (0.8), and 3.2 (0.8), respectively. PGI-C: Patient Global Impression of Change.

Discussion

Overview

This study was designed to address the feasibility of the home-based, therapist-independent biofeedback system Cerebri as a preventive treatment in adults with episodic migraine to serve as a preparatory step toward a clinical efficacy trial. Additionally, major emphasis was given to assessing the usability and the safety of the invention.

Principal Findings

Daily biofeedback session adherence declined throughout the course of the study from 80% in weeks 1 - 4 to 20% in weeks 9 - 12. The decline in diary adherence was much less pronounced, with a reduction from 90% to 75% in the same time interval. Low adherence is a common concern for nonpharmacological headache treatments [22]. This is also true for biofeedback treatment, as seen in a previous pilot on a precursor to the Cerebri system [18], as well as in another mHealth app for biofeedback intervention in migraine [23]. In this study, several causes for low adherence were identified.

First, software bugs in the last part of the study period hampered adherence, causing at one point all iPhone users to be logged off the app. Second, as eDiary adherence was better, software malfunction cannot be the sole cause for the declining biofeedback adherence. Usability assessments, including MAUQ scores, identified several other software elements that should be improved. Details were elucidated in semistructured interviews held in a subset of participants for product development purposes. The achievement features conveyed unrealistic goals for some participants, and failure to reach them was misinterpreted as a failed session by some. In addition, the goal of the HRV biofeedback training was difficult to understand.

This study was not designed to assess efficacy, and outcomes must be interpreted with caution. There was an observed tendency for improvements in several headache parameters, including quality of life measures. Notably, a not statistically significant average reduction in migraine days was observed across all three 28-day intervals compared to baseline, with an estimated reduction of 1 migraine day in weeks 1 - 4 and weeks 5 - 8. On PGI-C scoring, 24% (4/17) of participants described their overall health condition as “much improved” at week 12.

The intervention was safe, with no device-related or serious AE.

Interpretation

This study highlights the potential for therapist-independent, multimodal biofeedback systems to address unmet needs in migraine management, despite challenges in adherence. Adherence challenges, observed in this and prior studies [18,23], emphasize the need for robust technology platforms and user-centered design to secure long-term engagement, particularly in home-based interventions.

A possible explanation for the decreasing adherence to the biofeedback sessions, despite consistently high eDiary adherence, is that users experienced some sort of improvement from the therapy, and therefore, adjusted the frequency of treatment sessions while retaining the treatment effect. However, it may also be an expression of a lack of perceived effect, and

XSL•FO
RenderX

either way, user interviews did not identify this as a major mechanism.

There is no consensus on the optimal treatment duration or frequency of home-based mHealth behavioral interventions in migraine. Traditional therapist-dependent biofeedback is typically provided as hour-long sessions once or twice weekly, sometimes with intermittent home-training of shorter duration. In a recent pilot study examining a home-based single-modality surface EMG biofeedback intervention for episodic migraine, participants engaged in weekly sessions lasting 40 - 45 minutes under the remote guidance of a biofeedback therapist over a 6-week period [24]. Participants were instructed to do additional sessions of 30 minutes 3 times a week and keep track of their home practice. Participants attended on average 4.8 (SD 1.2) of the 6 sessions, whereas adherence to the therapist-independent sessions was not reported in the paper.

It can be hypothesized that increased treatment duration yields larger treatment effects. For home-based therapist-independent treatment, long sessions may hamper adherence, whereas short sessions may reduce potential efficacy. In a pilot study on a combined HRV-biofeedback-virtual reality device, participants attended an initial in-person session, after which they were instructed to perform sessions at home a minimum of 3 times per week, with each lasting at least 10 minutes [10]. There was an attrition rate of 9 out of 25 participants in the intervention group, compared to 3 out of 25 in the control group. No statistically significant reduction in headache days between the groups was observed. Results from this study suggest the possibility of significant dropout even with less frequent sessions. Therefore, increased session duration or frequency may not necessarily be determining factors for adherence to the intervention. This pilot study did identify adherence challenges, though other underlying mechanisms seem more important than session duration and frequency itself. Future work should empirically investigate optimal treatment duration and frequency.

Electronic behavioral interventions are dependent on sufficient user satisfaction to secure adherence. The overall positive perceptions of the app's ease of use and utility underscore Cerebri's potential to serve as an accessible, self-administered treatment option. However, the decline in median scores for certain usability aspects, particularly users' likelihood of using the app again, could signal the need to revise and improve certain elements of the app's design. On the other hand, a lack of perceived clinical effect could also explain such a finding. Regardless, addressing concerns related to usability features is crucial to maintaining patient compliance. To that end, revisions related to app achievement features should be a priority to mitigate misunderstandings that may affect participants' motivation and perceived treatment effectiveness. Other strategies to reinforce habit formation should be explored.

Furthermore, our results suggest that the app interface of the HRV biofeedback modality should be revised to facilitate the correct performance of training within this modality. This could be achieved by including a visual guiding line matching the optimal sinus curve for the selected breathing frequency. In addition, improving HRV-related textual information in the app may increase user accessibility.

Limitations

This pilot study has several limitations. First, the sample size of 20 participants makes the study underpowered to make claims regarding efficacy. Additionally, the absence of a control group limits our ability to attribute effects specifically to the intervention. A notable limitation of our qualitative analysis is the small sample size in the final user interviews, where only 3 participants participated. Additionally, the sequential selection of interview participants during the week 4 follow-up appointments could have introduced a selection bias as they were not randomly drawn. However, we aimed to include a diverse representation of age, gender, and adherence, and thus, opted for a sequential selection.

Participants were biofeedback naïve, but had already kept a headache diary with a minimum of 80% adherence in the 4 weeks prior to inclusion as part of routine clinical care, and were experienced smartphone users. Thus, study results may not be representative of a smartphone and eDiary naïve population.

Furthermore, as the study included only individuals with episodic migraine, caution is advised when inferring results to other patient groups, including chronic migraine or other primary headache disorders.

Conclusions

Cerebri is a unique multimodal, app-based, and therapist-independent biofeedback intervention that, in this study, underwent a rigorous feasibility and usability evaluation. The main feasibility obstacle was declining adherence to daily biofeedback sessions throughout a 12-week treatment period. On the other hand, eDiary adherence was consistently high. Usability issues and software bugs were identified and will be addressed in the final product development of Cerebri prior to a pivotal randomized controlled trial.

Abstract

Background: Musculoskeletal disorders significantly impair physical function and quality of life, necessitating systematic rehabilitation. Electrically powered orthopedic exercisers, such as continuous passive motion devices, are widely used to enhance joint mobility and muscle recovery. However, existing devices often lack advanced functionalities and user-specific adaptability, limiting their effectiveness. To address these shortcomings, the Rebless Pro was developed as a novel device supporting active and passive exercises with personalized treatment programs.

Objective: This study aimed to conduct a formative usability evaluation of the Rebless Pro prototype using focus group interviews (FGIs) and satisfaction surveys with health care professionals specializing in rehabilitation medicine. The goal was to identify areas for improvement to enhance the safety, usability, and information clarity of the device.

Methods:: Usability evaluation was performed at the National Rehabilitation Center with 10 participants (5 physiatrists and 5 physical therapists) who had prior experience using similar devices. FGIs were conducted to collect qualitative insights into user experiences, while satisfaction surveys provided quantitative data on ease of use of the user interface and identifiability and understanding of information. Data collection focused on identifying risk factors and usability challenges.

Results: Three key areas for improvement were identified: (1) product upgrades to ensure patient safety, including adjustments to exercise speed and resistance; (2) hardware and software improvements to improve usability, including adjustments to the location of the emergency button and improvements to the graphical user interface elements; and (3) improvements to the user manual, including detailed contraindications, patient criteria, and clearer operating instructions. Although the mean score of physiatrists (mean 4.463, SD 0.298) was higher than that of physical therapists (mean 4.114, SD 0.829) in terms of the ease of use of the user interface, the difference was not statistically significant (P=.69). Similarly, in the category of identifiability and understanding of information, higher scores were again reported by physiatrists (mean score 4.467, SD 0.506) than by physical therapists (mean 3.733, SD 0.894), but this difference was also not statistically significant (P=.22).

Conclusions: Usability evaluation provided actionable insights into improving the Rebless Pro's safety, usability, and information clarity. To further refine the device, iterative usability evaluations involving both health care professionals and patients are recommended. These efforts are expected to contribute to the development of a safe, effective, and user-friendly electrically powered orthopedic exerciser suitable for commercialization.

Introduction

Background

Musculoskeletal (MSK) disorders, resulting from diseases or injuries affecting muscles, tendons, ligaments, and bones, are a major cause of reduced physical function and quality of life [1]. Patients with MSK disorders often experience difficulties in performing independent daily activities due to reduced joint mobility, weakened muscle strength, and chronic pain, necessitating systematic and continuous rehabilitation therapy [2]. In clinical rehabilitation, electrically powered orthopedic exercisers play a crucial role in facilitating joint tissue regeneration and muscle strength recovery [3].

Continuous passive motion (CPM) devices are representative examples of exercisers; they are widely used to prevent joint stiffness and promote tissue healing, particularly after orthopedic

XSL•FO
RenderX

surgeries [4,5]. However, despite their therapeutic benefits, conventional CPM devices have several limitations that hinder optimal rehabilitation outcomes. First, they typically provide only passive range of motion (ROM) exercises without accommodating more dynamic modes, such as active-assisted or resisted exercises, which are essential for patients requiring progressive muscle strengthening or functional restoration [6,7]. Second, these devices lack user-specific customization features. Most CPM units operate on fixed protocols that do not account for individual differences in pain tolerance, ROM progression, or rehabilitation goals [8,9]. As a result, patients may experience discomfort or disengagement due to inappropriate exercise intensity or duration. Third, many CPM devices are ergonomically unsuitable for certain populations, such as individuals with obesity, severe joint deformities, or an inability to maintain a supine position. Since most CPM devices are designed for supine use, they may also limit usability and patient compliance in nonhospital settings [10,11].

To address these issues, alternative models, such as sitting-type CPM devices, have been developed. These devices allow patients to perform rehabilitation exercises in a seated position, which can enhance comfort, accessibility, and safety. Some studies have reported that sitting-type CPM devices offer comparable efficacy to conventional models while improving patient satisfaction [9]. Nevertheless, these alternatives are still relatively underused in clinical practice, partly due to limited availability and familiarity among clinicians.

In response to the need for more adaptive and patient-centered solutions, the Rebless Pro was developed as a next-generation orthopedic exerciser supporting both passive and active-assisted exercises. The device was designed to allow personalized treatment protocols and improve usability in various clinical settings.

Electrically Powered Orthopedic Exerciser

The Rebless Pro (H Robotics Inc) is an electrically powered orthopedic exerciser developed to support full ROM exercises and facilitate active and passive rehabilitation of the knee and ankle in individuals with neurological or MSK disorders (Figure 1). During the initial design phase, user requirements were collected from clinicians to inform the development of device functionalities and interface elements. Currently in its prototype stage, the Rebless Pro comprises a main unit and a tablet-based controller operated via the Rebless Pro app.

Figure 1. Electrically powered orthopedic exerciser.

The app features an intuitive graphical user interface (UI) and is structured around five core functional modules: (1) passive ROM, which enables therapist-initiated joint mobilization; (2) active-assisted ROM, providing adjustable support for patient-initiated movement; (3) evaluation ROM measurements, allowing objective tracking of joint range; (4) resisted ROM, designed to improve muscular strength and motor control through applied resistance; and (5) interactive custom setup, which enables therapists to personalize treatment protocols according to patient-specific needs.

The device operation workflow begins with patient registration and profile setup. Therapists select exercise modes and set individualized parameters—such as ROM extent, resistance, and assistance levels—based on therapeutic goals. During sessions, the app provides real-time feedback on joint movement, resistance, and exercise performance. Upon completion, session data are automatically stored, supporting longitudinal progress monitoring and outcome evaluation.

The Rebless Pro is intended for use by physical therapists and physiatrists, with the primary patient population being individuals with neurological or MSK impairments, including lower-extremity muscle paralysis or joint contractures, as well as people undergoing postsurgical rehabilitation. These users often require guided motor recovery and muscle strengthening to improve functional outcomes.

Usability Evaluation

Usability issues in medical devices can directly affect patient safety and treatment outcomes, often arising from deficiencies in UI design [12]. To mitigate such risks, the International Electrotechnical Commission (IEC) introduced the IEC 62366 standard, which emphasizes the integration of usability engineering throughout the device development process, distinguishing between formative and summative evaluations [13-15]. Formative evaluations, conducted during the early stages of design, aim to identify UI-related strengths, weaknesses, and potential use errors. These evaluations are iterative and typically involve direct input from intended users to guide design refinement [16], such as from focus group interviews (FGIs), which are widely used during the formative phase to collect user feedback on prototype usability [17,18].

This study conducted a formative usability evaluation of the Rebless Pro, which is currently in its implementation phase. Using FGIs and user satisfaction surveys with rehabilitation medicine professionals—the device's intended users—this study aimed to identify areas for improvement to enhance the safety and convenience of the device, in accordance with IEC 62366.

XSL•FO
RenderX

Methods

In this study, FGIs and satisfaction surveys were conducted to collect quantitative and qualitative data on an electrically powered orthopedic exerciser.

Ethical Considerations

This study was approved by the institutional review board of the National Rehabilitation Center (NRC; NRC-2023-03-020). All participants provided voluntary consent to participate after receiving a comprehensive explanation of the study objectives and methods. No compensation was provided for participating in the study. For the protection of personal information and the confidentiality of the participants, all data were anonymized.

Participants

The evaluation included 10 NRC-affiliated individuals, including 5 physiatrists and 5 physical therapists, who were recruited through peer referral and a bulletin board announcement at the NRC Usability Testbed.

The inclusion criteria were being a licensed physical medicine and rehabilitation or physical therapist with experience usingelectrically powered orthopedic exercisers and sufficient proficiency in Korean and English to comprehend software terminology. Individuals lacking experience in electrically powered orthopedic exercisers were excluded from the study. The participants provided voluntary consent after receiving a comprehensive explanation of the study objectives, methods, and procedures. All participants had at least 1 year of clinical experience using electrically powered orthopedic exercisers, such as CPM devices. The full formative assessment process, including the FGIs, was conducted separately for the physiatrist group and the physical therapist group.

Usability Evaluation Procedure

A usability evaluation was conducted at the NRC Usability Testbed. The evaluation was carried out in 2 separate sessions, one each for the physiatrist group and the physical therapist group, with each session lasting 90 minutes. The evaluator provided an introduction to the assessment to familiarize participants who may have been unfamiliar with usability evaluations, explaining the objectives, methods, and procedures of the product evaluation. Following this, participants were required to confirm their understanding of the evaluation details, after which informed consent was obtained for voluntary participation as well as for video and audio recordings. The FGIs commenced with questions regarding the general characteristics of the participants. Subsequently, the evaluator confirmed that the participants had reviewed the relevant information on the Rebless Pro and inquired about their prior experiences with similar devices, including the specific names of those devices. A demonstration of the use scenarios (Multimedia Appendix 1) was then conducted in conjunction with the FGIs using the Rebless Pro. Upon completion of the interviews, a satisfaction survey was administered to gather participants' feedback.

The usability evaluations were conducted in environments that closely resembled real-world use scenarios; such environments have been reported to accurately capture user experience and satisfaction, thereby playing a pivotal role in enhancing the commercial viability of medical devices [19]. In alignment with past findings, this study implemented formative evaluations within a simulated environment designed to replicate actual use conditions. The usability evaluations included a simulated physical therapy environment in which the Rebless Pro was used; the device was set up on a Bobath table (Figure 2). The luminous intensity, temperature, and relative humidity of the evaluation sites were measured before usability evaluation. The luminous intensity was 550 (SD 100) lux, temperature was 24ºC (SD 2ºC), relative humidity was 50% (SD 10%), and ambient noise was 50 (SD 5) dBA. Scenes of the evaluation are shown in Figure 3.

Figure 2. Evaluation environment.

XSL•FO
RenderX

Figure 3. Scenes of the evaluation.

FGI Procedure

FGIs were used as a qualitative data collection method to evaluate the usability of the Rebless Pro prototype. Each FGI session was conducted once per group, with 1 moderator, 1 observer for recording, and 5 participants present in the evaluation space. The moderator posed identical questions to each participant sequentially, ensuring that all participants—from the first to the fifth—had an opportunity to respond. The FGI questionnaire was structured following the guidelines of Krueger and Casey [17], incorporating introductory, transitional, key, and end questions (Multimedia Appendix 2). To gather feedback on the Rebless Pro, product demonstrations were conducted according to predefined use scenarios. Scenarios for 8 tasks were designed based on the user manual. Participants observed the device during these demonstrations and provided insights into predictable or identified risk factors and areas for UI improvement. The core questions focused on collecting participants' opinions regarding the UI of the Rebless Pro after observing its functionality and use. Additionally, participants offered suggestions for mitigating risks and improving usability based on their observations during the product demonstrations. Content analysis was conducted on the data obtained from the FGIs [20,21]. Microsoft Excel was used throughout the processes of data transcription, coding, and thematic derivation.

Satisfaction Surveys

After the FGIs, satisfaction surveys for the Rebless Pro were conducted to collect quantitative data. The satisfaction survey consisted of 51 items on the ease of use of the UI (Cronbach α=0.987) and 3 items on identifiability and understanding of information (Cronbach α=0.617). The survey items were rated on a 5-point Likert scale ranging from 1 (very difficult) to 5 (very easy). The difference in satisfaction between the physiatrist group and the physical therapist group was analyzed using the Mann-Whitney *U* test in SPSS (version 25; IBM Corp). The satisfaction survey results are presented as means and SDs for each item by group (Multimedia Appendices 3 and 4).

Results

Participant Characteristics

In the physiatrist group, clinical experience ranged from 1 year and 3 months to 2 years and 3 months. Experience in using similar medical devices ranged from 3 months to more than 1 year. In the physical therapist group, clinical experience ranged from 7 to 28 years, and experience using similar medical devices was more than 1 year for all members (Table 1). All members of both groups had experience using electrically powered orthopedic exercisers, such as MOTOmed (RECK-Technik GmbH) and other CPM devices, but all were using the Rebless Pro for the first time.

XSL•FO
RenderX

Table . General participant characteristics.

Number	Sex	Age (years)	Experience	Occupation	Experience using similar medical devices	Similar medical device
1	Female	29	2 yr 3 mo	Physiatrist	1 yr, >once a day	MOTOmed
2	Female	27	2 yr 3 mo	Physiatrist	1 mo, once a day	CPM[a] device
3	Male	26	2 yr 3 mo	Physiatrist	6 mo, once a day	MOTOmed
4	Female	28	1 yr 3 mo	Physiatrist	4 mo, once a day	MOTOmed
5	Male	25	1 yr 3 mo	Physiatrist	3 mo, twice a day	MOTOmed
6	Female	51	28 yr 10 mo	Physical therapist	1 yr, 3 times a day	MOTOmed
7	Male	40	14 yr	Physical therapist	1 yr, once a day	MOTOmed
8	Female	36	9 yr 10 mo	Physical therapist	1 yr, once a day	MOTOmed
9	Female	32	9 yr 6 mo	Physical therapist	1 yr, once a day	MOTOmed
10	Female	29	7 yr 3 mo	Physical therapist	1 yr, 3 times a day	MOTOmed, CPM device

[a]CPM: continuous passive motion.

FGI Results

The FGIs revealed 3 key factors and 7 subfactors representing possible improvements to the Rebless Pro. The three key factors were as follows: (1) product upgrades to ensure safety, (2) hardware and software improvements for convenience of use, and (3) improvement of the manual for better identifiability and understanding of the information (Table 2).

Table . Outcome of content analysis.

Factor	Suggested solution
1. Product upgrades to ensure safety	• Improve the exterior • Fasten the device to the table • Adjust the motor for exercise speed and resistance
2. Improvements for convenience of use	• Improve the hardware user interface • Improve the software user interface
3. Improvement to the manual for better identifiability and understanding of the information	• Input details about the intended patient group and medical indications • Input details about device use and operation

Product Upgrades to Ensure Safety

The participants prioritized patient safety and suggested the following potential risks of and improvements to the Rebless Pro:

> *The device should be fastened to the table, but force applied by the therapist should allow it to slide or move.*
>
> *The exterior requires improvement as the device has a complex structure and accidents may be caused through items getting caught on its exterior.*
>
> *The device should be secured using an anti-slip pad.*
>
> *Patients may complain of pain because the speed of the basic exercise may be too fast. The initial position angle should be adjusted while the device is being fitted.*
>
> *Movement speed needs to be more finely adjusted. The operating exercise speed should be shown on the controller display.*
>
> *The basic resistance intensity of the device may be too high for the patient to counteract.*
>
> *There is a high likelihood of errors occurring during ROM measurement, and measurement range errors may occur.*

Hardware and Software Improvements for Convenience of Use

For user convenience and ease of use, the following hardware and software improvements to the Rebless Pro were suggested:

> *The power (on, off) button should be repositioned.*
>
> *The emergency stop button should be repositioned, and separate buttons should be provided for the patient and therapist.*
>
> *The material of the fastening strap where the device is secured to the patient should be changed.*
>
> *Noise from the motor may interfere with the treatment of other patients. The motor noise should be adjusted.*

XSL•FO
RenderX

As this device is provided to the patient by medical staff, the wording of the instructions should be improved to make it easier for patients to understand (instead of using medical terminology).

The information about intensity and stiffness sensitivity is provided only in the manual. It is cumbersome to have to refer to the manual while using the device.

A pop-up window with a summary of each function should be added to the controller display.

Control icons, such as up and down arrows, should be presented more clearly on the display.

Improvement of the Manual for Better Identifiability and Understanding of the Information

Participants suggested the following improvements to the Rebless Pro manual to allow better identifiability and understanding of information by users:

Detailed information about the contraindications for intended patient groups, stages of life and age groups, specific criteria for applicable patients, and the patient's position when fitting the device should be provided.

With respect to use of the device, calf/thigh measurement criteria, exercise intensity criteria based on Manual Muscle Test or Modified Ashworth Scale standards, and clear exercise speed criteria should be provided.

Satisfaction Survey Results

To identify the difference in satisfaction between physiatrists and physical therapists, a Mann-Whitney *U* test was conducted. When comparing the overall ease of use of the UI, the satisfaction of the physiatrists (mean score 4.463, SD 0.298) was higher than that of the physical therapists (mean score 4.114, SD 0.829), but this was not a statistically significant difference (U=10.000; Z=−0.522; P=.69). In addition, when comparing the overall information identifiability, the satisfaction of the physiatrists (mean score 4.467, SD 0.506) was higher than that of the physical therapists (mean score 3.733, SD 0.894), but this was not a statistically significant difference (U=6.000; Z=−1.375; P=.22).

Discussion

Principal Results

A formative evaluation is a usability evaluation performed to improve the design of a medical device under development. To gain qualitative and quantitative insights into the course of the development of the Rebless Pro, an electrically powered orthopedic exerciser, we conducted a formative evaluation. This was achieved using FGIs and satisfaction surveys with rehabilitation medicine professionals who had experience using other electrically powered orthopedic exercisers.

FGIs enable individuals to freely express their own experiences and engage in discussions using not only their own knowledge but that of others, thereby providing diverse perspectives and detailed information on a specific topic [17]. Moreover, FGIs are used to identify and analyze expert responses as experts share information and experience in using a particular product or service. Therefore, FGI findings may be used to develop or improve products and services [22].

Motorized medical devices can cause unintended movements by the patient or user, potentially leading to discomfort or injury [23]. Because the operator of the Rebless Pro is a medical professional and the user is a patient, the participants in this study prioritized patient safety and presented opinions on improvement of the exterior structure of the device and upgrades to the device fastening method, exercise speed, and resistance strength. These points suggest that patient and operator safety is crucial when designing a rehabilitation device and that the product should be upgraded to ensure safety.

A previous study concluded that devices using robotic technology should be equipped with at least one emergency stop button that is easily accessible to the user [24], and another study reported that an emergency stop system should be installed to prioritize user and patient safety in the event of device malfunction or user error [12]. On the basis of their own experience using similar medical devices and the product demonstration, the participants in our study indicated the need for the emergency button to be redesigned and repositioned so that it would be more visible and easily accessible to medical staff or patients in the event of an emergency. Consequently, we determined that the emergency stop system of a medical device has a direct impact on the ability to prevent device malfunction and that it plays an important role in ensuring device safety and efficacy.

The Rebless Pro is a novel device currently under research, meaning that all users, including medical staff and patients, can be considered novices in its operation. As the device is primarily operated by medical staff but worn by patients, it is crucial that the UI design and user manual prioritize intuitiveness and accessibility. This ensures that both medical staff and patients can easily learn to operate the device. Consistent with previous findings, simple terms should be used in the manual to facilitate quick and accurate operation, allowing users to interact with the device intuitively and consistently [25].

From an ergonomic perspective, the medical device design should consider not only convenience and usability but also the prevention of possible injuries caused by repeated strain and the physical defects of individual people [26]. The key to CPM devices is their ability to deliver the same movement as the actual human body through human lower-extremity ROM and accurate alignment [27]. As in previous studies, marking the joint ROM and axes on the surface of the medical device was suggested in this study as an area of improvement for electrically powered orthopedic exercisers, considering the individual physical factors of each patient.

The user manual of a medical device is important not only for usability but also for identifying and understanding information [28]. The user manual explains device operation, maintenance, and troubleshooting, which can potentially affect patient safety [29]. The participants in this study also requested specific information regarding specific operating standards and clear

XSL•FO
RenderX

information about the intended patient groups, including contraindications and applicable age. Based on previous and the present studies, the development of a high-quality user manual is essential for the effective use of the device.

The high average scores (≥4) for ease of use of the UI were likely influenced by the fact that participants assessed the device during a controlled product demonstration rather than real clinical use. The findings also showed that the mean satisfaction for information identifiability and understanding of information were lower in the physical therapist group than in the physiatrist group. In rehabilitation medicine, physiatrists and physical therapists form a collaborative, multidisciplinary team; however, physiatrists are responsible for establishing the overall treatment plan, whereas physical therapists specialize in assessing motor problems and providing rehabilitation training [30-32]. The satisfaction scores may have been lower for physical therapists than for physiatrists because the physical therapists assigned scores for identification and understanding of the Rebless Pro on the basis of their own experience. These findings confirm that when developing a medical device, the intended users should be clearly defined so that they can satisfy the information identifiability and understanding requirements.

Because continuous formative evaluations of improved medical devices are important to ensure their efficacy [33], repeated formative evaluations are required for the commercialization of our high-quality electrically powered orthopedic exerciser. Improving the UI to reduce errors that may cause serious harm is recommended to enhance device efficacy and safety.

Limitations

Owing to the nature of rehabilitation devices, both medical staff who operate the device and patients who receive therapy are considered users. However, this study focused on evaluating the usability of the Rebless Pro prototype from the perspective of rehabilitation professionals, specifically examining tasks performed by medical staff, such as operating the tablet-based controller and assisting patients in wearing the device. Although we did not include patients as direct participants, we obtained valuable insights from health care professionals specializing in rehabilitation medicine, including perspectives from the patient's viewpoint during the evaluation process. Also, standardized tools such as the System Usability Scale were not used for quantitative data collection in this study. To ensure further refinement of the device through iterative formative evaluations, future studies should incorporate standardized tools to collect quantitative data.

Conclusions

If improvements are made to the safety of the electrically powered orthopedic exerciser, the identifiability and comprehensibility of information related to it, and its ease of use based on identified risk factors and areas for UI enhancement, the device can be refined to better meet user needs. This study primarily identified physiatrists and physical therapists as key user groups for evaluating the electrically powered orthopedic exerciser, given their expertise in device operation and patient safety. Future evaluations should further integrate patient feedback to ensure usability and safety from both clinical and end-user perspectives. Iterative formative evaluations involving these specific user groups, alongside the systematic implementation of necessary modifications, will facilitate a summative evaluation of the final product. These efforts are expected to contribute to the commercialization of an electrically powered orthopedic exerciser that prioritizes both safety and usability for its intended users.

Abstract

Background: Within the surgical field, there has been an evolution in the application of robotic technology. Fully automatic robotic systems and augmented visualization tools are being introduced and may eventually replace existing surgical extenders such as the da Vinci surgical system. The literature on public perception of robotic surgery is growing, though specific drivers of these attitudes remain under investigation.

Objective: The aim of this study is to investigate the underlying motivators of public perceptions toward robotic surgeries with varying levels of autonomy through a formal technology acceptance model.

Methods: An online survey was distributed via the Amazon Mechanical Turk platform. Survey participants were provided definitions of a continuum of robotic technologies: robotic surgical extenders (technology without independent actions), semiautonomous robotic surgery (technology that provides guidance to the surgeon and requires surgeon input), and fully autonomous robotic surgery (technology that performs tasks autonomously without direct human interaction). The survey assessed overall attitudes toward each application of robotic technology in surgery and included questions delineating specific receptivity based on (1) perceived usefulness, (2) social risk, (3) time risk, (4) personal risk, and (5) reliability. A technology acceptance model was built to identify associations between these factors and overall attitudes toward robotic and semiautonomous surgeries.

Results: A total of 1221 survey responses were recorded (mean age 38, SD 12 y; females: n=635, 52%). Individuals were more willing to accept robotic surgical extenders and semiautonomous robotic surgery compared to autonomous robotic surgery. Higher levels of education and better self-reported health were correlated with more positive attitudes toward autonomous robotic surgery. Perceptions of these technologies were not associated with age, gender, or income. Overall, attitudes toward robotic technologies in surgery were driven by views on the reliability, safety, and efficiency of the procedures. There was less concern regarding time risk and social risk associated with robotic and semirobotic surgeries.

Conclusions: The public is more accepting of semiautonomous surgery and surgical extenders than fully autonomous surgery. General perceptions of the reliability, safety, and efficiency of these technologies drive variations in attitude. Time and social risk do not appear to have a significant impact on receptivity. Understanding these perspectives can help guide education within an advancing surgical field.

Introduction

Applications of robotic and artificial intelligence technologies in surgery are rapidly developing [1-6]. The predominant robotic surgical technology currently available is surgical extenders such as the da Vinci (Intuitive)—these robotic technologies move only in response to surgeon input and provide nonaugmented visualization to the surgeon. Following surgical extenders, several semiautonomous systems have emerged in various surgical fields. At present, these technologies generally involve the incorporation of image guidance or augmented reality to identify anatomic structures and navigate an operative field [7,8]. Within orthopedics, semiautonomous systems are being used for improved hardware placement during spine surgery and hip surgery [9-13]. Looking further, researchers have developed fully autonomous robotic systems capable of performing tasks such as cochlear implantation [14-16] and

XSL•FO
RenderX

laparoscopic bowel anastomosis [17,18]. Although not yet commercially available, these systems may emerge as standard complements to the surgical workflow.

Despite the promising developments within robotic surgery technologies, there remain social, financial, and regulatory barriers to these systems becoming commonplace. One obstacle is a nascent understanding of the public's perception and tolerance of these technologies. Currently available robotic systems have been shown to improve operating room efficiency and surgical planning [19-23], and the public's attitudes toward these technologies continue to evolve. There is a growing body of research investigating the relationship between sociodemographic factors and views on autonomous technologies within medicine [24,25]. However, the underlying drivers of these perceptions are not fully explored. Given the growing prevalence of autonomous and semiautonomous technologies in our day-to-day lives, we sought to investigate the public's perspectives of the spectrum of robotic systems in surgery. Using a technology acceptance model, we investigate the public's attitudes, and drivers of those attitudes, toward a range of robotic surgery technologies.

Methods

Ethical Considerations

This study was reviewed and approved by the Johns Hopkins institutional review board (IRB00267594). A survey was designed on Qualtrics (Qualtrics LLC) and distributed through Amazon Mechanical Turk (MTurk) in October 2020 (Multimedia Appendix 1). MTurk is a crowdsourcing platform that allows individuals to complete assignments online in an anonymous fashion. All study data were deidentified after collection was complete. A US $0.25 compensation was provided for those who completed the survey and correctly answered all attention check questions.

Participant Recruitment

Respondents were included if they were over 18 years of age and a US resident. The survey included multiple attention check questions to ensure active engagement (eg, "Please select the number 3"). Respondents were excluded if their primary language was not English or if they failed to answer attention check questions correctly. We do not have data on the number of people who viewed but elected not to partake in the survey; therefore, we cannot calculate traditional participation rates. The completion rate of those who started the survey was 97.2%.

Survey Instrument

The survey instrument was designed to assess perceptions and attitudes toward applications of robotic technology in surgery. Each survey started by providing the participant with definitions of 3 levels of robotic technology in surgery:

- Robotic surgical extenders: robot controlled via surgeon, does not perform actions independently without the input of the surgeon.
- Semiautonomous robotic surgery: provides guidance to surgeon based on a patient's information. The robot does not perform actions independently without surgeon input.
- Autonomous robotic surgery: operates and performs tasks on its own, without direct interaction with the surgeon.

Questions in the survey were adopted from previously validated surveys assessing acceptance of technology [26-28]. Respondents rated statements on a 7-point Likert scale from "strongly disagree" to "strongly agree." Higher scores indicated a more positive or favorable opinion toward the technology being assessed. A respondent's overall attitude (A) was interrogated directly via questions in the survey. Further questions were designed to assess one of the following latent variables:

- Perceived usefulness (PU): The ability for robotic technology to improve the care that one receives in surgery.
- Social risk (SR): The possibility that using robotic technology in surgery would lead to disapproval from one's friends, family, or social group.
- Time risk (TR): The loss of time and inconvenience that would result from the use of robotic technology in surgery.
- Personal risk (PR): The physical safety of robotic technology in surgery.
- Reliability (R): The ability of robotic technology in surgery to work reliably over time.

Each latent variable was evaluated by multiple questions, abbreviated by the question number and the latent variable assessed (eg, PU1 and PU2 were the two questions assessing perceived usefulness). All questions were completed for each application of robotic technology in surgery (ie, each latent variable was assessed for robotic surgical extenders, semiautonomous robotic surgery, and autonomous robotic surgery). The relationship between the latent variables and the overall attitude was determined with structural equation models (SEMs) based on the technology acceptance model [29] and theory of planned behavior [30,31]. Participants were also asked to rate their personal comfort and trust with technology, as well as their own health on a 5-point Likert scale. Demographic data of each respondent were also collected. The survey instrument is included in the Multimedia Appendix 1.

Data Analysis

Descriptive analyses, including frequency distribution and central tendency, were performed to illustrate the demographic characteristics and participants' questionnaire responses. Participant education and self-perceived health levels were further stratified into quartiles. ANOVA, *t* tests, and Pearson correlation coefficient were used to compare participants' attitudes and intentions among the surgical extender types, as well as differences in viewpoints among demographic variables.

Confirmatory factor analysis was used to measure the relationship between the measured variables (question responses) and the latent variables (key factors) through factor loading. Multiple SEMs were built to identify associations between the latent variables and overall attitude. Standard regression coefficients calculated by the model represent the ability of our survey questions to capture data on its latent variable. The assumption of multivariate normality was assessed and confirmed with skewness and kurtosis tests. Cronbach α was computed for each key factor to determine the internal

XSL•FO
RenderX

consistency of the research construct. Values of >0.7 indicate high reliability, between 0.5 and 0.7 indicate moderate reliability, and <0.5 indicate low reliability [32].

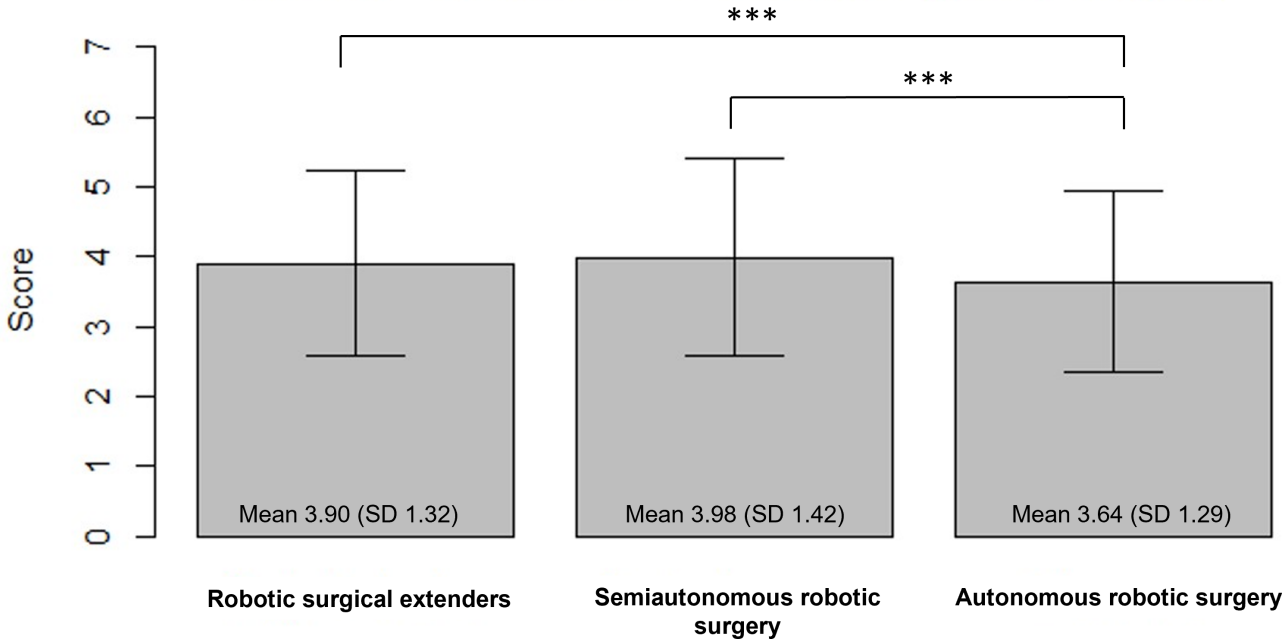
Root mean square error of approximation and X^2 tests were used to measure the discrepancy between the model-based and observed correlation matrices. The final structural model was built and standard regression coefficients were calculated. Data analyses were performed with R (version 4.1.2; R Foundation for Statistical Computing), with SEM calculations performed using the *lavaan* package. All α levels and error probabilities were set at the standard .05 level.

Results

Background Characteristics

A total of 1221 surveys were included for analysis. The mean age of participants was 37.7 (SD 12.1) years. Females made up 51.7% (n=631) of respondents, and the majority (n=940, 77%) were White. Full demographics are listed in Table 1.

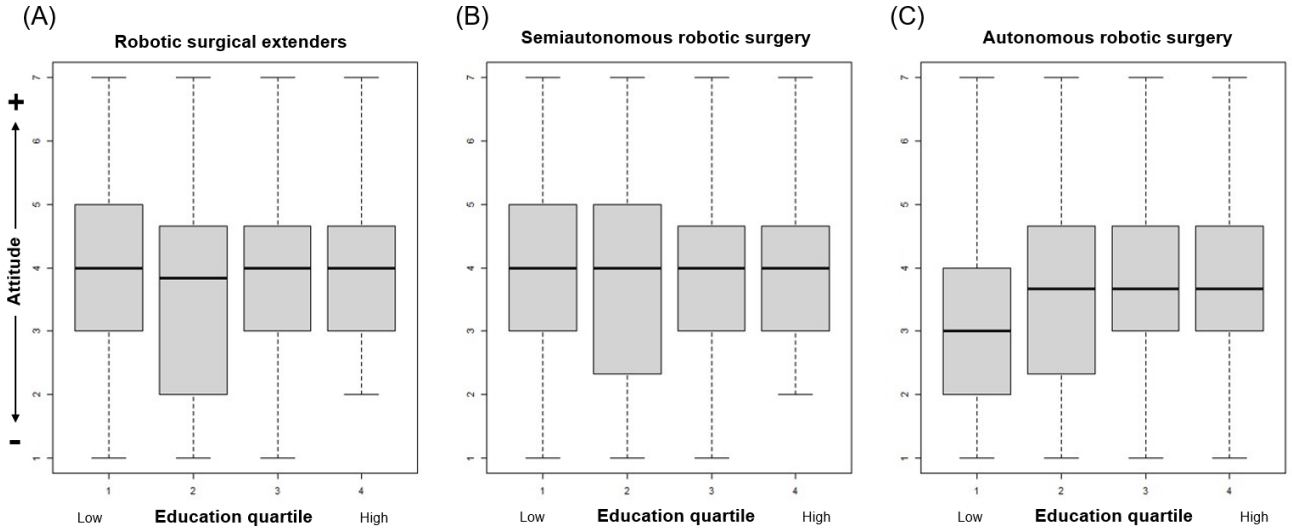
Table . Participant sociodemographics and personal health ratings.



Characteristics	Values
Age (years), mean (SD)	37.7 (12.1)
Gender, n (%)	
Male	580 (47.5)
Female	631 (51.7)
Nonbinary	10 (0.8)
Race/ethnicity, n (%)	
White	940 (77)
African/African American	124 (10.2)
American Indian/Alaska Native	37 (3)
Asian	91 (7.5)
Other	29 (2.4)
Highest level of education, n (%)	
High school graduate or less	78 (6.4)
Some college	226 (18.5)
College degree	671 (55)
Advanced degree (Master's, PhD, MD, etc)	246 (20.1)
Personal rating of health, n (%)	
Excellent	266 (21.8)
Very good	533 (43.7)
Good	334 (27.4)
Fair	73 (6)
Poor	15 (1.2)

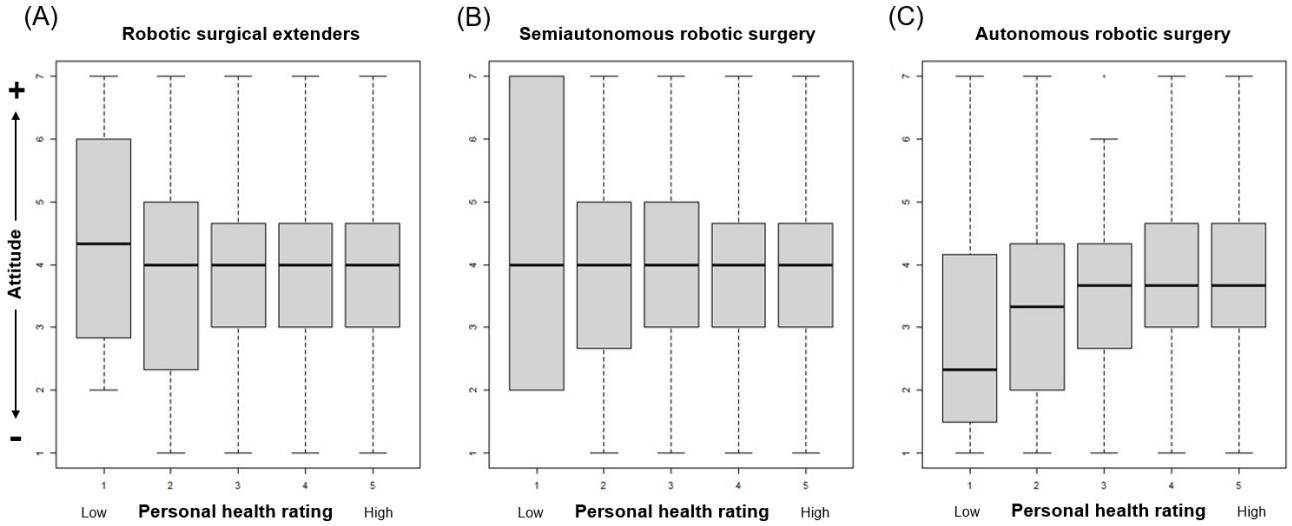
Sociodemographic Associations

The surveyed cohort expressed more positive attitudes toward robotic surgical extenders and semiautonomous robotic surgery compared to autonomous robotic surgery (Figure 1). There was no significant correlation between age and attitude toward robotic surgical extenders (r=0.024, 95% CI −0.032 to 0.080), semiautonomous robotic surgery (r=0.017, 95% CI −0.039 to 0.073), or autonomous robotic surgery (r=−0.0124, 95% CI −0.069 to 0.044). Similarly, there was no significant correlation between gender and race relative to attitude toward all applications of robotic technologies in surgery. There was a positive correlation between comfort with technology and overall attitudes for robotic surgical extenders (r=0.090, 95% CI 0.034 to 0.145), semiautonomous robotic surgery (r=0.088, 95% CI 0.032 to 0.143), and autonomous robotic surgery (r=0.118, 95% CI 0.062 to 0.173).



XSL•FO
RenderX

Figure 1. Comparison of overall attitudes toward different applications of robotic technology in surgery. ***P<.001.



Attitudes toward robotic surgical extenders (P=.24) and semiautonomous robotic surgery (P=.57) did not vary based on level of education. However, respondents with higher levels of education did have more positive attitudes toward autonomous robotic surgery (P<.001, Figure 2). Similarly, there was no significant difference in attitudes toward robotic surgical extenders (P=.60) and semiautonomous robotic surgery (P=.29) across all levels of personal ratings of health. Those with higher ratings of health held more favorable attitudes toward autonomous robotic surgery (P=.003, Figure 3). There was no significant difference in attitudes toward all applications of robotic technology between individuals with or without a surgical history (all P>.05).

Figure 2. Relationships between education and overall attitudes toward different applications of robotic technology in surgery.

XSL•FO
RenderX

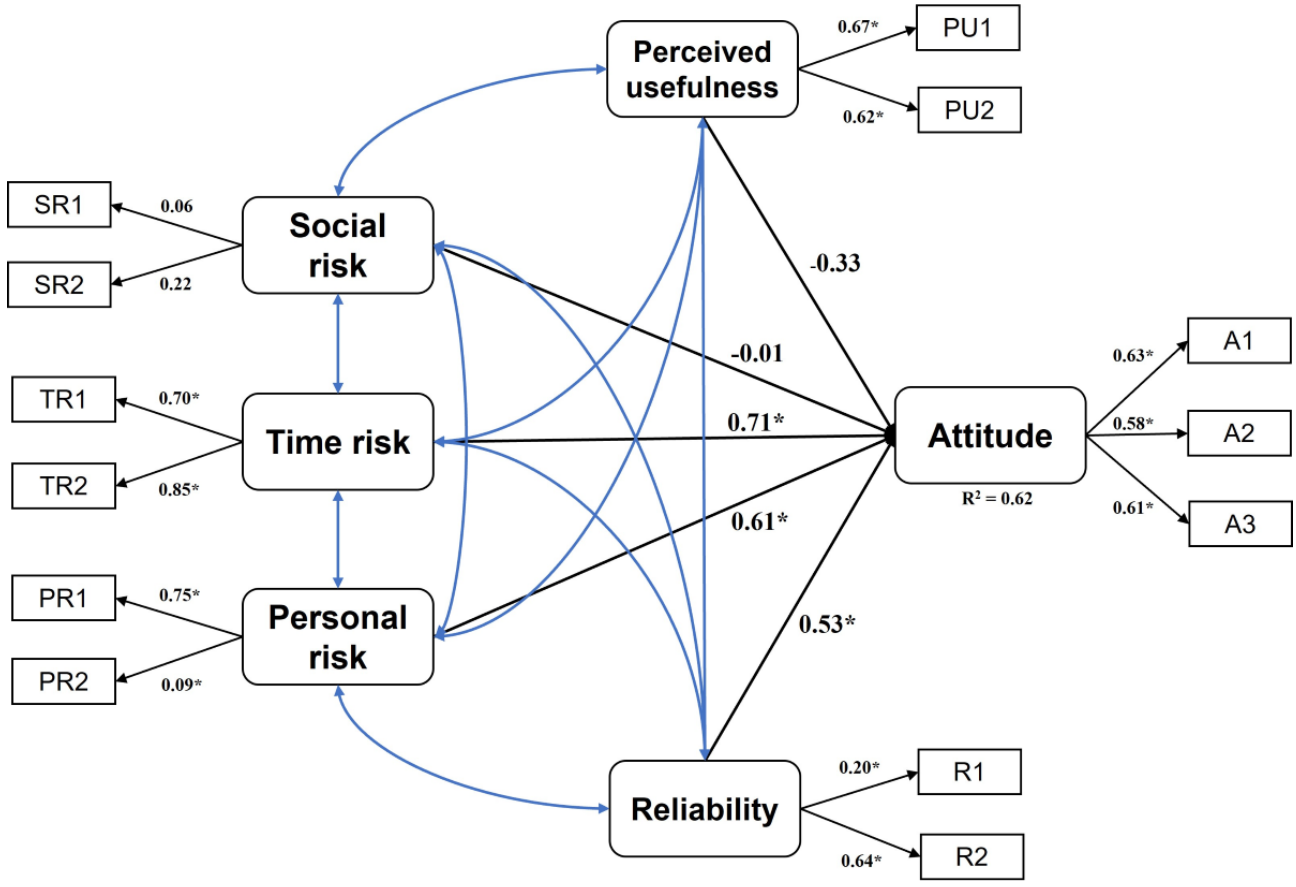


Figure 3. Relationships between personal ratings of health and overall attitudes toward different applications of robotic technology in surgery.

Technology Acceptance Model

An SEM was built to explore the relationships between the latent variables (PU, SR, TR, PR, and R) and overall attitude (Figure 4). The correlation between survey questions for each latent variable was calculated using Cronbach α (Table 2). The low coefficient magnitude (SR1: 0.06, SR2: 0.22) combined with the lack of statistical significance suggest that the concept of "social risk" was poorly characterized by our survey questions. Attitudes toward robotic technologies in surgery were predicted by TR (β=0.71, P<.05), PR (β=0.61, P<.05), and R (β=0.53, P<.05). Together, these variables explain 62% of the variance of attitudes (R^2=0.62, coefficient of determination). SR (β=−0.01, P>.05) and PU (β=−0.33, P>.05) did not significantly affect attitude.

Figure 4. Results of structural equation modeling analysis. A: attitude; PR: personal risk; PU: perceived usefulness; R: reliability; SR: social risk; TR: time risk. *P<.05.

Table . Cronbach α of the survey questions assessing the included latent variables (perceived usefulness, social risk, time risk, personal risk, reliability) and overall attitude.

	Robotic surgical extenders	Semiautonomous	Autonomous	Total
Perceived usefulness	0.81	0.46	0.26	0.59
Social risk	0.01	0.09	0.15	0.02
Time risk	0.76	0.8	0.68	0.75
Personal risk	0.01	0.16	0.34	0.22
Reliability	0.24	0.28	0.38	0.26
Attitude	0.46	0.52	0.45	0.63

Discussion

Principal Findings

Implementation of robotic technology in the operating room setting has the potential to improve the delivery of health care. From a surgeon's perspective, the technical benefits of robotic surgery include improved visualization, better maneuverability, and favorable ergonomics [33,34]. As automated technologies become increasingly integrated into medicine, there has been a growing body of literature on how the public perceives the continuum of robotic procedures [35]. Palmisciano et al [19] found that patients are more favorable toward the use of autonomous technology in noninvasive applications, such as operative planning and preoperative imaging, compared to surgical procedures. In our study, we similarly found that the public is more open to surgical extenders and semiautonomous technologies than fully autonomous systems. Based on our technology acceptance model, the differences in these attitudes appear to be driven primarily by concerns involving safety and reliability, more so than social pressures or apprehension about the usefulness of the technologies. These findings may help guide efforts in patient education as these robotic systems become more commonplace in surgery.

Sociodemographic Correlations

Our study found that individuals with higher levels of education, as well as those with higher personal ratings of health, tend to be more receptive toward fully autonomous surgeries. Education has been well-studied within the technology acceptance model; numerous investigations have demonstrated increased acceptance and utilization of technology among those with secondary or tertiary degrees [36-38]. Werner et al [39] have postulated that this is associated with a relative increase in access to and familiarity with new technologies, while Chen et al [40] have noted that these cohorts are more self-efficacious and may have less technology-related anxiety. From a health perspective, we found that participants with poorer self-ratings of health were associated with a more negative attitude toward fully robotic surgeries. This finding is congruent with studies investigating patterns of use of mobile health devices; for example, Chandrasekaran et al [41] showed that healthier patients are more likely to adopt new health care–associated technology [42]. However, these associations are complex and likely depend on the specific technology in question. Further study is necessary to elucidate the complicated relationship between the perceived health and technology acceptance of surgical patients.

Interestingly, we did not find a correlation between age and attitude toward fully autonomous surgeries. Recent studies investigating technology acceptance within aging populations, such as in Japan and South Korea, have similarly demonstrated a positive perception of robotic technology in an older cohort [43,44]. This is in part driven by the growing ubiquity of semiautonomous technology within day-to-day life, which increases familiarity, builds trust, and changes beliefs and attitudes toward new technology [45].

Drivers of Public Perception

In investigating the drivers of overall patient attitude toward robotic surgeries, we found that risk to patient, reliability of technology, and perceived time risk were the primary concerns. There was less consideration for usefulness or social risk. These results are similar to those found in the autonomous automobile industry [46,47] and for assistive technology in patients undergoing physical rehabilitation [48]. Other studies have also found that apprehension toward adoption of robotic surgeries is driven by fears of equipment error or malfunction [34,49]. The evolution of attitudes toward autonomous driving may be particularly informative. Studies in this space suggest that increased system transparency, which refers to improved user understanding of the operational predictability, is positively associated with acceptance of the technology [46]. Within surgery, an increase in system transparency may begin with addressing misconceptions about these robotic surgical technologies. The colloquial definition and usage of the term "robot" tends to imply a programmable machine that can replicate the actions of a person. For those not familiar with robotic technology in health care, the nuances of its uses may not be readily obvious. In 2016, Boys et al [34] published a survey-based study specifically investigating the perceptions of robotic surgical extenders; interestingly, 21% of their 747 respondents believed that robotic surgical extenders had autonomous function during surgery. To address these misconceptions, the creation of accessible patient education materials, specifically focusing on reliability, safety, and efficiency, may be the best way to impact overall attitudes toward robotic technologies in surgery.

Limitations

There are several limitations to this study. First, while questions in our instrument had been previously validated [26-28], the

XSL•FO
RenderX

consistency of responses related to the latent variables, specifically the social risk, was lower than expected. This may reflect inherent difficulty in summarizing a broad variable within 2 - 3 questions, particularly within health care. However, the drivers of patient attitude that our group identified are similar to those implicated in other areas with a growing autonomous technological presence, including online banking and self-driving cars [26,27,50]. This concordance is reassuring and suggestive of a similar pattern of technological acceptance between fields. Second, we understand that there may be a slight selection bias in the population sampled, as we used an online survey platform, which may have a younger and more technologically savvy population compared to the prototypical patient. However, it is notable that the mean age of patients undergoing the most common robotic procedure in the United States is around 41.5 years, consistent with our survey population. The racial and ethnic breakdown of patients undergoing robotic surgeries is similar to our survey cohort [51]. Additionally, prior studies have also shown that the Amazon MTurk survey results are comparable to those collected by more traditional methods [52-54]. Third, our survey was not able to capture additional socioeconomic variables, such as income or employment status, which may be hidden confounders of our findings. To address some of these limitations, future studies will include an in-person investigation into treatment decision-making and patient preference within robotic surgeries.

Conclusion

Current public perception toward surgical extenders and semiautonomous robotic surgery is more positive than that toward autonomous robotic surgery. Overall attitudes appear to be driven by concerns about the reliability, safety, and efficiency of these technologies. As robotic technologies emerge and continue to evolve within surgery, these findings can inform efforts in directed education. Comprehensive preoperative discussions targeted at the reliability and efficacy—rather than the usefulness or social risk—of these technologies may be more impactful. However, further work is needed in exploring potential obstacles to implementation of robotic systems within surgical practices.

Abstract

Background: Malaysia, an upper middle-income country in the Asia-Pacific region, has an HIV epidemic that has transitioned from needle sharing to sexual transmission, mainly in men who have sex with men (MSM). MSM are the most vulnerable population for HIV in Malaysia. In 2022, our team developed a web-based artificial intelligence (AI) chatbot and tested its feasibility and acceptability among MSM in Malaysia to promote HIV testing. To enhance the usability of the AI chatbot, we made it accessible to the public through the website called MYHIV365 and tested it in an observational study.

Objective: This study aimed to test the usability of an AI chatbot in promoting HIV testing among MSM living in Malaysia.

Methods: This observational study was conducted from August 2023 to March 2024 among 334 MSM. Participants were recruited through community outreach and social-networking apps using flyers. The interactions between participants and the AI chatbot were documented and retrieved from the chatbot developer's platform. Data were analyzed following a predefined metrics using R software (Posit Software, PBC).

Results: The AI chatbot interacted with 334 participants, assisting them in receiving free HIV self-testing kits, offering information on HIV, pre-exposure prophylaxis (PrEP), and mental health, and providing details of 220 MSM-friendly clinics, including their addresses, phone numbers, and operating hours. After the study, 393 human-chatbot interactions were documented on the chatbot developer's platform. Most participants (304/334, 91.0%) interacted with the AI chatbot once, 30 (9.0%) engaged 2 or more times at different intervals. Participants' interaction time with the chatbot varied, ranging from 1 to 31 minutes. The AI chatbot properly addressed most participants' questions (362/393, 92.1%) about HIV and PrEP. However, in 31 interactions, participants posed additional questions to the chatbot that were not programmed into the chatbot algorithms, resulting in unanswered interactions.

Conclusions: The web-based AI chatbot demonstrated high usability in delivering HIV self-testing kits and providing clinical information on HIV testing, PrEP, and mental health services. To enhance its usability in community and clinical settings, the chatbot must offer personalized health information and precise interaction, powered by sophisticated machine learning algorithms. In addition, establishing an effective connection between the AI chatbot and health care systems to eliminate stigma and discrimination toward MSM is crucial for the future implementation of AI chatbots.

KEYWORDS

artificial intelligence; chatbot; feasibility; HIV prevention; HIV testing; men who have sex with men; MSM; mHealth; pre-exposure prophylaxis; PrEP; usability; mobile health

Introduction

Men who have sex with men (MSM) are the most vulnerable population for HIV globally, accounting for 44% of new HIV cases in the Asia-Pacific region [1]. Malaysia, an upper middle-income country in this region, is experiencing one of the fastest growing HIV epidemics in MSM [2,3], characterized by a shift from needle sharing to sexual transmission [4]. The vulnerability of MSM to HIV is associated with various factors, including the stigma and discrimination against HIV and same-sex sexual behaviors [3,5,6]. In Malaysia, same-sex sexual behaviors are criminalized by both secular and Shariah law

XSL•FO
RenderX

[3,7], and discrimination against MSM has extended to clinical settings in physicians and medical students [5]. As a result, MSM in Malaysia must navigate through individual, clinical, and policy barriers that perpetuate stigma and discrimination to minimally access HIV-prevention services, including HIV testing and pre-exposure prophylaxis (PrEP). To increase access to quality HIV-prevention services where stigma and discrimination against MSM persist, leveraging cutting-edge technologies is crucial for developing culturally tailored interventions. Therefore, we propose using an artificial intelligence (AI) chatbot to promote HIV testing and PrEP uptake in Malaysia, aiming to counteract the discriminatory environment MSM face and increase their likelihood of accessing high-quality health care.

An AI chatbot is a software technology embedded with machine learning algorithms that can simulate human conversations through text or voice interactions [8]. Since the emergence of ChatGPT (OpenAI Inc), the world has witnessed the popularity of AI chatbot use. In the literature, numerous studies have discussed the potential of AI chatbots in promoting the efficiency of health care and improving people's access to quality health care services [8]. In the health care industry, however, evidence of testing AI chatbots is urgently needed for guiding the future research and implementation of AI chatbot technology to complement current health care systems, particularly in countries and regions where certain vulnerable populations have limited access to high-quality nonstigmatizing health care services. Studying innovative technologies, such as AI, machine learning, and chatbots, is essential because a major barrier to the implementation of conventional digital health interventions in community and clinical settings is that they often require high-intensity and sustained human inputs, management, and maintenance [8-10]. As AI technology advances, AI chatbot–powered digital interventions are poised to overcome the barrier as they simplify the process of obtaining responses by eliminating the need for users to manually sift through search results as required in web-based searches [8] or navigating complex app interfaces among various app features. With advancements in the AI chatbot algorithms, the search for health information is likely to evolve into a streamlined Q&A process in the future.

AI chatbots applied in health care, however, must be sophisticated enough to provide precise and personalized information and update their responses based on users' inputs without human interventions. This feature is particularly important and promising in intensively busy health care systems, where a significant amount of human labor has traditionally been required to provide health care services regularly and manually. The development and implementation of AI chatbots in health care is still in its early stages. Our team has been conducting research on AI chatbots since 2020, and we have created an AI chatbot and tested its feasibility and acceptability for promoting HIV testing among MSM in Malaysia. We found that such an AI chatbot is acceptable by MSM [3,6]. To further enhance the algorithms and features of the AI chatbot, it is essential to test its usability among a large number of end-users using predefined metrics. Therefore, we conducted this observational study to evaluate the usability of our AI chatbot for promoting HIV testing among MSM in Malaysia.

Methods

Study Design and Participants

The AI chatbot was created and embedded into the website MYHIV365.com. The description of the chatbot and the website has been published elsewhere [6]. In this study, participants were recruited from August 28, 2023, to March 9, 2024, through community outreach and social-networking apps. Three research assistants in Kuala Lumpur, Malaysia, distributed recruitment flyers to MSM-friendly clinics and nonprofit organizations. They also posted the flyers on social-networking apps commonly used by MSM in Malaysia, including WhatsApp, Twitter, Telegram, Facebook, TikTok, Grindr, and Instagram. The eligibility criteria for participants include: (1) aged 18 years or older, (2) able to speak and read Bahasa Malaysia or English, and (3) self-identified as MSM. Participants who reside outside Malaysia were excluded because this study aimed to create an AI chatbot that is culturally tailored for MSM living in Malaysia. We recruited 334 participants, who generated 393 interactions with the AI chatbot. An interaction was defined as a contact initiated by a user with the chatbot.

The 3 research assistants collected research data on human-chatbot interactions through the AI chatbot developer's platform using predefined metrics (Table 1), including satisfaction, recommendation score, number of speech bubbles in each interaction, unanswered questions, interaction time, topic selection, HIV self-testing kit order, depression screening, and clinic searching. A speech bubble was defined as a unit of conversation, which is a visual element commonly used in chat interfaces to represent a chatbot's or user's inputs. For instance, if a user accessed the AI chatbot once and asked 10 questions, then there would be 1 interaction and 10 speech bubbles.

XSL•FO
RenderX

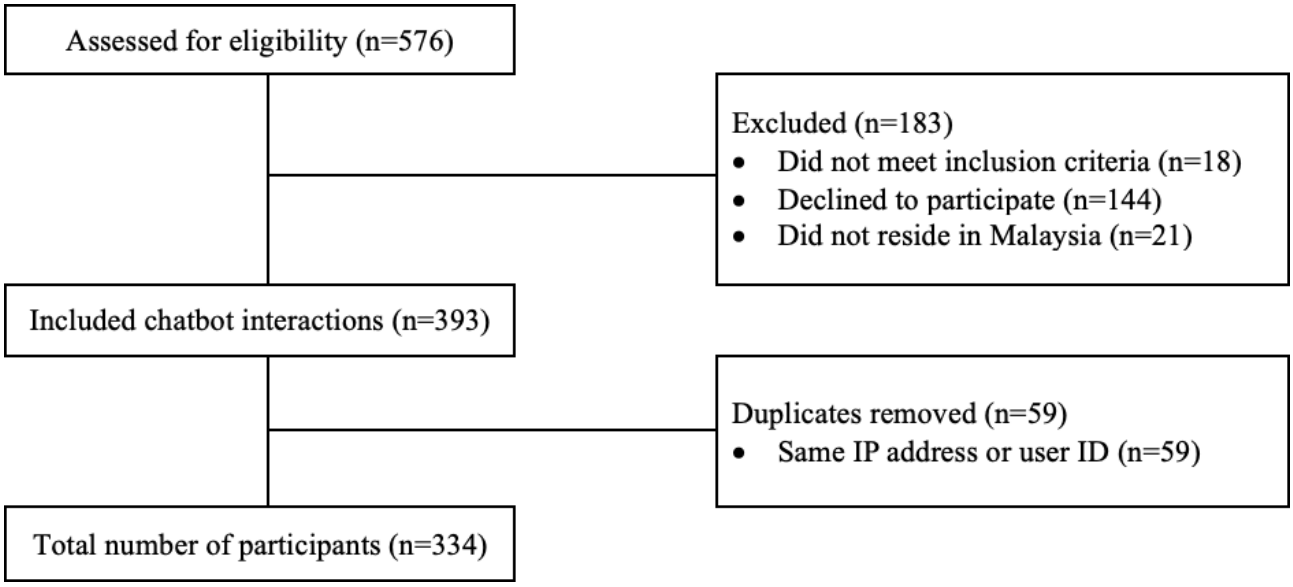
Table . The chatbot usability metrics.

Metrics	Description	Data type
Satisfaction with the chatbot		
Satisfaction level	Do you think this chatbot is useful? "Thumb up" or "Thumb down"	Ordinal
Frequency of the satisfaction evaluation	The frequency with which the chatbot evaluates participants' satisfaction level.	Categorical
Recommendation score	"How likely are you to recommend this chatbot to others?" On the scale, 0 stands for extremely unlikely, and 10 stands for extremely likely.	Numerical (discrete)
Number of speech bubbles	A speech bubble is a visual element commonly used in chat interfaces to represent a chatbot's or user's inputs. Higher counts of speech bubbles reflect greater levels of engagement.	Numerical (discrete)
Unanswered questions		
Additional questions asked by participants	Additional questions asked by participants that were not included in the chatbot algorithms.	String (text data)
Frequency of unanswered questions	Participant's questions to which the chatbot responded with "I cannot understand your question."	Categorical
Interaction time		
Duration	Total time duration of a human-chatbot interaction.	Numerical (discrete)
Contact frequency	Total number of contacts from each participant. Higher frequencies reflect greater engagement with the chatbot.	Categorical
Topic selection	The frequency of topic choices (ie, HIV testing, PrEP, and mental health) selected by participants.	Categorical
HIV self-testing kit order	The number of participants who ordered an HIV self-testing kit.	Numerical (discrete)
Depression screening	The frequency of screening depression using the chatbot.	Categorical
Clinic searching	The frequency of searching for details of MSM-friendly clinics, including their addresses, phone numbers, and operating hours.	Categorical

Statistical Analyses

Descriptive statistics were calculated to summarize the variables listed in the chatbot usability metrics. Categorical variables, such as language used, satisfaction level, satisfaction evaluation, unanswered questions, contact frequency, topic selection, depression screening, and clinic searching were reported as frequency (n) and percentage (%). Numerical variables including recommendation score, number of speech bubbles, duration, and HIV self-testing kit order were reported as mean and SD. All analyses were performed using R (version 4.3.3) software (Posit Software, PBC).

Ethical Considerations



This study received ethical approval from the Yale University Institutional Review Board (Protocol ID: 2000030718) and the Medical Research Ethics Committee of University of Malaya Medical Centre. Participation was voluntary and data were anonymized, thus no compensations were provided. Prior to participation, all participants were provided with a Participant Information Sheet detailing the study. Participants provided electronic consent before beginning the study.

Results

As mentioned, we recruited 334 participants for this study (Figure 1).

XSL•FO
RenderX

Figure 1. The flowchart of participants' recruitment.

Language

In this study, 52.2% (205/393) of the interactions were in English, 47.1% (185/393) were in Bahasa Malaysia, and 0.8% (3/393) were in both languages.

Participants' Satisfaction

The AI chatbot automatically and randomly assessed participants' satisfaction in 127 (32.3%) human-chatbot interactions out of a total of 393. The frequency of evaluations during a single interaction varied randomly; there were occasions when the chatbot assessed participants' satisfaction multiple times but on different topics (eg, HIV testing, PrEP, and mental health). Specifically, the frequency of satisfaction evaluations about the usefulness of the information on HIV testing, PrEP, and mental health was 53, 52, and 32, respectively. We calculated all participants' chatbot evaluations using a scoring system where thumbs up were assigned a value of +1 and thumbs down were assigned a value of −1, resulting in a mean satisfaction score of 1.3 (SD 1.1) (Table 2). Out of the 127 participants who evaluated the AI chatbot, only 14 (11%) provided negative "Thumbs down" feedback. The chatbot randomly assessed the recommendation scores of 43 participants (10.9%) using the Net Promoter Scale, yielding a mean score of 8.4 (SD 2.3).

Variables	Interactions (N=393)	
	Value, n (%)	Mean (SD)
HIV testing	25 (5.9)	
PrEP	65 (16.5)	
Mental health	16 (4.1)	

[a]Not applicable.

[b]In the scoring system, thumb up was assigned as +1, and thumb down was -1.

[c]The chatbot randomly evaluated 127 participants' satisfaction score. In every evaluation, the chatbot may randomly assess more than one topic selected from HIV testing, PrEP, and mental health.

[d]The chatbot randomly evaluated 43 participants' recommendation score.

[e]The contact frequency of 334 participants.

[f]Among the 393 interactions, some were related to more than one topic.

[g]PrEP: pre-exposure prophylaxis.

[h]PHQ-9: Patient Health Questionnaire-9.

Unanswerable Questions

The AI chatbot properly responded to 92% of participants' questions that have already been embedded or trained in the chatbot algorithms. However, in 31 human-chatbot interactions, the AI chatbot failed to respond or provide information for participants' questions. For example, a participant requested to interact with an actual human agent through the AI chatbot, but the AI chatbot failed to do so. Another example is that a user inquired about the existence of NGO clinics in Sepang District, Malaysia, but the AI chatbot failed to provide information.

Chat Bubble Count

We analyzed the number of speech bubbles generated during the human-chatbot interactions. In total, the AI chatbot and participants produced 9665 and 4597 speech bubbles, respectively. On average, the AI chatbot produced 24.6 (SD 14.7) speech bubbles, ranging from 2 to 107, while users contributed an average of 11.7 (SD 8.6) speech bubbles, with a range of 1 to 71. Notably, when participants inquired about all 3 topics (HIV testing, PrEP, and mental health), the number of speech bubbles increased.

Duration of Human-Chatbot Interaction, Contact Frequency, and Topics

The participants' interaction time with the AI chatbot varied, ranging from less than 1 minute to 31 minutes. Among the 393 interactions, 21 (5.3%) interacted with the AI chatbot for less than 1 minute. A total of 303 (77.1%) interactions were conducted over 1 minute to 5 minutes, while 42 (10.7%) interactions took place between 6 to 10 minutes, and 27 (6.9%) interactions extended beyond 10 minutes.

Most participants (91%) interacted with the AI chatbot only once, while 24 (7.2%) engaged with the AI chatbot twice at different times during the study. Four participants (1.2%) interacted with the AI chatbot 3 times, and 2 participants (0.6%) engaged with the AI chatbot 4 times during the study. The most selected topics provided by the AI chatbot were HIV testing (79.6%), followed by PrEP (25.7%) and mental health (12.5%). In this study, 260 (66.2%) orders for HIV self-testing kits were submitted.

Depression

Only 27 (6.9%) participants were assessed for depression, with a mean Patient Health Questionnaire-9 (PHQ-9) score of 13.4 (SD 7.8). Based on the PHQ-9 scoring system, 6 participants were identified as having mild depression, 2 as moderate, 2 as moderately severe, and 8 as severely depressed.

Clinic Information

The AI chatbot provided participants with information on 3 types of clinics–HIV, PrEP, and mental health–including their addresses, phone numbers, and operating hours. In the 393 interactions, 93 (23.7%) participants requested clinics' information through the AI chatbot. Of the 393 interactions, 65 (16.5%) participants inquired about PrEP clinics, 25 (5.9%) inquired about HIV testing clinics, and 16 (4.1%) requested mental health counselors' information.

Discussion

Principal Findings

Our AI chatbot has the capacity to reach a large number of MSM, assisting them in receiving HIV self-testing kits and providing them with information on MSM-friendly clinics to facilitate access to services on HIV testing, PrEP, and mental health. Among all chatbot features, offering free HIV self-testing kits was the most popular, followed by inquiries about MSM-friendly clinics' information, including addresses, phone numbers, and operating hours. The mean satisfaction score of 1.3 (SD 1.1) and mean recommendation score of 8.4 (SD 2.3) reveal participants' favorable view of our AI chatbot. This study demonstrates that an AI chatbot embedded with culturally tailored health services and information has the potential to complement the current health care system by offering automatic and algorithm-based educational materials, consulting services, and free medical tools to facilitate and empower health care consumers. However, a significant barrier to increasing the usability of this AI chatbot is the lack of sophisticated algorithms to facilitate precise and personalized interactions with participants. For example, our AI chatbot showed limitations in addressing questions that were relevant but not directly embedded or trained in its algorithms. To integrate this AI

XSL•FO
RenderX

chatbot into community and clinical settings that offer HIV prevention services to MSM in Malaysia, its algorithms must be improved by integrating more sophisticated AI algorithms and by contextualizing it for specific settings. Without robust algorithms, AI chatbots will not be able to fulfill their potential to streamline processes and improve patient care. They will only be able to undertake simple tasks, such as appointment scheduling and prescription refill reminders, but will be incapable of handling more complex tasks in real clinical settings, including symptom checking, patient triage, mental health support, and answering complex health queries [11]. Not to mention providing empathetic consultation or building trust with users. To develop sophisticated AI chatbot algorithms, emerging techniques such as preference-based fine-tuning, retrieval-augmented generation, and quantum machine learning can enable researchers to build more dynamic, context-aware, and customizable chatbots. These approaches warrant systematic testing and incorporation into health care applications.

In addition to the fundamental role of technical sophistication in supporting AI chatbots' capacities, evidence from the literature demonstrates that researchers worldwide have reached a consensus that the primary factors influencing user engagement with AI chatbots include privacy protection, trustworthiness, and accuracy of information [3,8,11,12]. Despite the promising future of integrating large language models into chatbots as AI advances, testing the efficacy of AI chatbots in HIV prevention and addressing associated ethical and practical concerns remains inadequate [12]. So far, only a limited number of studies have been conducted to evaluate the efficacy of AI chatbots in HIV prevention. These studies are mainly focused on high-income countries and regions, such as the United States, Canada [13], and Hong Kong [14]. There is a scarcity of evidence from low-income nations [15], and very few studies have investigated the feasibility of leveraging AI chatbots to facilitate self-management among people living with HIV [13]. In addition, research comparing the effectiveness of AI chatbots with conventional digital tools, such as short message service (SMS) and mobile apps, remains limited. This gap underscores the importance of conducting this study in Malaysia, as it will provide essential user feedback to enhance our AI chatbot before future efficacy testing against other digital health interventions.

Given that the ChatGPT-4 omni (ChatGPT-4o) has robust and sophisticated algorithms capable of facilitating effective human-chatbot conversations, equipping our AI chatbot with ChatGPT's open-source algorithms might be a solution to the concern that our AI chatbot is not precise and personalized enough for use in real-world health care settings. Therefore, in future studies, we will explore the feasibility of integrating the open-sourced ChatGPT-3 algorithms (ChatGPT-4 is not open-sourced yet) with our AI chatbot to test whether an updated version would be able to overcome this issue. While this integration might be a solution, it has significant barriers. First, the information entered on ChatGPT-3 is documented and could potentially be used for other purposes by the OpenAI Inc. or other third parties; therefore, privacy is a major concern that must be addressed by researchers and chatbot developers. To maintain the confidentiality and security of the information entered, we propose that future AI chatbots equipped with self-developed algorithms and the ChatGPT-3's open-source algorithms should be hosted on a safe and secure server owned by a responsible stakeholder, such as a university's cloud environment, where the evaluation of information security has been completed and ethical approval has been received. For researchers who do not have such resources, we recommend defensive measures to avoid data breaches, including backing up data locally, avoiding storage of sensitive information on the cloud, encrypting all cloud data, installing antivirus software to protect encrypted data, creating strong passwords, changing passwords routinely, and requiring at least 2 identification questions to confirm the authorized users.

Second, ChatGPT's algorithms are used for the public, not specifically designed for HIV prevention and MSM; therefore, after upgrading the algorithms, testing the AI chatbot is a key. The focus of the chatbot testing should be on the chatbot's capability to address contextualized problems and on customized training to improve its usability based on end-users' feedback. The testing and training will be an interactive process, during which health scientists and chatbot engineers need to closely collaborate to tailor the AI chatbot's programming language and codes. More importantly, researchers and engineers interested in developing AI chatbots for health purposes must identify the real-world needs in health care settings. They must create user-friendly AI chatbot solutions to meet the expectations of health care professionals and fulfill the needs of health care consumers. In this study, the frequency of unanswered questions was 31 (8%), which could potentially be addressed by improving the AI chatbot's algorithms. Although this study used an observational design, the contact frequency of 304 (91%) indicates that most participants interacted with the AI chatbot only once. This finding suggests that long-term engagement remains a concern that should be explored and tested in future research. The HIV self-testing kit order rate of 260 (66.2%) indicates that most participants primarily used the AI chatbot to order testing kits. Since participants were able to order free HIV self-testing kits through our AI chatbot, this service appeared to be a key incentive for its use. Providing additional free services and integrating them into the AI chatbot would likely increase sustained user engagement. For future implementation of AI chatbots, the priority is to establish an effective connection between the AI chatbot and trusted health care systems to reduce stigma and discrimination toward MSM, while also offering convenient and free services.

Despite the rapid evolution of research on AI chatbots in health care, the application of AI chatbots in health care systems is still in an early stage. There is a need for clear regulations and standards governing the use of AI chatbots in health care, particularly focusing on privacy protection, accuracy of chatbot outputs, cost-effectiveness, and continuous adaptation. For example, depression is a common health concern among MSM globally, and the use of AI chatbots in providing mental health support has gained attention. In our study, the AI chatbot randomly assessed a small proportion of MSM for depression and identified some as having depression. However, the rationale and rules for the random selection of participants are unknown, and after identifying participants with depression, the next step

XSL•FO
RenderX

of linking them with trusted health care systems is unclear. Future research should be conducted to address these questions.

Linking AI chatbots with health care systems to promote high-quality and easy-access health care services is the ultimate goal of our chatbot project. Given that the design of this study is centered on observing users' interaction with the chatbot, we were unable to evaluate the impact of chatbot use on actual HIV prevention behaviors. Our next step is to conduct a randomized controlled trial to test the efficacy of the AI chatbot in promoting HIV testing in the Malaysian context. We have conducted a series of formative studies, including focus group interviews and alpha and beta tests of AI chatbots [3,6,8]. Combining prior study findings with the results of this national observational study, we aim to create an AI chatbot equipped with our own chatbot algorithms and the open-source ChatGPT-3 algorithms in the social-networking app Telegram, which is a widely accepted app for embedding an AI chatbot among MSM in Malaysia, particularly among young MSM [6]. To test the efficacy of the AI chatbot, we will compare it with an attention chatbot in a longitudinal study aimed at improving HIV testing.

Limitations

This study has contributed important information to the usability of AI chatbots in Malaysia, but it has several limitations. First, participants self-reported whether they met the study's inclusion criteria. Since this is a web-based national observational study, we were unable to validate all participants' eligibility. Second, we counted the number of participants using their internet protocol (IP) address. While this method is accurate in calculating the number of participants who used the same IP address to interact with the AI chatbot, it might not capture the same participant who used different IP addresses. Therefore, the actual sample size of the participants might be less than the calculated total sample size. To address these limitations, in our future randomized controlled trial, we will assign a unique study identification number to every participant along with a unique hyperlink to access the AI chatbot. In addition, since the AI chatbot randomly assessed participants' satisfaction and recommendation scores, this approach might have introduced selection bias, as respondents may have been more engaged or satisfied users. Finally, patients with moderate to severe depression were provided with clinical information, but whether they were linked to care or referred to psychiatrists or mental health specialists for treatment and support was not clear to our study team. Future research should include this follow-up information on participants' engagement with clinical care.

Conclusions

The AI chatbot demonstrated high feasibility in delivering HIV self-testing kits and providing clinical information on HIV testing, PrEP, and mental health services. To enhance its usability in community and clinical settings, the AI chatbot must offer personalized health information and precise interaction, powered by sophisticated machine learning algorithms. In addition, establishing an effective connection between the AI chatbot and health care systems to eliminate stigma and discrimination toward MSM is crucial for the future implementation of the AI chatbot.

Abstract

Background: During the COVID-19 pandemic, in-person visitation within hospitals was restricted and sometimes eliminated to reduce the risk of transmission of SARS-CoV-2. Many health care professionals created novel strategies that were deployed to maintain a patient-centered approach. Although pandemic-related restrictions have eased, these systems, including videoconferencing or web-based bedside visits, remain relevant for visitors who cannot be present due to other reasons (lack of access to transport, socioeconomic restraints, geographical distance, etc).

Objective: The aims of this study were (1) to report the experience of intensive care nursing staff using a bespoke videoconferencing system called ICU FamilyLink; (2) to examine the scenarios in which the nursing staff used the system; and (3) to assess the future use of videoconferencing systems to enhance communication with families.

Methods: A modified Telehealth Usability questionnaire was administered to the nursing staff (N=22) of an intensive care unit in a model 4 tertiary hospital in Ireland 1 year after implementing the bespoke videoconferencing system.

Results: In total, 22 nurses working in the intensive care department at University Hospital Galway, Ireland, responded to the survey. A total of 23% (n=5) of participants were between the ages of 25 and 34 years, 54% (n=12) were between 35 and 44 years, and 23% (n=5) were between 45 and 54 years. Most (n=15, 68%) of the participants reported never using videoconferencing in the intensive care setting to communicate with family members before March 2020. The modified Telehealth Usability Questionnaire showed overall satisfaction scores for each subcategory of ease of use and learnability, interface quality, interaction quality, reliability, satisfaction and future use, and usefulness. In total, 21 (95%) participants agreed or strongly agreed with the statement, “I would use the ICU FamilyLink system in future circumstances in which family members cannot be physically present (ie, pandemics, abroad, inability to travel, etc),” and 1 participant responded neutrally. One participant highlighted a common scenario in intensive care settings in which a videoconferencing system can be used “Even without COVID, web-based communication is important when patients become unexpectedly ill and when families are abroad.”

Conclusions: This study provides valuable insights into health care professionals’ experience using a videoconferencing system to facilitate web-based visits for families. We conclude that videoconferencing systems when appropriately tailored to the environment with the users in mind can be an acceptable solution to maintain communication with family members who cannot be physically present at the bedside. The bespoke videoconferencing system had an overall positive response from 22 nursing staff who interacted with the system at varying frequency levels.

Introduction

Background

In recent years, many intensive care departments have adopted a patient- and family-centered care approach. This includes having close family members physically present at the bedside during day-to-day activities and attending care meetings. Previous studies have highlighted the psychological and physical benefits of this approach for patients and their families during an individual's inpatient stay in intensive care [1-3]. However, having family members physically present at the patient's bedside can be difficult or even impossible due to geographical distance, financial challenges, and other family obligations. A significant barrier to bedside visits in the recent past was the COVID-19 pandemic.

The pandemic imposed severe and often complete restrictions on visits and forced health care professionals to change their traditional way of delivering patient care [4]. Prior to COVID-19, critical care nursing staff had been striving toward involving relatives in the intensive care unit (ICU) setting. However, many ICUs suspended these practices with the imposition of visitor restrictions [5]. These restrictive policies were introduced to decrease the risk of transmission of COVID-19 in health care settings [4]. These policies have been shown to be extremely isolating for patients, distressing for family members, and even hampering clinical care provided by health care professionals [1,6]. In particular, patients who are critically ill or vulnerable are often reliant on family for support, and at times, families are surrogate decision makers for patients. Health care professionals quickly realized the impact of visitor restrictions on family-centered care in intensive care settings. They called urgently for ways to maintain communication with family members who were no longer allowed to be physically present at the bedside [7]. At the beginning of the pandemic, hospitals quickly adopted technological solutions, including videoconferencing systems, to maintain or reopen communication channels. Previous studies have shown that adopting telemedicine solutions has numerous barriers, including the user's acceptance and experience with the technology [8-10]. Other studies have shown positive patient experiences using videoconferencing systems for web-based family support during patient rounds. However, other studies identify challenges for health care professionals, including additional workload and difficulty learning and integrating new technology into clinical practice [11,12].

Prior to the pandemic, videoconferencing in the intensive care department was limited to tele-ICU and rarely used for remote family communication. At the start of the COVID-19 pandemic, ICUs worldwide adopted various modes of maintaining communication with family members who were not allowed to be physically present at the bedside due to the risk of transmission of COVID-19. Intensive care units often serve wide geographical areas, so videoconferencing systems have the potential to improve communication with patients' families and reduce the psychological effects of intensive care admission on both patients and families. Videoconferencing systems can enable family members who cannot be physically present to be more involved during a patient's intensive care journey.

Aim of the Study

The aims of this study were (1) to report the experience of intensive care nursing staff using a bespoke videoconferencing system designed for patients and staff to communicate with patients' families remotely during hospitalization in an intensive care department of a tertiary referral hospital that had no prior video-calling system in place; (2) to examine the scenarios that nursing staff used the videoconferencing system; and (3) to assess the future use of videoconferencing systems to enhance family communication in intensive care settings using a modified version of the validated Telehealth Usability Questionnaire (mTUQ) [13].

Methods

Overview of ICU FamilyLink

A bespoke videoconferencing system called "ICU FamilyLink" was developed for the intensive care environment to allow for ad hoc web-based bedside visits available 24/7 with 1 or more close family members who may be in separate households [14]. The system was designed to be easy to use and to allow health care professionals to maintain appropriate control to maintain the security and privacy required for a hospital setting. The technology was chosen to deliver a reliable connection with high-quality audio and video. Several key requirements were previously identified during the iterative process of development [14]. This system used a 23-inch touch-screen video end point mounted on a mobile unit stand with a commercial cloud videoconferencing platform (Figure 1).

XSL•FO
RenderX

Figure 1. Video end point mounted on a mobile unit stand at an intensive care unit bedside.

A simple menu was designed for ease of use and maximum video-call security. Functions such as recording, chat, and screen sharing were disabled for security and privacy. The home screen mirrored the department's naming scheme for patient bed spaces and had the minimum number of clicks to connect. Three mobile video units were available for bedside web-based visits, and a stationary unit was available in a quiet room for medical staff to meet with families digitally.

A suite of documents, email templates, and multimedia was also created to support staff training, use, and troubleshooting. In addition, volunteer IT professionals operated a helpline for family members to ensure clinical staff were not burdened by technical queries outside their clinical training scope. A Data Protection Impact Assessment was completed, and the system was in keeping with hospital protocol and General Data Protection Regulation compliant.

The system was developed and rapidly introduced, with the first call within 2 weeks and the complete system rollout in under 3 weeks. Despite this rapid rollout, significant emphasis was placed on staff training, completion of relevant hospital risk assessments, and adherence to hospital policies. Focus on these areas was essential to ensure that staff, who were the main facilitators of the system, would find the system acceptable.

Survey Development

The validated Telehealth Usability questionnaire (TUQ) was used with minor modifications to capture relevant information to the specific use case [13]. The modified questionnaire (mTUQ) was developed with input from clinicians, engineers, a medical physicist, and a senior intensive care nurse.

The survey consisted of 40 questions in total. It included 22 questions from the TUQ, using a 7-point Likert scale, to assess the ease of use and learnability, interface quality, interaction quality, reliability, satisfaction and future use, and usefulness. The remaining questions ascertained participants' demographics and details on the respondent's use of the videoconferencing system in the ICU. Free-text comment boxes were available to gather additional qualitative data.

XSL•FO
RenderX

Recruitment

The mTUQ was distributed in paper form and via a web-based survey 1 year after the ICU FamilyLink was deployed. This allowed the system to become established in the department and minimized any bias that may have been created at the peak of the pandemic. All ICU nursing staff were eligible to participate in this study. Nursing staff were the primary users and facilitators of the ICU FamilyLink system. The system was mainly used for web-based bedside visits, rather than formal medical updates from the ICU medical team, although it was available if needed. The survey was open to any ICU staff member. Staff were recruited via emails, verbal reminders at nursing handover, and paper copies of surveys left in break rooms and main staff areas.

Data Analysis

Data were exported from the web-based survey and manually inputted from the paper surveys into a Microsoft Excel spreadsheet for analysis.

Ethical Considerations

Ethics approval for this study was obtained from the Galway Hospital Clinical Research Ethics Committee (ref C.A. 2674), and written informed consent, including web-based signatures for web-based participants was obtained from all respondents. All respondents participated voluntarily, could opt out at any point, and did not receive financial compensation. All data were anonymized.

Results

A total of 22 nurses who had been working in the intensive care unit at University Hospital Galway responded to the survey. All the respondents had used the ICU FamilyLink system at least once, although prior usage was not a requirement for participation in this study.

Characteristics of Participants

All participants were nursing staff, of these, 18% (n=4) were nurse managers. In total, 23% (n=5) of participants were between the ages of 25 and 34 years, 54% (n=12) were between 35 and 44, and 23% (n=5) were between 45 and 54 years. A total of 68% (n=15) of participants reported that they had never used videoconferencing in the intensive care setting to communicate with family members prior to March 2020 (Table 1).

During the initial introduction of the system, short training sessions were held, “superusers” were trained, and an instruction manual and video training were created. The survey showed that 36% (n=8) of participants watched a colleague before independent use and 77% (n=17) asked a colleague to teach them.

Table . Baseline characteristics of respondents.

	Respondents (N=22), n (%)
Age categories (years)	
25-34	5 (23)
35-44	12 (54)
45-55	5 (23)
Role	
Staff nurse	18 (82)
Nurse manager	4 (18)
Prior experience with any videoconferencing software in the critical care setting to communicate with patient’s family members	
Yes	7 (32)
No	15 (68)
Frequency of use (number of video calls)	
1-2	6 (27)
3-5	3 (14)
6-10	4 (18)
10-20	4 (18)
>20	5 (23)

Participants’ Use of ICU FamilyLink

The system’s usage was examined based on the frequency of video calls made (Table 1) and various scenarios (Table 2). In total, 27% (n=6) of participants used the system only 1-2 times, while 23% (n=5) of participants used the system over 20 times. Participants most commonly used the system for family time with patients while the staff were present (n=19, 86%), family time with the patient without clinical staff present (n=15, 68%), and providing daily progress updates (n=10, 45%). In total, 27% (n=6) used the system for remote family support while 1 family member was physically present at the bedside. While 9% (n=2) of respondents used the system to deliver bad news, 14% (n=3) used the system for an end-of-life scenario; 1 respondent

XSL•FO
RenderX

reported using the system for a formal care team meeting with the family. In addition, respondents were asked what purposes they felt the system was not suitable for (Table 3). A total of 45% (n=10) of respondents felt that delivering bad news and end of life were not suitable scenarios for using the videoconferencing system (Table 3). One respondent commented that, "Ideally, you would give bad news in person, but it could be used if not possible."

Table . Use of the ICU FamilyLink system.

Scenarios that the respondent has used the ICU FamilyLink system	Respondents (N=22), n (%)
Family time with the patient (while clinical staff carry out routine care)	19 (86)
Family time with the patient (without clinical staff present)	15 (68)
Daily progress updates	10 (45)
Remote family support for a designated in-person family member	6 (27)
End of life	3 (14)
Giving bad news	2 (9)
Formal care team meeting or family meeting	1 (4)
Education session for family	0 (0)

Table . Scenarios that participants felt were not suitable for the ICU FamilyLink system.

Clinical scenarios	Respondents (N=22), n (%)
Giving bad news	10 (45)
End of life	10 (45)
All are suitable	7 (32)
Formal care team meeting or family meeting	3 (14)
Education session for family	2 (9)
Daily progress updates	1 (4)
Other	1 (4)
Family time with the patient (without clinical staff present)	1 (4)
Family time with the patient (while clinical staff carry out routine care)	1 (4)
Remote family support for a designated in-person family member	0 (0)

Usability Attributes of the Videoconferencing System Using the mTUQ

The mTUQ showed an overall positive satisfaction score for all subcategories, including ease of use and learnability, interface quality, interaction quality, reliability, satisfaction and future use, and usefulness (Table 4).

XSL•FO
RenderX

Table . Responses to the modified Telehealth Usability questionnaire (N=22).

	Strongly disagree, n (%)	Disagree, n (%)	Somewhat disagree, n (%)	Neutral, n (%)	Somewhat agree, n (%)	Agree, n (%)	Strongly agree, n (%)
Ease of use and learnability							
1. It was easy to learn how to set up and use the system.	0 (0)	0 (0)	2 (9)	3 (14)	6 (27)	3 (14)	8 (36)
2. It was simple to use the system.	0 (0)	0 (0)	3 (14)	2 (9)	8 (36)	2 (9)	7 (32)
3. Compared to facilitating and managing in-person visits, the FamilyLink system was a more time-efficient way to engage with families.	0 (0)	2 (9)	1 (4)	4 (18)	7 (32)	6 (27)	2 (9)
Interface quality							
4. I am able to navigate setup, initiate, and complete calls without difficulty.	0 (0)	1 (4)	2 (9)	4 (18)	4 (18)	3 (14)	8 (36)
5. The onscreen menu for FamilyLink was intuitive to navigate.	0 (0)	1 (4)	0 (0)	2 (9)	5 (23)	6 (27)	8 (36)

Usefulness							
21. The ICU FamilyLink system provides for continuity of communication while visiting is limited.	0 (0)	0 (0)	0 (0)	0 (0)	2 (9)	5 (23)	15 (68)
22. The ICU FamilyLink system has positively impacted the overall care of patients in critical care during the visitor restrictions.	0 (0)	0 (0)	0 (0)	1 (4)	3 (14)	5 (23)	13 (59)

Ease of Use and Learnability

The majority of nursing staff responded positively to ease of use and learnability questions. Interestingly, when specifically asked to compare the time efficiency of organizing in-person visits versus web-based visits (question 3), 18% (n=4) of participants responded neutrally, 14% (n=3) provided negative responses, and 68% (n=15) gave positive responses (Table 4, questions 1-3).

Two comments were made about the process of sending the videoconferencing link to family members, indicating the need to improve the process.

The equipment itself was very easy to use, it can be a pain to log out of the computer and relog in, an app on the computer at the nurses station would be better.

[Respondent who used the system 10-20 times]

I think it would be beneficial if the email sent to the families to download the software could be sent to every computer in the unit.

[Respondent who used the system more than 20 times]

These comments indicate an area for improvement to reduce the burden of work for staff members and highlight the frustration staff commonly feel when newly introduced technology adds extra tasks. There are limitations to fully integrating technology; however, decreasing the administration time for the clinical staff could lead to better technology uptake. Despite this feedback, the 2 participants reported frequent use of the system.

Interface Quality

Nursing staff most frequently responded with “strongly agree” to the interface quality questions, question 4 (n=8; 36%), question 5 (n=8; 36%), and question 6 (n=10; 45%), respectively (Table 4).

XSL•FO
RenderX

Free text comments from 2 participants included “very simple and easy to use” and “good quality.”

Interaction Quality

A total of 64% (n=14) participants strongly agreed that the video and audio quality was good and provided clear 2-way conversation. When asked about their preference for the ICU FamilyLink monitor on a stand rather than a handheld device or smaller tablet, the majority of participants (n=16, 73%) responded in the positive, only 6 (27%) participants were neutral, and none responded in the negative. Most of the respondents (n=17, 77%) felt that compared to telephone conversations, the ICU FamilyLink was better for communicating and expressing important messages (Table 4, questions 7-11).

One participant highlighted the importance of network coverage for family members, though beyond the hospital’s control, was an important factor: “Very dependent on internet coverage for the family.” Another participant indicated that the visual aspect of the system was better than phone communication: “It helped build a connection with families that isn’t possible via phone.”

Reliability

Overall, respondents more frequently responded positively to reliability (Table 4, questions 12-15). However, 4 (18%) respondents disagreed or strongly disagreed with the statement, “I felt the ICU FamilyLink system facilitates private and secure communication.”

Satisfaction and Future Use

All participants responded positively to the statement, “The ICU FamilyLink system is an acceptable way to communicate while visitors are restricted.” In total, 21 (95%) participants agreed or strongly agreed with the statement, “I would use the ICU FamilyLink system in the future circumstances in which family members cannot be physically present (i.e., pandemics, abroad, inability to travel, etc),” and 1 participant responded neutrally (Table 4, questions 16-20).

Qualitative data also indicate health care professionals’ positive feedback and wish to use the system in the future:

Even without COVID, online communication is important when patients become unexpectedly ill, and families are abroad.

Extremely valued by family members, I have had limited exposure to its use due to working mostly night shifts.

Familylink has been a lifesaver during the pandemic; in my opinion, it is very easy to use and great for patients to be able to see their relatives onscreen while visiting is restricted. I will use it at any opportunity.

Usefulness

In total, 21 (95%) participants responded positively to questions about usefulness (Table 4, questions 21 and 22), except 1 neutral response to question 22: “The ICU FamilyLink system has positively impacted the overall care of patients in intensive care during the visitor restrictions.”

Discussion

Overview

With an overall shift toward a patient- and family-centered approach, health care professionals can harness technology to enable and optimize this approach. However, with the introduction of any technology into a new environment, particularly one as complex as health care delivery, careful design, assessment, and research should be completed to ensure acceptability, usability, and impact on all users. While health care professionals are trained to a high degree in health and medicine, their training, understanding, and use of technology vary widely.

Strengths, Limitations, and Future Directions

This study included participants who had only interacted with the ICU FamilyLink system a handful of times and also very frequent users. It also was inclusive for all age ranges and had both staff grade and senior nurses. In usability studies, it is vital to capture input from all spectrums of technical users.

One limitation of this study was that it did not interview or survey patients or their families. While this was considered, due to limited staff and stressful circumstances for patients and families, it was not included as a component of the study. There have been studies recently published examining family and patient experiences in using both phone and video for web-based visits [15-17]. Staff acceptance is critical for implementing systems like the ICU FamilyLink into regular practice. ICU staff are usually required to facilitate these calls due to the dependency needs of the ICU patients.

This study, like many similar studies, was conducted under pandemic conditions. The TUQ was modified to account for these conditions. It is encouraging that responses to questions on usefulness and future use are overall positive, with 68% (n=15) of respondents “strongly agreeing” that they would use the ICU FamilyLink system in future circumstances in which family members cannot be physically present (question 18). While there are positive indications for postpandemic use and its potential value is noted by the staff members, confirming these results outside of pandemic conditions would be important.

Conclusions

The findings of this study provide valuable insights into health care professionals’ experiences using a videoconferencing system to facilitate web-based bedside visits for family members. We conclude that when appropriately tailored to the environment and with the users in mind, videoconferencing systems can be an acceptable solution for maintaining communication with family members who cannot be physically present at the bedside. Further studies are needed to better understand usability factors for technology in order to enhance and augment communication with ICU patients, staff, and patients’ family members.

Abstract

Background: Using wearable activity trackers shows promise in measuring physical activity in patients with axial spondyloarthritis (axSpA). However, little is known regarding the feasibility of long-term use.

Objectives: This study aimed to explore the feasibility of recording physical activity using a wearable activity tracker and describe wear-time patterns among patients with axSpA.

Methods: Data from a randomized controlled trial (NCT: 05031767) were analyzed. Patients with axSpA and low disease activity were recruited from an outpatient clinic and asked to wear a Garmin vívosmart 4 activity tracker for 1 year. The activity tracker measured steps and heart rate. Trial feasibility (eligibility, inclusion rate, and patient characteristics), technical feasibility (data recorded, tracker adherence, ie, days worn, and missing data), and operational feasibility (synchronization reminders and tracker replacements) were analyzed. Tracker adherence was calculated as the percentage of recorded minutes of the maximum possible minutes. Unsupervised hierarchical clustering was used to explore tracker wear-time patterns.

Results: Of the 160 patients screened, 75 (47%) agreed to use the tracker and 64 (85%) were analyzed (11 had insufficient data). The median activity tracker adherence over 1 year was 66% (IQR 30 - 86). There was 30% missing step and 0.01% heart rate data in the physical activity dataset. A median of 18 (IQR 9 - 25) reminders per patient to synchronize activity data were distributed. Analysis of wear-time patterns resulted in 3 groups: Adherent (33/64, 51% of patients), Minimal Use (17/64, 27%), and Intermittently adherent (14/64, 22%).

Conclusions: Trial feasibility was low, while technical and operational feasibility were acceptable. Only 51% of the patients were highly adherent. Activity trackers, though trendy, have low to moderate feasibility over 1 year in patients with axSpA. Automated synchronization and adherence barriers should be further explored.

KEYWORDS

physical activity; wearables; axial spondyloarthritis; activity trackers; feasibility

Introduction

Recent technological advancements enable novel ways of managing patients with chronic disease by using wearable devices, such as activity trackers [1]. In addition to measuring physical activity, wearable activity trackers can act as motivators to increase levels of physical activity [2-4]. axSpA is a chronic inflammatory joint disease, primarily characterized by sacroiliitis, back pain, and stiffness [5]. First-line management

XSL•FO
RenderX

includes nonsteroidal anti-inflammatory drugs and regular exercise [6]. However, there are indications that patients with axSpA engage in lower levels of physical activity compared with healthy people [7-9] and that they report more barriers to engaging in physical activity compared to controls [10]. Identifying physically inactive patients allows for optimized treatment by supporting patients' self-management of their disease and potentially enhancing exercise adherence [11,12]. The passive collection of data using wearables has been highlighted as a goal within remote monitoring in rheumatology, as it may ease the monitoring of disease activity besides using electronic patient-reported outcomes [13,14]. In addition, continuous measurement with an activity tracker has the potential to provide further insight into how the physical activity levels of patients with axSpA are affected by their disease [15-17].

In other patient groups, such as osteoarthritis and gout, research has shown low to acceptable adherence to the use of activity trackers during 3- and 6-month periods, with declining adherence toward the end of the studies [18,19]. However, further investigation is warranted, given the lack of evidence on the feasibility and adherence to long-term use of wearable activity trackers among patients with axSpA [20-24].

The aim of this study was to explore the trial, technical, and operational feasibility of measuring physical activity using commercially available wearable activity trackers over 1 year among patients with axSpA. Second, the study aimed to analyze wear-time patterns and compare patients' demographic and clinical characteristics between the wear-time clusters.

Methods

Study Design and Setting

This study includes a post hoc analysis of a randomized controlled trial, titled Remote Monitoring in Specialist Health Care Study (ReMonit, ClinicalTrials.gov: NCT05031767). The primary results of the trial are reported elsewhere [25]. The ReMonit Study was a 3-armed randomized controlled trial comparing remote monitoring and patient-initiated care to usual care (prescheduled regular hospital visits) among patients with axSpA [26]. Patients were recruited from an outpatient clinic at Diakonhjemmet Hospital, Oslo, Norway, and randomized 1:1:1 ratio to receive usual care, remote monitoring, or patient-initiated care. Patients randomized to the remote monitoring and patient-initiated groups were asked to use the activity tracker for 1 year. This was a commercially available activity tracker (Garmin vívosmart 4). Physical activity data recorded by the vívosmart 4 was wirelessly transferred manually by patients each week via Garmin Software Development Kit to the MyDignio app [27].

Patients

In the ReMonit study, patients with axSpA with low disease activity (Axial Spondyloarthritis Disease Activity C-Reactive Protein Score (ASDAS-CRP) <2.1) and stable treatment with a tumor necrosis factor inhibitor (TNFi) over the past 6 months were included [26]. Since we used the Garmin Software Development Kit for the present study, patients who already used a Garmin device and the Garmin Connect app could not be included, as this interfered with synchronization of data to the MyDignio app. In addition, due to privacy regulations, direct downloading of data from the patients' private Garmin devices was not allowed. Therefore, patients could not use their private devices in the present study.

Data Collection

At baseline, patients completed a digital questionnaire including age, sex, education level, and working status. BMI was calculated based on self-reported body height and weight, and information on years since diagnosis of axSpA was obtained from their medical records. The patients completed the recommended disease-specific questionnaires [28] such as Bath ankylosing spondylitis disease activity index (BASDAI) (0 - 10, 10 being the worst score), Bath ankylosing spondylitis functional index (BASFI) (0 - 10, 10 being the worst score), and patient global assessment (0 - 10, 10 being the worst score) [29,30]. The ASDAS-CRP was calculated based on patients' self-reported disease activity-related questions and measurement of C-reactive protein [31]. The Work Productivity and Activity Impairment item 6 (WPAI) (0 - 10, 10 being the worst score) was used for measuring the impact of the disease on patients' everyday life [32]. In addition, eHealth literacy was measured by 4 scales from the eHealth Literacy Questionnaire [33]: Using technology to process health information (Scale 1), Ability to actively engage with digital services (Scale 3), Feel safe and in control (Scale 4), and Motivated to engage with digital services (Scale 5). For measuring self-reported physical activity and exercise, we used 3 items from a population-based study measuring the frequency, duration, and intensity of exercise [34]. We then further stratified the patients into 3 groups based on whether the level of physical activity was below recommended (below 150 min of moderate-intensity exercise per week), at recommended (150 moderate or 60 vigorous minutes each week), or above recommended [35].

Feasibility

To assess the feasibility of using activity trackers for measuring physical activity, we categorized feasibility into 3 novel subcategories inspired by a previous feasibility study on activity trackers [18].

Trial Feasibility

This included the inclusion rate (number of patients included), eligibility of patients (characteristics of patients who declined and those included), proportion of patients with recorded data, and differences in patient characteristics between patients in the clusters. For evaluating the trial feasibility, we considered the inclusion rate and proportion of patients with recorded data corresponding to <50% as low, 50 - 70% as moderate, and >70% as high.

Technical Feasibility

This included the number of physical activity minutes recorded by patients, adherence to wearing the activity tracker, and missing data on steps or heart rate. Adherence to the use of the activity tracker was defined and calculated as the number of minutes with recorded data by each patient (per minute) divided by the total number of minutes during daytime (16 h; 348,000

XSL•FO
RenderX

min × 100). Adherence was classified as either low (<50%), moderate (50 - 70%) or high (>70%). An acceptable level of missing data was determined to be below 40% [36].

Operational Feasibility

This included the number of automatic reminders sent to the patients (in comparison to the total maximum possible number of 3900 reminders, eg, 52 weeks × 75 patients), and number of replaced activity trackers during the 1-year period. Equal to or less than a median of 26 reminders per patient (eg, in 50% of the weeks) and<15% replacements of activity trackers in the study sample were deemed acceptable.

Measurement of Physical Activity

The patients received oral and written instructions stating that the activity tracker should be worn on the non-dominant wrist for at least 10 hours a day. It should not be worn on the outside of garments but could be used while swimming and showering. Instructions were also given regarding charging, connecting, and synchronizing the device with the app. Contact information for the study team was provided in the event of technical issues.

The Garmin vívosmart 4 activity tracker (Olathe) was integrated into the MyDignio app by the company Dignio. Physical activity data were recorded at a minute level, measuring both steps per minute and average heart rate during the concurrent minute. The Garmin vívosmart 4 uses an accelerometer for measurement of physical movement and activity and a photoplethysmography sensor for measuring heart rate [37].

In order to reduce data noise from the activity tracker, a filter was applied by Dignio, which filtered out heart rate values below 20 beats per minute. The native Garmin motivational messages and notifications were muted. Patients were instructed to weekly synchronize physical activity data manually from the device using the MyDignio app due to limited internal memory of the activity tracker. If patients failed to synchronize in time, the MyDignio app automatically sent a push notification as a reminder. If patients still did not synchronize after receiving the push notification, the study team followed up with an SMS text message reminder. The number of manual SMS text message reminders sent out was not registered. Any technical issues regarding app connectivity or the activity tracker were primarily resolved by the study team, or if necessary, by developers at Dignio.

Data Analyses

Median values with IQR or mean values with SD were used for describing the demographical and clinical variables. Data regarding the trial, technical, and operational feasibility were described by either percentage, mean with SD, or median with IQR. Differences between patients agreeing to use a wearable compared to those declining were assessed by the Mann-Whitney *U* test or Student's *t*-test.

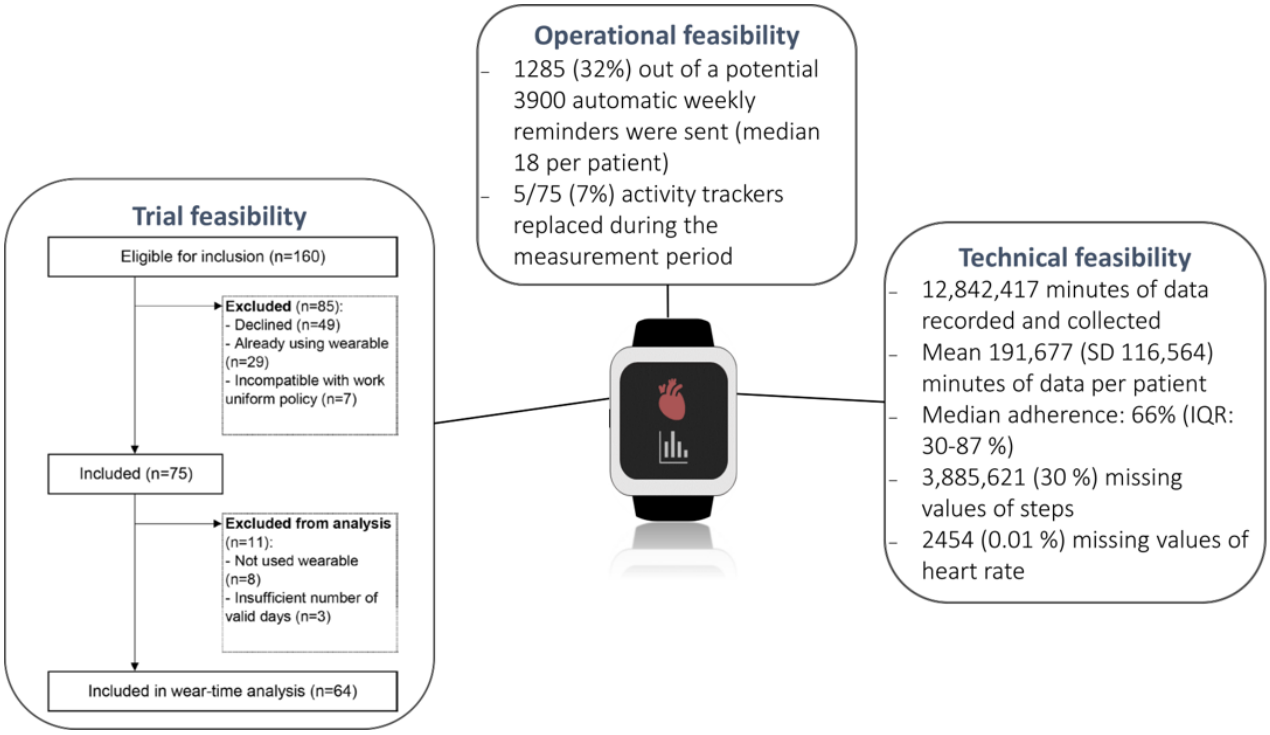
To assess wear-time patterns based on the data returned from the activity tracker, we used the hourly level data, which were summed up on a weekly level. Each patient's first week of recording was assigned as their baseline week. Unsupervised hierarchical clustering using the pheatmap package in RStudio was used for assessing different wear-time patterns based on the number of hours of physical activity data recorded [38]. The optimal numbers of predefined clusters were based on the visual inspection of the clustered heatmap and internal validation from the R-package clValid [39]. The cluster groups were named according to their observable patterns that occurred within each group. Patient characteristics in the clustering groups for wear-time patterns were compared and tested for significant differences using the Kruskal-Wallis test, and Dunn test if the initial Kruskal-Wallis test had a *P*-value below 0.05. The Fisher exact test was used for testing differences in the distribution of sexes between the groups. Preparation and analysis of data were conducted using RStudio and Stata (version 18.0; StataCorp LLC).

Ethical Considerations

The study was conducted according to the Helsinki Declaration. All patients provided written consent to participate and were informed that they could stop using the activity tracker at any given time during the study. Data were de-identified and stored at a secure research server. The Regional Committees for Medical and Health Research Ethics South-Eastern Norway approved the study (ref: 229187).

Patient and Public Involvement

In total, 2 patient research partners were involved in the planning of the study. They also pilot-tested the activity tracker and gave feedback on the instructions to the patients and on the study logistics. One of the patient research partners (SH) also contributed to analyzing and discussing the results and is a co-author of this manuscript.



Results

Trial Feasibility

A total of 75 (47%) out of 160 patients agreed to use the activity tracker for 1 year and were included in this study (Figure 1). Among the 85 non-participating patients, 49 (31%) declined to wear an activity tracker, 29 (18%) were already users of a Garmin activity tracker device, and 7 (4%) could not wear an activity tracker due to uniform regulations at their workplace (Figure 1). Baseline characteristics were mostly similar between patients who agreed and those who declined to use the activity tracker, with minor numerical variances in self-reported physical activity levels (Table 1). Patients who declined had significantly lower eHealth literacy scores compared with those who agreed to use the activity tracker, but the numeric differences in mean scores were small (Table 1).

RenderX

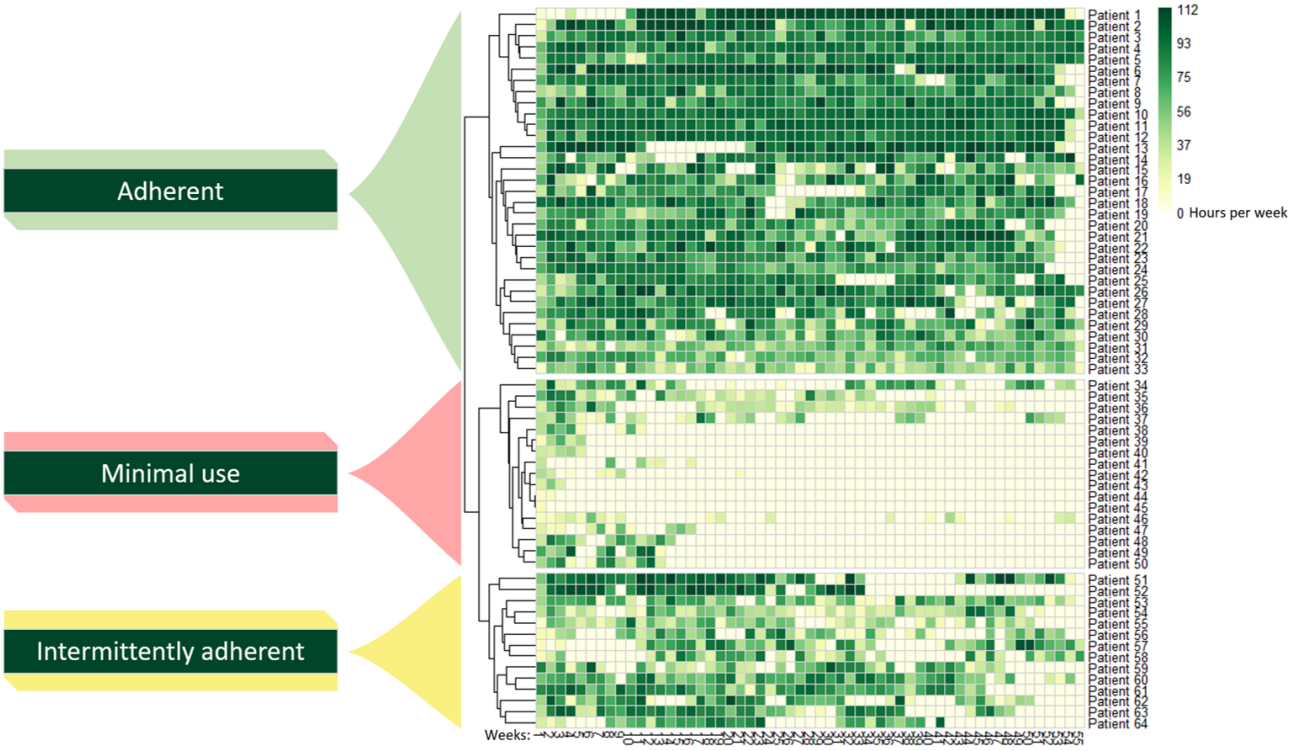
Technical Feasibility

Among the 75 patients who agreed to use the activity tracker, 64 (85%) had valid physical activity data and a median adherence to use the activity tracker of 66% (IQR 30 - 86) (Figure 1). Over the 1-year measurement period, 8 out of 75 patients never recorded any data. In total, 3 patients returned less than 1000 minutes of data recorded (corresponding to approximately a total of 16 h of physical activity data) and were subsequently excluded from the wear-time pattern analyses during aggregation of data (Figure 1). A total of 12 million datapoints were returned, corresponding to a mean of 191,677 (SD 116,564) minutes of data per patient (Figure 1). Analyses showed that the proportion of missing data was higher for the steps (30%) compared to heart rate data (0.01%).



Operational Feasibility

To remind patients to synchronize the activity tracker data, a total of 1285 (32%) out of a potential 3900 automatic push notifications were distributed, with a median of 18 (IQR 9 - 25) notifications per patient. In total, 5 activity trackers required replacement during the study, of which 4 were caused by connectivity issues with the app and one due to a loss of the activity tracker (Figure 1).

Wear-Time Patterns

Data on wear time were grouped in clusters according to the visual wear-time patterns, and 3 cluster groups were found to be the optimal number of clusters. The 3 cluster groups were categorized as “Adherent” (n=33), “Minimal use” (n=17) and “Intermittently adherent” (n=14) according to their visible wear-time patterns (Figure 2). The patients included in the Adherent group had a steady recording of physical activity data, the Minimal use group showed longer periods of no recorded data, and the Intermittently adherent group presented with a notably larger variation in the amount of recorded data (Figure 2). We found that the Adherent group had a median of 85% (IQR 72 - 89) adherence to the use of the activity tracker, while the Minimal use and Intermittently adherent groups had lower adherence with 7% (IQR 4 - 16) and 49% (IQR 43 - 59), respectively (Table 2).

Figure 2. Hierarchical clustered heatmap containing 3 cluster based on wear-time patterns, expressed as hours of physical activity data per week per patient (n=64). The x-axis shows the weeks for each patient who recorded data, with the y-axis showing the number of hours of recorded data per week. Dendrograms at the left show the clustering.

XSL•FO
RenderX

Table . Age, sex, self-reported physical function, impact on daily activities, and disease activity across 3 cluster groups with different wear-time patterns.

	Adherent (n=33)	Minimal use (n=17)	Intermittently adherent (n=14)
Age, years median (IQR)	46 (42 - 55)	35 (32 - 50)	40 (33 - 53)
Sex, males n (%)	23 (70)	16 (94)	10 (71)
BASFI[a], median (IQR)	1.1 (0.2 - 1.9)	0.2 (0.0 - 0.4)	0.7 (0.3 - 1.9)
WPAI[b], median (IQR)	1.0 (0.0 - 3.0)	0.0 (0.0 - 1.0)	1.0 (0.0 - 2.0)
ASDAS[c], median (IQR)	1.2 (0.7 - 1.8)	0.8 (0.6 - 1.2)	1.1 (0.7 - 1.7)
Adherence[d], % median (IQR)	85 (72 - 89)	7 (4-16)	49 (43 - 59)

[a]BASFI: Bath ankylosing spondylitis functional index (0-10, 10 being worst).

[b]Work Productivity and Activity Impairment, Ability to perform daily activities (WPAI Item 6, NRS 0-10, 10 being worst).

[c]ASDAS-CRP: Ankylosing spondylitis Disease Activity Score.

[d]Adherence to use the activity tracker was calculated as data returned divided by maximum amount of day time data.

The Minimal use group had a significantly (*P*=.019) lower median age (35 y, IQR 32 - 50) compared to the Adherent (46 y, IQR 42 - 55) and Intermittently adherent groups (40 y, IQR 33 - 53) (Table 2). There were nonsignificant between-group differences (*P*=.107) in the proportion of sex, with 23 out of 33 (70%) males in the Adherent group, 16 out of 17 (94%) in the Minimal use group, and 10 out of 14 (71%) in the Intermittently adherent group. There were no differences between the groups in disease activity, self-reported physical function, or the impact on daily activities.

Discussion

Principal Findings and Comparison With Previous Works

This study explored the feasibility and wear-time pattern of long-term use of a commercially available activity tracker over 1 year among patients with axSpA. The results indicated a low trial feasibility and acceptable technical and operational feasibility. In total, 3 different cluster groups were identified, with the largest group demonstrating adherence to using the wearable activity tracker.

In the assessment of trial feasibility, we found a low inclusion rate for the activity tracker, with less than half of the 160 eligible patients agreeing to wear the activity tracker for 1 year. This might indicate that the willingness to use a wearable activity tracker over a long period may not be present among the majority of patients with axSpA with low disease activity. However, we believe that a higher inclusion rate could have been achieved if direct data downloads from patients' private Garmin devices had been possible. Implementing such solutions may require specially adapted software and the use of "proxy-users" [40], potentially leading to complex data management.

We observed that a small proportion of patients either did not record any data or recorded less data than the cutoff for a valid day (>10 hours). An earlier study on patients with gout reported similar findings, showing that 33 of 44 patients had valid data, and 40% of the total data was missing [19]. Missing data, when measuring at this high-level granularity, are expected but yet remain a challenge considering the use of activity trackers in clinical settings [41]. A possible reason for the high proportion of missing steps data might be due to differences between Android and iOS phones in the interpretation of the step data, where Android phones misinterpreted inactivity as missing data instead of providing the numerical value of 0. The low number of missing heart rate data may be due to the filter that deleted observations of heart rates below 20 beats per minute, possibly resulting in a skewed representation of the number of missing heart rate data. Additionally, the discontinuation of using the activity tracker has been discussed in earlier studies, showing that perceived usefulness and inaccuracy of data could be a reason for discontinuing the use of activity trackers among patients with osteoarthritis and for healthy people [18,42]. Patients' perception of data inaccuracy may also play a role in our study. Since we only recorded steps and heart rate as measures of physical activity, we effectively limited our recordings to step-related activities, thereby excluding popular Norwegian activities such as bicycling, cross-country skiing, and swimming.

The operational feasibility showed that a median of 18 reminders were sent out per patient, indicating a fairly low number based on the fact that reminders were sent out on a weekly level. It was also observed that the majority of tracker replacements were due to connectivity issues, which could lead to longer periods without recording physical activity.

The hierarchical clustering analysis showed that the largest cluster group was patients who showed adherence to using the activity tracker. Since this represents 33 out of a possible 160 patients, it could be argued that using activity trackers is only feasible for this specific group of patients. The between-group comparisons of patient characteristics revealed numerically small differences between the 3 wear-time cluster groups regarding age and proportion of sex. However, all 3 groups had a small sample size, which limits trust in the between-group comparisons.

Considering the potential benefits of physical activity monitoring, activity trackers may prove valuable in guiding and motivating patients to engage in higher levels of physical activity [2]. Longitudinal data on physical activity can potentially offer

XSL•FO
RenderX

new insights into how axSpA impacts patients' activity levels and can aid in developing targeted exercise and physical activity interventions. The collection of longitudinal physical activity may potentially support physiotherapists and other health care professionals in prescribing lifestyle interventions for patients with axSpA [2]. However, challenges such as low adherence and technical issues must be addressed. A potential increase in adherence might have been achieved if health care professionals had provided personalized guidance on each patient's physical activity level and had set specific goals. These strategies warrant further research to explore their impact on enhancing adherence to using activity trackers.

Strengths and Limitations

The strengths of this study are the long measurement period of 1 year. This allowed for longitudinal analysis of how many patients recorded physical activity and how many discontinued their recordings. This insight further explains how activity trackers may function in clinical settings. Further strengths include the aspect of technical and operational feasibility, showing that the use of wearable activity trackers may involve an increased workload for the health care providers and require complex data management.

Limitations in the study include that we did not set cutoff values as to what constituted a valid week with physical activity measurement. This was decided because we wanted to explore the adherence to using the activity tracker. However, using >10 hours of valid day measurement has also been used by previous studies [22,40]. The hierarchical clustering analysis with the different wear-time patterns has a notable limitation, as it was conducted on a limited sample. This reduces the external validity of our study's findings. Furthermore, the low number of patients per cluster group makes the comparison between these groups prone to biases and skewed data. Lastly, the definition of adherence used in this article may be misleading, as it uses the total amount of physical activity data that was returned. For example, technical issues related to synchronization may have led to missing physical activity data, thus not reflecting the actual use of the activity tracker.

Implications

In order to increase the feasibility of wearable activity trackers, some optimizations are needed. First, data transfer should be automated, allowing for a "passive" collection of data. In the present study, patients had to use the MyDignio app and manually transfer data each week, which might have increased the burden on patients. Second, providing additional measurements beyond steps and heart rate would provide a more comprehensive overview of physical activity levels with time spent in different intensities and perhaps would increase adherence to using the activity tracker. Lastly, using wearable activity trackers, as demonstrated in this study, results in a vast amount of data. Considering the ethical perspectives of storing massive amounts of data, a structured and well-thought-out plan for how data are to be used should be implemented before physical activity data collection is initiated.

Future research should be based upon the recently published Wearable Activity Tracker Checklist for Healthcare (WATCH), which disposes a 12-point list of aspects to consider when implementing a wearable activity tracker in health care [43]. The checklist should be used in studies, preferably conducted in a real-world clinical setting. Additionally, "bring your own device" clinical studies may also hold promise as study design by representing a more accurate resemblance of real-world settings in which some patients already are owners of activity trackers [44]. Future research should incorporate qualitative methods to explore contributing factors behind the variations in wear-time patterns and adherence to using activity trackers.

Conclusions

Despite the trendiness in both research on and commercial use of wearable activity trackers, long-term use of activity trackers had low to moderate feasibility over 1 year in patients with axSpA in low disease activity. The trial feasibility of using wearable activity trackers was low, while technical and operational feasibility were acceptable. Based on the wear-time patterns, we found that only 51% had consistently high activity tracker adherence. Future research should aim to ensure automated synchronization and investigate motivational factors influencing tracker adherence.

Abstract

Background: Artificially intelligent (AI) chatbots that deploy natural language processing and machine learning are becoming more common in health care to facilitate patient education and outreach; however, generative chatbots such as ChatGPT face challenges, as they can misinform and hallucinate. Health care systems are increasingly interested in using these tools for patient education, access to care, and self-management, but need reassurances that AI systems can be secure and credible.

Objective: This study aimed to build a secure system that people can use to send SMS with questions about substance use, and which can be used to screen for substance use disorder (SUD). The system will rely on data transfer via third party vendors and will thus require reliable and trustworthy encryption of protected health information .

Methods: We describe the process and specifications for building an AI chatbot that users can access to gain information on and screen for SUD from Be Well Texas, a clinical provider affiliated with the University of Texas Health Sciences Center at San Antonio.

Results: The AI chatbot system uses natural language processing and machine learning to classify expert-curated content related to SUD. It illustrates how we can comply with best practices in HIPPA (Health Insurance Portability and Accountability Act) compliance in data encryption for data transfer and data at rest, while still offering a state-of-the-art system that uses dynamic, user-driven conversation to dialogue about SUD, screen for SUD and access SUD treatment services.

Conclusions: Recent calls for attention to user-friendly design concerning user rights that honor digital rights and regulations for digital substance use offerings suggest that this study is timely and appropriate while still advancing the field of AI.

Trial Registration: Not Applicable

Introduction

Given the ongoing opioid epidemic in the United States [1], consideration of how and whether we can use digital tools to facilitate a response is warranted. One way that digital solutions may be deployed is by using them to scale screening for substance use disorder (SUD). Screening for SUD is critical to identify people at risk [2], as it can lead to referrals for services including outpatient as well as medically managed intensive inpatient services [3]. Although Screening, Brief Intervention, and Referral to Treatment (SBIRT) programs have been widely used to facilitate screening [4], and these programs are available electronically [5], there is still a major gap in screening, given current estimates indicate fewer than 10% of those at risk for SUD ever screened. This exacerbates an already costly response to the opioid epidemic, given that the United States spends more than $271 billion annually to address SUD-related health issues, crime, and lost productivity [6]. If we could enroll more people at-risk in treatment, we would save $4 for every treatment dollar expended [7].

XSL•FO
RenderX

Artificially intelligent (AI) chatbots that deploy natural language processing (NLP) and machine learning (ML) are becoming more common in health care to facilitate patient education and outreach [8,9]. These systems advance earlier generation rule-based chatbots that rely on "fixed state" messages that force users to choose from a predetermined set of responses to an interactive, user-driven system where people can initiate conversations on any number of topics and chatbots can generate answers on-the-fly. The current AI chatbots, particularly generative chatbots such as ChatGPT [10], rely on access to a large language model (LLM) for training bots to correctly classify and respond to queries. These LLMs represent a much more sophisticated way to interact with people that allows for rapid exploration of vast data sources to learn how to correctly understand the intention of the queries that people make, to make inferences from data, and generate relevant answers in response to user queries.

There is an ample body of evidence from investigations of earlier, fixed-state message systems showing they can be used effectively to positively impact health behaviors and health outcomes [11]. Although we do not yet know the impact of moving from fixed-state chatbots to conversational and generative AI systems, health care systems that have adopted these AI systems are optimistic that they will offer ample return on investment [12]. Since the more advanced AI systems are nascent, we have not yet established standards for best practices in their design. System users and developers of AI chatbots, including generative chatbots such as ChatGPT, have raised concerns related to their use that warrant attention for health-related applications [13] Ethical concerns include observations that systems could discriminate against stereotype or stigmatize users, and could also compromise privacy and data sovereignty [14,15]. Researchers have documented tendencies for generative chatbots to misinform [16], hallucinate [17], and obscure information about how data are being accessed and used [18].

Recent reviews and published literature have highlighted the critical challenges that are inherent in maintaining security for AI chatbots. They highlight chronic concerns with data breaches and malicious input and called for standards such as end-to-end encryption, organizational control, and adversarial training (ie, purposefully attempting to confuse a system during development to train it to recognize potentially malicious inputs) to mitigate these [19,20]. One researcher has highlighted additional critical concerns that are specific to health care organizations that seek to use AI chatbots, including a need to align chatbot design and security with Healthcare Insurance Portability and Accountability Act (HIPAA) regulations that govern patient protections in care delivery [21].

Optimizing digital tools for substance use is warranted. However, we currently do not have digital tools that focus explicitly on user rights, including privacy; are evidence-based; user friendly; easily accessible, person-centered [22]; and can be delivered without generating or reinforcing stigma.

In this paper, we present the infrastructure and technical specifications used to design Be Well Buddy, an AI chatbot focused on raising awareness and access to screening and treatment for SUD. It intentionally addresses the security and ethical concerns identified here. We also present findings from a beta test of the system whose goals were to verify system security and functionality.

Methods

This work represents a partnership between Clinic Chat, LLC, a health technology start-up company, and The University of Texas Health Sciences Center at San Antonio (UT Health San Antonio), a US-based university with a robust clinical program called Be Well Texas, focused on screening, treatment, and social support for SUD. The principals from Clinic Chat have a background in scientific research related to health as well as the technical skill to design and deploy AI chatbots; UT Health San Antonio and Be Well Texas have a wide-reaching health education initiative focused on substance use prevention and treatment. The partnership was established to adapt health AI chatbots to focus specifically on raising awareness and providing access to screening for and treatment of SUD within the university program.

System Specifications

Given concerns that generative chatbots can hallucinate and misinform, along with ample evidence that careful attention to the design of messages for health communication can be more impactful than generic messaging, we determined it appropriate to develop and curate messages specific to SUD that could be delivered by a closed-domain AI chatbot system (ie, one where messages returned in response to user queries would only come from this specific library of messages). This approach allows us to avoid a common pitfall of generative AI such as ChatGPT that can reinforce biases or misinform when seeking responses to user queries. By using a closed library of responses that have been reviewed for accuracy, empathy and tone, our system can only choose from a limited group of options that are medically correct and consistent with clinical guidelines for care. Guided by literature documenting approaches to health communication that can increase engagement with messages [23], we generated content that allowed for tailoring to individual users to increase content relevance (eg, by prefacing each message with their first name or by inviting them to name and explore preferred topics) [24]; that could offer intuitive suggestions for behavioral decision-making [25,26]; that offered narrative, emotional messaging, status-enhancing and skill-building content [27]; and that worked to destigmatize substance use [28]. These message design strategies have consistently been shown to have a positive impact on health behavior [29-31]. We developed an initial library of messages and then reviewed the message content in a formative process with members of the intended audience of the chatbot to obtain their feedback on the message content, tone, acceptability, and capacity to engage people in dialogue. One key outcome from this process was the name "Be Well Buddy," which we gave to the system, generated from a participant in this formative message development process (Sarah Mumby, MPH, email August 15, 2024).

Beta Testing

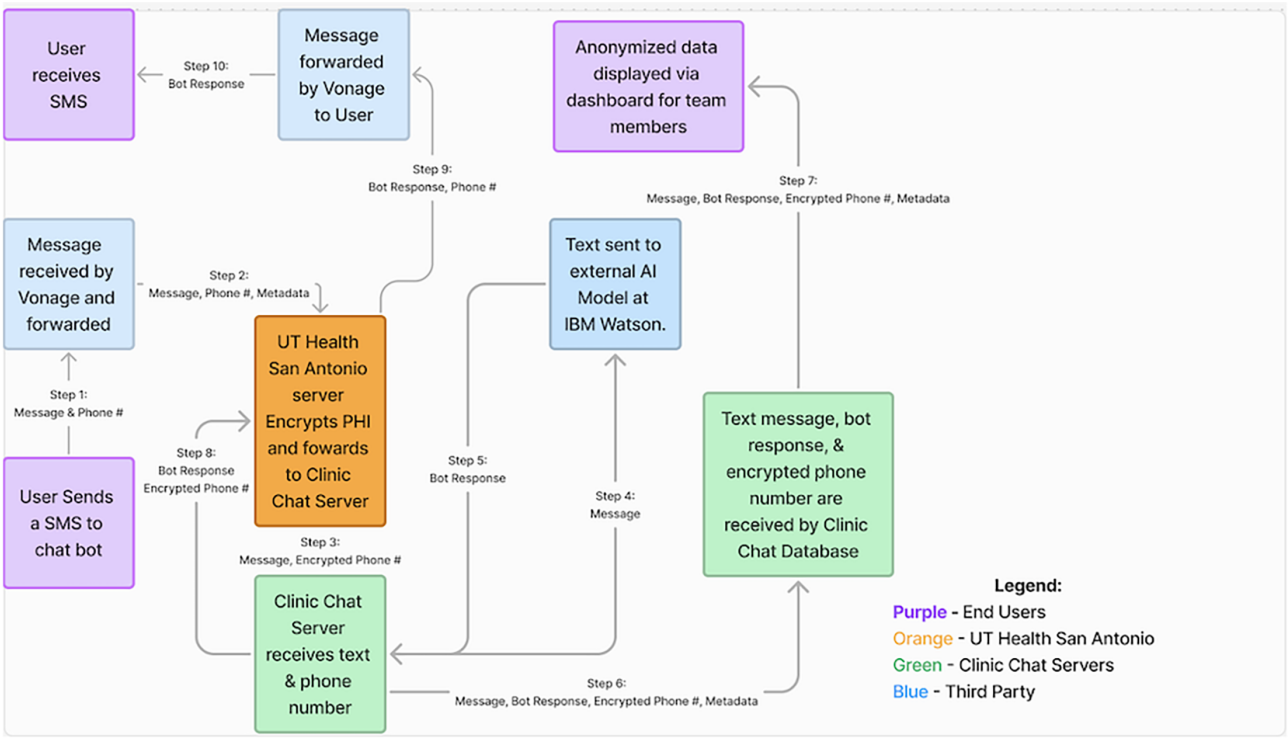
Once the system was designed and built, we conducted a one-day beta test to ensure system functionality with members

XSL•FO
RenderX

of the study team from Clinic Chat and UT Health San Antonio. All participants were encouraged to try and push the system to its limits. Specifically, they asked expected questions (eg, What is a substance use disorder? What is medication-assisted therapy? How much does treatment cost?) and asked multiple questions in a short period of time (ie, five-six questions in a minute). They made queries in different languages and completed all the screeners embedded in the system. They deliberately worked to confuse the system with questions that were nonsensical or unrelated to SUD. Our goals for the beta test were to (1) identify errors in sending and receiving messages and use this to determine the system's precision (ie, whether responses sent by the system appropriately matched the intent behind the user queries); (2) identify any problems with encryption; and (3) identify any delays in message delivery.

Ethical Considerations

The work we describe here was reviewed by UT Health San Antonio Institutional Review Board, who deemed these activities as preliminary to research conducted exclusively by paid research staff and therefore exempted from requirements for human subjects' approval. Identifying data for persons beta-testing the system included telephone numbers, which were encrypted once outside the UT Health San Antonio firewall. The data presented in this paper informed an observational study that has been reviewed and approved by the UT Health San Antonio Institutional Review Board (protocol number 20230662H).



A description of system specifications and functionality, and results of the beta test is given below.

Results

System Specifications

Figure 1 illustrates how the system retrieves and shares information, along with a description of the security steps that are in place to ensure user data are protected. In this figure, purple boxes represent end users of the system, ie, people who send and receive text messages via SMS. The blue boxes represent any third-party vendor that retrieves or sends information from the user to the Clinic Chat AI Chatbot, called "Be Well Buddy." The orange box represents the firewall for UT Health San Antonio, home to Be Well Texas, the clinical entity whose patients and prospective patients are the intended users of Be Well Buddy.

Figure 1. System workflow. AI: artificial intelligent; PHI: protected health information.

Data exchanges between users and the AI chatbot are described as steps in Figure 1. In Step 1, Be Well Buddy initiates a dialogue with users when it sends an initial SMS message to them after receiving information on their first name and telephone number from UT Health San Antonio, which they provide upon enrolling a user in the feasibility study. All SMS messages—incoming and outgoing—are handled by our third-party provider, Vonage Telecommunications Company (Step 2).

System users can respond to any message from Be Well Buddy. When this is done, the data are forwarded to the UT Health San Antonio Server (Step 3), where we host a Flask application designed for minimal impact on system performance. This Flask app uses a webhook to ingest the information efficiently. The lightweight nature of Flask, as opposed to heavier frameworks like Django, is crucial in maintaining fast processing speeds behind the secure firewall. The information received by the Flask app includes one piece of protected health information (PHI)— the phone number—which is now encrypted using SHA-256 bit encryption. This robust encryption method ensures

XSL•FO
RenderX

that the data cannot be read or altered without the encryption key and remains encrypted anywhere outside the firewall, including Clinic Chat Amazon Web Server (AWS).

The message content and metadata without identifiers (eg, message time, type), along with the encrypted phone number are sent to a Clinic Chat-owned and managed AWS, known as EC2 instance that hosts a Django application to authenticate and retrieve information from the Be Well Buddy chatbot; only whitelisted IP's can send requests to the AWS EC2 instance.

At this point, a request is made to our IBM Watson AI (version 10.2.0) assistant that includes only the message body from the SMS message (Step 4). IBM Watson currently serves as our NLP AI system to classify message content. Prior to forwarding messages to Watson, our Django app (version 5.2) performs a variety of preprocessing tasks using regex and custom code to effectively manage number inputs, survey and screener responses, and any content that does not constitute a direct user query. While IBM Watson effectively classifies message content and returns a response (Step 5), we plan to transition to an internally hosted LLaMA integration in the future to leverage the impressive capabilities of LLMs. This response, along with the encrypted phone number, is sent back to a Flask app—a lightweight application optimized for faster processing—hosted behind the university server before being forwarded to the user through Vonage.

The response, message, metadata, and encrypted phone number are sent to an Amazon Web Server (AWS) Relational Database Service (RDS) instance for storage (Step 6). A dashboard hosted on the Clinic Chat subdomain (through another AWS EC2 instance) can then send requests for the system to retrieve data so team members can view large or small trends in anonymized message data (Step 7).

The system relies on data transfers with multiple third-party vendors, including Vonage that aggregates message delivery via multiple cell phone providers; IBM Watson, which classifies message content; and AWS that stores data. Following is a description of how each of these providers operate with the Be Well Buddy chatbot.

Vonage is our third-party telecommunications provider. They manage all outgoing and incoming messages. As they handle phone numbers, which are considered PHI that is regulated under the HIPAA, they have executed a Business Associate Agreement with Clinic Chat. This Business Associate Agreement ensures that both Vonage and Clinic Chat remain compliant with HIPAA regulations related to PHI by redacting all phone numbers and messages from Vonage logs. To retrieve the phone numbers and message information, the UT Health San Antonio server has generated a whitelist of IP addresses from Vonage (ie, the IP addresses for computers used by Clinic Chat staff) that will limit JSON data intakes exclusively from these IP addresses. All data will be sent to Vonage and received from Vonage through HTTPS, a secure data transfer protocol that encrypts data during transfer.

IBM Watson is used t0 store data to train our AI models, allowing the system to more precisely interpret incoming queries from users so the system can then respond with a message from our curated library that corresponds to the intent behind each user query. IBM Watson will never receive any PHI in any form from messages—they only receive user queries as the text message body, which is used to match to one of our answers in our library of responses before returning it to the Clinic Chat AWS instance [32] (Step 8).

We are using two AWS EC2 server instances—one to host the backend server responsible for connecting the UT Health San Antonio server, IBM Watson and the database, and a second to host the front-end team interaction and database. Both are configured according to AWS HIPAA guidelines, although unencrypted PHI will never reach AWS. The backend server will only connect to the UT Health San Antonio server via HTTPS connection, IBM Watson, and AWS RDS. We whitelist the UT Health San Antonio server IP (and a few developer IPs for testing purposes), but no other IPs will be able to hit the server. The front end is also whitelisted to limited team member IPs and contains a login and user authentication system to view anonymized data.

We also use an AWS RDS instance to store our data for the project. All PHI are encrypted when entering AWS and are stored in encrypted form in RDS; they are never decrypted in AWS. The RDS database is connected to EC2 instances. The backend will only write data to the database, and the front end will only pull data.

The UT Health San Antonio server hosts a Flask app to process and encrypt PHI before passing it on to AWS, and process and decrypt phone numbers when sending it to Vonage. The app has a webhook that interprets a series of whitelisted IPs from Vonage, which will send JSON data including phone number and message content. Phone numbers are the only PHI the system receives, so the Flask app encrypts the phone number using Python Fernet encryption before sending the message content and encrypted phone number to our AWS EC2 backend instance. Additionally, the Flask app has a webhook that receives incoming JSON data from the same AWS EC2 instance. The AWS EC2 instance is whitelisted, and along with Vonage, these are the only servers that are whitelisted (outside of a dedicated IP for a developer to fix any issues). The Flask app will take in an encrypted phone number and response message from the EC2 instance, decrypt the phone number, and pass the phone number and response message back to Vonage to be sent to the user (Steps 9 and 10).

In anticipation of possible system attacks, we also built in protocols to reduce their impact should they occur. We exposed our model to anticipated queries that are adversarial (eg, "I don't want to screen for SUD, leave me alone," or "Your answers are stupid") to train for resilience and respond professionally (eg, "I'm sorry you are disappointed with my response. I would be happy to try again or discuss a different topic"). When a user asks the system a question, the response is chosen from the library using NLP and then relies on probabilistic models to determine how likely it is that a response from our library will match the intent behind the user query. We monitor all logs to determine if system users and system content are behaving as expected and to identify any suspicious interactions.

XSL•FO
RenderX

Beta Testing

The beta test was conducted over the course of one day with six users. Users sent 426 messages to the system (for an average of 71 messages per user, with a range of 25 - 110 messages), and the system responded 800 times. The additional system responses included intentional follow-up prompts (eg, "Ask me about something else! I can answer your questions about medication-assisted therapy" or "Are you interested in screening for SUD?") that were appended to responses. We documented two instances where users received responses in Spanish, although the content in the library was only available in English. Upon investigation, we determined that the system was retrieving messages from a different library within the Clinic Chat system focused on chronic illness self-management. We unlinked the libraries between the SUD and chronic conditions content to avoid this error in the future. These two errors were the only ones we documented when the system returned an incorrect response (ie, 2 of 426 or <1%). When a user sent a nonsensical query or one that did not align with SUD, the system correctly responded with "I'm sorry, I am still learning and did not understand your question. Will you please ask again in different words?" Thus, we established a >99% level of system precision overall. We documented three instances where message return was quite slow (ie, a >90 seconds to return a response). In all other instances, responses were sent within the first 10 seconds of message receipt. We recognized this as a problem with Vonage and reached out to report the message delays to them. We identified a problem with the responses returned to users who screened for anxiety, depression, and SUD, where those with high risk were not alerted to their risk and given a referral, necessitating a review and correction of the referral algorithm. The algorithm for screening and responses related to screening were incorrect and fixed. We did not identify any problems with system encryption or data security in transferring queries via SMS. Given the short time frame and small sample of beta testers, we did not experience any adversarial attacks to our system during the beta test and cannot report on the robustness of our protocol to address these attacks in this paper.

Discussion

In this study, we present the technical specifications included in Be Well Buddy to facilitate access to information and screening for SUD for Be Well Texas, a clinical organization affiliated with the UTHSA. Our system adheres to HIPAA regulations for the protection of PHI while avoiding pitfalls of current generative AI chatbots by using curated chat content that does not misinform or hallucinate. Users of Be Well Buddy can get credible and complete information about SUD and can access care on a 24/7 basis. The beta test uncovered and resolved two functional errors; ie,(1) delivery of messages unrelated to SUD and (2) an incorrect algorithm for screening feedback. After correcting these errors, we verified that the system functions as intended and has a high level of precision [33].

This study is not without limitations. Our objective was to ensure that the system worked without error and was secure; therefore, using a small number of beta testers was appropriate to achieve these findings [34]. However, the small number of beta testers did not allow us to delve deeply into how well the content resonated for users. Further, as noted above, given the short time frame and small sample of beta testers, we did not experience any adversarial attacks to our system during the beta test and thus cannot report on the robustness of our protocol in such scenarios. These topics would be appropriate for a subsequent trial of system use.

While we stand behind our approach of using a closed library system to avoid challenges with misinformation and hallucination, this model requires regular updates to content to ensure it remains consistent with medical and professional guidelines related to SUD, SUD screening and treatment referrals. This task may evolve to become cumbersome if library updates are frequent or extensive.

AI chatbots can struggle with delineating between nuanced concepts, making it difficult to support complex questions from users. As we rely on IBM Watson for classification and other language models, this challenge persists and will require careful attention to identify inaccuracies to allow for appropriate reclassification of content when systems do not respond with precision.

Finally, we recognize that the datasets used to train AI chatbots have inherent biases, which we risk reproducing when scaling this system. This risk can be particularly challenging for the Be Well Buddy chatbot whose explicit goal is to reduce stigma. Extra effort is recognized to ensure that the content does not produce or reinforce stereotypes about substance use or people who use substances [35].

According to a recent McKinsey report [12], a large group of surveyed health care leaders indicated that their organizations are eager to use generative AI to enhance operations—particularly patient engagement processes—but most are still adopting a wait-and-see approach. While traditional rule-based chatbots have already proven effective, the AI-driven chatbots, particularly those that are driven by generative models such as ChatGPT, have yet to be proven safe for health care applications. In particular, a number of ethical concerns, such as privacy, confidentiality, bias and fairness, transparency, accountability, regulatory compliance, risk anticipation and copyright complications remain the subject of active research and mitigation in generative models. Additionally, the risks of misinformation, perpetuation of bias, or hallucination continue to dampen enthusiasm for widespread deployment of AI Chatbots in health care [8].

Until effective and proven solutions are developed to address these concerns, widespread use of AI-driven chatbots in health care applications is not anticipated.

In this paper, we introduced the Be Well Buddy chatbot, a novel AI-driven chatbot that adopts a secure and reliable approach to engage with patients with SUD. Our system circumvents challenges with misinformation, bias, and hallucination, while securely delivering and supporting access to SUD screening and treatment options.

Our research is consistent with recent recommendations for optimized digital substance use interventions, such as solutions

XSL•FO
RenderX

that emphasize digital rights of privacy and confidentiality, accessibility, and user-friendliness [15]. In the future, we will further experiment with Be Well Buddy to evaluate and report its efficacy in promoting self-screening and referral for SUD. We anticipate integration with treatment providers who wish to accelerate referrals for care by inviting persons living in their catchment areas to use the system and for self-screening. This system may also be integrated into other organizations adjacent to SUD treatment, such as the criminal justice system where care may be mandated, or the parole system where people may seek to closely monitor their own or clients' risk for SUD.

Acknowledgments

The authors gratefully acknowledge the participants who were willing to engage with the system and offer their feedback. This work was supported with funding from the National Institutes of Health, National Institute of Drug Abuse (NIDA) under grant number 1R41DA059275-01.

Abstract

Background: Mobile health (mHealth) apps provide easy and quick access for end users to monitor their health-related activities. Features such as medication reminders help end users adhere to their medication schedules and automatically record these actions, thereby helping manage their overall health. Due to insufficient mHealth tools tailored for HIV preventive care in young men who have sex with men (MSM), our study evaluated the usability of the mChoice app, a tool designed to enhance preexposure prophylaxis (PrEP) adherence and promote sexual health (eg, encouraging the use of condoms and being aware of the partner's HIV status and PrEP use).

Objective: This study aimed to apply systematic usability evaluations to test the mChoice app and to refine the visualizations to better capture and display patient-reported health information.

Methods: Usability testing involved heuristic evaluations conducted with 5 experts in informatics and user testing with 20 young MSM who were taking or were eligible to take PrEP.

Results: End users demonstrated satisfaction with the appearance of the mChoice app, reporting that the app has an intuitive interface to track PrEP adherence. However, participants highlighted areas needing improvement, including chart titles and the inclusion of "undo" and "edit" buttons to improve user control when recording PrEP use.

Conclusions: Usability evaluations involving heuristic experts and end users provided valuable insights into the mChoice app's design. Areas for improvement were identified, such as enhancing chart readability and providing additional user controls. These findings will guide iterative refinements, ensuring that future versions of the app better address the needs of its target audience and effectively support HIV prevention.

(JMIR Hum Factors 2025;12:e59780) doi:10.2196/59780

KEYWORDS

HIV prevention; data visualization; patient-reported health information; mHealth; digital health; usability; human immunodeficiency virus; preexposure prophylaxis; men who have sex with men; apps; HIV; PrEP

Introduction

The incidence of HIV, although having declined modestly overall in the United States, remains a significant public health problem for men who have sex with men (MSM) [1,2]. Notably, young MSM aged 13 to 34 years represent 58% of the estimated HIV infections in 2021, indicating a pressing need for targeted intervention in this group [2]. Preexposure prophylaxis (PrEP) is a highly effective biomedical prevention strategy to reduce HIV incidence and curb the HIV epidemic [3-10]. When taken as prescribed (daily or at least 4 times per week), PrEP reduces HIV transmission by up to 99% among MSM [7-9,11-13]. While awareness of PrEP has increased among MSM [14,15], those who are most disproportionately affected have been found to be less aware of PrEP [15], and overall, widespread uptake among those with the greatest indications for PrEP remains low [14-17].

To overcome this clinical and public health challenge, technological interventions, such as mobile health (mHealth) apps, have emerged to support public health care initiatives [18]. However, despite the potential of mHealth for delivering sexual health and HIV prevention awareness, mHealth is underutilized for supporting PrEP adherence [19,20]. In response, our study team developed mChoice, an innovative PrEP adherence monitoring app, which combines the CleverCap smart pill bottle with WiseApp, allowing end users to

XSL•FO
RenderX

self-monitor and manage their medication adherence. The CleverCap pill bottle dispenses the prescribed medication and interfaces with WiseApp for real-time tracking. The app was created by Compliance Meds Technology and has been used in prior studies among persons living with HIV [10,21-25]. It was adapted for the mChoice study. The app's key functionalities include monitoring PrEP adherence, visualizing data trends, and documenting sexual behavior, particularly among young MSM from diverse backgrounds.

A notable issue in the proliferation of mHealth apps is the development of this technology with minimal input from end users, leading to poor design, inadequate consideration of user needs, and ultimately, poor usability [26]. Poorly designed apps, lacking in usability, are prone to misuse, underutilization, and failure to achieve their intended objectives.

To ensure the best utilization of mHealth apps, it is essential to understand their usability, keeping in mind target end users (eg, young MSM), tasks (eg, PrEP adherence management and sexual health tracking), and cultural contexts (eg, language and beliefs). Adherence to PrEP is crucial for its effectiveness in preventing HIV, yet many young MSM face challenges such as inconsistent medication schedules and limited access to tailored support tools. The mChoice app was designed to address these barriers by providing intuitive features, including medication reminders, adherence tracking, and functions to support sexual health decision-making. In this study, we sought to apply systematic usability evaluations to test the mChoice app and to refine the functions to better capture and display patient-reported health information.

Methods

Ethical Considerations

The Columbia University Institutional Review Board reviewed and approved all study activities (approval number AAAT8812). Participants signed informed consent forms prior to participating in usability testing. In our dataset, each participant was assigned an identifier, and information was deidentified at the point of analysis.

Heuristic Evaluation

Sample

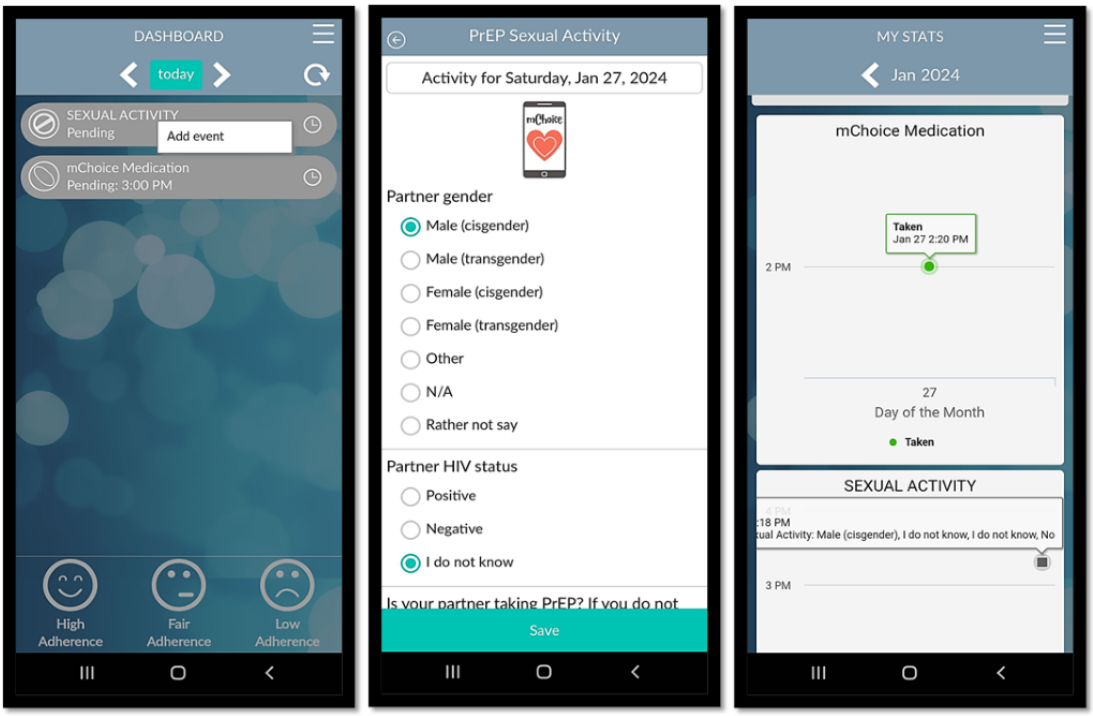
Usability testing of the mChoice app included heuristic evaluation conducted with experts in informatics and end-user testing conducted with young MSM. Five experts were recruited as evaluators in accordance with Nielsen's recommendation to include 3 to 5 experts in usability testing [27]. Of the 5 experts, 4 had a PhD in Nursing with expertise in human-computer interaction, interface design, and usability testing. The experience of the experts varied between 7 and 23 years, with several impactful publications in the field of informatics.

Procedure

The experts were provided with the mChoice app and asked to complete a session in the app through case scenarios that represented the main functions of the system and think-aloud methodology [28]. The mChoice app required a password, and all study data were encrypted and stored on secure HIPAA-compliant servers at Columbia University. The experts were asked to describe what they were thinking, seeing, and doing as they completed the following 10 scenarios: (1) log in to the CleverCap app; (2) complete a sexual activity log; (3) mark your PrEP dose for today as "Taken"; (4) view tomorrow's pending PrEP dose; (5) edit your sexual activity log; (6) delete your sexual activity log; (7) view information on PrEP dosing over the past month; (8) send a chat to the study team; (9) watch a video about an HIV story; and (10) find PrEP information (see Figures 1 and 2 illustrating app functions and Figure 3 demonstrating the CleverCap smart pill bottle). Following their use of the app, the experts completed an online Heuristic Evaluation Checklist to assess how the system adhered to Nielsen's 10 usability principles [27] using Qualtrics XM, an online survey software. Each question ranged from 0 (not a usability problem) to 4 (usability catastrophe). A member of the research team analyzed the experts' comments regarding usability problems to identify areas of usability concern that could be targeted for improvement. The mean usability problem severity scores were calculated for each of the 10 usability heuristics.

XSL•FO
RenderX

Figure 1. Sexual activity log. A confidential and secure feature for users to record their sexual activities, such as gender of partner, whether a condom was used, and the HIV status of their partner. Users of the on-demand/intermittent (2-1-1) preexposure prophylaxis (PrEP) regimen can use this feature to trigger subsequent PrEP dose reminders following sexual activity (ie, one pill 24 hours and one pill 48 hours after sexual activity).



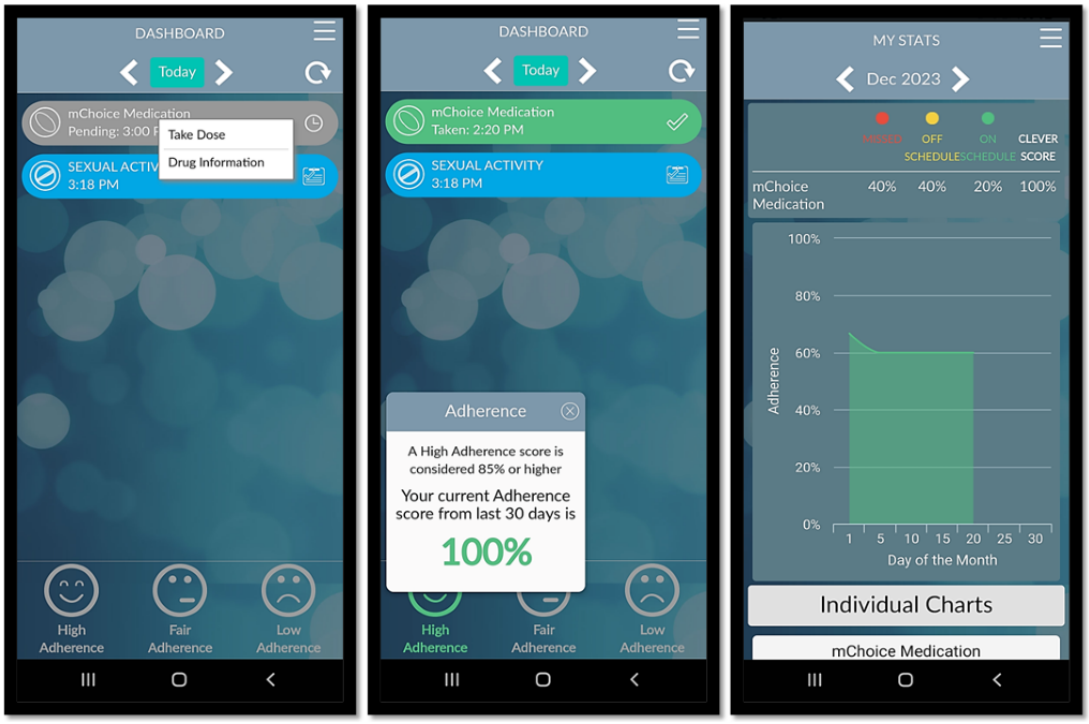


Figure 2. Preexposure prophylaxis (PrEP) adherence tracking. A simple interface for users to track PrEP intake, facilitating adherence monitoring over time. This feature is linked with the CleverCap device, a smart pill bottle that tracks when users take their medication. PrEP tracking is also customizable for users on different PrEP regimens (ie, 2-1-1, injectable, or daily oral dose) to ensure the timely intake of PrEP medication. For instance, users on injectable PrEP will be alerted of their upcoming appointment or need for their PrEP injection.

XSL•FO
RenderX

Figure 3. CleverCap device. A smart pill bottle linked with the mChoice app to track preexposure prophylaxis (PrEP) medication.

End-User Testing

Sample

Twenty end users were recruited for the usability testing. The eligibility criteria were young MSM between 18 and 39 years old, English speaking, living in New York or Alabama, and taking or eligible to take PrEP. The inclusion criteria were designed to ensure the mChoice app was evaluated by its intended target audience, ensuring a diverse usability evaluation. Potential end users were contacted using a research database and invited to participate in the study.

Procedure

During usability testing, the end users were provided with a brief explanation of the mChoice app and its functions. The end users were directed to complete the same 10 scenarios completed by the experts in the heuristic evaluation. Sessions took place remotely via Zoom meetings (Zoom Communications, Inc), and a member of the team was present during sessions to provide guidance when an end user was unable to move through a task independently and to take notes. Following their use of the app, the end users completed a survey using the Qualtrics XM software.

The survey included demographics and two validated measures of usability. The first usability measure was the self-reported ease of use measured by using the Health Information Technology Usability Evaluation Scale (Health-ITUES) [29,30]. This 20-item tool is designed to support customization at the item level to match the health information technology while retaining standardization at the construct level. It has been demonstrated to be useful for evaluating the usability of mHealth [31]. It is scored on a 5-point Likert scale ranging from 5 (strongly agree) to 1 (strongly disagree), where higher scores indicate a system that is easier to use. The second measure was the short version of the Post-Study System Usability Questionnaire (PSSUQ), a 16-item survey that assesses users' perceived satisfaction with a system [32]. Scoring is based on a 7-point Likert scale ranging from 1 (strongly agree) to 7 (strongly disagree). Lower scores indicate satisfaction with the system. Through validated measures, the end users contributed feedback on the app's functionality and user experience.

Data analysis was performed using R statistical software (version 4.1.2; R Foundation for Statistical Computing) to analyze the usability measures. The mean scores were calculated for each survey.

Results

Heuristic Evaluation

Overall, the severity scores ranged from 0.8 to 2.2 for the 10 items on the heuristic checklist, where scores closest to 0 indicate a more usable system. The mean severity scores for each heuristic item are presented in Table 1. The area identified as the most in need of improvement was "user control and freedom," where the experts identified that the app did not have an "undo" button or "edit" button for the PrEP medication entry.

The next most identified area for improvement was the "visibility of the system status," for which experts identified the lack of one "add" button to add a new sexual event. To improve the "visibility of the system status," the experts suggested we provide one "edit" button for modifying recorded sexual encounters and incorporate a separate "add" button for logging new encounters, especially in instances of multiple events. Additionally, "consistency and standards" was an area of concern with difficult terminology in charts. "Error prevention" was another concern, and experts highlighted the importance of one "edit" button to edit medication time as an issue that might impede system usability. Experts provided favorable feedback on the app's user experience. One expert (Expert 2) reported, "the app is very simple and intuitive interface…and it's nice that the button changes color with pleasant colors."

The rating score ranged from 0 (ie, best) to 4 (ie, worst), with a score of 0 indicating no usability problem, 1 indicating a cosmetic problem only, 2 indicating a minor usability problem, 3 indicating a major usability problem, and 4 indicating a usability catastrophe.

XSL•FO
RenderX

Table . Mean severity scores for items on the heuristic evaluation.

Heuristic principles	Mean (SD) severity score	Experts' comments to identify the areas of usability concerns
User control and freedom	2.2 (1.3)	• "No undo or edit for the medication entry. This is a big problem." (Expert 5)
Visibility of the system status	1.6 (1.1)	• "…When adding a sexual encounter record, it is not clear whether it edits or adds a new one, so there should be two buttons, one for edit and one to add a new one. The screen when you use edit also shows the old entry, which implies you are editing it, not starting a new one, but actually it is starting a new one. That is confusing." (Expert 3)
Consistency and standards	1.6 (1.1)	• "Not clear if the clever score is just adherence or if it means something else." (Expert 4) • "…I think in the menu it says stats. Rather than stats, it'd be adherence stats or adherence tracking over time. You know something that makes it really clear what people are clicking on." (Expert 2)
Error prevention	1.6 (1.1)	• "When entering the time of a medication, it might be easy to miss the AM/PM change. I don't think there's any design change to be made for this, but rather the user needs to be able to edit their entry if they forget to adjust this." (Expert 4)
Match between the system and the real world	1.4 (1.3)	• "Would like to see one section specific to PrEP information." (Expert 5)
Recognition rather than recall	1.4 (0.9)	• "Some of the main features can be moved to more obvious places." (Expert 1) • "Organization for videos could be improved, especially if you plan to add more content." (Expert 4)
Help and documentation	1.4 (1.3)	• "Information buttons and an introduction to the app would be helpful." (Expert 1)
Help users recognize, diagnose, and recover from errors	1.2 (1.1)	• "When the dose was missed, no way to edit if it was a mistype." (Expert 5)
Aesthetic and minimalist design	1.2 (1.1)	• "Graphs need clearer tiles and more labels." (Expert 1) • "Need more medication information or guidance if adherence is low." (Expert 5)
Flexibility and efficiency of use	0.8 (1.1)	• "…Search function for videos. Tags for topics would be good, too." (Expert 4)

End-User Testing

The end-user group for evaluating the mChoice app's usability consisted entirely of men, with the majority identifying as homosexual (14/20, 70%). The mean (SD) age was 28 (3.4) years. Half of the end users were White, and 75% (15/20) were non-Hispanic or Latino. Considering education, 50% (10/20) had a college degree. Two specific measures were employed for the usability assessment: the Health-ITUES and the PSSUQ, as detailed in Table 2.

The Health-ITUES scale, where a higher score indicates better usability, showed that "perceived ease of use" scored the highest with a mean (SD) score of 4.6 (0.5), suggesting a favorable user assessment. However, "user control" received the lowest score in this category, with a mean (SD) score of 3.8 (0.9), corroborating the heuristic evaluator's ratings.

Conversely, the PSSUQ, where a lower score indicates better usability, reflected different aspects of the mChoice performance. "System quality" scored the lowest with a mean

XSL•FO
RenderX

(SD) of 1.7 (1.2), while "interface quality" had the highest score with a mean (SD) score of 3.0 (1.8). These results suggested a positive user experience with notable ease of use and system quality strengths. However, there were areas for improvement, particularly in enhancing user control and interface quality.

Table . Usability measures.

Measures	Mean (SD) score
Health-ITUES[a]	
Perceived ease of use	4.6 (0.5)
Impact	4.1 (0.8)
Perceived usefulness	4.0 (0.8)
User control	3.8 (0.9)
Overall Health-ITUES score	4.2 (0.4)
PSSUQ[b]	
System quality	1.7 (1.2)
Information quality	2.4 (1.3)
Interface quality	3.0 (1.8)
Overall PSSUQ score	2.3 (0.6)

[a]Health-ITUES: Health Information Technology Usability Evaluation Scale (rating the score from 5 being the best score to 1 being the worst score).

[b]PSSUQ: Post-Study System Usability Questionnaire (rating the score from 1 being the best score to 7 being the worst score).

Discussion

Principal Results

Our study evaluated the mChoice app's usability in enhancing PrEP adherence for young MSM. Overall, heuristic experts and end users demonstrated satisfaction with the mChoice app, reporting that it is a simple and intuitive interface for tracking PrEP adherence. Graphs, charts, and icons are the main features of mHealth apps that help end users track their goals, habits, and achievements [33,34]. The mChoice app combines iconography (eg, emoticons) and color-coded charts to provide clear and immediate feedback on PrEP adherence. These diverse visualizations allow end users to interpret their data in several formats. The app includes emoticons in different colors (green for high adherence, red for missed doses, and yellow for off-schedule doses) to represent adherence status. For instance, a sad emoticon in red for low adherence might highlight medication adherence challenges and prompt self-reflection on areas needing improvement. Such immediate visual feedback can motivate end users to improve their medication routine. In addition, graphs showed the trend of PrEP medication adherence over time, including evidence-based information on the percentage of missed, off-schedule, and on-time doses.

While prior research has indicated that varied data visualization options help match different end users' preferences [33] and color-coded visual cues can aid in quick decision-making and interpretation of health data [35-38], our study did not directly assess end-user interpretations of these visual elements. The mChoice app incorporates these evidence-based design principles, but further research would be needed to evaluate their impact on user comprehension and medication adherence behaviors.

Our findings suggest that the visual elements available in the mChoice app offer a positive end-user experience and function accessibility that could assist in timely medication intake and monitor adherence. However, our heuristic evaluation highlighted areas needing improvement, particularly in the need for clearer chart titles and more labels to exemplify each component (eg, Clever score), underscoring the importance of refinement of the mChoice design for optimized end-user experiences.

The accuracy of the information collected through the mChoice app was another area of attention that heuristic experts raised concerns, particularly highlighting the absence of "undo," "edit," and "add" buttons. These limitations restricted user control, potentially affecting the accuracy of patients' health information input. For instance, the absence of "undo" and "edit" buttons could lead to inaccuracies if end users mistakenly enter the time of their PrEP dose intake. Additionally, the lack of an "add" button for recording multiple sexual events was seen as an important barrier, restricting end users from documenting their sexual event entries accurately. These findings underscore the need for enhanced app capabilities to ensure accurate and comprehensive user input and customizations. Similarly, other studies [39,40] reported concerns about user experiences and data accuracy in mobile apps, reinforcing the findings of our study.

The actionable finding from this study is to reevaluate the functions of the mChoice app after integrating end-user feedback and addressing heuristic violations. Iterative usability evaluations should be considered as a best practice in the app development process to ensure the effectiveness of the app's future iterations.

RenderX

Limitations

A limitation of our study was the convenience sample, recruited from a database that included participants who had participated in past research and expressed interest in future studies. Additionally, while our sample targeted young MSM, English-speaking men, and those living in New York or Alabama, this demographic representation might limit our ability to understand how the app might perform for medication adherence across diverse populations. Given that PrEP users come from varied cultural, linguistic, and socioeconomic backgrounds, our findings may not be generalizable to groups whose cultural beliefs, language preferences, and health care engagement patterns differ from those of our study population. While end users were central for evaluating the usability of the mChoice app through validated quantitative measures, qualitative data were collected only from experts during heuristic evaluations. In this study, we did not evaluate the artificial intelligence or algorithmic components that could enhance personalization and medication adherence predictions. Despite these limitations, we identified areas of improvement to refine the mChoice app. In addition, this study enriched the body of research on evaluating the mHealth usability for HIV prevention. This was achieved by employing end users and heuristic experts to assess this innovative app designed for PrEP adherence and HIV prevention.

Conclusions

Our usability study of the mChoice app involved rigorous evaluations through interactive heuristic evaluations and end-user testing. The results demonstrated the app's simplicity and user-friendly interface, showcasing its potential in monitoring health-related activities such as PrEP adherence. Further research could explore how these usability enhancements might influence user engagement and behavior change to support HIV prevention efforts.

Acknowledgments

Abstract

Background: Wearable transdermal alcohol sensor (TAS) devices generate continuous data on alcohol consumption through the indiscernible sweat vapors on the skin. This continuous alcohol monitoring capability could provide a new method for alcohol services to monitor service users at various stages of their alcohol treatment.

Objective: We aimed to assess the feasibility of using a TAS as part of alcohol treatment with alcohol service users using the device with or without contingency management (CM).

Methods: A feasibility study was conducted of a convenience sample of 29 current service users from 3 South London alcohol services. Participants were randomized into either a control (treatment as usual) or CM group (treatment as usual+CM). We assessed the feasibility of enrollment, participation, device tampering and return, and device wearability and the accuracy of data capture. These data were reported descriptively where appropriate, the groups were compared, and alcohol self-report data were compared to the transdermal alcohol concentration to assess accuracy.

Results: A total of 34 individuals were approached, and 32 (94%) were enrolled and randomized (n=17, 53% to the control group and n=15, 47% to the CM group) over 5 months. In total, 3 participants withdrew (n=2, 67% from the control group and n=1, 33% from the CM group). There was a total of 203 meetings arranged (29 participants × 7 meetings), and 185 (91.1%) were attended. Only 1 of the 29 participants (3%) admitted to turning the TAS off to avoid monitoring. There were some issues with the TAS not functioning properly and not being able to be cleaned. Removals were recorded, but the definition of TAS removal may need to be improved for future trials. There was a high TAS return rate (28/29, 97% of the participants returned the TAS). Secondary outcomes suggest that the BACtrack Skyn remains an accurate tool to monitor alcohol consumption compared to self-report data and that it is acceptable to wearers over 2 weeks, with many participants (27/28, 96%) answering that they would wear it again and for longer but that the CM procedure could be made clearer.

Conclusions: The delivery of CM via a TAS was feasible in this study, but recommendations for a future larger trial include that the study design should be changed to provide an operationalized rather than manual method of checking whether TAS data meet CM criteria. This would reduce researcher burden and researcher and participant time. Current recruitment and research meeting design seem suitable for a future larger trial.

Introduction

Background

Various wearable transdermal alcohol sensor (TAS) devices have been developed. These devices measure alcohol consumption from alcohol vapors in the skin via sweat, known as transdermal alcohol concentration (TAC), and can record at automated regular intervals. One potential use of TASs is as a tool for objective alcohol measurement in clinical alcohol treatment.

TASs could be used in specialist community alcohol services for monitoring alcohol consumption before detoxification to determine drinking levels and patterns, during detoxification, or after detoxification to be combined with sessions with key workers and other psychosocial or medication treatment. The recorded alcohol data could be used to consider triggers and provide evidence of abstinence or alcohol reduction and proof of engagement, which may be useful as evidence for funded treatment, or TASs could be used to implement contingency management (CM) for alcohol reduction. However, before TASs can be implemented into treatment, their accuracy, acceptability, and feasibility in this setting must be validated.

There have been several studies that have investigated the various TAS device brands on TAC data accuracy compared to self-report, blood alcohol concentration, and breath alcohol content data [1-17]. Most of this previous research was conducted with healthy adult volunteers [18,19]. Various brands of TASs have been developed and are in differing stages of validation and research. There have only been a few studies conducted with a specific focus on exploring TAS acceptability and feasibility measures [12,20-26] and even fewer specifically on TAS implementation of CM rewards [1,2,26-31]. While most of the TAS research reports on the SCRAM monitor, there is a growing number of individuals using a newer generation of TASs, the BACtrack Skyn [7,12-14,32-42].

CM has been evidenced as an effective treatment for substance use. It is an established treatment recommended by the National Institute for Health and Care Excellence [43] and has proven to be effective for a range of substance use treatments [44-47]. Although initially developed to be used with alcohol use disorder (AUD) treatment, it has had limited use in this area [48,49]. This is due to the nature of alcohol metabolism and its short detectability within the body [50,51].

Currently used methods for alcohol measurement include breath, blood, and urine tests, which have a relatively short time frame to detect alcohol [52]. Thus, to accurately implement CM in alcohol treatment, the individual would require frequent, multiple breath, blood, or urine tests daily to prove abstinence or alcohol reduction and accurately achieve CM rewards [47,49,53,54]. This is not always feasible with staff time and resources and increases the burden on both service users and staff. The portable mobile phone–linked breathalyzer has also tried to address this limitation and appears to work well in tracking alcohol treatment progress [55-58]. However, it still requires repeated daily compliance from the individual completing each breathalyzer test.

The development of TASs has the potential to address CM implementation with alcohol use and can provide a low-burden, low-intensity solution [1,2,26-31]. Previous literature has started to explore how TASs can implement CM [1,2,26-31]. These studies have found the SCRAM monitor successful in implementing the CM procedure and found that the CM intervention was able to significantly reduce alcohol consumption [1,2,27,29]. Of these 8 studies, none recruited alcohol-dependent participants. In total, 2 involved recent driving while intoxicated offenders with differing criteria on alcohol consumption, 1 with an Alcohol Use Disorders Identification Test score of ≥4 [28] and the other with an Alcohol Use Disorders Identification Test score of ≥8 [30]; 2 recruited HIV-diagnosed individuals with higher levels of alcohol consumption [26,31]; and the other 4 classified participants as risky or heavy drinkers with varying ways to define this [1,2,27,29]. The length of TAS wear periods and CM length ranged from 1 to 4 months, and all studies were conducted in the United States and used the SCRAM monitor.

This study followed a previous study that used the Skyn with individuals in alcohol treatment wearing the device for 1 week and interviewed staff on their thoughts [36,59,60]. From this previous study, we found that most of the individuals were willing to wear the device for longer and that staff want patients wearing the device for longer than a week for it to be used in alcohol treatment. Therefore, for this study, we extended the wear time for 2 weeks and added the CM component. The findings of this study will contribute to the knowledge on TAS feasibility in alcohol research and providing CM in alcohol services in South London.

Objectives

This study aimed to explore the feasibility, strengths, and limitations of using a TAS to monitor alcohol consumption in individuals in treatment for AUD with or without CM to promote abstinence or low-level alcohol consumption.

Methods

This was a randomized controlled trial with a 1:1 allocation ratio to the control and CM groups.

Patient and Public Involvement and Staff Consultation

To ensure that the recruitment, study design, and outcomes were appropriate, when designing this study, we conducted monthly patient and public involvement groups and staff consultation for 6 months. Service users and staff from 3 South London alcohol services were invited to attend. There were 2 meetings held each month, one for service users (in person) and one for

XSL•FO
RenderX

staff (on Microsoft Teams). In these groups, we discussed study aspects and the participants' thoughts on potential challenges.

Setting

In total, 3 drug and alcohol services were recruited from South London and Maudsley National Health Service Foundation Trust. The 3 services were the Pier Road Project (Erith), Wandsworth Community Drug and Alcohol Service (Wandsworth and Richmond), and the Assertive Alcohol Outreach Team (Camberwell). All services were willing to be involved in this study and had recruitment occur at their facilities. At each service, after referral, patients typically completed a community detoxification, were prescribed any medication if appropriate, and started to attend group meetings and regular one-to-one meetings with their key worker. All participants that were recruited for this study were currently attending groups and one-to-one sessions.

Participants and Sample Size

Participants were referred by service staff and by the researcher attending patient groups to discuss the study. One of the aims of this trial was to investigate the feasibility of conducting a larger trial. Therefore, this study conducted no formal statistical sample size calculation but aimed to recruit 30 participants (15 in each arm).

The inclusion criteria were (1) reception of alcohol treatment for an AUD in one of the participating South London alcohol services, (2) age of ≥18 years, (3) ability to speak English competently, (4) ability to meet throughout the study period, (5) no current participation in any other research trials, and (6) willingness to provide informed consent to participate. Exclusion criteria were (1) current use of any illegal or addictive substances (excluding cannabis), (2) age of <18 years, and (3) inability to speak English without a translator.

The study inclusion criteria were intentionally kept broad, enabling individuals receiving any treatment for an AUD (provided that they met the other criteria) to participate.

Randomization

Participants were randomized via dedicated software and sealed envelopes by an independent statistician. The team member recruiting participants (EB) was not aware of the randomization allocation sequence until the sealed numbered envelope was opened at each participant's first research meeting. EB enrolled all participants and assigned participants to their allocated group. The researcher and participants were not blind to the allocation; both were aware of whether they were receiving CM rewards.

Procedure

At enrollment, participants were randomized into one of two groups: (1) treatment as usual+wearing a TAS (control group) or (2) treatment as usual+wearing a TAS+CM for low or no alcohol consumption as measured using the TAS (CM group).

Each participant had 7 research meetings arranged across 15 days. At the first meeting, the participant was trained in using the TAS and provided with a quick leaflet guide to take home with them, had the study protocol explained, and was randomized into a group. Meetings 2 to 6 were for TAS data download and timeline followback (TLFB) completion. At the final meeting, meeting 7, participants also had TAS data downloaded and completed the TLFB as well as a postwear survey. This procedure is shown in Table 1.

Table 1. Study procedure—an example of the research meetings if the first meeting happened on a Monday.

	Meeting description
Week 1	
Monday	Meeting 1—talk participants through the study and train them in using the TAS[a]
Wednesday	Meeting 2—TAS data download and TLFB[b] (+CM[c])
Friday	Meeting 3—TAS data download and TLFB (+CM)
Week 2	
Monday	Meeting 4—TAS data download and TLFB (+CM)
Wednesday	Meeting 5—TAS data download and TLFB (+CM)
Friday	Meeting 6—TAS data download and TLFB (+CM)
Week 3	
Monday	Meeting 7—TAS data download, TLFB (+CM), and postwear survey

[a]TAS: transdermal alcohol sensor.

[b]TLFB: timeline followback.

[c]CM: contingency management.

If the participant was randomized into the CM group, in addition to the aforementioned steps, at each meeting (meetings 2-7), the TAS data were checked to confirm whether the participant had been abstinent or consumed an amount of alcohol below our set threshold and whether they had been wearing the TAS. If they met these 2 criteria, they were then rewarded with the corresponding amount for the days of abstinence or low level of drinking.

The reason for the research meeting design was for regular TAS data download to ensure that the TAS did not start overwriting data. At the time of this study, the Skyn could store up to 72 hours before overwriting data. Participants also completed a

XSL•FO
RenderX

TLFB with the researcher at every meeting, so they only had to recall alcohol consumption for the previous 2 to 3 days [61].

CM Intervention

Participants who were randomized to the CM group could also earn rewards by being abstinent or for low drinking as measured using the TAS and wearing the TAS consistently (we specified that removal of no more than 60 minutes per day was allowed for a shower or bath). The CM reward was a £5 (US $6.25) voucher for each day that the target behavior occurred. There were also bonuses for consecutive days of the target behavior occurring. At each meeting (meetings 2-7), the researcher checked their TAC data and provided any earned CM rewards since the previous meeting. If the participant met the target behavior every single day for the study period, there was an additional bonus given at the end (£35 [US $43.75]). Therefore, a total of £180 (US $225.02) over the study period could be given in CM vouchers. If there was a day in which this behavior did not occur, then participants received no CM for that day and were not eligible for that bonus. The CM plan is shown in Table 2.

Table 2. Contingency management (CM) plan—an example of the CM plan for a Monday start. Participants were ineligible for CM if the device was removed (skin temperature of <30 °C for >1 hour). A 1-time 1-hour removal was allowed per day.

Day number	Day	CM for 1-day abstinence (£5 [US $6.25] per day)[a]	CM bonus for consecutive-day abstinence (£5 [US $6.25] per day)[b]	CM bonus for 14 consecutive days of abstinence (£35 [US $43.75] for 14 days)[c]
1	Monday	£5 (US $6.25)	—[d]	—
2	Tuesday	£5 (US $6.25)	—	—
3	Wednesday	£5 (US $6.25)	£10 (US $12.50; second meeting)	—
4	Thursday	£5 (US $6.25)	—	—
5	Friday	£5 (US $6.25)	£10 (US $12.50; third meeting)	—
6	Saturday	£5 (US $6.25)	—	—
7	Sunday	£5 (US $6.25)	—	—
8	Monday	£5 (US $6.25)	£15 (US $18.75; fourth meeting)	—
9	Tuesday	£5 (US $6.25)	—	—

13	Saturday	£5 (US $6.25)	—	—
14	Sunday	£5 (US $6.25)	—	—
15	Monday	£5 (US $6.25)	£15 (US $18.75; seventh meeting)	£35 (US $43.75; seventh meeting)

[a]Total of £75 (US $93.76).

[b]Total of £70 (US $87.51).

[c]Total of £35 (US $43.75).

[d]Not applicable.

Measures

BACtrack Skyn

The TAS used in this study was the BACtrack Skyn (model T15). It was worn on the participants' preferred wrist, but they could change which wrist they wore it on during the study period if that was comfortable for them. The Skyn continuously measured the participant's TAC while being worn, as well as skin temperature (°C). Output was analyzed at 1-minute intervals. The participants could remove the TAS at any time if they did not wish to wear it and were required to remove it for bathing as it is not waterproof. The CM group were told that they could remove it once a day for up to 60 consecutive minutes to bathe and still be eligible for their CM reward. If it was removed for longer than an hour, they would no longer be able to receive the CM reward. If they wore the TAS according to this and the TAC did not increase above our set threshold of 115.660 µg/L, they were eligible for the CM reward for that day. Our set threshold was based on previous work by the research team [35].

TLFB Method

A TLFB was completed at meetings 2 to 7 to assess self-reported alcohol consumption and compare it against TAC. The TLFB is a calendar-based measure to record self-reported substance use. A day was considered from midnight to 11:59 PM.

Postwear Surveys

Participants completed a postwear survey on their experience of wearing the Skyn at their last meeting. This survey was adapted from the work by Alessi et al [20]. If participants were randomized to the CM group, they also completed a survey on their CM experience. This survey was adapted from the work by Miguel et al [62].

XSL•FO
RenderX

Outcomes

Feasibility of the Trial

This primary outcome was the feasibility of this study design. Feasibility was defined by enrollment, participation, device tampering, removals, adjustments, malfunction rates, and the number of TASs returned.

Enrollment

Participants who were identified, approached, eligible, and enrolled were recorded. Participants who were approached but did not wish to participate were asked about their main reason for this. Participant safety was recorded via adverse events for each participant. The number of participants enrolled on each service was also recorded.

Participation

The number of attended meetings by enrolled participants, withdrawal rate, compliance with wearing the TAS, and reasons for incomplete participant data (nonattendance, TAS data overwriting, and TAS technical faults) were recorded. Participants were asked what their main reason was for nonattendance or for not complying with TAS wear.

Removals

TAS removals were defined as a skin temperature of <30 °C for >2 minutes. Removals were recorded for each participant.

Tampering

Participants were asked about tampering with the TAS if there was no clear reason for missing TAC data in the output.

Malfunction

TAS errors, missing data due to a technical fault, and charging or syncing issues were recorded, as well as how much data were missing for these reasons.

TAS Return

The number of Skyn devices that were returned to the research team at the end of each participant's study period was recorded.

CM Delivery

The feasibility of TASs to measure CM target behavior was a combination of the factors mentioned previously, including compliance, removals, TAS tampering, malfunction, and accuracy.

Secondary Outcomes

Acceptability

This was measured using the postwear survey.

Accuracy

Accuracy outcomes were measured using the TLFB and TAC data. The TLFB was self-reported [63] and was used to determine alcohol-drinking days and how many units were consumed (in the United Kingdom, 8 g or 10 mL of pure ethanol=1 unit). The TAS (BACtrack Skyn) continuously measured TAC and skin temperature (°C), and from this, Skyn removal and then reported drinking days based on the TAC (µg/L) were determined. The TLFB and TAC data were analyzed to determine TAS accuracy compared to self-report data.

To note, the alcohol-drinking day defined using TAC is different to the CM intervention criteria, which allowed for a low amount of drinking and had a higher TAC criterion of 115.660 µg/L.

Data Handling

There is currently no guidance from BACtrack to determine drinking event criteria. Courtney et al [34] described their procedure for processing Skyn output to identify drinking episodes, and we used these guidelines when processing participant data. We replaced any negative values recorded with 0 in the data output. Missing data were classified as any minutes not reported. Removed data were those reporting a temperature of <30 °C for >2 minutes.

An alcohol event was based on TAC greater than a specific value (µg/L) for more than a set number of minutes. These criteria were chosen due to previous work carried out by this research team [35,59].

Analysis

Descriptive statistics were reported for baseline and demographic variables. All statistical analyses were conducted using SPSS (version 28; IBM Corp).

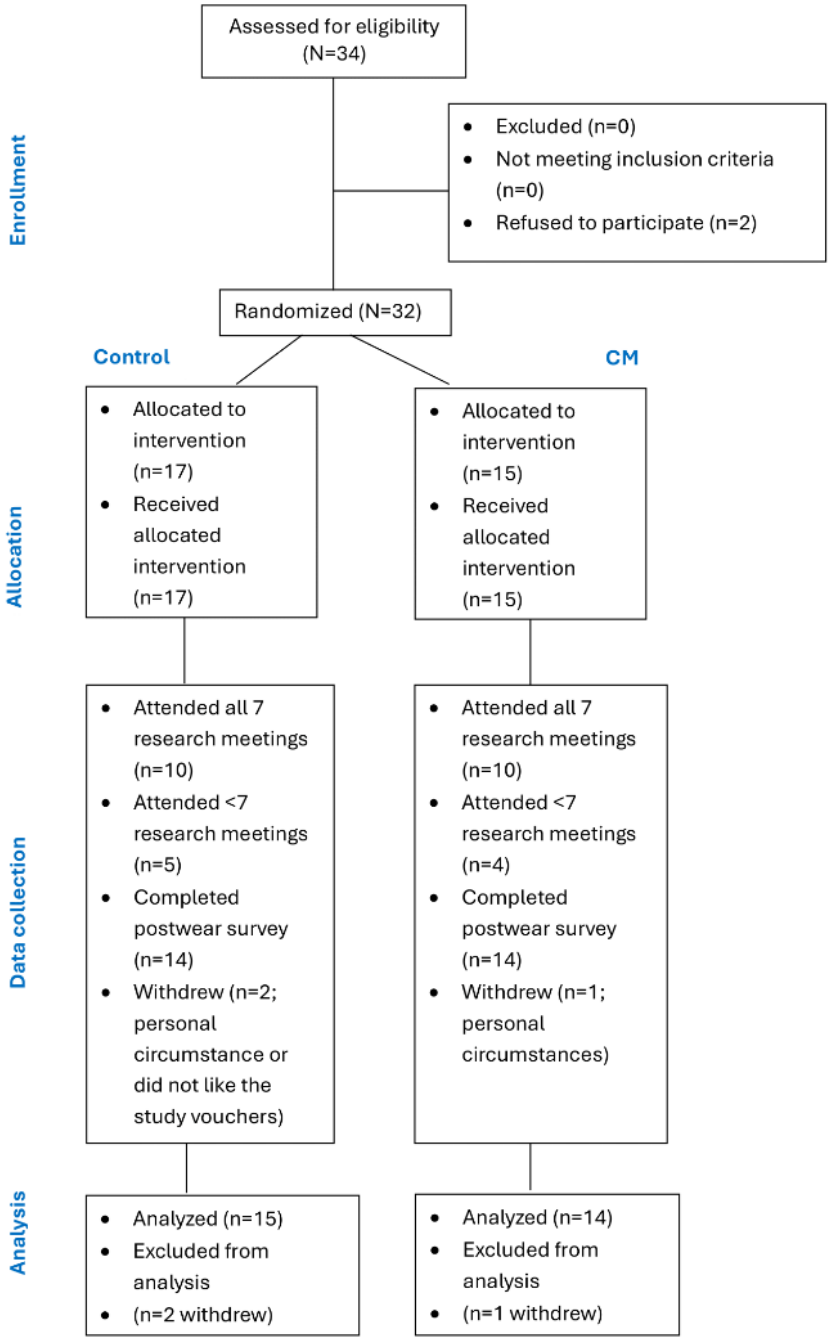
The feasibility outcomes reported included enrollment and recruitment rate, participant attendance, response and compliance, removals, TAS tampering and error, and TAS return. Appropriate summary statistics were reported, and independent-sample 2-tailed *t* tests were used to compare means between the control and CM groups when appropriate.

Summary statistics were reported for the secondary outcomes to be explored for a possible future larger trial. The postwear survey answers were reported. TAS accuracy was determined by analyzing the TAS data compared to self-report TLFB. The analysis focused on the sensitivity, specificity, positive predictive value, negative predictive value, and percentage accuracy in classification of TAC compared to TLFB as the gold standard. Recorded drinking and abstinent days were assessed using Spearman rank correlations. Sensitivity in detecting alcohol events and specificity in classifying an alcohol-drinking day versus a non–alcohol-drinking day were assessed using different TAC criteria: TAS 15 (TAC>15 µg/L for >15 min), TAS 60 (TAC>15 µg/L for >60 min), and TAS 90 (TAC>15 µg/L for >90 min).

Ethical Considerations

This study was approved by the Cornwall and Plymouth Research Ethics Committee (reference: 23/SW/0066) and registered on the Open Science Framework and International Standard Randomised Controlled Trial Number (reference: ISRCTN46845361). Informed written consent was obtained from all participants and their data were anonymized. All participants received a £5 (US $6.25) voucher at every meeting they attended (total for all 7 meetings=£35 [US $43.75]), a voucher for the return of the TAS on the last meeting (£10 [US $12.50]), and reimbursement for travel costs to each meeting.

XSL•FO
RenderX



Therefore, each participant could have received up to £45 (US $56.25) for their participation plus travel costs.

Results

Participants

A total of 32 healthy adult participants (n=10, 31% female and n=22, 69% male) enrolled, and a total of 29 (91%) completed the study. In total, 3 participants withdrew (n=2, 67% from the control group and n=1, 33% from the CM group). Of these 3 withdrawals, 2 (67%) happened during the study period (P8 [control group] on day 3 and P28 [CM group] on day 12), and 1 (33%) occurred at the end of the first meeting (control group) due to the specific type of voucher, which could not be used at the participant's local supermarket. P8 and P28 withdrew because of personal circumstances changing. Therefore, a total of 29 participants were included in the analysis (n=10, 34% female and n=19, 66% male; Figure 1). Table 3 shows the characteristics of the 29 participants included in the analysis split by group (control vs CM).

XSL•FO
RenderX

Feasibility of the Trial

Enrollment

A total of 34 potentially eligible participants were approached. Only 6% (2/34) who were identified by staff declined to participate after discussing the study with the researcher. Their reasons were (1) that they did not like wearing a watch so did not think that they would like to wear a TAS and (2) that they were very busy and could not commit to the regular meetings. No adverse events occurred. The services involved were also willing to help with recruitment, and all recruited at least 4 participants over the 5-month recruitment period.

Participation

It was feasible to enroll more than our target sample size (30 participants) within 5 months. The first participant was enrolled on July 5, 2023, and the final participant (N=32) was enrolled on December 6, 2023. These data could be used to inform the sample size power calculation for a future larger trial.

Among the 29 participants who completed the study period and did not withdraw, a total of 203 meetings were arranged (29 × 7 visits). Of these 203 meetings, 185 (91.1%) were attended. Reasons for nonattendance included illness, their partner being ill, being double booked with another health appointment, a broken phone so the researcher could not be contacted, and hospitalization. The research team decided to book research meetings one at a time, so at meeting 1, meeting 2 was agreed upon, and so on. The day before each meeting, a reminder SMS text message was sent out with the time and date and asking the participants to let the research team know whether this needed to be changed. This design seems feasible to maintain a high attendance rate.

Only 1 of the 29 participants (3%) spoke to the research team about removing their TAS early and removed it at the sixth meeting (2 days early) because they did not want to wear it anymore as they felt that “it is messing with my head” (P22).

Among the 3 services involved, the Assertive Alcohol Outreach Team recruited 53% (17/32) of the participants, the Pier Road Project recruited 34% (11/32) of the participants, and Wandsworth Community Drug and Alcohol Service recruited 12% (4/32) of the participants.

Removals

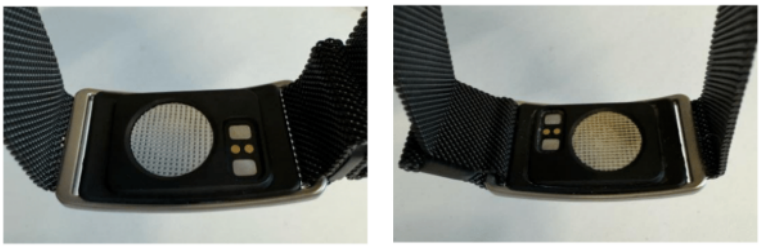
We defined TAS removal as >2 minutes during which the skin temperature was of <30 °C. We reminded participants to wear the TAS as much as possible, including while asleep. However, the TAS is removable by the wearer, and they could choose not to wear it if they wanted to and must remove it for water activities (bathing and swimming). Of the total minutes collected from the 29 participants (464,324 minutes of data, approximately 322 days), there was a total of 19.59% (90,982/464,324) of minutes of removals (approximately 63 days).

The control group had a total of 20.21% (60,879/301,179) of minutes of removals. The CM group had a total of 10.79% (30,103/278,862) of minutes of removals (t_{27}=1.843; P=.08; d=0.685).

Tampering

One participant (P1) admitted to turning the Skyn off while wearing it when they did not want to be monitored. No other evidence or reports of tampering from any other participant was recorded. This participant had 65.65% (13,173/20,067) of minutes of their participation time successfully recorded and 34.35% (6893/20,067) of missing data. Of these missing data, approximately half could be due to not attending meetings and data being overwritten (3386/6893, 49.12%). However, all other meetings were attended, so the 50.88% (3507/6893) of minutes of missing data could be due to the TAS being turned off or technology error and additional data overwriting (approximately 2.5 days’ worth of data).

Malfunction



A total of 16 Skyns were ordered in phases during the study period. The first order of 6 Skyns had 2 issues: one Skyn had trouble pairing for the first 2 weeks, and another would not charge or pair with any research iPhone. BACtrack sent 3 Skyn replacements, and 2 of these would not pair with a research iPhone at first (they did 1 month later). We ordered a second batch of 7 Skyns halfway through data collection, and there were no issues with any devices from this order. BACtrack were unsure about the reasons for the issue with pairing and charging. Other issues experienced included syncing taking >40 minutes on occasions (the usual time is approximately 5 minutes). This was most likely due to poor connection or Wi-Fi.

Apart from 1 Skyn that arrived and could not be charged, there were no charging issues. The Skyn website states that the battery lasts for approximately 10 days; however, we found that it lasted for >2 weeks. Participants were provided with a fully charged Skyn at the first meeting. There were 2 participants whose battery decreased to a low level within their 2-week study period, so the warning red light started flashing. As the TASs were typically able to retain the charge for the entire study period, we did not provide the charging cable to participants. If the TASs will be used for >2 weeks in a future study, either the charging cable will need to be provided or there will need to be planned charging time with the researchers.

There was evidence of Skyn degradation after 2 months, which is partly why it was decided to order another batch of Skyns halfway through data collection [33]. Another reason for this order was their state of cleanliness (Figure 2). BACtrack do provide guidelines on how to clean the sensor; however, after following these instructions, the sensor could not be cleaned well.

XSL•FO
RenderX

Figure 2. These 2 photos of the BACtrack Skyn sensor show a brand-new, unworn Skyn (left) and a worn Skyn (right).

TAS Return

All but 1 Skyn were returned. This was due to the participant disengaging from the service and not being contactable by the researcher or key worker. One other participant did not attend their last research meeting, but they arranged an additional meeting to return the TAS.

CM and Intervention Delivery

CM rewards were delivered if 2 criteria were met: (1) the TAC for the day (midnight-11:59 PM) had a peak of <115.660 µg/L and (2) there were no removals lasting >60 minutes (temperature of <30 °C).

The TAS data were downloaded at each meeting (meetings 2 to 7) and checked, and any CM vouchers were provided for the previous 2 to 3 days. This was considered the best way to implement CM as close to those days in which the behavior occurred as possible. Table 4 details the amount of CM rewards earned by each participant and any reason why CM rewards were not earned.

XSL•FO
RenderX

Table 4. Contingency management (CM) rewards earned by participants in the CM group.

Participant ID	Days in which CM rewards were earned[a]	Total amount earned[b]	Days in which CM rewards were not earned[c]	Reason why CM rewards were not earned[d]
P4	0	£0	15	15 days=TAC[e] over the limit
P5	13	£105 (US $131.26)	2	1 day=TAC over the limit; 1 day=removal for >60 min
P6	12	£95 (US $118.76)	3	1 day=TAC over the limit; 2 days=removal for >60 min
P7	10	£85 (US $106.26)	5	1 day=TAC over the limit; 4 days=removal for >60 min
P10	12	£90 (US $112.51)	3	1 day=TAC over the limit; 2 days=removal for >60 min
P11	0	£0	15	15 days=TAC over the limit
P16	2	£10 (US $12.50)	13	6 days=removal for >60 min; 7 days=DNA[f] appointment and data overwritten
P17	5	£25 (US $31.25)	10	6 days=TAC over the limit; 2 days=removal for >60 min; 2 days=DNA appointment and data overwritten
P18	9	£55 (US $68.75)	6	6 days=removal for >60 min
P19	9	£75 (US $93.76)	6	3 days=removal for >60 min; 3 days=DNA appointment and data overwritten
P21	13	£110 (US $137.51)	2	2 days=removal for >60 min
P22	1	£5 (US $6.25)	11	9 days=TAC over the limit; 2 days=removal for >60 min; handed TAS[g] back 2 days early
P25	3	£15 (US $18.75)	12	2 days=TAC over the limit; 10 days=removal for >60 min
P29	11	£85 (US $106.26)	4	4 days=removal for >60 min

[a]Total: 48.3% (100/207) of days.

[b]Total: £755 (US $943.82).

[c]Total: 51.7% (107/207) of days.

[d]Total: 24.6% (51/207) of days with transdermal alcohol concentration over the limit, 21.3% (44/207) of days of removals, and 5.8% (12/207) of days of data overwritten.

[e]TAC: transdermal alcohol concentration.

[f]DNA: did not attend.

[g]TAS: transdermal alcohol sensor.

Control group participants attended 89.5% (94/105) of the meetings, and the CM group participants attended 92.9% (91/98) of the meetings (t_{27}=−0.573; *P*=.57; *d*=−0.213). The control group self-reported 48.6% (107/220) of abstinent days, and the CM group self-reported 70% (147/210) of abstinent days (t_{27}=−1.403; *P*=.17; *d*=−0.522). The proportion of days in which the Skyn data reported <1 hour of removals was 15.9% (35/220) for the control group and 24.8% (52/210) for the CM group (t_{27}=−1.326; *P*=.20; *d*=−0.493). The difference in the amount of units consumed between groups was not statistically significant (control: mean 109.33, SD 27.47; CM: mean 53.33, SD 24.91; t_{27}=1.503; *P*=.14; *d*=0.559).

Acceptability and Postwear Survey

A total of 97% (28/29) of the participants completed the postwear survey. One participant did not complete it because they did not attend their final research meeting and became unreachable. When asked about physical comfort, most participants (11/28, 39%) rated it to be quite to very comfortable, with the average score being 8.57/10 (SD 0.71; 10=very comfortable). Social comfort (how they felt wearing it in public) was also rated highly, with an average score of 9.63/10 (SD 0.00; 10=very socially comfortable). When asked how often they noticed the Skyn on their wrist, only 11% (3/28) of the participants said that they never noticed it when wearing it. Most (18/28, 64%) noticed it once or twice a day to every hour, but 25% (7/28) did report noticing it several times per hour. When asked to rate its interference with various activities

XSL•FO
RenderX

(exercise, mood, normal work, enjoyment of life, ability to concentrate, social life, and clothing choices), these were all rated with an average score of <2 (1=no interference at all; general activity: 1.75, SD 0.00; exercise: 1.07, SD 0.00; mood: 1.11 SD 0.00; work: 1.07, SD 0.00; enjoyment of life: 1.21, SD 0.00, ability to concentrate: 1.43, SD 0.00; social life: 1, SD 0.00; choice of clothing: 1.24, SD 0.00). The only activity that ranked higher was sleeping, with an average score of 2.71 (SD 2.83; 1=no interference at all).

A total of 32% (9/28) of the participants reported experiencing a mark on their skin from the TAS, with the other 68% (19/28) reporting never experiencing a mark or side effect. These side effects included itching (mean 1.95, SD 0.00), sweating (mean 1.88, SD 0.00), soreness (mean 1.07, SD 0.00), and irritation (mean 1.50, SD 0.00), with the scale being from 1=not noticeable to 10=unbearable. Participants were asked whether they would continue to wear the TAS for longer than the 2-week study period, and 96% (27/28) reported *yes*, and only 4% (1/28) reported *no*.

The following statements—"the device is too uncomfortable to wear for any longer," "I wouldn't want to wear it any longer because I am embarrassed," and "I want to wear short sleeves but won't while wearing the device"—were answered by all participants with "not true." Statements asking about changing their clothing choices, wanting to remove the TAS, and not liking the regular download visits all had an average score of 0.25 (SD 0.00 for all these statements) (on a scale of 0-4 where 0=*not true* and 4=*very true*). Only 4% (1/28) of the participants stated that they were tired of explaining the device to people. In total, 4% (1/28) stated that they were "ready to stop wearing the device because I am just ready to be done," and another participant (1/28, 4%) said that the "financial compensation for wearing the device any longer than this would not be worth it." A total of 7% (2/28) of the participants said that it was true that "I would not continue wearing the device because I do not like having to do the downloads at a specific time."

When asked about their drinking, 11% (3/28) self-reported that they were able to completely reduce their drinking, 25% (7/28) reported that they reduced it quite a bit, 14% (4/28) reported that they reduced it somewhat, 7% (2/28) reported that they tried but did not reduce it, and 11% (3/28) reported that they did not reduce or try to reduce it. In total, 32% (9/28) of the participants were abstinent throughout their study period.

Many participants (12/28, 43%) liked the in-person vouchers that were given at each meeting; however, 7% (2/28) would have preferred an e-voucher, 21% (6/28) would have preferred a bank transfer, and 18% (5/28) would be happy with any of these options (in-person voucher, e-voucher, or bank transfer). In total, 7% (2/28) reported preferring only an e-voucher or bank transfer, and 4% (1/28) preferred an in-person voucher or a bank transfer. Finally, participants were asked about the ease of meeting the researcher for the meetings, and 89% (25/28) reported that it was *not at all difficult*, whereas the other 11% (3/28) reported that it was *a little bit difficult*.

CM Survey

The 48% (14/29) of participants who were allocated the CM group completed another survey specifically on their experience of the CM rewards. All participants in the CM group (14/14, 100%) completed this survey. When asked about how easy it was to understand the CM reward procedure, most (9/14, 64%) said that it was very easy, but 21% (3/14) rated it as very difficult. When asked whether the CM had any effect on their response to treatment, half (7/14, 50%) said that it helped them either a lot or a little, 43% (6/14) said that it did not make a difference, and 7% (1/14) said that it had a negative impact. When asked whether they liked the CM rewards, all (14/14, 100%) said that they liked them either a lot or a little. When asked when CM rewards would help other people who seek substance treatment for alcohol dependence, 86% (12/14) said that it would help them a lot or a little, and 14% (2/14) said that it would depend on the person.

Accuracy

Participants wore the TAS for a cumulative total of 580,040 minutes. A total of 80.05% (464,324/580,040) of minutes of this participation was successfully recorded by the TAS. Of these 464,324 minutes of recorded data, there was a total of 90,982 (19.59%) minutes that suggested removal, a total of 56,858 (12.25%) minutes that were missing for unknown reasons, and a total of 58,986 (12.7%) minutes that were missing due to being overwritten as a result of not attending appointments. The Skyn is not waterproof, so participants were required to remove it for showering, baths, and any other water activities (eg, swimming). No fit adjustments were required.

The TAS recorded data for a total of 388 days. Of these 388 days, 337 (86.9%) had >60 minutes of removals or missing data. There was a total of 68.6% (266/388) of days in which there were >300 minutes of removed or missing data (not necessarily a consecutive 5-hour period).

TLFB Versus Skyn TAC

Overview

TLFB drinking days were recorded via the participant reporting any alcohol consumed. TAS drinking days were recorded according to the TAC criteria. We considered 3 different criteria for detecting alcohol-drinking days: TAC of >15 µg/L for >15 minutes, TAC of >15 µg/L for >60 minutes, and TAC of >15 µg/L for >90 minutes. The agreement between the TLFB and these criteria is reported in Table 5.

XSL•FO
RenderX

Table 5. Timeline followback (TLFB)– and transdermal alcohol sensor (TAS)–reported alcohol-drinking and nondrinking days.

Criteria	Alcohol-drinking days detected	Alcohol-drinking days in agreement (n=388), n (%)	Non–alcohol-drinking days in agreement (n=388), n (%)	Days reported by the TAS but not by TLFB as alcohol-drinking days (n=388), n (%)	Days reported by TLFB but not by the TAS as alcohol-drinking days (n=388), n (%)
TAC[a] >15 µg/L for >15 min		164 (42.3)	145 (37.4)	65 (16.8)	14 (3.6)
TLFB	185				
TAS	227				
TAC>15 µg/L for >60 min		146 (37.6)	171 (44.1)	39 (10.1)	32 (8.2)
TAS	185				
TLFB	185				
TAC>15 µg/L for >90 min		139 (35.8)	179 (46.1)	31 (8)	39 (10.1)
TAS	185				
TLFB	170				

[a]TAC: transdermal alcohol concentration.

Criteria for a Drinking Event of TAC>15 µg/L for >15 Minutes

The TLFB and TAS agreed on 42.3% (164/388) of days as alcohol-drinking days and on 37.4% (145/388) of days as abstinent days. There were 3.6% (14/388) of days in which the TLFB reported an alcohol-drinking day and the TAS did not and 16.8% (65/388) of days in which the TAS reported an alcohol-drinking day and the TLFB did not.

When splitting the groups and conducting a correlation between TAS- and TLFB-reported drinking days, both were positively significantly correlated, but the CM group had a stronger correlation effect (control group: r_{15}=0.625 and P=.01; CM group: r_{14}=0.836 and P<.001).

Criteria for a Drinking Event of TAC>15 µg/L for >60 Minutes

The TLFB and TAS agreed on 37.6% (146/388) of days as alcohol-drinking days and on 44.1% (171/388) of days as abstinent days. There were 8.2% (32/388) of days in which the TLFB reported an alcohol-drinking day and the TAS did not and 10.1% (39/388) of days in which the TAS reported an alcohol-drinking day and the TLFB did not.

When splitting the groups and conducting a correlation between TAS- and TLFB-reported drinking days, both were positively significantly correlated, but the CM group had a stronger correlation effect (control group: r_{15}=0.764 and P<.001; CM group: r_{14}=0.895 and P<.001).

Criteria for a Drinking Event of TAC>15 µg/L for >90 Minutes

The TLFB and TAS agreed on 35.8% (139/388) of days as alcohol-drinking days and on 46.1% (179/388) of days as abstinent days. There were 10.1% (39/388) of days in which the TLFB reported an alcohol-drinking day and the TAS did not and 8% (31/388) of days in which the TAS reported an alcohol-drinking day and the TLFB did not.

When splitting the groups and conducting a correlation between TAS- and TLFB-reported drinking days, both were positively significantly correlated, but the CM group had a stronger correlation effect (control group: r_{15}=0.805 and P<.001; CM group: r_{14}=0.913 and P<.001).

Skyn TAC

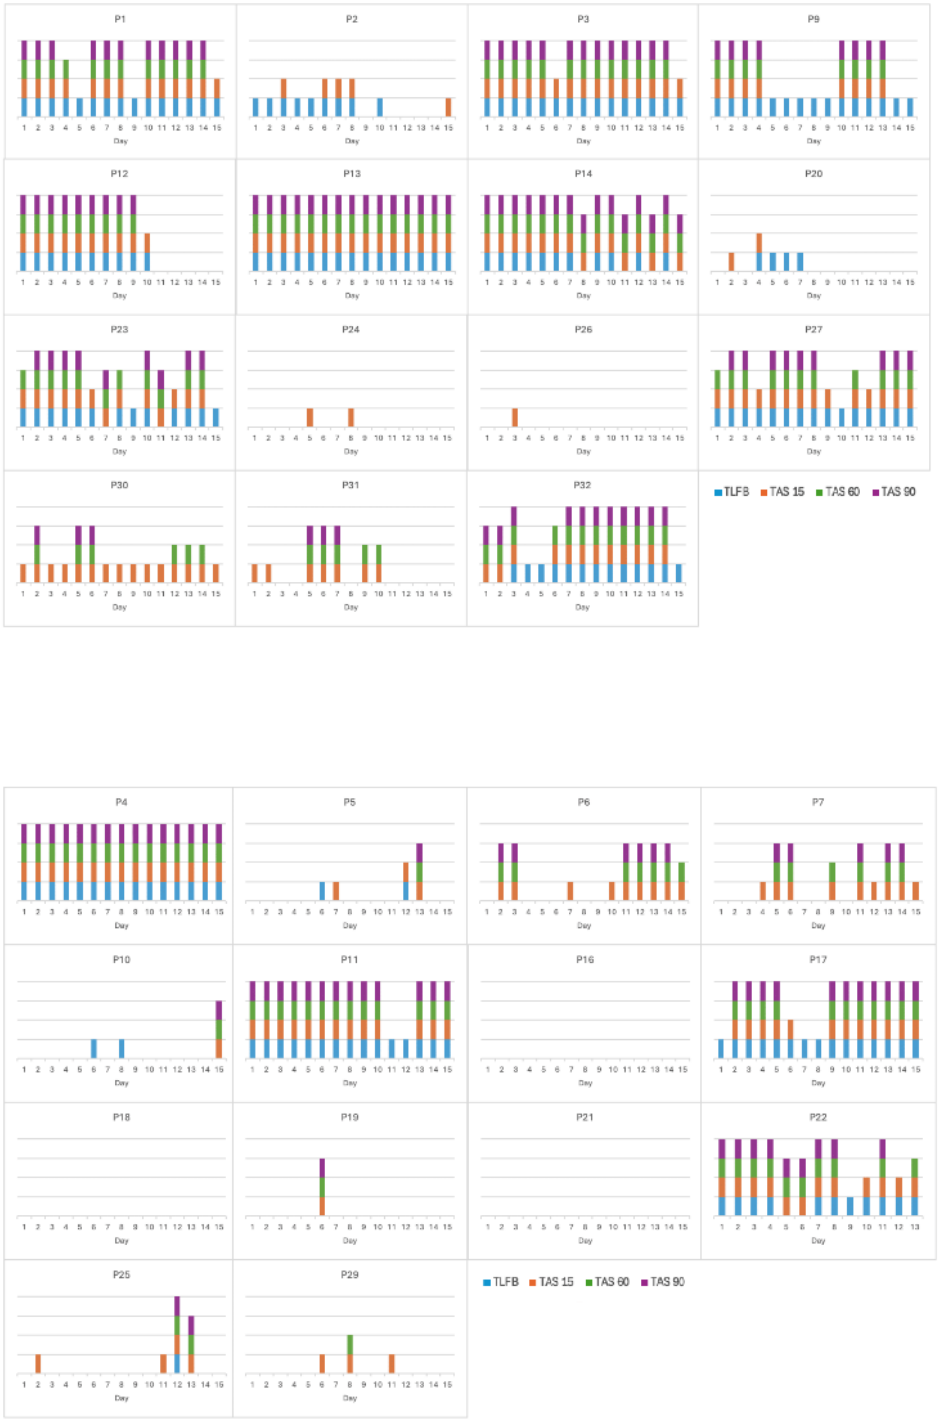
Reasons why the TAS did not detect an alcohol event but it was reported in the TLFB could include a large amount of missing data; TAS removal; a low amount of alcohol self-reported; or it being the last day of participation, which may mean that there was not enough time for alcohol to appear in the TAC output. There were other days in which there was no obvious reason why the TAS did not detect alcohol consumption.

Reasons why the TAS reported an alcohol-drinking day but the participant did not self-report alcohol consumption could include a sudden TAC spike, which suggests contact with an alcohol-containing product (eg, aftershave, deodorant, or hand sanitizer); the skin temperature suggesting that the TAS was not being worn at the time of TAC event detection, so the TAS may have been on a table near an alcohol spill or alcohol-containing product; and the TAS appearing to detect an alcohol event, so the self-report was inaccurate. There were other days in which there was no obvious reason why the participant did not self-report alcohol consumption.

In Figure 3, a visual presentation of the data for each TAC criteria is provided. It shows TLFB and the TAS criteria of TAS 15 (TAC>15 µg/L for >15 min), TAS 60 (TAC>15 µg/L for >60 min), and TAS 90 (TAC>15 µg/L for >90 min). The presence of the color corresponding to each of these TAC criteria indicates that an alcohol-drinking day was detected.

XSL•FO
RenderX

Figure 3. Visual representation of participants' Timeline Followback (TLFB)– and transdermal alcohol sensor (TAS)–detected alcohol-drinking days for (A) the control group and (B) the contingency management (CM) group. The figure includes 3 different TAS criteria for detecting a drinking day: TAS 15 (transdermal alcohol concentration [TAC]>15 µg/L for >15 min), TAS 60 (TAC>15 µg/L for >60 min), and TAS 90 (TAC>15 µg/L for >90 min).



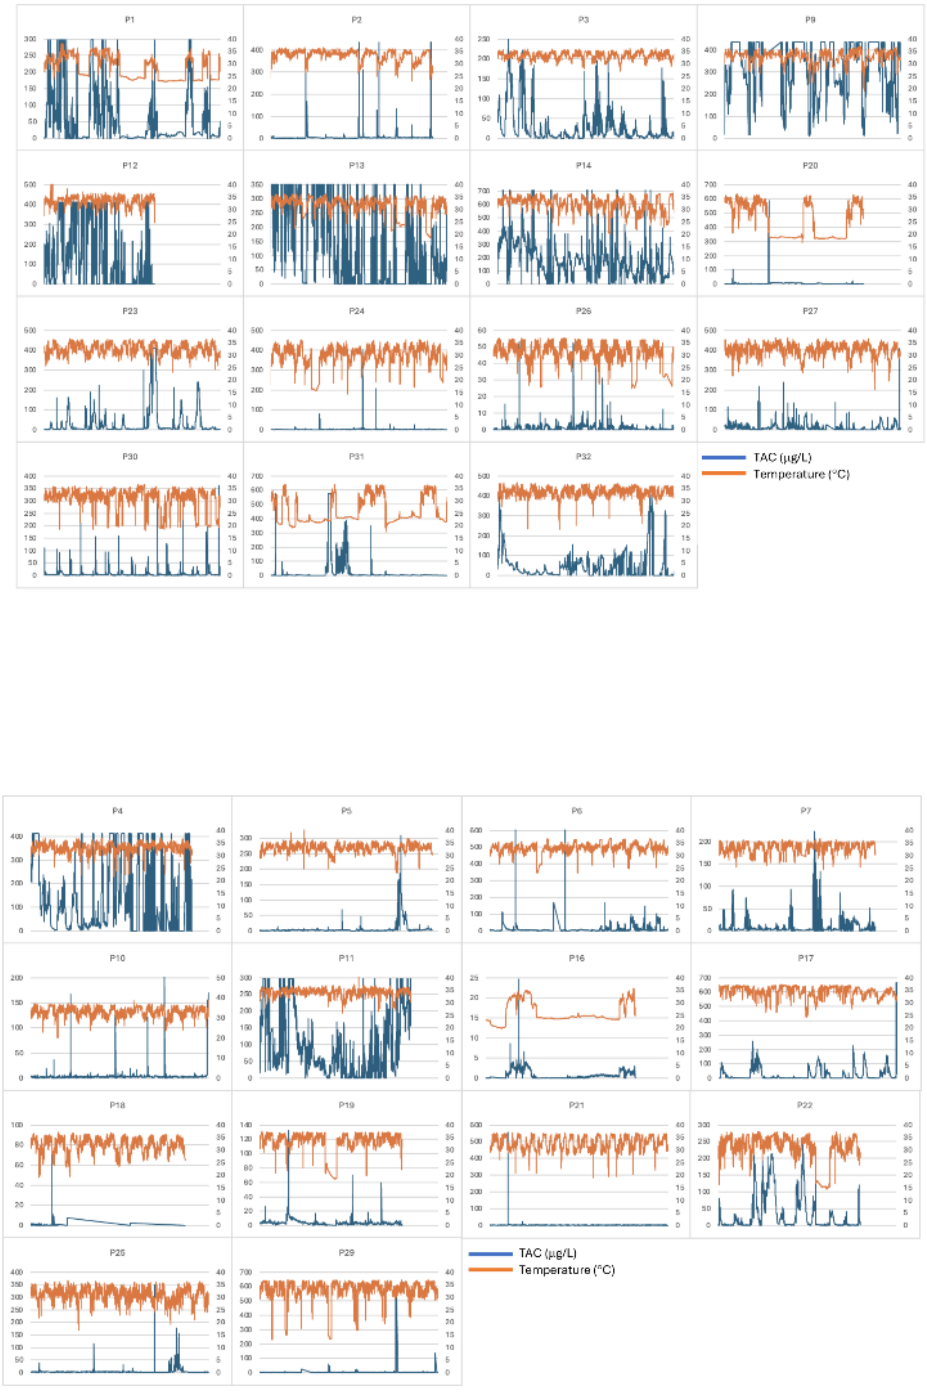


Figure 4 shows the data for TAC and the skin temperature of all participants who wore the TAS for the entire study period. There were participants whose TAC (blue line) peaked on separate occasions, suggesting multiple alcohol events, for example, P5 or P17. In contrast, other participant data suggest more frequent alcohol consumption, for example, P9 and P13. The orange lines depict the skin temperature recorded; the skin temperature for P1 and P20 suggests regular, long TAS removal.

XSL•FO
RenderX

Figure 4. Individual participant Skyn data (excluding withdrawn participants). The primary axis shows the transdermal alcohol concentration (TAC; µg/L) data (blue line), and the secondary axis shows the skin temperature (°C) data (orange line).

Sensitivity, Specificity, and Correlations

We calculated the sensitivity, specificity, positive predictive value, negative predictive value, and percentage accuracy in classification for 3 drinking event thresholds: TAS 15 (TAC>15 µg/L for >15 min), TAS 60 (TAC>15 µg/L for >60 min), and TAS 90 (TAC>15 µg/L for >90 min), shown in Table 6.

XSL•FO
RenderX

Table 6. Transdermal alcohol concentration (TAC) criteria—sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and percentage accuracy classification (PAC).

Criteria	Sensitivity (%)	Specificity (%)	PPV (%)	NPV (%)	PAC
TAC>15 µg/L for 15 min	92.7	68.29	71.74	91.5	0.80
TAC>15 µg/L for 60 min	82.49	80.5	78.92	83.85	0.81
TAC>15 µg/L for 90 min	78.09	85.31	81.76	82.19	0.82

A Spearman correlation found a significant relationship between TLFB- and Skyn-measured alcohol-drinking days at the TAC>15 µg/L for >15 minutes threshold (r_s=0.695, bias–corrected and accelerated [BCa] 95% CI 0.417-0.883; *P*<.001) [29]. A Spearman correlation between the number of standard alcohol units self-reported and the average TAC values was also found to be significant (r_s=0.770, BCa 95% CI 0.632-0.852; *P*<.001) [29].

A Spearman correlation found a significant relationship between TLFB- and Skyn-measured alcohol-drinking days at the TAC>15 µg/L for >60 minutes threshold (r_s=0.773, BCa 95% CI 0.599-0.861; *P*<.001) [29]. A Spearman correlation between the total number of standard alcohol units self-reported and the TAS-reported drinking days at the TAC>15 µg/L for >60 minutes threshold was also found to be significant (r_s=0.740, BCa 95% CI 0.439-0.891; *P*<.001) [29].

A Spearman correlation found a significant relationship between TLFB- and Skyn-measured alcohol-drinking days at the TAC>15 µg/L for >90 minutes threshold (r_s=0.784, BCa 95% CI 0.625-0.868; *P*<.001) [29]. A Spearman correlation between the total number of standard alcohol units self-reported and the TAS-reported drinking days at the TAC>15 µg/L for >90 minutes threshold was also found to be significant (r_s=0.745, BCa 95% CI 0.460-0.892; *P*<.001) [29].

Discussion

Principal Findings

This study aimed to explore the feasibility, strengths, and limitations of using a TAS to monitor alcohol consumption in individuals in treatment for AUD with or without CM to promote abstinence or low-level alcohol consumption. The findings suggest that TAS-delivered CM to encourage alcohol reduction was feasible and acceptable to participants. There was a high correlation between TAS-recorded alcohol-drinking days and self-reported alcohol units, suggesting that the TAS was accurate in measuring the desired behavior. There was also high recruitment, attendance, and compliance of participants. Good rates of meeting attendance and data completeness were achieved. It was feasible to deliver CM using the TAS; however, key features of this process were identified for improvement. This is the first study of TAS-delivered CM in the United Kingdom and the first targeted at alcohol service users for alcohol treatment and reduction.

Participants found the wear of the TAS acceptable and comfortable even for social occasions. They found that it did not interfere with daily activities, and most (19/28, 68%) did not experience any side effects (such as a rash or skin irritation) from the strap. There was a high attendance rate and willingness to participate from those approached. Participants liked the reminder SMS text messages about each meeting, and there were few issues when arranging meetings. Only 3% (1/29) of the participants lost contact with the researcher during participation and did not return the TAS.

However, the answers to the CM survey suggest that this process may need to be improved. Some participants (3/28, 11%) reported it as difficult to understand, and half (7/14, 50%) said that it made no difference or did not help their treatment. These findings suggest that there should be more consideration on how the CM procedure is described and presented to participants at the start. Most (12/14, 86%) said that they did think that CM rewards would help other people who seek treatment for alcohol dependence a little to a lot, with the other 14% (2/14) of the participants saying that it would probably help but only if the patient was motivated.

To deliver the CM, TAS data were downloaded and reviewed at meetings 2 to 7. This was feasible; however, there were issues that arose that would need to be dealt with before scaling up the study size. Considering other options for automated TAC data interpretation will reduce the time-consuming manual data checking, which would only increase the researchers' time burden if conducted on a larger trial. In addition, creating an automated system could increase consistency and avoid human error.

The recruitment and follow-up rates from this study were the same as or higher than the recruitment and follow-up rates of other TAS feasibility or pilot studies. Previous studies using TASs had sample sizes for analysis of 5 to 13 participants [2,12,34,64]. In total, 2 of these studies used the SCRAM monitor [2,64], and 2 used the BACtrack Skyn [12,34], but 3 [2,34,64] mentioned discomfort with the TAS as key feedback, with Courtney et al [34], who used the BACtrack, having one participant drop out due to discomfort.

Overall, the findings support the feasibility of implementing and delivering CM using a TAS over a 2-week wear period with alcohol service users currently receiving alcohol treatment. The TAS used, BACtrack Skyn, was well liked and rated as comfortable by participants, with little daily interference. The recruitment rates were high and are encouraging for a larger trial. TAS delivery of CM has been shown to be effective in the United States using the SCRAM monitor [1,2,26-31,65], but this pilot shows promise for translation to other TAS brands delivering CM in the United Kingdom, with these findings highlighting aspects to address and improve before scaling to a larger study design. On the basis of these results, future work could explore the possibility of solutions to these challenges and a cost-effectiveness assessment.

XSL•FO
RenderX

In the future, we would also recommend collecting initial data from the participants to determine each participant's baseline skin temperature. This could be done with the researcher present to ensure correct TAS wear. Some participants were observed by the researcher to be wearing the Skyn during the meeting but the Skyn temperature was reported as <30 °C. Therefore, it may be better to establish a baseline for each participant to then use for their Skyn data for better accuracy at determining wear and removals.

Strengths and Limitations

The strengths of this study are that it was able to demonstrate the feasible use of the BACtrack Skyn over 2 weeks with individuals currently diagnosed with alcohol dependence and receiving alcohol treatment. Participants wore the TAS in their natural settings and unsupervised, consistent with how it should be worn. While the objective of this study was to assess the feasibility of a larger trial, the data collected as part of this study were able to provide more evidence of how this population wears, uses, and experiences a TAS. There was a high meeting attendance and TAS return rate for this study and no issues with participants being unsure or needing additional training for using the TAS after the baseline training. This study continues to support the use of TASs among the population.

The limitations of this study are similar to those of the design of all the studies conducted as part of this PhD—participants were only recruited if they were willing to wear the TAS from the start of the study period. This means that no participants were recruited who were not willing to attempt wearing the TAS. While this is not a limitation in some considerations as the TAS would be a voluntary treatment option to service users if implemented in services, it does mean that the postwear survey findings may be skewed more positively. Only those who were interested in and willing to wear the TAS had the chance to complete the postwear survey at the end of the 2 weeks. However, participants being willing to wear the TAS for the study does not necessarily mean that they were positive about the technology or that they had a good experience of wearing it; therefore, while we note that the study design does exclude those who are not initially willing to attempt wearing a TAS, this may reflect a truer view of service users who would try wearing the TAS as part of alcohol treatment if TASs were to be implemented in clinical settings.

Conclusions

To conclude, if planning a future larger trial for TAS delivery of CM, the proposed design changes from this study are (1) changes to how TAC data are checked for CM rewards from a manual to an automatic process, (2) a clearer explanation of the CM procedure, (3) consideration of the times available for participant meetings to improve participant availability and reduce missed appointments, (4) consideration of other TAS brands that have longer data storage, (5) consideration of whether participants should be provided with an iOS device and trained to sync their data or whether participants should have this option with their personal iOS device if using the BACtrack Skyn (which has been deemed feasible by wearers), and (6) consideration of the assessment of each participant's baseline skin temperature. These points could be assessed via an internal pilot study.

Acknowledgments

This is a summary of independent research funded by the National Institute for Health and Care Research (NIHR) Applied Research Collaboration South London. The views expressed are those of the authors and not necessarily those of the National Health Service (NHS), the NIHR, or the Department of Health and Social Care. CD and PD were supported by the NIHR Maudsley Biomedical Research Centre at the South London and Maudsley NHS Foundation Trust and King's College London. They were also supported by the NIHR Collaboration for Leadership in Applied Health Research and Care at King's College Hospital NHS Foundation Trust and the NIHR Applied Research Collaboration South London at King's College Hospital NHS Foundation Trust. CD was supported by an NIHR Senior Investigator Award. SP has been partly funded by income from research grants obtained from Mundipharma Research Ltd and Camurus AB. SP was a Research Fellow at King's College London at the time of writing. The authors would also like to acknowledge Andrea Solar-Reyes and Noel Kehoe for their data collection work alongside EB for this study and Simon Coulton for his help in participant randomization.

Authors' Contributions

EB led on the conceptualization, methodology, analysis, investigation, resources, data curation, project administration, visualization, and drafting and revision of the manuscript. CD supported the conceptualization, methodology, analysis, supervision, and revision of the manuscript. SP supported the supervision and revision of the manuscript. PD supported the conceptualization, methodology, analysis, supervision, and revision of the manuscript.

Abstract

Background: Abnormal brain activity is the source of epileptic seizures, which can present a variety of symptoms and influence patients' quality of life. Therefore, it is critical to track epileptic seizures, diagnose them, and provide potential therapies to manage people with epilepsy. Electroencephalography (EEG) is helpful in the diagnosis and classification of the seizure type, epilepsy, or epilepsy syndrome. Ictal EEG is rarely recorded, whereas interictal EEG is more often recorded, and the results can be abnormal or normal even in the case of epilepsy. The current digital care pathway for epilepsy (DCPE) lacks the integration of data-driven seizure detection, which could potentially enhance epilepsy treatment and management.

Objective: This study aimed to determine the requirements for integrating data-driven medical software into the DCPE to meet the project's goals and demonstrate practical feasibility regarding resource availability, time constraints, and technological capabilities. This adjustment emphasized ensuring that the proposed system is realistic and achievable. Perspectives on the feasibility of data-driven medical software that meets the project's goals and demonstrates practical feasibility regarding resource availability, time constraints, and technological capabilities are presented.

XSL•FO
RenderX

Methods: A 4-round Delphi study using focus group discussions was conducted with 7 diverse panels of experts from Oulu University Hospital to address the research questions and evaluate the feasibility of data-driven medical software for monitoring individuals with epilepsy. This collaborative approach fostered a thorough understanding of the topic and considered the perspectives of various stakeholders. In addition, a qualitative study was carried out using semistructured interviews.

Results: Drawing from the findings of the thematic analytics, a detailed set of guidelines was created to facilitate the seamless integration of the proposed data-driven medical software for EEG seizure monitoring into the DCPE. These guidelines encompass system requirements, data collection and analysis, and user training, offering a comprehensive road map for the effective implementation of the software.

Conclusions: The study outcome presents a comprehensive strategy for improving the quality of care, providing personalized solutions, managing health care resources, and using artificial intelligence and sensor technology in clinical settings. The potential of artificial intelligence and sensor technology to revolutionize health care is exciting. The study identified practical strategies, such as real-time EEG seizure monitoring, predictive modeling for seizure occurrence, and data-driven analytics integration to enhance decision-making. These strategies were aimed at reducing diagnostic delays and providing personalized care. We are actively working on integrating these features into clinical workflows. However, further case studies and pilot implementations are planned for future studies. The results of this study will guide system developers in the meticulous design and development of systems that meet user needs in the DCPE.

Introduction

Background

Epilepsy is a neurological condition that is characterized by recurrent and unprovoked seizures [1]. Epilepsy is one of the most common neurological conditions, affecting millions of people worldwide [2]. Epileptic seizures occur due to abnormal brain electrical activity, leading to a wide variety of symptoms and manifestations. This condition can substantially impact patients' quality of life. Therefore, to effectively manage and provide support for people with epilepsy, it is essential to understand epilepsy, including its causes, diagnosis, available treatments, and comorbidities [3]. One of the most critical aspects of adequate care is knowing thoroughly about the seizure types, etiology, and provoking factors [4,5].

Electroencephalography (EEG) data play a crucial role in detecting epileptic seizures by capturing distinct patterns and anomalies associated with epileptic seizures by recording the brain's electrical activity. Sharp waves and spikes, slow waves, rhythmic patterns, and interictal epileptiform discharges are some of the possible EEG findings of people with epilepsy [4,6-10]. Experienced neurologists or automated algorithms can visually identify and analyze these abnormal patterns. The possibilities of EEG data processing for seizure detection have been substantially enhanced by recent developments in machine learning and artificial intelligence (AI) [11,12]. It is possible to train algorithms to recognize and categorize seizure occurrences automatically, giving individuals or health care professionals real-time notifications.

On the basis of the discussion with health care professionals, the current digital care pathway for epilepsy (DCPE) faces several issues and shortcomings. Despite therapeutic advances, the classification, diagnosis, and treatment of epilepsy remain complex. Current medications only manage seizures in around two-thirds of people with epilepsy, which emphasizes the need for more potent therapies [13]. The current DCPE lacks data-driven seizure detection integration, which could enhance differential diagnosis and treatment in drug-resistant patients. The addition of data-driven technologies could offer significant improvements, including more accurate seizure detection and prediction, personalized treatment plans, better management of medication-resistant epilepsy, and shared decision-making. However, implementing AI solutions such as machine learning for seizure detection and monitoring is not yet a standard component of DCPE. Integrating a new data-driven medical software for EEG seizure monitoring into the current DCPE requires a thorough understanding of the user's needs and system requirements. Furthermore, robust requirement engineering and precise stakeholder requirements definitions are needed to design and develop data-driven medical software to ensure patient safety, privacy, compliance with regulatory standards, functional accuracy and relevance, interpretability, scalability, and sustainability [14-16].

This Study

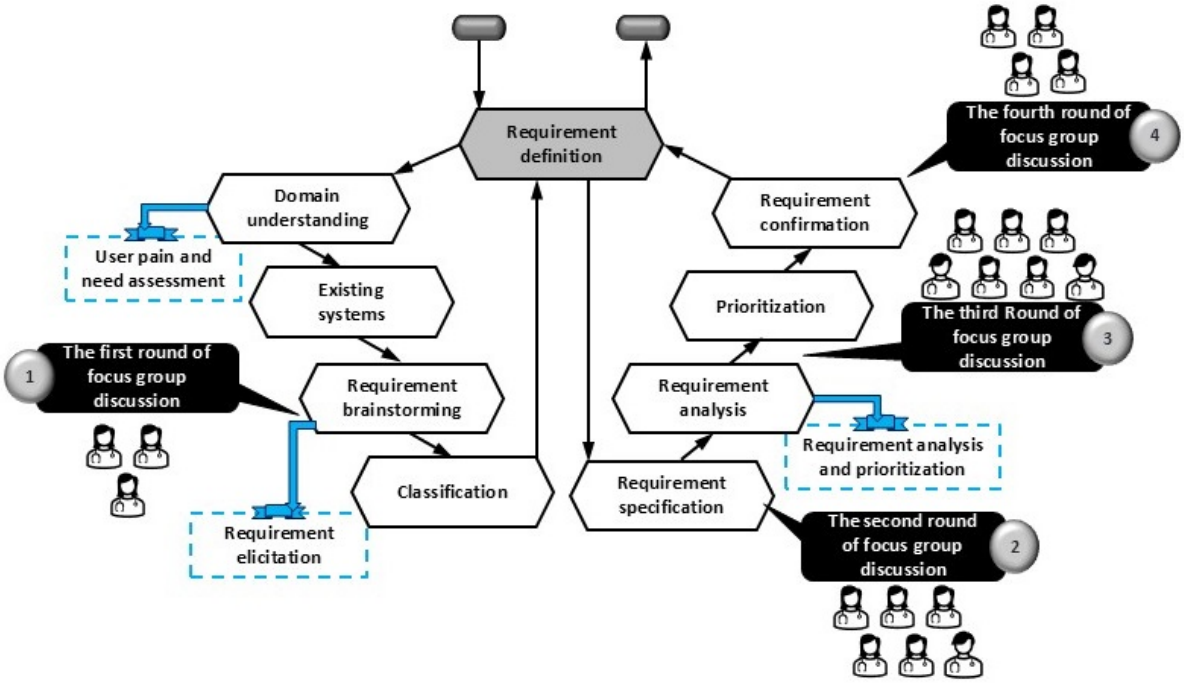
This study aimed to define the system requirements for developing and integrating data-driven medical software for EEG seizure monitoring (EEG-EpiDigi) in a clinical setting. The system requirement analysis (SRA) focused on assessing user needs, gathering those requirements, analyzing them, and prioritizing their importance. While patient-centered care is a key focus of this system, the initial phase of the study emphasized collecting insights from health care professionals about system requirements. Future research will include patient perspectives and experiences, particularly regarding home monitoring systems, to ensure the software is user friendly. This study explicitly investigated health care professionals' opinions to identify the requirements for implementing data-driven medical software for EEG seizure monitoring within hospitals,

XSL•FO
RenderX

thereby assisting in their decision-making processes. The main research questions of this study were as follows:

- What are the user needs from EEG-EpiDigi in DCPE?
- What are the system requirements for developing and integrating the EEG-EpiDigi system in the current DCPE?
- What are the priorities of the EEG-EpiDigi system in the current DCPE?

The study aimed to determine the feasibility of integrating data-driven medical software in the DCPE. After addressing the research questions and assessing the proposed system requirements, a 4-round Delphi study using focus group discussions with health care professionals from Oulu University Hospital, including neurologists, digital health specialists, pediatric neurologists, experts in EEG signal processing, and clinical neurophysiologists, was conducted from May to November 2023. Semistructured interviews were conducted, and the data were analyzed qualitatively. The final round of the Delphi study directs the discussion to the system requirements confirmation as the first step of the new EEG-EpiDigi system development life cycle. The remainder of the paper is organized as follows: the details of the proposed methodology, such as study design, participants, interview guide, and data analysis, are discussed. Afterward, the results and analysis are added, which include the data exploration, study mind map, and the thematic analysis of the system requirements for EEG-EpiDigi. The paper is wrapped up with a Discussion section, including the futuristic architecture for EEG-EpiDigi and the proposed SRA-EpiDigi.



Methods

Overview

This study focused on expert opinions to determine the requirements of implementing and integrating data-driven medical software for EEG seizure monitoring in the current DCPE within hospitals and to assist health care professionals in decision-making. Although the proposed system emphasizes patient-centered solutions, the primary goal of this initial research was to collect only health care professionals' opinions on the system's needs. This study was done to implement the proposed system within the hospital only, whereas future research focuses more on home monitoring systems to take patient viewpoints into account.

A 4-round Delphi study, widely used in health care research to gather and refine expert opinions, was conducted using focus group discussions with health care professionals from May to December 2023. The aim was to identify the system requirements for integrating data-driven medical software for EEG seizure monitoring in DCPE. Several steps were taken while conducting the Delphi study to define the system requirements, leading us to form a process, as shown in Figure 1. The Delphi approach was selected for its ability to collect expert opinions and refine the system requirements iteratively and systematically. Each round had distinct objectives as follows:

Figure 1. The process of system requirement definitions for data-driven medical software for electroencephalography seizure monitoring in the digital care pathway for epilepsy.

XSL•FO
RenderX

Round 1 of the Delphi study was dedicated to identifying the current issues in the DCPE and user needs. The focus was on integrating data-driven medical software for EEG seizure monitoring, emphasizing the user-centric approach. This round was designed to ensure that the user needs were at the forefront of the study, making the audience feel that their needs were being prioritized.

Round 2 aimed at defining system requirements based on expert feedback from the first round.

Round 3 of the Delphi study was a pivotal stage where the system requirements were prioritized and refined through expert discussions. This thorough process was designed to ensure that the system aligned with clinical needs, instilling confidence in the audience about its alignment with their requirements.

Round 4 confirmed and validated the system requirements, incorporating final expert feedback for development.

The requirement analysis process began with the initial definition of system requirements, where user needs and pain points were assessed. On the basis of the domain understanding and comparison of the existing system, a guideline was prepared and presented to the health care professionals in the first round of the Delphi study. With their extensive experience and knowledge, these professionals were instrumental in starting the requirement elicitation. The idea of data-driven medical software for EEG seizure monitoring integration in DCPE was presented, and requirement brainstorming was started. The main point of this round of the Delphi, according to the health care professionals, was as follows:

> *The main issue is when the patients are alone during their seizure, or no one is around them to monitor their seizure. It would be nice if we can have the track of the seizures using EEG as well as the video and recording of the seizure to check the symptoms, the type of the seizure.* [Experts 1 and 2]

Therefore, the user pain point is the lack of monitoring and assistance for patients during their seizures, especially when no one is around them. The user needs a system that can track and record the patient's EEG and a video of the seizure to assess symptoms and seizure type and reduce the risk of any dangerous incident during the seizure. Currently, the hospital has video EEG recording systems in Finland that can track different types of seizures for several days up to 2 weeks. Monitoring and analyzing patients' historical seizure data can help predict and prevent future incidents. On the basis of reviewing existing systems and the first round of Delphi study discussions, the monitoring systems for epilepsy were classified into five main categories based on their aims: (1) self-management and medication adherence, (2) EEG-based systems for seizure detection, (3) cardiac-based systems, (4) non-EEG seizure detection systems using wearables, and (5) video-tracking systems. The system requirements were updated based on the study in the second category, EEG-based systems for seizure detection.

After updating the system requirement, the second round of the Delphi study was started with the aim of a requirement specification. Six health care professionals attended the session for 60 minutes. The main points of this session were as follows:

> *The type of sensors used for seizure remote monitoring are challenging. We can start with commercially available devices that have already been validated. The system can be specified for Continuous EEG monitoring at the ICU first. It would be nice to add more electrodes with additional channels into the current validated devices.* [Experts 1 and 2]

Subsequently, SRA and prioritization were initiated, and the third round of the Delphi study was conducted. Seven health care professionals, including an EEG signal processing specialist, worked closely with the industry to create EEG sensors. This session lasted 55 minutes. The experts discussed the preferences and system requirement prioritization in this session:

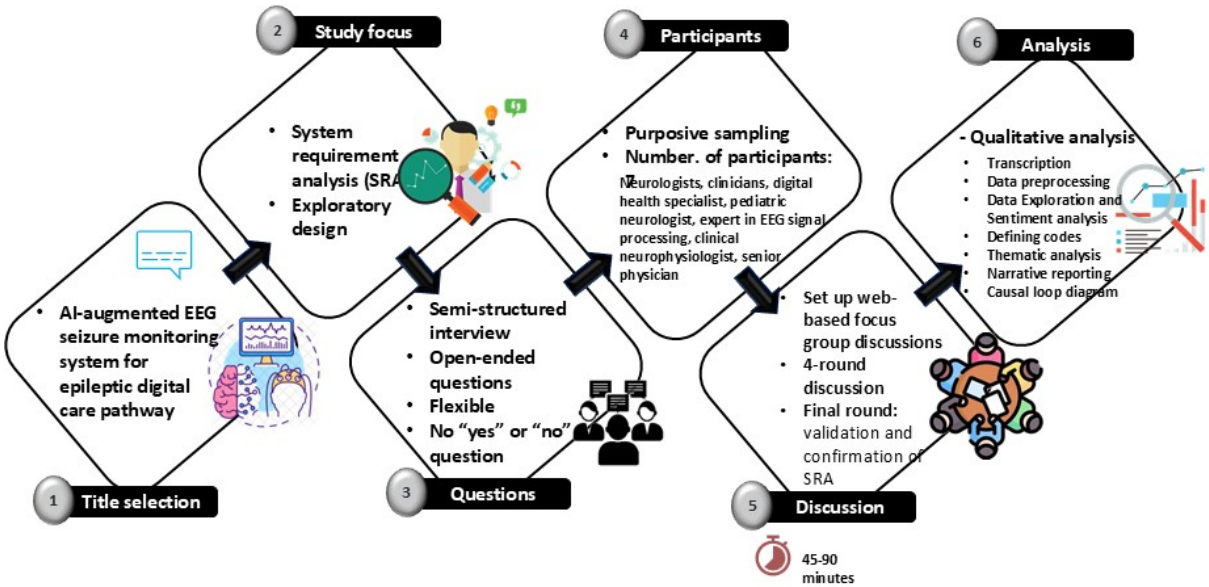
> *Probably, it is good to have some preferences considering how the proposed system fits our plans. For example, jumping right into the home remote monitoring and putting much effort into it might be not easy. Still, we can bind the project around developing the University Hospital care pathway for status epilepticus. EEG monitoring for the patients with status epilepticus or sudden unconsciousness due to unknown etiology at the emergency department, neurological department, or intensive care unit, could be the first target of the system, especially for the neurological department or intensive care unit.* [Expert 1]
>
> *The commercially available device at the current form requires a server that is installed inside the hospital network. But since we already have this kind of server in use in the intensive care unit.* [Expert 2]
>
> *It is better to start with the adults at the emergency and ICU department. After the system is validated, it can be specialized for patients of different age groups, preferably above 12 years old. The system can be used for patients with different ages and demographics.* [Experts 1, 2, and 3]

On the basis of the discussion, the development of data-driven medical software for EEG seizure monitoring needs to be started for the emergency department at the hospital targeting adult patients. If the system is adopted successfully, it can be extended to a home monitoring system, and a video recording system can be added as an additional feature. The home monitoring system is part of a plan that requires a requirements analysis study and co-design sessions with patients as the primary users of the system, along with other stakeholders.

Compatibility with existing hospital systems, such as electronic health records and EEG monitoring infrastructure, was a primary consideration. The EEG-EpiDigi system is designed to integrate with current systems without requiring extensive modifications. However, the hospital is preparing the new infrastructure to accommodate the modern version of EEG-EpiDigi.

XSL•FO
RenderX

The final interview round was done in December 2023 with 4 experts to summarize and confirm the system requirements and the discussion of the previous rounds. The interview lasted around 55 minutes.



Study Design

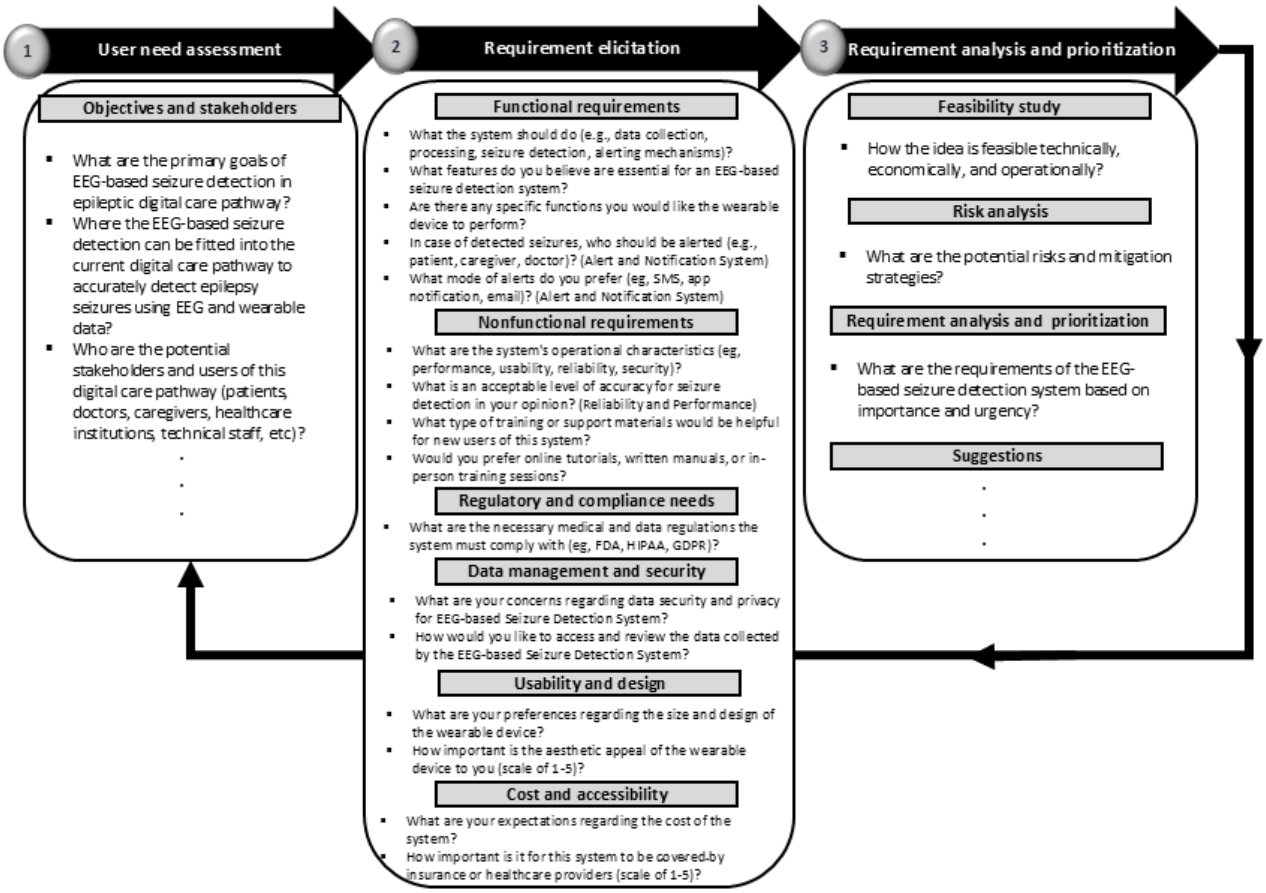
To address the research questions, a 4-round Delphi study using focus group discussions was chosen to systematically gather expert opinions and iteratively refine the system requirements for data-driven medical software designed for EEG seizure monitoring (EEG-EpiDigi) in the DCPE (Figure 2).

The first round concentrated on identifying current issues within the DCPE and understanding user needs, focusing on integrating data-driven medical software for EEG-based seizure monitoring. In the second round, we aimed to define the system requirements based on the feedback received from experts in the first round. The third round prioritized and refined these requirements through further expert discussions to ensure the system met clinical needs. Finally, the fourth round confirmed and validated the system requirements, incorporating additional expert feedback to guide development.

After reviewing the existing systems and assessing the user needs and the shortcomings of the current DCPE based on discussion with health care professionals, data-driven medical software for EEG seizure monitoring was proposed, and the initial requirements were defined. The qualitative Delphi study using a focus group was centered on SRA for the proposed EEG-EpiDigi using exploratory design. A semistructured interview was conducted using a flexible, open-ended questionnaire. Each round of the Delphi study used a focus group that lasted 45 to 90 minutes and included 3 to 7 participants. The initial round of the Delphi study was conducted face-to-face, while the subsequent 3 rounds took place on the web via Teams (Microsoft Corp). This mixed method approach allowed for greater flexibility in expert participation, although it had a minimal impact on data collection and analysis. Thematic consistency was maintained across both formats, and the online discussions generated richer data due to the ease of participation. The first round focused on identifying user needs and the current issues related to DCPE. In contrast, the second to fourth rounds concentrated on defining system requirements, prioritizing them, and confirming their validity. The system requirements process was guided by the latest advancements in the field [17-19] and industry standards, including IEC 62304 for medical device software [20,21] and ISO 14971 for risk management [22-24]. These standards ensured that our approach aligns with best practices in medical software development. We analyzed the collected data qualitatively, coding the results to extract and present themes narratively, followed by interpretation.

Figure 2. The study design for a 4-round Delphi study using focus group discussions. AI: artificial intelligence; EEG: electroencephalography; SRA: system requirement analysis.

Participants



Purposive sampling aligns the sample with the goals and objectives of the study, thereby enhancing its rigor and the reliability of the data and findings [25]. For this study, purposive sampling was chosen to ensure that the expert panel is representative and diverse concerning epilepsy care and EEG monitoring. A group of health care professionals from Oulu University Hospital were selected, including neurologists, digital health specialists, pediatric neurologists, experts in EEG signal processing from the University of Oulu and industry, clinical neurophysiologists, and senior physicians. This diverse composition allowed for a comprehensive coverage of clinical, technical, and research perspectives. According to Burch et al [26], focus group discussions can be conducted with 4 to 8 participants for a minimum of 45 minutes. In this study, each round of the Delphi study was designed to include 4 to 7 participants and lasted between 45 and 90 minutes.

XSL•FO
RenderX

Interview Guideline

The Delphi study used focus group discussion and aimed at SRA for data-driven medical software for EEG seizure monitoring in DCPE. It was conducted using a semistructured interview guideline, as shown in Figure 2. To provide proper orientation, the interviewer was partially engaged in the discussion management. According to the studies by Keikhosrokiani [17], Catanio [27], Keikhosrokiani [28], and Grady [29], the interview guideline followed an iterative process from user need assessment to requirement elicitation, analysis, and prioritization. The iterative process encompassed 10 main topics: objectives and stakeholders, functional requirements, nonfunctional requirements, regulatory and compliance needs, data management and security, usability and design, cost and accessibility, feasibility study, risk analysis, analysis, and prioritization. The iterative process started from the initial round of Delphi and was enhanced for the next rounds. The interview questions were carefully designed based on a thorough review of relevant literature and insights from an expert panel, ensuring they aligned with the research questions. A pilot study was conducted before the primary research to improve the validity and clarity of the questionnaire. Feedback from this pilot study was essential in refining the questions, ensuring they effectively addressed the research objectives while remaining clear and accessible to participants. This iterative process significantly enhanced the reliability and relevance of the data collected from the Delphi study. Figure 3 illustrates the final version of the interview guideline, which was used for the fourth round of Delphi study discussions for requirement confirmation, composed in the previous rounds.

Figure 3. The interview guideline for a semistructured Delphi study using focus groups for requirement confirmation. EEG: electroencephalography; FDA: Food and Drug Administration; GDPR: General Data Protection Regulation; HIPAA: Health Insurance Portability and Accountability Act.

Data Analysis

The data analysis steps for the focus group discussion are shown in the final step of Figure 1. The transcribed data were initially read before the data analysis process to ensure the data's general content and scope. The data analysis began with data preprocessing and data cleaning to remove unnecessary words, symbols, etc, and the data were organized based on the topics. Next, data exploration using visualizations and sentiment analysis was performed to overview the story of the data at a glance. Afterward, data coding was done using qualitative tools to examine patterns, keywords, and concepts throughout the text. The broader themes representing larger text sections were defined based on the initial codes. The themes were reviewed to ensure they were coherent, distinct, and effectively represented the dataset. After explaining each theme, articulating what each cover was and how they relate to the content was done. Finally, the results were reported narratively with interpretation and quotations. A causal loop diagram was created for further analysis and discussion to complement the results.

Ethical Considerations

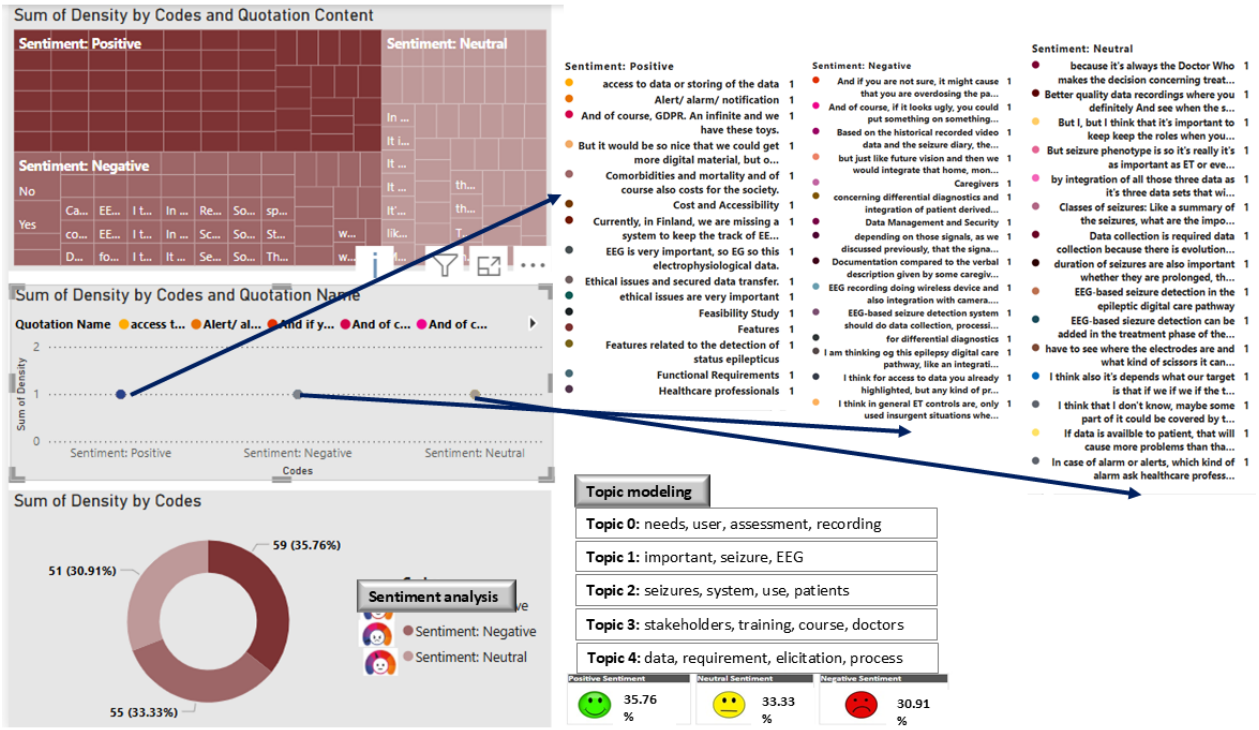
Ethical approval from the regional medical research ethics committee of the Wellbeing Services County of North

XSL•FO
RenderX

Ostrobothnia was granted for the EpiDigi project to involve human participants who are health care professionals and patients (approval number EETTMK: 59/2023). Verbal informed consent was taken from the participants. The names of the participants, products, and the company were anonymized. No compensation was provided to the participants.

Results

Data Exploration



Data were explored from the interview transcripts before the thematic analysis to understand the overall data. Word frequency analysis, topic modeling, and sentiment analysis were used for text exploration, as shown in Figure 4.

The most frequent words in the word cloud indicated that health care professionals preferred wearable video EEG seizure detection systems at the hospital to provide accurate and timely data on seizure types for epilepsy classification and treatment decision-making. They requested courses to train them in using the proposed system and were interested in expanding the system for home monitoring using wearable devices.

On the basis of the topic modeling results, 5 main topics were highlighted from the data. Topic 0 focused on user needs and assessment, whereas topic 1 centered around data, seizures, EEG, and related concepts. Topic 2 discussed seizures, systems, use, and patients, while topic 3 concerned stakeholders, their views, and course of action. Finally, topic 4 was related to data requirements and elicitation processes.

Sentiment analysis was also performed on the data collected from the interviews. As shown in Figure 4, most sentiments toward the data-driven medical software for EEG seizure monitoring were positive, followed by neutral, and negative, respectively.

Figure 4. Data exploration for the interview using word frequency, topic modeling, and sentiment analysis. EEG: electroencephalography.

Study Mind Map for the Qualitative Data Analysis

The study mind map was prepared based on transcribed data to be used as a guide for SRA. As shown in Figure 5, SRA consists of 3 steps: user needs assessment, requirements elicitation, and requirements analysis and prioritization. The needs assessment evaluated the system's aims, objectives, and stakeholders. In contrast, functional requirements, nonfunctional requirements, regulatory and compliance needs, usability design, data management, and security were reviewed in the requirements elicitation and feasibility study, and risk analysis and requirement prioritization were considered in the requirements analysis and prioritization step. The main keywords for each subevaluation are addressed in Figure 5.

As outlined in Table 1, SRA consisted of 3 steps: user needs assessment, requirements elicitation, and requirements analysis and prioritization. The needs assessment step evaluated the system's aims, objectives, and stakeholders. In contrast, functional requirements, nonfunctional requirements, regulatory and compliance needs, usability design, data management, and security were reviewed in the requirements elicitation and feasibility study, and risk analysis and requirement prioritization were considered in the requirements analysis and prioritization step. The main keywords for each subevaluation are addressed in Table 1.

Users Need Assessment

Primary Goals

After data were transcribed, coding was done to assist us in the thematic analysis. A coding network was generated for each part of the mind map, as shown in Figure 5. A sample of a network of coding for the primary goal of data-driven medical software for EEG seizure monitoring is illustrated in Figure 6.

The focus group discussion on user need assessment led us to some themes and subthemes, as summarized in Table 2. For instance, the experts mentioned the following:

> *EEG-based seizure detection is especially required in the emergency department for the status epilepticus phase. It is also helpful because we cannot get the 24/7 EEG recording from all those patients...*
>
> *[W]e need continuous electrocardiogram (ECG) monitoring all the time in the ICU. We can proceed with adult patients first, then use it for children...*

Thus, the primary goal was to implement EEG-based seizure detection specifically for emergencies, such as prolonged seizures or status epilepticus, starting from the emergency room to intensive care units (ICUs). A critical theme is the need to minimize *diagnosis time* during severe epileptic events, emphasizing rapid detection and treatment initiation. This discussion led us to the subtheme *enhancing emergency seizure management.*

Furthermore, the discussion emphasizes leveraging *remote detection technology to identify seizures*, potentially integrating AI-based analytics to enhance time and cost-efficiency. In addition, the discussion that "EEG-based wearable seizure detection system should be available and provided for doctors for differential diagnostics and treatment decision-making, especially if the seizure is prolonged..." and "Currently, we would need a recording, especially in the in the emergency in the status epilepticus phase" suggests the need for long-duration EEG recording, especially for status epilepticus.

Health care professionals continued the discussion by stating the following:

> *This wearable EEG-based seizure detection could help health care professionals in decision-making...thus, in this pilot process, we are focusing on emergency where you have a prolonged seizure, especially status epilepticus as a neurological emergency...We could start from the emergency room to the ICU intensive care unit.*

EEG-based seizure detection is mentioned as a tool to aid health care professionals in deciding whether to admit patients to *intensive care*, especially in nonconvulsive status epilepticus or nonepileptic seizures. EEG-based seizure detection in the DCPE treatment is proposed to improve patient management.

Moreover, the experts highlighted that "there is a need for EEG analytical models to assist the neurologists in differential diagnostics, especially in the evenings and weekends..." It was argued that there is a need for the most suitable type of wireless devices and wearables for seizure recording and video systems to detect seizures, highlighting the importance of technology in monitoring and data storage. Predictive analytics based on historical recorded video data and seizure diaries can be used to predict future seizures and their types, indicating a need for advanced analytic tools in health care.

The experts further mentioned, "Since the EEG analysis is time-consuming, if we could utilize AI-based preliminary analytics before the decision-making of health care professionals, it would be very efficient and cost-effective." This kind of solutions emphasizes the need for cost-effective solutions, suggesting that wireless EEG devices could aid in differential diagnostics and reduce the burden on clinical neurophysiologists. Furthermore, they emphasized the importance of integrating patient-derived data, device data, and electronic medical records for decision-making.

Future integration of home monitoring as part of the DCPE is touched upon as an extension of current hospital-based approaches.

Phases of DCPE

As highlighted in the primary goals mentioned subsequently, the primary aim is to implement the proposed system for hospital environments first, specifically for the *treatment phase* on the current DCPE:

> *Developing a system for hospital environments and then proceeding with remote monitoring systems from home...differentiating between epileptic and non-epileptic seizures...plans to incorporate EEG recordings into the DCPE, focusing on emergency and treatment phases for patients, especially for those with drug-resistant epilepsy, can assist health care professionals...*

If the patients successfully adopt the system, expanding it to the home remote monitoring system using suitably validated wearables is recommended.

The system's initial development within a hospital environment would be feasible, emphasizing hospitals' foundational role in the care pathway system. It mentions the subsequent *plan* to proceed with a remote monitoring system from the home, indicating a phased approach to implementation and an expansion of care beyond the hospital setting.

The importance of *epileptic versus nonepileptic seizures* was stated in the discussion to point out the need to separate seizures into epileptic and nonepileptic categories, suggesting a focus on specificity in diagnosis and treatment within the DCPE.

Plans to incorporate *EEG-based detection* into the DCPE were discussed, indicating a direction toward more advanced, technology-integrated solutions for monitoring and diagnosis. It was added that EEG-based detection is primarily used in emergencies and for follow-up treatment effects, but it is specifically aimed at health care professionals rather than patients. This highlights a focus on enhancing professional decision-making.

The pathway discusses a phased approach, starting with hospital-based systems and expanding to home monitoring. This indicates a comprehensive care strategy that extends beyond immediate hospital care.

Stakeholders

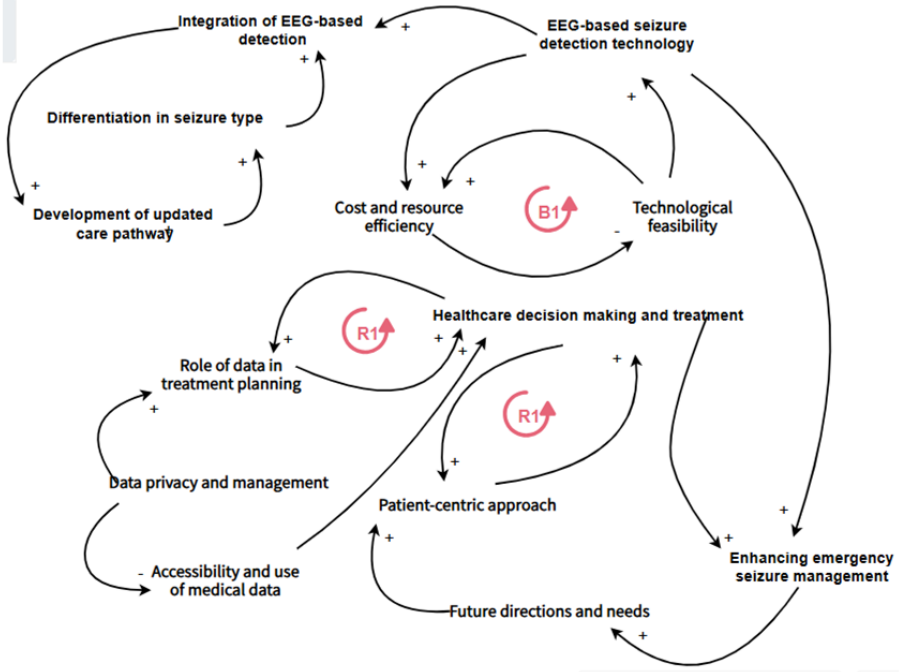
This section presents the user needs assessment focusing on various stakeholders, particularly relating to epilepsy management and the *use of data* in DCPE. The stakeholders identified include patients, caregivers, technical staff, institutions, and health care professionals. The document discusses the use of EEG recording data, seizure recordings, and other types of medical data.

The discussion suggests that the analysis of EEG recording should not be shown to patients or informal caregivers because it might not be beneficial and could lead to more problems than benefits. The assertion is that patients are generally not involved in decision-making related to diagnostics and thus might not need direct access to these data. In contrast, health care professionals are seen as requiring access to these data to make informed decisions about diagnosis, treatment, and care. The data can be transported or analyzed by another physician from a different hospital, indicating a need for data sharing and interoperability among health care institutions.

The discussion emphasizes the health care providers' role in making treatment decisions, often during inpatient consultations. It highlights the importance of keeping roles defined, with the physicians and patients or caregivers working together based on the information provided by the health care providers. While not explicitly mentioned, the concern over patient *access to data* and the need for health care professionals to share and analyze data suggest underlying themes *of data privacy, security, and effective data management* in health care. The discussion iterates that health care providers use data to inform treatment options and discuss these with patients and caregivers, depending on the situation. Data are central to *treatment planning* and the patient–care provider relationship. Furthermore, the following implications for each stakeholder were highlighted:

- For patients, improved understanding and communication about why specific data are not shared with them might be necessary.
- For health care providers, there is a need for practical tools and systems to manage, share, and analyze patient data securely and efficiently.
- For technical staff and institutions, ensuring technological solutions' reliability, usability, and security for data recording and predictive analysis is crucial.

Themes Relationships



A causal relationship was created between the extracted themes, as shown in Figure 7, that shows the enhancement of emergency seizure management is significantly affected by the quality and accuracy of the EEG-based seizure detection technology. Furthermore, its improvement leads to more refined future directions and user needs, reflected in better patient-centric approaches. EEG-based seizure detection technology reduces the time and resources required for the system while improving cost and resource efficiency. Technological feasibility is the primary influence on the quality of EEG-based seizure detection technology. Better decision-making leads to improved patient outcomes, enhancing overall emergency seizure management. Improving cost-efficiency and resource efficiency enables further investment and improvement in the health care system. Balancing feedback might occur if costs reduce the ability to invest in newer technologies. Focusing on individual patient needs and outcomes (patient-centric approach) ensures the quality of emergency seizure management, and it is influenced by health care decision-making and treatment as better strategies and future technologies are developed.

As DCPE are updated and improved, there is a natural progression toward refining the understanding and categorization of conditions treated within those pathways, such as epilepsies. Once there is an established need or desire to differentiate seizure types more effectively, integrating more precise diagnostic tools such as EEG becomes a priority. With the integration of innovative technologies and diagnostic methods, the care pathway itself may be updated to incorporate these advancements, completing the loop and potentially starting a new cycle of updates and improvements.

XSL•FO
RenderX

A positive link between accessibility and the use of medical data and health care decision-making indicates that better accessibility improves decision-making capabilities. Moreover, informed decision-making positively influences how data are used in planning treatment. There is a negative link between data privacy and management and accessibility and the use of medical data, suggesting that inflexible data privacy policies might limit the accessibility of medical data. In contrast, adequate data privacy and management practices enhance the role of data in treatment planning. Finally, a positive feedback link between the role of data in treatment planning and health care decision-making illustrates that the effective use of data in treatment planning feeds back into improving decision-making in health care.

Figure 7. A causal loop diagram for the main objective. EEG: electroencephalography.

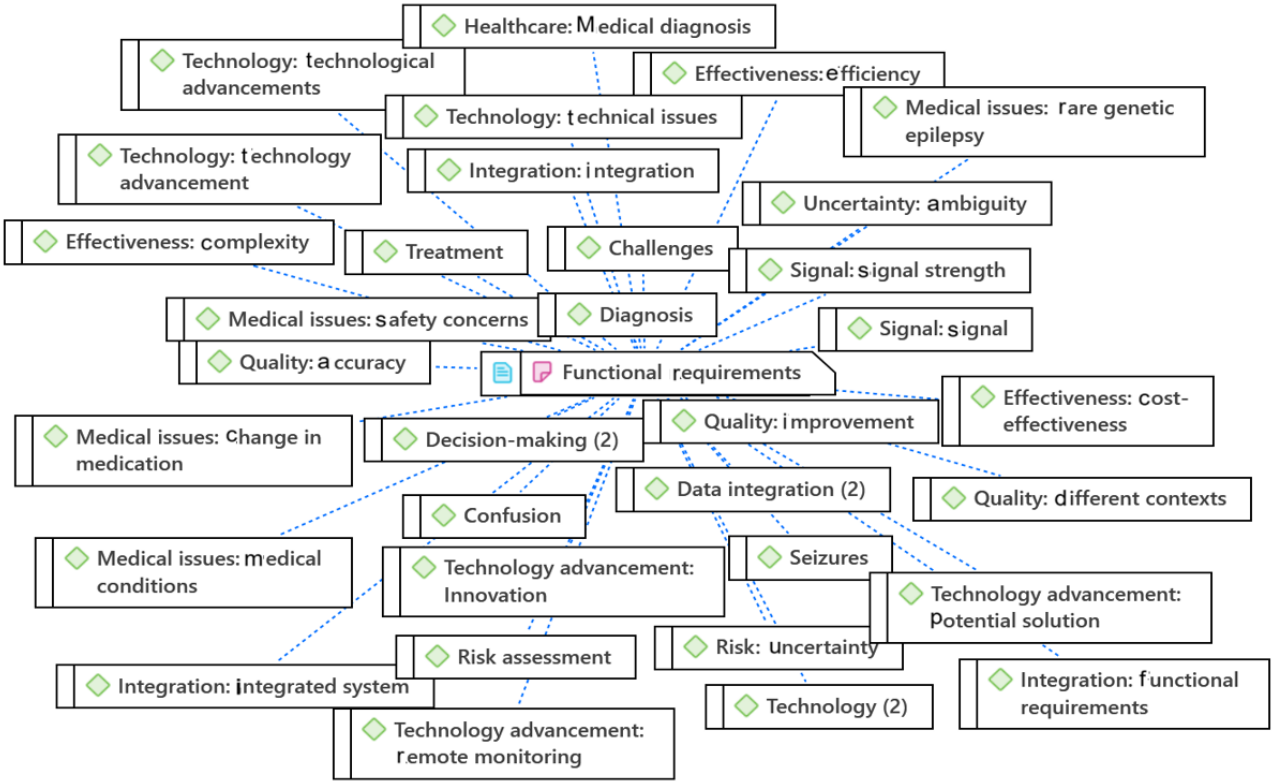
Requirement Elicitation

Functional Requirements

On the basis of the focus group discussion with health care professionals, the coding network is shown in Figure 8, and the themes and subthemes are listed in Table 3—functional requirements emphasize the functions of the systems, features, wearables, and alert systems.

The conversation "the functional requirements are probably very different for home monitoring and hospital use..." notes the variation in functional requirements between home monitoring and hospital use, emphasizing the need for *contextual adaptable* solutions tailored to different settings. According to the discussion, "It would be good to integrate all types of data concerning the seizures in the system, such as motions, movement, sleep, video," the system should *integrate various data types* (eg, motions, movements, sleep, and video) along with the number of seizures and device data to comprehensively understand the patient's condition.

Efficiency in seizure detection, data processing, and *alerting* mechanisms was mentioned as a vital component. Furthermore, the challenge of differentiating between epileptic seizures and nonepileptic events was highlighted. The requirement emphasized the need for accurate diagnosis to prevent overtreatment and adverse events.



The evaluation of remote monitoring systems is closely linked to privacy and security risk concerns. Furthermore, real-time monitoring and the quality of service continue to pose challenges for remote monitoring services. Health care professionals identified several key issues with these systems, particularly concerning the types of wearable devices used for seizure detection, the accuracy of algorithms that classify seizures, and the overall trustworthiness of the system from the patient's perspective.

One major challenge highlighted by health care professionals was the need for real-time access to patients' seizure activity. Interviews conducted emphasized the evolving nature of epilepsy and stress the importance of continuous data collection and seizure phenotyping to adjust treatments and improve diagnostic accuracy. High-quality data recordings are crucial, especially for accurately capturing the onset of symptoms.

Integrating various data types, including video recordings, is essential for effective remote monitoring. The discussion also explored the potential of home remote monitoring systems that combine cameras, wireless EEG recording, and other technologies, envisioning a future where continuous and comprehensive monitoring is achievable. Wearable devices, which have already been tested, can be further refined for these remote monitoring systems.

XSL•FO
RenderX

Figure 8. A sample network of codes for functional requirements.

The need for *user compliance*, especially in scenarios such as detecting prolonged seizures at night, was mentioned. The system should *effectively* alarm caregivers and integrate smoothly with hospital protocols. Furthermore, the discussion outlined various *features* or requirements for a system, possibly related to health care or patient monitoring, given the references to EEG, electrocardiogram, and ICU monitoring.

The discussion about *quality and usability concerns* started by highlighting the need for quality and ease of use in devices, particularly those related to brain monitoring (eg, EEG systems). This suggests a priority on user-friendly and high-quality *wearable devices* for monitoring purposes. There was a specific mention of using "good quality wearables and devices for monitoring." This might refer to the need for reliable and accurate devices in a clinical setting, particularly for *continuous monitoring*.

The interview mentioned the need for continuous EEG monitoring in the ICU, indicating an emphasis on uninterrupted patient monitoring. This requirement is critical, starting with adult patients and extending to children. Moreover, the health care professionals discussed using *alarms* to detect nonconvulsive seizures. Emphasis on the placement of electrodes around the head and the reference to seizures spreading to the hemispheres suggested a focus on detailed and responsive monitoring systems that could detect and alarm medical staff about patient conditions. *Age-specific considerations were one of the critical points of discussion for the new system.*

The highlight of starting with adults and then extending monitoring capabilities to children indicates a phased, careful approach to implementing these technologies, likely due to the different physiological and anatomical considerations between adults and children. Prioritizing the features based on the *target demographics*, such as age group, and understanding which features are essential and desirable, requires stakeholder consultation.

For each requirement, technical feasibility and potential impact on patient care and health care workflow must be assessed [30]. Given the technical and clinical nature of the requirements, consulting with health care professionals and technology experts would be crucial in further refining and validating these needs. Additional steps would involve deeper stakeholder engagement, technical assessment of the proposed features, and a structured approach to integrating these requirements into a cohesive system design.

A health care professional stated the following:

> *We start with adults first, then we could implement a research project focusing on children...If we choose a device, it should be suitable for home use, minimize artifacts, and be user-friendly for patients or parents. It should be sensitive and specific...The device should inform users about seizures and be capable of detecting different kinds of seizures...We need to consider electrode placement and the types of seizures it can detect, focusing on devices that capture generalized seizures, particularly tonic-clonic seizures, while minimizing false alarms...Look into developing methods for ICU use, leveraging artificial intelligence...Determine the device's suitability for children of certain ages.*

Table 3. A summary of themes, subthemes, and codes for requirement elicitation.

Themes and subthemes	Codes extracted from quotations
Functional requirements	
Contextual adaptability	Adaptable solution tailored to different settings
Comprehensive data integration	Data type (eg, EEG[a], motions, movements, sleep, and video)
Alerting and detection efficiency	Alarm, alerting mechanism, and seizure detection
Differential diagnostics	Differential diagnosis, epileptic seizures, and nonepileptic events
Evolutionary data collection	Seizure phenotyping, treatment, diagnosis, and diagnostic precision
Quality of data recording	Quality, data recording, capturing, and video recording
Remote monitoring and technological integration	Home monitoring, remote monitoring, and wearables
User compliance and system effectiveness	Prolonged seizures, night, alarm, and caregivers
Quality and usability concerns	Ease of use, wearable device, user friendly, brain monitoring, and high-quality
Use of wearables and devices	Good quality, wearable device, clinical setting, and continuous monitoring
Continuous monitoring	Continuous EEG monitoring, uninterrupted patient monitoring, adult, and children
Alarm for seizure detection	Health care professionals, alarms, responsive monitoring systems, and nonconvulsive seizures
Age-specific considerations	Adults, children, age group, and features
Target demographic	Differing physiological and developmental needs, adults, children, specific age, and design
Usability and user friendly	Noninvasive, easy to use, user friendly, home care routines, simplicity, and intuitive design
Technical specifications	Sensitivity, specificity, customization, and tonic-clonic seizures
Information delivery	Inform, seizures, and communication
Innovation and development	Innovative, artificial intelligence, and predictive analytics
Nonfunctional requirements	
Types of seizures	Duration, nonepileptic, epileptic, nonconvulsive seizures, and tonic-clonic seizures
EEG importance	EEG, vital, and seizure
Seizure phenotypes	Types, variety, seizure, symptom, and abnormal
Duration of seizures	Duration and seizure
Materials and contents for training and support	Training, educational materials, on the web, in person, documentation, and digital content
Regulatory and compliance needs and data management and security	
Access and storing of data	Complexity, sensitivity, handling patient data, storing, and access
GDPR[b] compliance	GDPR, regulations, and storage
Ethical issues	Ethical considerations and authorized personnel
Standardization and legal issues	Lack of standardization and regulatory frameworks
Case study—Nelli system	Nelli system, developed by Tampere University and Tampere University Hospital
Usability and design	
Size and aesthetic considerations for patient devices	Device size, patient movement, younger patients, customizable elements, colorful caps, children, less intimidating, user friendly, and hiding
Designing for demographics and user-centered design in medical devices	Children, tailored design, personalized medical devices, patient's age, user-centered design, and physical psychological needs
Cost and accessibility	
Cost of implementation by hospital	Accessibility, affordable services, and brand-new hospital
Cost of services by insurance	Insurance and services
All public and private hospitals	Public and private

XSL•FO
RenderX

Themes and subthemes	Codes extracted from quotations
Rural areas	Remote and rural areas

[a]EEG: electroencephalography.

[b]GDPR: General Data Protection Regulation.

On the basis of the aforementioned discussion, the themes related to wearables were extracted. The device was initially targeted at adults and then adapted for children. This indicates a phased approach, likely due to differing physiological and developmental needs. *Age specificity* is another crucial factor when selecting a device. The device's suitability for children of certain ages is to be determined, indicating the need for customization or scalability in design. It was further discussed that the device should be *suitable for home use*, implying it needs to be noninvasive, *easy to use*, and potentially integrated with home care routines. It should be easy for the patients and parents to use, emphasizing simplicity and intuitive and *user-friendly* design. Regarding the *technical specifications*, the device must accurately detect seizures (high sensitivity) and not overreport nonseizure events (high specificity). It should minimize the recording of artifacts, which are irrelevant signals that could obscure seizure detection. Considering electrode placement and seizure types, it should be able to detect seizures, focusing on generalized and tonic-clonic seizures, and be amenable to customization or adaptable to various seizure types.

The *device should effectively inform users about seizures for information delivery*, indicating a need for clear alerts or communication mechanisms. The discussion about using current commercially available devices suggests leveraging existing innovative technology platforms as a starting point or benchmark. Considering the development of ICU use and leveraging AI, ambitions for advanced monitoring capabilities and predictive analytics are suggested.

Nonfunctional Requirements

The nonfunctional requirements were mainly emphasized in terms of seizure phenotypes, the importance of EEG, the duration of seizures, and training and support. While discussing the variety and importance of understanding different seizures, it was pointed out that although a seizure might be broadly categorized, the specific type and duration were critical. In addition, it emphasized the role of EEG in seizure detection and analysis, acknowledging its limitations since not all seizure types exhibited noticeable changes in EEG patterns depending on electrode placement. The significance of observable characteristics of seizures, such as facial expressions, eye movements, and other physical symptoms that are crucial for proper identification and need to be correlated with EEG data were highlighted. The importance of seizure duration, particularly in terms of the potential risks associated with prolonged episodes, such as status epilepticus was noted.

Regarding the types of seizures, the interview suggested a nuanced view of seizures, urging the need to understand different types and durations. For nonfunctional requirements, this theme emphasized the need for systems to accommodate a variety of seizure presentations and durations. EEG is recognized as a vital tool in seizure detection but is also noted for its limitations. Thus, there is a need for systems incorporating EEG data, but it is also possible to suggest integrating additional data sources and testing awareness. Moreover, the discussion described phenotypes as critical in seizure analysis, perhaps even more than EEG in some cases. This emphasizes the importance of comprehensive observational data in seizure monitoring software, possibly advocating for multimodal approaches. Duration of seizure was highlighted as a significant factor, especially concerning the risks associated with prolonged seizures. Systems must be sensitive to the duration of seizures, possibly incorporating alerts or interventions for protracted episodes.

The interview listed educational materials, including documentation, web-based tutorials, user manuals, in-person training sessions, and digital health parts. This theme explored the diversity and scope of materials available for epilepsy education and awareness. The materials were designed for different audiences, such as teenagers, caregivers, and patients.

A real-world application of EEG monitoring in a pediatric setting where a wearable device is used for seizure detection and continuous monitoring can be considered a practical example of this application. Incorporating case studies, such as a child with epilepsy who uses a wearable device that tracks seizures and alerts caregivers, could illustrate current technologies' effectiveness and limitations. This example can clarify how the device recognizes seizure patterns and integrates with mobile apps for parents and health care providers.

However, some challenges remain unresolved in integrating data-driven software into the DCPE, such as data privacy and technical integration. Data privacy remains a critical issue in health care technology. A practical challenge is how an EEG device processes patient data while ensuring compliance with General Data Protection Regulation (GDPR). There is a potential risk of unauthorized access if role-based access is not strictly enforced, and the design must include secure data transmission methods, such as encrypted channels. For technical integration, exploring how the EEG device communicates with other medical systems could highlight potential barriers, such as interoperability issues, where devices from different manufacturers need help to share data effectively. Incorporating perspectives from various stakeholders, including health care professionals, patients, and regulatory bodies, can provide a more comprehensive view. For example, engaging physicians in discussions about the importance of EEG data alongside observable seizure characteristics can help identify what features are essential for them. Gathering feedback from patients and caregivers about their experiences with existing devices can emphasize the user-centered design approach. Moreover, including insights from regulatory bodies can shed light on the compliance challenges they face, addressing gaps in current frameworks for epilepsy monitoring technology. By integrating these elements, we can create a more robust discussion that

XSL•FO
RenderX

addresses nonfunctional requirements and acknowledges the complexities of implementing health care technologies in a practical and user-friendly manner.

Regulatory and Compliance Needs and Data Management and Security

On the basis of the interview discussion, the SRA revealed several key themes surrounding regulatory and compliance needs in health care, particularly regarding data management, GDPR compliance, ethical considerations, and specific case studies or systems.

The critical nature of where and how data are accessed and stored was mentioned in the discussion, especially in hospital systems and for research purposes, highlighting the complexity and sensitivity of handling patient data. In addition, GDPR is mentioned as an overarching and strict regulation affecting the storage and handling of data. The health care professionals suggested that GDPR compliance is a significant challenge that requires continuous discussion and resolution at the ministry level. Ethical considerations in accessing patient data were highlighted, emphasizing that only authorized personnel (eg, physicians and nurses involved in patient care) should access patient data. The importance of role-based access and strict data access logging to maintain privacy and accountability was underlined. The discussion further suggested a lack of standardization, particularly for patients with epilepsy, indicating a need for consistent legal and regulatory frameworks across different diagnostic groups. Finally, a specific system called the Nelli system at Tampere University was described [31]. It details a program for handling patient data, including AI scanning, anonymous analysis, and specialized handling by trained nurses or technicians. The system appears to be a part of a digital health care initiative, possibly relating to epilepsy treatment, as it includes familiarity with EEG techniques.

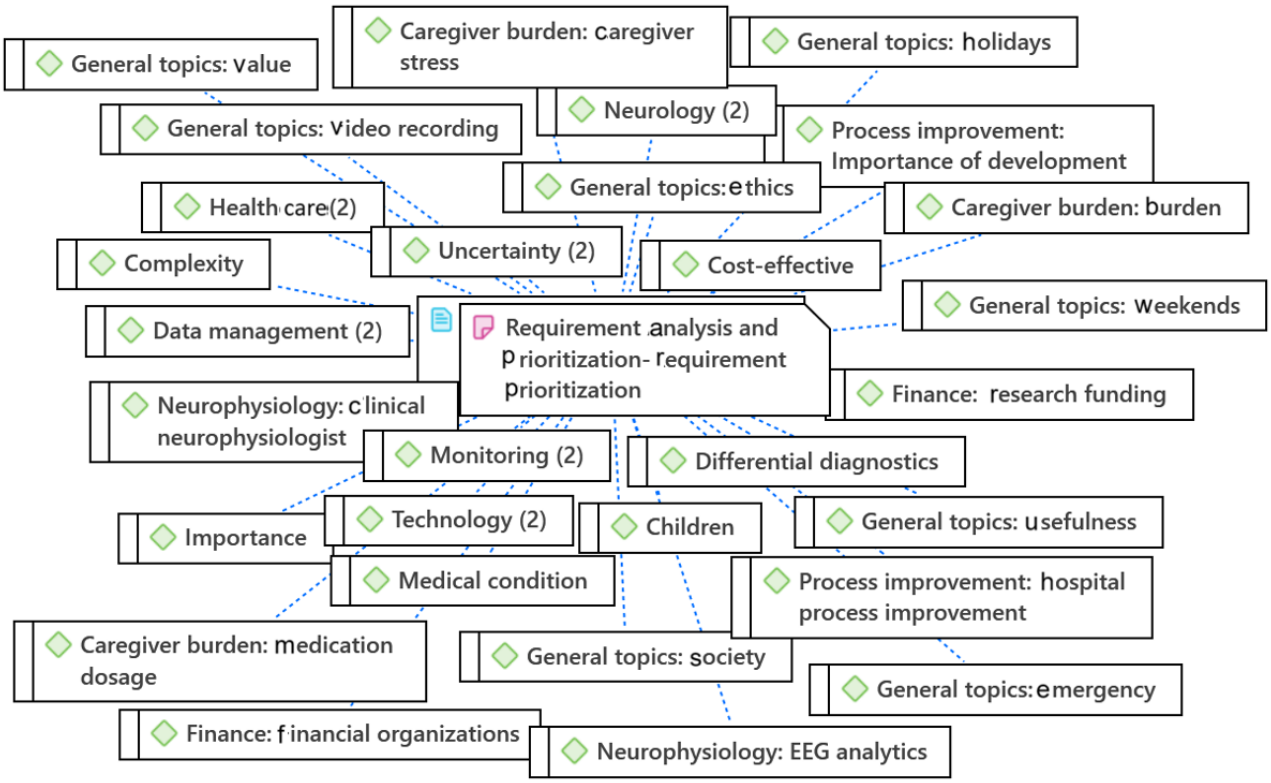
Usability and Design

The "usability and design" discussion discusses the importance of size and aesthetics in medical devices, particularly those used by patients for home care or remote care in hospitals. On the basis of the extracted theme of *size and aesthetic considerations for patient devices, it was highlighted that* devices should be functional and stable without restricting patient movement, especially for younger patients. The devices should not cause discomfort or pain to the patient. Aesthetics can be improved by adding customizable elements such as colorful caps, particularly to appeal to children. The idea is to make the device less intimidating and more user friendly, hiding its medical nature.

> *To focus on designing for demographics and user-centered design in medical devices, making the devices less intimidating and more appealing to children implies a tailored design approach where the patient's age and preferences are considered. This suggests a move toward more personalized medical devices catering to specific demographics. The emphasis on comfort, lack of restriction in movement, and aesthetic appeal point to a user-centered design approach. It reflects an understanding that medical devices should be designed to meet the end user's physical and psychological needs beyond mere functionality. Human-centered design will be beneficial in the design of medical devices by reducing resources in software-related processes. It provides interactive and user-friendly solutions by focusing on user needs and requirements. User-centered design must involve software design, testing, and development phases* [32]

The discussion on size, aesthetics, and the balance between functionality and comfort in medical devices reflected broader themes in the medical device industry. These include the importance of user-centered design, the need for personalization in medical equipment, and the recognition that the success of a medical device is not solely dependent on its functional effectiveness, but also on its usability and acceptance by patients. Moreover, the health care providers mentioned the necessity of balancing technical requirements with human factors, advocating for designs that consider the patient's physical comfort, psychological well-being, and overall acceptance of the medical device.

Cost and Accessibility



Regarding the cost and accessibility of the proposed system, the interviewees mentioned that "maybe some part of the cost of the services provided by the new system can be covered by the patient or their insurance systems, but the costs should not be like prohibiting the use of the system...however, the hospitals can bear the cost of developing and implementing the system...the system needs to be accessible to all public and private hospitals...also in the rural areas..." Moreover, they mentioned, "The system would be essential and cost-effective for the whole society, and we cannot estimate the value at the individual level." They concluded the interview by highlighting "Comorbidities and mortality and, of course, also costs for the society."

Requirement Analysis and Prioritization

As discussed in the interview, some priorities were set for developing the EEG-EpiDigi. For instance, the system will be implemented in the hospital environment with a target on the emergency unit and ICU. The system will be used for adults first and expanded for other age groups. If the system is adopted successfully, remote home monitoring will be added as an extra module. The relevant themes were extracted based on the network of codes for requirement prioritization illustrated in Figure 9. The list of themes, subthemes, and codes extracted from the quotations for SRA and prioritization are shown in Table 3.

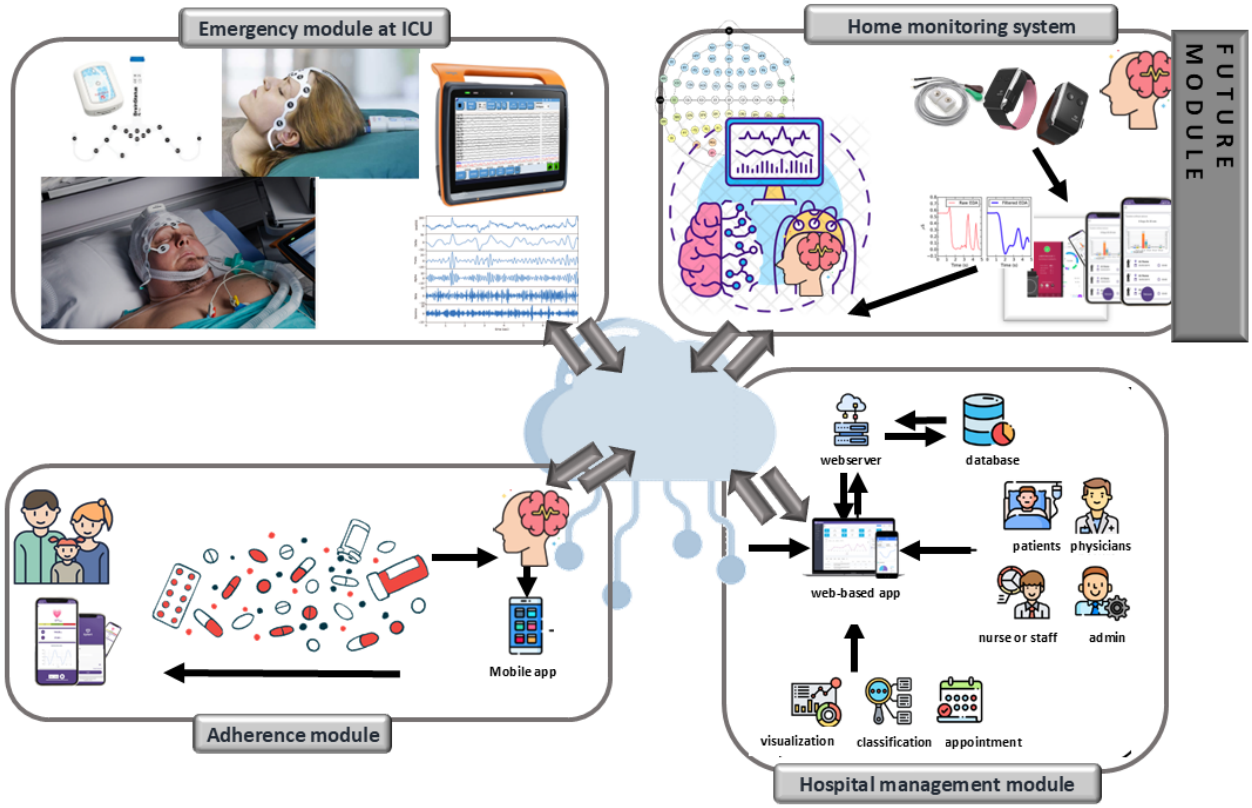
XSL•FO
RenderX

Figure 9. An example network of codes for prioritizing requirements. EEG: electroencephalography.

Feasibility Study

In the focus group discussion, the health care professionals emphasized, "It would be more feasible to start from the hospital monitoring system and then expand it to a home remote monitoring system in the future." Therefore, the following options must be considered to assess the feasibility of integrating data-driven medical software for EEG seizure monitoring into the DCPE. On the basis of the themes and subthemes outlined in Table 3, the *demand for hospital or home remote monitoring systems* needs to be carefully evaluated. This demand was assessed through expert feedback, focusing on current clinical needs and future potential for home monitoring systems. The idea of a home monitoring system is the next step after implementing it in the hospital. Therefore, data collection for requirement analysis and co-design sessions with patients will be performed after successfully implementing the proposed system in the ICU. The experts prioritized hospital-based monitoring (ICU and emergency departments) before expanding to home-based systems. Evaluation criteria included feasibility, scalability, and clinical relevance. Furthermore, *technological resources need to be carefully planned.* Before starting the project, the technology and infrastructure available for monitoring systems must be examined. In addition, the impact of monitoring systems on patient care and *health outcomes* needs to be determined. The financial implications of implementing and maintaining monitoring systems must be estimated. The feasibility of EEG-EpiDigi is high for hospital-based use, particularly in ICU settings. However, challenges include data privacy, integration with existing hospital infrastructure, and ensuring AI interpretability for clinical decision-making. Further research is required to address these challenges, especially for home-based monitoring.

The feasibility of the EEG-EpiDigi system, designed for managing epilepsy through digital tools, hinges on several critical factors outlined in Textbox 1, including technological integration, user acceptance, regulatory compliance, and data management.



Based on the study's results and assessing the feasibility, developing and integrating a system capable of monitoring EEG recording is required and feasible in DCPE (Figure 10).

XSL•FO
RenderX

Textbox 1. Key factors influencing the feasibility of the electroencephalography (EEG)-EpiDigi system.

1. Technological integration: the successful implementation of EEG-EpiDigi will require seamless communication between EEG devices and other medical systems. Challenges include interoperability issues, where devices from different manufacturers need help to share data effectively. Ensuring that machine learning algorithms can accurately analyze the data from diverse sources is also vital. Creating standardized protocols and frameworks that enable this integration would be necessary while preserving data integrity.
2. User acceptance: engaging users, including patients, caregivers, and health care professionals, is crucial for the system's success. The system must be designed with a user-centered approach, addressing the needs and preferences of different demographics. For instance, if the design does not consider the comfort and aesthetics of devices used by children or young adults, it may face resistance from these groups. Continuous feedback loops should be established to refine user experiences based on real-world inputs.
3. Regulatory compliance: navigating the complexities of regulations such as General Data Protection Regulation (GDPR) is a significant challenge. The system must ensure that all patient data are stored, accessed, and transmitted promptly. This includes implementing strict role-based access controls and maintaining comprehensive data access records. Moreover, as regulations evolve, the system may need to adapt to new compliance requirements, which could entail ongoing updates and modifications.
4. Data management and security: the EEG-EpiDigi system would need robust mechanisms for data management to handle sensitive patient information. Security features such as encrypted data transmission and secure storage are paramount to mitigate the risks of unauthorized access. In addition, ensuring the ethical use of data, including informed consent from patients, is necessary to build trust and acceptance among users.
5. Continuous monitoring and adaptation: the nature of machine learning systems requires ongoing training and validation of algorithms to ensure their effectiveness over time. This includes continuously updating the system based on new research findings and user feedback. The challenge lies in establishing systems for routine monitoring that can keep pace with the rapid advancements in AI and epilepsy research.
6. Stakeholder collaboration: collaboration across various stakeholders, including health care professionals, patients, and regulatory bodies, will be essential to address the multifaceted challenges of the EEG-EpiDigi system. Building a platform for dialogue can help ensure that the system meets clinical needs while adhering to compliance and ethical standards. In summary, while the EEG-EpiDigi system has the potential to revolutionize epilepsy management through enhanced data integration and user engagement, careful consideration of technological, regulatory, and user-centered challenges is necessary for successful practical applications. Engaging diverse stakeholders and implementing robust data management practices will be crucial for navigating these challenges and maximizing the system's potential benefits.

Figure 10. The proposed system architecture for EEG-EpiDigi in the digital care pathway for epilepsy. ICU: intensive care unit.

Risk Analysis

The risk analysis of the proposed system in DCPE depends on the treatment effectiveness, health care system coverage, diagnostic tools, and resources of health care professionals. This involves understanding treatment, management, and factors impacting their efficacy. *The health care system coverage* theme suggested what aspects of treatment or diagnosis are covered by health care systems. Finally, *diagnostic tools and indications*

XSL•FO
RenderX

must be clarified to show how different diagnostic tools, such as EEG, are used and under what circumstances.

Requirement Prioritization

The "requirement prioritization" discussion focused on prioritizing requirements for the data-driven medical software for EEG seizure monitoring for epilepsy, specifically in a hospital environment. On the basis of Table 4, the discussion emphasized the importance of a *step-by-step* approach to developing the system. Furthermore, it was mentioned that there is a specific focus on patients with *urgent neurological emergency* events, such as status epilepticus. *The* interview discussed the need for *EEG analytics* and video recording in hospitals, particularly during evenings and weekends, for differential diagnostics. *Children* were highlighted as a unique group for consideration due to their inability to make decisions or consent themselves. Moreover, the importance of data *storage and privacy*, especially in EEG-based systems, was mentioned.

The system is mainly aimed at helping patients with *drug-resistant seizures*. The system's *utility during holidays* and weekends for private and government hospitals was noted, along with its voluntary nature. The discussion further underscored the importance of the system in terms of *cost-effectiveness* and its *value to society*. Moreover, it was highlighted that the implications of monitoring in chronic stages should be considered to avoid adding burdens on patients, families, and health care professionals. The discussion pointed out the need to carefully consider who the right person was to use the system on, which suggested the theme of decision-making *and responsibility*. The need to prioritize developing this system and securing funding from financial organizations was further emphasized. The system is intended to have a broad application across demographics for many users, including children, adults, teenagers, and older adults. The system must be successfully implemented for adults first, then expanded for other age groups. From this analysis, it is clear that the discussion was centered around developing and implementing a health care system with a strong focus on neurological emergencies, EEG analytics, and patient-centric considerations, especially regarding data privacy, accessibility, and cost-effectiveness.

Table 4. A summary of themes, subthemes, and codes for requirement analysis and prioritization.

Theme and subthemes	Codes extracted from quotations
Feasibility	
Demand for monitoring systems	Hospital, home, and remote monitoring systems
Technological resources	Technology, infrastructure, and start
Health care outcomes	Patient care and health outcome
Costs	Cost, implementation, maintenance, and implications
Risk analysis	
Treatment effectiveness	Treatment, effective, and efficacy
Health care system coverage	Aspects, treatment, and diagnosis
Diagnostic tools and indications	Different diagnostic tools, EEG[a], and circumstances
Requirement analysis and prioritization	
Step-by-step process	Step-by-step, developing
Focus on urgent neurological cases	Urgent, neurological, emergency events, and status epilepticus
EEG analytics in hospitals	EEG, analytics, video recording, and differential diagnostics
Special consideration for children	Children and special groups who are unable to make decisions give consent
Data storing and privacy	Data, storing, and privacy
Drug-resistant seizures	Drug-resistant seizures help patients
Accessibility and utility during off hours	Holidays, weekends, and voluntary
Cost-effectiveness and societal value	Cost-effective and society value
Chronic stages monitoring	Chronic stages, burden, patients, families, and medical care
Decision-making and responsibility	Careful decision, right person, and the use of the system
Priority in development and funding	Secure funding, organizations, priority, hospital environment, and emergency
Broad application across demographics	Wide range, different uses, children, adults, teenagers, and older people

[a]EEG: electroencephalography.

Quality of Care

The paper outlines several strategies aimed at improving the quality of care and resource management within the context of the proposed EEG seizure monitoring system. The identified strategies and their development process are outlined in Textbox 2.

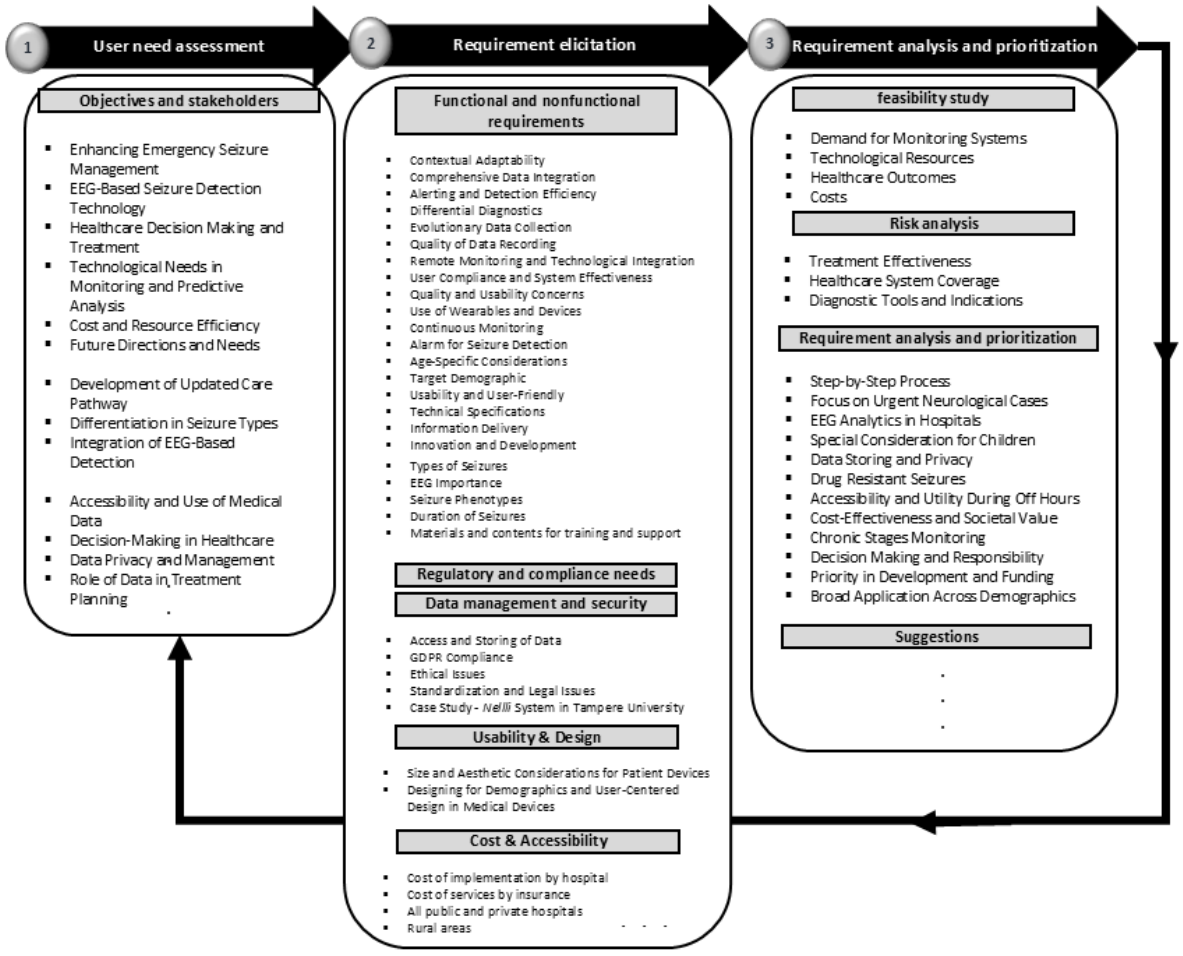
The strategies were developed through a systematic 4-round Delphi study involving focus group discussions with health care experts. Details on the 4 rounds are as follows:

1. Identifying current issues within the DCPE and gather user needs
2. Defining system requirements based on the initial feedback
3. Prioritizing and refining these requirements through further expert discussions
4. Confirming and validating the specific system requirements for development

This iterative approach ensures the strategies are well-informed and aligned with clinical realities and user demands.

While the paper does not provide specific case studies, the methods used (eg, focus group discussions and expert panels) are grounded in recognized best practices for medical software development. The emphasis on user-centered design and compatibility with existing technologies reflects practices successfully used in various health care settings to support implementing new systems.

Furthermore, the intention to start with adults in emergency and ICU settings is supported by existing literature highlighting the importance of targeted, evidence-backed implementations in enhancing patient outcomes and optimizing resource use. Future cases could arise once the EEG-EpiDigi system is operational, as real-world applications will provide concrete examples of how these strategies improve care quality and resource management.



Based on the focus group discussion and thematic analysis results, this study proposed an SRA-EpiDigi for data-driven medical software to enhance EEG seizure monitoring quality in DCPE, as shown in Figure 11. SRA-EpiDigi addressed all research questions of this study.

Textbox 2. Strategies for improving care and resource management in electroencephalography (EEG) seizure monitoring.

1. Integration with existing systems: ensuring compatibility with current hospital systems, such as electronic health records and EEG monitoring procedures, is vital for seamless implementation. This approach minimizes disruptions and enhances workflow efficiency.
2. User-centered design: the development of the EEG-EpiDigi system incorporates co-design sessions with primary users, including patients and health care professionals, to gather insights and preferences. This helps tailor the system to meet user needs, enhancing user satisfaction and care quality.
3. Phased implementation: focusing the system on adult patients in emergency and intensive care settings allows for more controlled and effective validation. Once the system proves effective, it can be expanded to cater to pediatric populations.
4. Focus on data-driven decision-making: using real-time EEG data aid clinicians in making informed decisions, improving responsiveness and treatment accuracy.
5. Feedback loops and iterative development: the Delphi study method ensures that expert feedback is continuously integrated into the design and development process. Each round serves to refine and adjust system requirements based on expert input.

Discussion

Principal Findings

The World Health Organization has stated that epilepsy is among chronic diseases causing the most comorbidity and mortality, and that it also incurs significant costs for society. It affects people of all ages, and it is one of the most common neurological diseases worldwide [2]. This highlights the severity and broader impact of epilepsy beyond the individual, affecting public health systems and society's economic burden. As mentioned earlier, the health care professionals reviewed the current DCPE's shortcomings in the focus group discussion. It was emphasized that despite several sophisticated electrocardiograms monitoring heart problems for decades, there are no comparable methods for EEG signal monitoring. The determination of seizure type is critical for choosing an appropriate medication, but predicting patient response to drugs is another challenge. About one-third of people with epilepsy have incomplete seizure control with current medicines, highlighting the need for more effective treatments [13]. Furthermore, the health care professionals highlighted the following:

> *Currently, the time taken to diagnose epilepsy is too long, and there is a need to minimize this duration. It would be a real risk to the patient, as the seizure could potentially prolong further.*

Therefore, developing and integrating a system capable of monitoring EEG recording is required in DCPE (Figure 10). The focus group discussion outlines a need for advanced wearable wireless EEG–based seizure detection tools in emergency care for epilepsy, emphasizing quick diagnosis, efficient treatment, and cost-effective technology integration. However, implementing widespread sensor-based EEG seizure monitoring software, especially with AI integration, requires assessing technological feasibility and reliability. The solution would be cost-efficient, implying that budget and resource allocation will be key considerations. The patient-centric approach was suggested for further improvements in DCPE, especially in emergency contexts, pointing toward a more patient-centric approach focusing on rapid and personalized care. The study analysis revealed a comprehensive approach to enhancing care for epileptic seizures, suggesting significant implications for patient treatment, health care resource management, and technology integration in medical practices.

The proposed integration of EEG-based detection signifies an inclination toward the influence of technology to improve diagnostic accuracy and treatment effectiveness. This implies a broader digital transformation within health care systems and reflects an essential theme of enhancing professional capabilities while hinting at a need for more patient-centered tools in future developments.

XSL•FO
RenderX

The interview further outlines a focused, data-driven approach to developing a sustainable DCPE [32,33]. It prioritizes professional health care delivery, technological integration, and a phased expansion from hospital to home settings. Each theme reflects a commitment to improving care through specificity in diagnosis (differentiating seizure types), advanced monitoring technologies (EEG integration), and targeted user groups (health care professionals). The discussion suggests an evolving health care model that is adaptive, technologically advanced, and professional-centric. As health care continues to grow, such systems are crucial in guiding the development of more efficient, accurate, and comprehensive DCPE.

The functional requirements revolve around a versatile, accurate, and comprehensive seizure detection system that can adapt to different settings, integrate various data types, ensure high-quality recordings, and evolve with patient needs. There is an emphasis on balancing technological innovation with user needs and medical requirements to improve care for patients with epilepsy. Adopting and improving upon existing technologies and exploring data-driven systems, AI, and ICU applications show a commitment to cutting-edge solutions and broad applicability. The discussion, while brief, brings forward several essential aspects to consider in the context of nonfunctional requirements for seizure-related systems or analysis. It highlights the diversity and complexity of seizures, the roles and limitations of EEG, the importance of phenotypic observations, and the critical nature of seizure duration. Each of these themes has implications for the design and function of seizure monitoring, detection, and analysis systems, suggesting a need for comprehensive, adaptable, and sensitive approaches beyond traditional EEG data. This thematic analysis suggests directions for further research or development in enhancing seizure-related health care or monitoring technologies.

Furthermore, the discussion indicates the critical role of data in health care, the importance of clear roles and communication between patients and health care providers, and the potential of technology to improve patient care through advanced monitoring and predictive analytics. It also highlights the need to consider data accessibility and privacy concerns carefully. The study provides a glimpse into the complexities of health care regulation, especially concerning data handling, privacy, GDPR compliance, ethical considerations, and the need for specialized systems and training for health care professionals.

The study discusses the balance between making a functional and comfortable device for the patient. This includes not restricting patient movement, particularly for younger patients, and ensuring that the device does not cause discomfort or pain. Although functionality is paramount, aesthetics also plays a significant role in patient acceptance and comfort. The discussion suggests that aesthetics can be improved with customizable elements such as colorful caps, especially to make devices less intimidating for children. This shows a clear understanding that while the primary goal of a medical device is to serve a health-related function, its acceptance by patients, especially younger ones, can be significantly enhanced through thoughtful design that considers aesthetic appeal.

Conclusions

In conclusion, this study incorporates health care professionals' opinions, which can contribute significantly to a sustainable care pathway by providing insights and data-driven approaches that optimize resource allocation, improve patient outcomes, and integrate long-term solutions for patient care. Moreover, it offers valuable insights into the complex interplay among functionality, aesthetics, and user acceptance in medical system design. This research supports a thorough approach that considers patients' physical and emotional needs, aiming to enhance the overall user experience and acceptance of medical software in various care settings. This study seems to be a concise set of suggestions (Figure 8) regarding improved health care technology for care pathways for epilepsy. It draws attention to the advancements in epilepsy health monitoring to highlight the gap and potential in neurological monitoring. It touches on public health themes, technology disparity, and the call for future-focused health care innovations.

The proposed SRA-EpiDigi for data-driven medical software for EEG seizure monitoring in DCPE requires ongoing improvements. One major limitation identified is the lack of patient involvement in the focus group discussions, which primarily included health care professionals. Since the system will initially be implemented within a hospital setting to aid health care providers in decision-making, it is essential to incorporate patient perspectives. To enhance the study's future direction, emphasis should be placed on requirement analysis and co-design sessions, particularly for home monitoring systems tailored for people with epilepsy. The scope of development should not only include the EEG seizure monitoring software but also expand to real-time seizure video analytics.

In addition, these co-design sessions can effectively engage system developers and health care professionals in selecting optimal, user-friendly wearables and sensors for improved seizure management. This approach will ensure the system remains relevant and user friendly for health care providers and patients, thus enhancing its overall effectiveness and acceptance.

Acknowledgments

MI and JU contributed equally to this work. The authors thank the Oulu University Hospital, the health care professionals, and the related industry for their precious time and valuable feedback. Furthermore, the authors acknowledge using the generative artificial intelligence tool Grammarly [34] to edit the paper and address the reviewer's comments.

The authors express their heartfelt gratitude for the immense support from the 6G-enabled Sustainable Society (6GESS), Oulu University Hospital, healthcare professionals, and industry partners for their valuable time and feedback. Additionally, we note that some authors are members of the European Reference Network on Rare and Complex Epilepsies (EpiCARE). Lastly, the

Abstract

Background: Addressing the complex medical and psychosocial needs of older adults is increasingly difficult in resource-limited care settings. In this context, socially assistive robots (SARs) provide support and practical functions such as orientation and information delivery. Integrating large language models (LLMs) into SAR dialogue systems offers opportunities to improve interaction fluency and adaptability. Yet, in real-world use, acceptability also depends on minimizing both technical and conversational errors, ensuring successful user interactions, and adapting to individual user characteristics.

Objective: This study aimed to evaluate the impact of integrating an LLM into a SAR dialogue system in a hospital geriatric unit by (1) comparing system performance and interaction success across 2 experimental waves, (2) examining the links between robot errors, interaction success, and multidimensional user engagement, and (3) exploring how user characteristics influence performance and perceptions of acceptability and usability.

Methods: Over an 8-month period, 28 older adults (≥60 years of age) attending a geriatric day care hospital (Paris, France) participated in a single-session evaluation of a SAR. Interactions took place in the day care hospital and were video-recorded across 2 waves: wave 1 (basic dialogue system) and wave 2 (LLM-based system). From the recordings, system performance (error types and interaction success) and user engagement (verbal, physical, and emotional dimensions) were coded. Acceptability and usability were measured using the Acceptability E-Scale and the System Usability Scale. Sociodemographic data were collected, and quantitative results were supplemented with a thematic analysis of qualitative observations.

Results: Following LLM integration, error-free interactions increased from 27.8% (10/36) to 70.2% (66/94; P<.001), comprehension failures decreased from 47.2% (17/36) to 17% (16/94; P<.001), and interaction success rose from 25% (9/36) to 74.5% (70/94; P<.001). Acceptability (Acceptability E-Scale: 12.8 vs 20.8; P=.003) and usability (System Usability Scale: 40.0 vs 60.4; P=.04) were significantly higher in wave 2. Engagement scores did not differ significantly between waves, though emotional engagement correlated positively with interaction success (r=0.28; P=.008), and age was negatively associated with both physical engagement (r=–0.30; P<.001) and acceptability (r=–0.20; P=.03).

Conclusions: Behavioral engagement with a SAR in geriatric care is shaped by both system performance and individual user characteristics. Improvements in dialogue quality observed in wave 2, coinciding with the integration of the LLM, were associated with higher interaction success and enhanced user experience. Nevertheless, other contextual or group-related factors may also

XSL•FO
RenderX

have contributed to this outcome. These findings highlight the importance of combining multimodal behavioral analysis with self-reported measures to inform the iterative, user-centered design of socially responsive robots in clinical contexts.

KEYWORDS

human-robot interaction; socially assistive robot; older adults; behavioral engagement; multimodal analysis; geriatric care; large language models

Introduction

The rapid aging of the population worldwide, combined with a shortage of health care professionals, is placing growing pressure on care systems, particularly in geriatric hospitals and long-term care settings [1]. This strain is amplified when caring for older adults with neurocognitive disorders, such as Alzheimer disease and related dementias, whose needs extend beyond medical supervision to include sustained social, emotional, and cognitive support. However, many care institutions, including hospitals, long-term care facilities, and other residential settings, often lack the resources and structures needed to address these complex needs, resulting in care experiences characterized by unmet psychosocial demands, ineffective communication strategies, and increased vulnerability to distress and disorientation [2-4].

Socially assistive robots (SARs) have emerged as a promising technological complement to human-delivered care in such contexts. SARs are designed primarily for social rather than physical interaction, using speech, gesture, and expressive behaviors to engage users and deliver cognitive, emotional, or informational support [5,6]. Building on their social capabilities, SARs have shown potential in enhancing emotional well-being, reducing anxiety and apathy, and promoting social interaction among older adults, particularly in institutional settings, including but not limited to those living with dementia [7-9]. Beyond therapeutic applications, SARs are increasingly explored as tools to assist health care professionals in nonclinical tasks, such as welcoming patients, providing information, or facilitating recreational activities [10-12].

Institutional applications often encompass reception, visitor guidance, and wayfinding. For instance, studies have shown that robots acting as medical receptionists or lobby greeters can facilitate orientation, manage patient flow, and enhance the perceived quality of service, particularly in high-traffic environments [13,14]. A systematic review by González-González et al [15] further suggests that SARs in hospital contexts often adopt hybrid roles, combining informational support with emotional engagement, especially in waiting rooms or ambulatory care settings. Such use cases broaden the vision of SARs beyond therapeutic agents to include communication and orientation facilitators [16], aligning with broader efforts to improve patient experience where staff availability is limited.

However, despite advances in robotics, including improved sensor technologies, natural language processing, and adaptive user interfaces, the integration of SARs into real-world care environments remains limited, with technical limitations representing one of the most significant barriers [17]. Health care providers have reported frustration with issues such as complex operational steps, short battery life, slow system responses, and rigid dialogue systems [18,19]. These limitations may discourage routine use, particularly in dynamic care settings where efficiency is essential. In addition, persistent challenges in personalization and speech recognition further limit deployment, as current systems often fail to accommodate the wide range of capabilities, preferences, and interaction styles found among geriatric care users [20,21].

From the end user's perspective, errors in human-robot interaction (HRI), including comprehension failures, incoherent or incomplete responses, and misaligned task execution, can erode trust in the robot and reduce engagement [22]. For older adults, even minor conversational breakdowns (eg, misrecognitions or incorrect answers) may trigger confusion, frustration, and diminished trust, particularly when the task is perceived as important [23]. As shown by Kim [24], older adults can also struggle to adapt their speech to the rigid input formats required by conversational systems, sometimes realizing only after delivering a lengthy command that the system had failed to process their request. Such breakdowns not only cause irritation but also expose the gap between the intended "natural" interaction and the constrained, one-directional exchanges these systems often afford. Similar patterns have been observed elsewhere: Khosla et al [25] in a 3-month deployment of a SAR with 5 older adults reported that negative emotions (eg, anger, sadness, and anxiety) occasionally emerged during interactions with the robot, most often when it failed to respond as expected.

Recent advances in large language models (LLMs) offer the potential to mitigate some of these conversational limitations by improving fluency, contextual relevance, and adaptability in robot dialogue systems [26-28]. While early results from other domains (eg, customer service, museum guidance, and educational robotics) are promising, there is limited empirical evidence on how integrating LLMs into SARs affects real-time interactions, error rates, and user experience in real-world geriatric care contexts.

Another critical factor in SAR evaluation is user engagement, which is inherently multidimensional, encompassing verbal behaviors (eg, speech production and turn-taking), physical involvement (eg, gestures and posture), and emotional signals (eg, facial expressions or affective cues) [29]. In HRI, engagement not only serves as a proxy for interaction quality but also predicts subsequent outcomes, such as willingness to re-engage with the robot and the perceived value of the system [30]. Research in care environments, including work with older adults by Hebesberger et al [19], shows that sustained engagement is essential for acceptance and that both technical

XSL•FO
RenderX

reliability and interaction fluency shape the depth and duration of participation. Despite its theoretical and practical importance, little is known about how these engagement dimensions are influenced by robot performance, error frequency, or task success in geriatric care contexts, representing a notable gap in the literature.

Finally, user characteristics, including age, socioeducational background, and cognitive functioning, are likely to influence both observable HRI behaviors and subjective evaluations of SARs [31-34]. For instance, older age may be associated with reduced physical expressiveness, while higher cognitive functioning could support more complex conversational exchanges. Understanding these relationships is essential for informing adaptive robot design and deployment strategies that are inclusive and responsive to diverse user needs.

Given these gaps, this study investigated the deployment of a SAR in a hospital geriatric unit, focusing on three main objectives (1) to assess changes in system performance and interaction success following the integration of an LLM into the robot's dialogue system, comparing 2 experimental waves; (2) to examine the relationships between robot errors, interaction success, and user engagement, considering verbal, physical, and emotional dimensions; and (3) to explore how user characteristics relate to system performance and subjective evaluations of acceptability and usability.

By combining quantitative measures of performance, engagement, and user ratings with qualitative analysis of participant perceptions, this study provides a real-world grounded perspective on the opportunities and challenges of SAR deployment in aging care contexts.

Methods

Participants

Overview

The study involved older adults attending consultations at the geriatric day care hospital (DCH) of Broca Hospital (Assistance Publique—Hôpitaux de Paris), France. Inclusion criteria were (1) being 60 years and older of age; (2) participating in a scheduled DCH consultation; (3) having a Mini-Mental State Examination (MMSE) [35] score above 10, indicating the absence of severe cognitive impairment; (4) having no current symptoms of altered reality (eg, delusions or hallucinations); and (5) having fluent comprehension and expression in French. No exclusion criteria were applied based on sex, socioeconomic backgrounds, or ethnicity.

Recruitment

Recruitment was carried out using the DCH database, and participants were prescreened prior to enrollment, contacted over the phone, and invited to participate in the study the day of their next consultation. An information letter was sent by post, and informed consent was collected onsite.

A total of 41 older adults were recruited for the study. However, this analysis focuses on a subset of 28 participants who met the following criteria: (1) provided consent to be filmed; (2) completed a full interaction session with the robot; and (3) generated usable video data, defined by adequate visibility and recording quality. The remaining participants were excluded due to 1 or more of the following reasons: refusal to engage with the robot, technical malfunctions during the session, or withdrawal of consent for video recording.

Setting

The study was conducted between May 2023 and December 2023 in the DCH of a geriatric hospital in Paris (France). The DCH provides specialized outpatient care for older adults with physical or cognitive impairments, offering a wide range of consultations, including neurology, oncology, cardiology, psychiatry, and memory assessments.

The data collection occurred in 2 waves during this period, with distinct participant samples recruited for each phase. All interactions were carried out in a quiet, dedicated room located near the DCH waiting area. This space, typically used for rest and informal activities, was chosen to provide a calm and comfortable environment for testing, while maintaining proximity to the clinical setting.

Study Design

This cross-sectional observational study was conducted as part of a broader research protocol evaluating the integration of a SAR in geriatric care [36,37]. This analysis focuses on real-world HRI, combining behavioral observations with user-reported data. Each participant engaged in a single, nonscripted interaction session with the robot, followed by questionnaires. Data were collected across 2 experimental waves. The first wave involved a baseline version of the robot without LLM integration, while the second wave used an updated LLM-enabled version. Each wave included a different group of older adults.

Material

ARI Robot

The ARI robot developed by Pal Robotics (Spain) is a 1.65-m (5 ft 5 in) wheeled humanoid platform equipped with a touchscreen, cameras, microphones, animated eyes, and articulated arms (Figure 1). In this study, ARI was used as a socially assistive agent in a geriatric hospital setting.

XSL•FO
RenderX

Figure 1. Front and side views of the ARI robot (photo credit: PAL Robotics).

For this study, ARI was programmed with interaction modules developed as part of the European H2020 SPRING (Socially Pertinent Robots in Gerontological Healthcare) project, aimed at enabling SAR in real-world clinical environments [36]. Two different configurations of ARI's conversational system were tested during this study, as detailed in the System Evolution section. As ARI had not yet been commercially deployed in care institutions at the time of the study, its use in this context was part of a controlled, exploratory evaluation conducted within the hospital environment.

System Evolution

To assess the impact of iterative improvements to ARI's interaction capabilities, we conducted 2 experimental waves, each following a major system update informed by participant feedback.

- Wave 1 (May to July 2023) deployed a first version of ARI featuring a modular dialogue system based on traditional rule-based intent handling, retrieval-based responses, and basic open-domain generation. This initial architecture was supported by core diagnostic tools, on-screen speech transcription, and perceptual modules (eg, person tracking and facial recognition).
- Wave 2 (September to December 2023) introduced a redesigned conversational module centered on an LLM architecture. Specifically, the system was upgraded to integrate Vicuna-13B-v1.5, a 13-billion parameter LLM optimized for offline use. A custom prompt in French was developed to align with hospital-based use cases, ensuring context-sensitive, coherent interactions. Other system improvements included a refined transcription interface and more efficient vision module processing. All data were securely stored on servers dedicated exclusively to the project. This setup ensured robust data control, as the language model was hosted locally, giving the project partners full control over processing, storage, and use.

A detailed technical overview of these updates is available in SPRING Deliverable D1.6 [38].

Assessment Instruments

Demographic Data Collection

Basic demographic information was collected using a standardized paper-based form prior to the start of the interaction session. Participants were asked to report their age, sex, and level of education (years of formal education). The level of cognitive function (MMSE) was completed beforehand by the researcher.

System Performance

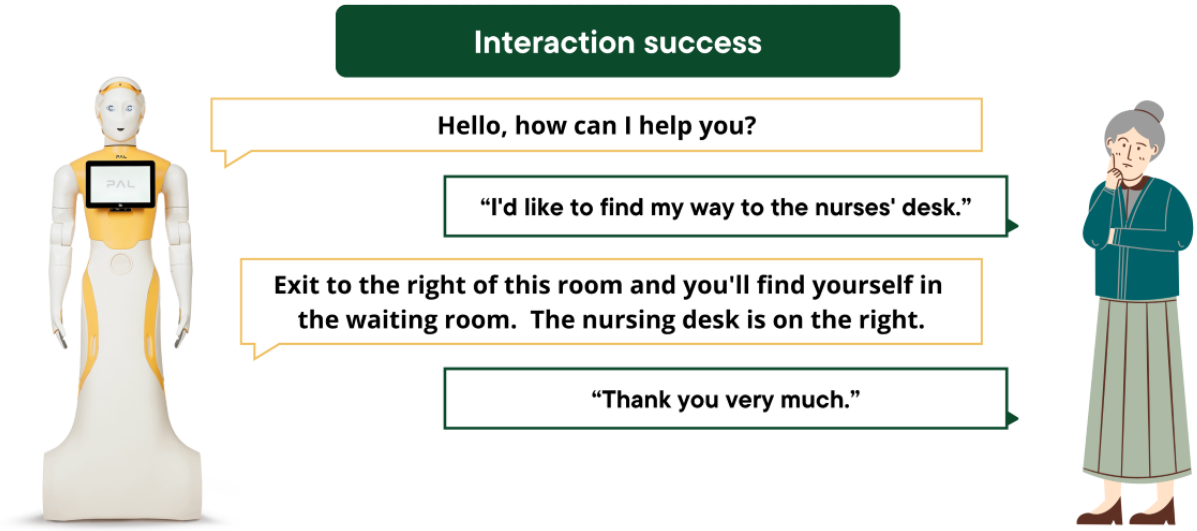
To assess system performance, all interactions were recorded and annotated based on robot behavior. Each interaction was defined as a conversational unit, beginning when the participant

XSL•FO
RenderX

initiated a verbal input and ending when the robot responded or failed to do so. For example, if a participant asked, “Where is the restroom?” and the robot replied, “To your right as you exit this room,” the exchange was considered complete, regardless of its duration. Participants could then initiate a new exchange, continue the dialogue, or end the session. This approach produced interactions of widely varying length, from brief question-answer sequences to longer, multiturn conversations, depending on participant intent and conversational flow.

Robot behaviors were annotated using a predefined classification scheme consisting of four categories:

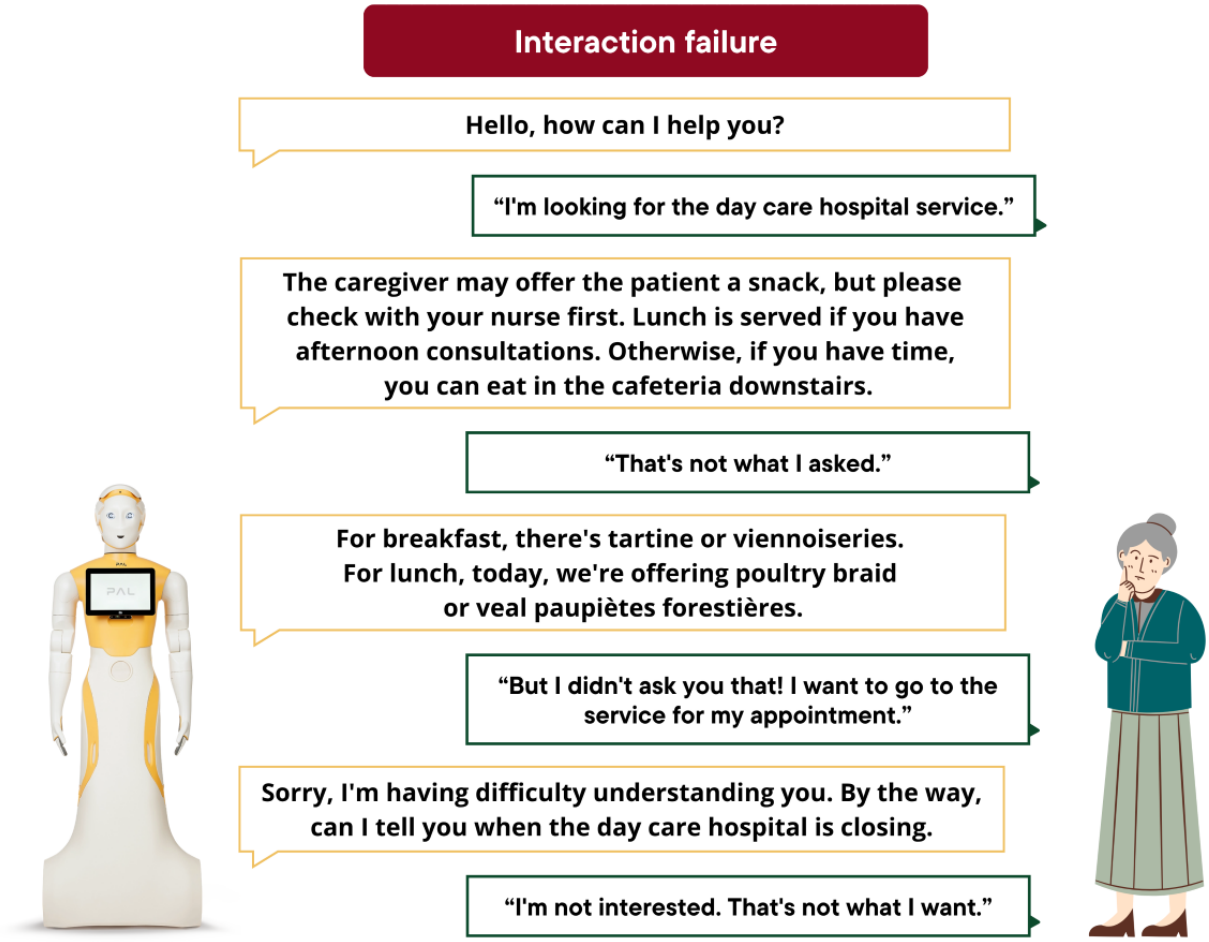
1. Comprehension failure: The robot fails to interpret or meaningfully respond to the user’s input, typically resulting in silence or a fallback message (eg, “I don’t understand”).
2. Inappropriate verbal response: The robot produces a reply that is unrelated, incoherent, or socially inappropriate in context (eg, to the question “What time is my appointment?” the robot replies “Of course. The hospital is open every day from 9 a.m. to 5.30 p.m.”).
3. Incomplete utterances: The robot produces an unfinished or abruptly cutoff response, resulting in a message that lacks necessary information (eg, when asked “Can you tell me where the toilets are?” the robot replies “The toilets are on your left as you come out of ...”).
4. Technical error: System-level malfunctions such as speech synthesis failure, audio dropout, or interface freezing.



The first 3 robot behaviors, comprehension failures, inappropriate verbal responses, and incomplete utterances, were classified as verbal-related errors. This categorization allowed for exploratory correlation analyses between robot behavior and user engagement, enabling a distinction between technical malfunctions and conversational breakdowns.

Multiple error types could be assigned to a single interaction when applicable (eg, a comprehension failure accompanied by a technical issue). This allowed for the analysis of both error frequencies and error co-occurrence patterns as well as comparisons across the 2 experimental waves to examine changes in system performance over time.

Interaction Success



Interaction success was defined as the robot providing a relevant and coherent response that appropriately addressed the user’s request or corresponded to the information provided. Examples of successful and failed interactions are illustrated in Figures 2 and 3.

Figure 2. Example of a successful interaction between the ARI robot and a participant.

XSL•FO
RenderX

Figure 3. Example of a failed interaction between the ARI robot and a participant.

User Engagement Coding Framework

User engagement was assessed using a structured behavioral coding scheme (Table 1), developed to capture 3 dimensions: verbal, physical, and emotional engagement. The verbal dimension reflected speech production and conversational responsiveness; the physical dimension encompassed posture, gesture use, body orientation, and other forms of physical involvement; and the emotional dimension captured visible emotional expressivity. Each dimension was rated on a 5-point scale, ranging from 1=minimal engagement or rejection to 5=high involvement and expressivity.

XSL•FO
RenderX

Table 1. User engagement dimensions and rating scale.

Dimension and score	Description
Verbal engagement	
1	Persistent silence or clearly disengaged verbal behavior (eg, hostile or rejecting remarks).
2	Minimal verbal output (eg, 1-word replies such as “yes” or “no”), delivered in a flat tone, with no spontaneous elaboration or follow-up.
3	Brief, functional responses that are appropriate and clearly articulated but emotionally neutral and lacking initiative.
4	Active participation through contextually appropriate answers and spontaneous follow-up contributions.
5	Fluent, sustained conversation featuring regular verbal initiative, coconstructed dialogue, and spontaneous, personally meaningful comments or anecdotes.
Physical engagement	
1	Defensive or avoidant posture (eg, crossed limbs and leaning away), evasive gaze, and rejecting or dismissive gestures.
2	Passive physical presence, with infrequent or minimal gestures and body oriented away from the robot.
3	Upright, neutral posture with limited physical expressivity; gaze may be directed toward the robot but lacks clear engagement; few gestures.
4	Open body orientation toward the robot, accompanied by expressive gestures and visibly responsive physical behavior (eg, nodding and leaning in).
5	Strong physical involvement, including spontaneous gestures, mimicry of the robot’s actions, or voluntary physical contact (eg, touching the robot).
Emotional engagement	
1	Clear negative emotional expression (eg, anger, frustration, and disgust), often accompanied by signs of interaction breakdown or withdrawal.
2	Very low emotional reactivity, flat facial affect, and visible signs of fatigue, boredom, or disinterest.
3	Neutral but attentive facial expression, stable gaze toward the robot, with limited or absent emotional expressivity.
4	Moderate social-affective signals, such as smiling, nodding, or short expressive reactions, indicating active but contained emotional engagement.
5	Strong affective display, including laughter, animated facial or physical expressions, and moments of emotional synchrony with the robot.

The coding grid was designed by the research team, grounded in prior work on social signal processing [39], and iteratively refined through preliminary testing to ensure clarity, consistency, and applicability in naturalistic HRI settings. It incorporated both affective and interactional markers, such as speech spontaneity, posture alignment, gesture expressiveness, and emotional display.

All interactions were independently coded by 2 trained researchers (LB and MP) using a detailed coding manual to reduce subjectivity inherent in qualitative behavioral analysis [40]. In cases of disagreement, coders discussed the item to reach consensus; if consensus could not be achieved, a third researcher (JC) acted as an arbitrator to determine the final score. This multicoder approach aligns with best practices in HRI research, which emphasizes the use of multiple raters to mitigate individual bias and enhance intersubjective reliability [39,41].

Emotional engagement scores were not assigned for 28 of 130 interactions due to limited facial visibility caused by surgical masks, which impeded the reliable interpretation of affective expressions. These interactions involved 5 participants, 3 who remained masked throughout and 2 who removed their masks partway. While excluded from emotional engagement analysis, these sessions were retained for all other measures.

In addition to the quantitative ratings, coders were encouraged to document any ambiguous, unexpected, or contextually meaningful behaviors using an open comment field. These qualitative annotations served to refine and contextualize the interpretation of engagement patterns observed in the coded data.

Assessment Scales

Two standardized self-report questionnaires were administered immediately after the interaction to assess participants’ perceptions of the robot’s acceptability and usability. The Acceptability E-Scale (AES), adapted from Heerink et al [42] and translated into French by Micoulaud-Franchi et al [43], measures perceived acceptability across 6 dimensions: trust, perceived usefulness, enjoyment, sociability, ease of use, and intention to use. The scale includes 6 items, each rated on a 5-point Likert scale, yielding a total score ranging from 6 to 30. AES scores above 25.81 of 30 are considered to reflect high perceived acceptability, while lower scores indicate limited acceptability. The adapted version of the scale used in this study is provided in Multimedia Appendix 1.

XSL•FO
RenderX

The System Usability Scale (SUS) [44] is a widely used, validated 10-item questionnaire designed to assess perceived usability. Items are rated on a 5-point Likert scale, and the final score is calculated according to standard scoring procedures, yielding a composite usability score between 0 and 100. According to standard interpretive guidelines, SUS scores below 50.9 are considered poor, scores between 51 and 71.4 are rated as OK to good, and scores above 71.4 reflect excellent perceived usability [45]. The adapted version of the scale used in this study is provided in Multimedia Appendix 1.

Assessment Procedure

Each session (~45 minutes) followed a standardized sequence consisting of a short reminder of the objectives of the study, informed consent, interaction with the robot, and postinteraction assessments. Participants were first introduced to the robot's general capabilities (eg, hospital orientation, entertainment, and appointment assistance) and informed that they could ask the robot questions freely related to these functions. No detailed interaction instructions or scripted prompts were provided, in order to preserve a naturalistic interaction context.

A fixed-position camera recorded the entire session for behavioral coding. A researcher (LB) was present throughout the entire session to provide assistance if needed, while minimizing interference.

Following the interaction, participants completed 2 standardized self-report questionnaires, the AES and the SUS, with support from the research team when necessary.

Data Analysis

Quantitative analyses were conducted using the jamovi software (version 2.4.11; The Jamovi Project) and focused on 4 dimensions: sociodemographic data, system performance, user engagement, and acceptability and usability.

For sociodemographic characteristics (age, sex, socioeducational level, and MMSE scores), descriptive statistics (mean, SD, minimum, and maximum) were first computed. Comparisons across experimental waves were then conducted using the Mann-Whitney *U* test, due to violations of normality and homogeneity of variance assumptions, as assessed by the Shapiro-Wilk and Levene tests.

For the analysis of HRIs, the unit of analysis was the individual interaction. Interaction duration was calculated for each HRI session based on video recordings. Mean durations were computed separately for each experimental wave, and the total cumulative duration of all recorded interactions was calculated to quantify the overall volume of video data analyzed. The definition of an interaction used in this study is provided in the System Performance section.

A descriptive analysis was first conducted for each wave, covering these elements: robot behavior categorized by 4 error types (comprehension failures, inappropriate verbal responses, incomplete responses, and technical errors) and the proportion of interactions with and without errors.

Subsequently, between-wave comparisons were performed. Robot behavior was compared across waves based on the average error rate per interaction. Analyses were first conducted considering all error types, followed by a focused analysis on the 3 verbal-related errors: comprehension failures, inappropriate verbal responses, and incomplete responses. These comparisons were conducted using Mann-Whitney *U* tests, due to nonnormal distributions and violations of homogeneity of variance in the error frequency data.

User engagement was then analyzed using multimodal behavioral coding across 3 dimensions: verbal, physical, and emotional engagement. A descriptive analysis was first conducted for each dimension. Subsequently, engagement scores were compared between experimental waves using Kruskal-Wallis tests, due to violations of normality and homogeneity of variance assumptions.

Interaction success was operationalized as the completion of a communicative goal, specifically, when the user successfully obtained the information requested from the robot. Success rates were compared between experimental waves using a chi-square test of independence to assess whether system upgrades influenced the likelihood of a successful exchange.

The dimensions of acceptability and usability, assessed using the AES and SUS questionnaires, respectively, were first examined through descriptive analysis. Subsequently, scores were compared between experimental waves using independent samples 2-tailed *t* tests, following confirmation of normality (Shapiro-Wilk test) and homogeneity of variance (Levene test).

To complement group-level comparisons, additional analyses were conducted to explore relationships between the dimensions of engagement, system performance, user experience, and participant characteristics. Pearson correlation analyses were used to examine associations between user engagement scores and interaction outcomes (ie, successful vs unsuccessful interactions) as well as between engagement scores and perceived acceptability (AES) and usability (SUS). Correlation analyses were also performed on the full sample to investigate relationships between sociodemographic characteristics (age, socioeducational level, and MMSE), system performance indicators (total and conversational error counts), user engagement dimensions (verbal, physical, and emotional), and subjective evaluations of the robot (AES and SUS). These analyses aimed to determine whether individual differences were associated with user experience, robot performance, or behavioral engagement during interactions.

A short qualitative analysis was conducted using thematic classification [46] of spontaneous, marginal comments made by participants during their interactions with the robot. These comments were not obtained through interviews or explicit discussions about the HRI but occurred naturally during the exchanges. Comments were categorized under emerging themes to complement the quantitative findings and provide additional insight into user engagement and interaction dynamics. Coding was performed independently by 2 observers (LB and MP), who then compared and discussed their categorizations to reach consensus on the final themes. Because of the small amount of data, no formal interrater reliability statistic (eg, Cohen κ) was calculated.

XSL•FO
RenderX

Ethical Considerations

The study was approved by the French National Ethics Committee ("Comité de Protection des Personnes, CPP Ouest II [21.02.03.45524 2021/20], Maison de la Recherche Clinique – CHU Angers [2020-A02643-36]"; and complied with the General Data Protection Regulation. Data processing was registered with the Data Protection Officer (reference 20210114153645) in the Assistance Publique—Hôpitaux de Paris registry. The study did not involve randomization or a clinical intervention. Informed consent was obtained from all participants, and they were informed that they could withdraw from the study at any time. The original consent included approval for secondary analyses without requiring additional consent. All participant data were anonymized, and no compensation was provided. From an ethical standpoint, the use of SARs raises several issues, particularly regarding confidentiality and transparency. Because these systems collect and process sensitive data (vocal, visual, or interactional), their use and potential reuse must be explicitly stated. Ethical guidelines also demand that users and participants are clearly informed, so they understand how their data are managed. With the integration of LLMs, this obligation further includes clarifying whether experimental results will be used for model training and under which conditions.

Results

Participant Characteristics and Baseline Equivalence

The sample included 28 older adults, with 10 participants in wave 1 and 18 in wave 2. The mean age was 78.2 (SD 6.25; range 67-93) years, and most participants were women (n=20). The average MMSE score was 26.3 of 30 (SD 3.73; range 18-30), with scores ≥26 generally indicating normal cognitive function. The mean socioeducational level was 12.8 (SD 1.94) years, ranging from 9 (completion of lower secondary education or vocational training) to 14 or more years (university-level qualifications such as a bachelor's degree or higher).

Baseline equivalence between groups was assessed using Mann-Whitney *U* tests for MMSE scores and socioeducational level, as both variables were nonnormally distributed. No significant differences were found between wave 1 and wave 2 for MMSE (U=49.5; P=.05; r=0.45) or socioeducational level (U=79.5; P=.57; r=0.12), supporting the comparability of the 2 experimental groups. The inclusion of effect sizes indicates that the observed differences were small to moderate in magnitude, further supporting baseline equivalence despite minor variability in MMSE. Participant characteristics by experimental wave are summarized in Table 2.

Table 2. Sociodemographic characteristics of participants by experimental wave.

Experimental wave	Sex		Age (years), mean (SD)	Education[a] (years), mean (SD)	MMSE[b] score, mean (SD)
	Male, n (%)	Female, n (%)			
Wave 1 (n=10)	3 (20)	7 (80)	78.6 (7.6)	13.1 (1.7)	28.0 (1.9)
Wave 2 (n=18)	6 (33.3)	12 (66.7)	77.9 (5.6)	12.6 (2.1)	25.3 (4.1)
Total (N=28)	9 (32.1)	19 (67.9)	78.2 (6.3)	12.8 (1.9)	26.3 (3.7)

[a]Years of education refer to the total years of formal schooling completed.

[b]MMSE: Mini-Mental State Examination (range 0-30); scores≥26 are generally considered within the normal cognitive range.

Interaction Duration and Dataset Composition

A total of 130 HRIs were analyzed (wave 1=36 HRIs and wave 2=94 HRIs), comprising the full dataset used for multimodal behavioral coding. Interaction durations ranged from 7 seconds to 3 minutes and 14 seconds, with a mean duration of 52 (SD 0.00038) seconds: wave 1=40 (SD 0.00037) seconds and wave 2=58 (SD 0.00037) seconds. In total, the recordings resulted in 1 hour, 53 minutes, and 55 seconds of video data. The experimental setup is shown in Figure 4, which depicts a participant interacting with the SAR during a session.

Figure 4. Experimental context: participant interacting with the socially assistive robot.

Robot Error Patterns and System Performance Across Waves

Overview

Table 3 presents the distribution of robot error types across the 2 experimental waves. Comprehension failures were the most frequent error, occurring in 25.4% (33/130) of all interactions, with a notably higher rate in wave 1 (17/36, 47.2%) compared to wave 2 (16/94, 17%). Incomplete utterances were absent in wave 1 but appeared in 14.9% (14/94) of interactions in wave 2. Inappropriate verbal responses were also more common in wave 1 (13/36, 36.1%) than in wave 2 (14/94, 14.9%), contributing to a combined rate of 20.8% (27/130). Technical errors remained relatively stable between conditions, occurring in 11.1% (4/36) of interactions in wave 1 and 11.7% (11/94) in wave 2. For analysis, each error type was binary-coded per interaction (0=absent and 1=present).

Table 3. Distribution of robot error types by experimental wave.

Robots' behaviors	Wave 1, n (%)	Wave 2, n (%)	Total, n (%)
Comprehension failures	17 (47.2)	16 (17)	33 (25.4)
Incomplete utterances	0 (0)	14 (14.9)	14 (10.8)
Inappropriate verbal responses	13 (36.1)	14 (14.9)	27 (20.8)
Technical error	4 (11.1)	11 (11.7)	15 (11.5)

Robot error types were compared across the 2 experimental waves based on total error counts. Verbal-related errors, including comprehension failures (U=989; P<.001; r=0.42), incomplete utterances (U=1440; P=.015; r=0.15), and inappropriate responses (U=1333; P=.008; r=0.21), differed significantly between wave 1 and wave 2. A higher number of verbal-related errors were recorded in wave 1, reflecting reduced conversational performance in this condition and suggesting improved system behavior following the updates implemented in wave 2.

An additional analysis was conducted at the level of individual interactions to compare error rates between experimental waves. Results showed higher error rates per interaction in wave 1 than in wave 2: comprehension failures occurred on average 2.03 times per interaction in wave 1 compared to 0.61 in wave 2; inappropriate responses occurred at a rate of 0.36 in wave 1

XSL•FO
RenderX

versus 0.15 in wave 2; and incomplete utterances, which were absent in wave 1, appeared with a mean frequency of 0.16 per interaction in wave 2. In contrast, technical error rates did not differ significantly between waves (U=1682; P=.93; r=0.01), indicating stable hardware performance across conditions.

Finally, the proportion of interactions without any system errors increased significantly in wave 2 following the introduction of the LLM (U=995; P<.001; r=0.41), indicating improved system stability and interaction reliability after the update. Only 27.8% (10/36) of interactions in wave 1 were error-free, compared to 70.2% (28/94) in wave 2. This substantial increase in error-free interactions suggests that the integration of the LLM contributed positively to the overall robustness and consistency of the system's performance.

User Engagement

Participant engagement was evaluated using multimodal behavioral coding across 3 dimensions: verbal, physical, and emotional. Each dimension was scored on a 5-point scale, with higher scores indicating greater levels of engagement.

The mean verbal engagement score was 3.64 (SD 0.64) in wave 1 and 3.47 (SD 0.77) in wave 2. A Kruskal-Wallis test revealed no significant difference in verbal engagement between the 2 waves (χ^2_1=2.5; P=.11).

For physical engagement, scores remained stable across waves, with a mean of 3.03 (SD 0.77) in wave 1 and 2.99 (SD 0.73) in wave 2. No significant difference was observed (χ^2_1=0.06; P=.80).

Emotional engagement showed a slight increase, from a mean score of 2.92 (SD 1.02) in wave 1 to 3.33 (SD 0.86) in wave 2. No significant difference was observed (χ^2_1=3.4; P=.06). Descriptive statistics by wave are presented in Table 4.

Table 4. Comparison of acceptability and usability scores, user engagement metrics, and interaction success across waves.

Dimension	Wave 1	Wave 2	Difference, *P* value
AES[a] score out of 30, mean (SD)	12.8 (4.58)	20.8 (6.52)	<.001
SUS[b] score out of 100, mean (SD)	40.0 (24.04)	60.4 (23.11)	<.001
Duration of interaction (seconds), mean (SD)	40 (32)	58 (32)	<.001
Verbal engagement mean score out of 5 (SD)	3.64 (0.64)	3.47 (0.77)	.24
Physical engagement mean score out of 5 (SD)	3.03 (0.77)	2.99 (0.73)	.79
Emotional engagement mean score out of 5 (SD)	2.92 (1.02)	3.33 (0.86)	.05
Interaction success, n/N (%)	9/36 (25)	70/94 (74.5)	<.001

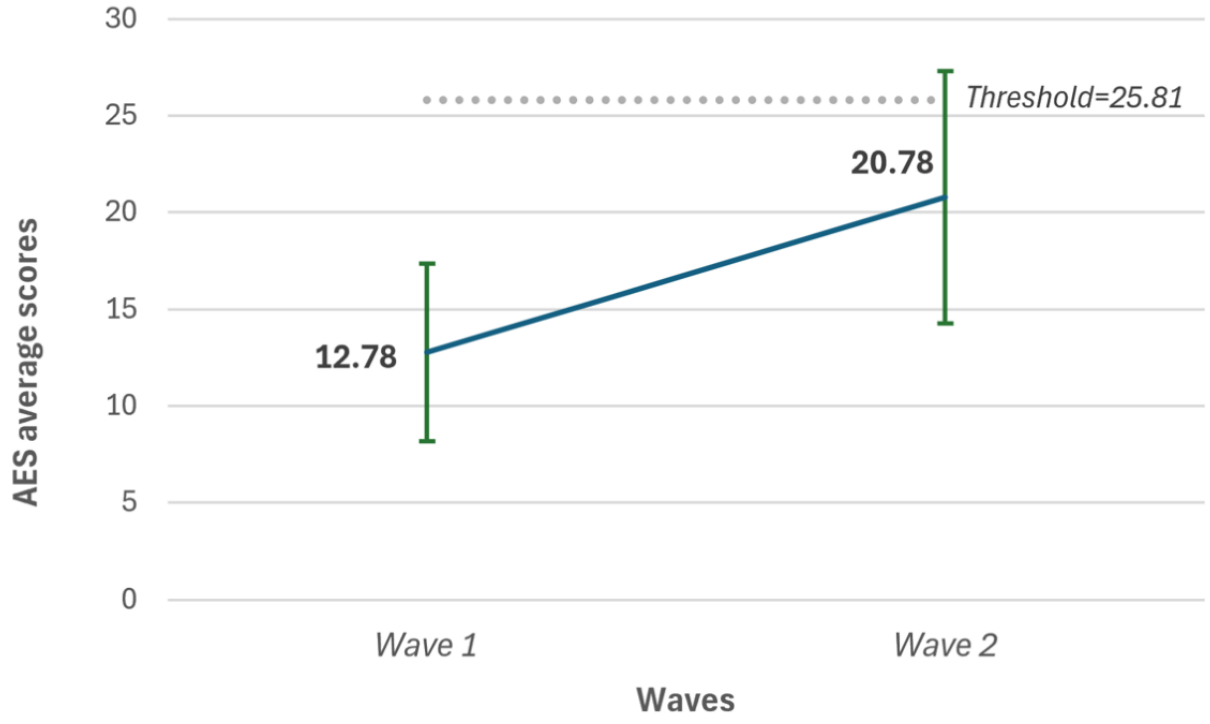
[a]AES: Acceptability E-Scale.

[b]SUS: System Usability Scale.

Interaction Success and Perceived Acceptability and Usability

Interaction success, defined as the completion of a communicative goal without breakdown, improved significantly across waves: 25% (9/36) in wave 1 versus 74.5% (70/94) in wave 2 (χ^2_1=26.7; P<.001).

Participants who experienced a successful interaction reported significantly higher ratings of both acceptability and usability. For the AES, mean scores were 21.6 of 30 (SD 5.84) in successful interactions, compared to 17.4 of 30 (SD 7.15) in failed ones (U=1261.5; P<.001; r=0.35). SUS scores followed the same pattern, with a mean of 63.3 of 100 (SD 22.5) for successful exchanges versus 51.1 of 100 (SD 26.5) for unsuccessful ones (U=1456.5; P=.01; r=0.25).



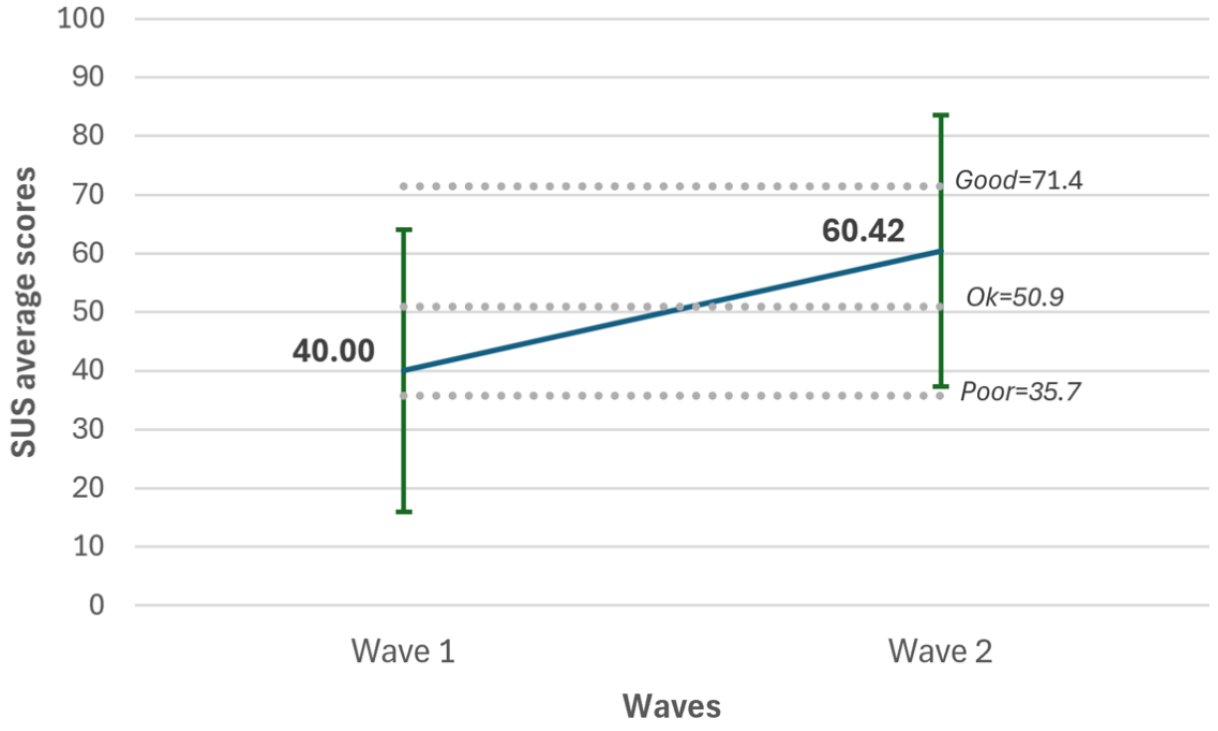
Importantly, no significant differences were found between participants who experienced successful versus unsuccessful interactions in terms of age (U=1898.5; P=.66; r=0.05), years of education (U=1915.5; P=.58; r=0.06), or MMSE scores (U=1921; P=.65; r=0.05), suggesting that interaction success was not dependent on participants' demographic or cognitive profiles.

Acceptability Assessment

In wave 1, acceptability scores ranged from 9 to 23, with a mean of 12.8 (SD 4.58). In wave 2, scores ranged from 7 to 30, with a mean of 20.8 (SD 6.52). The AES ranges from 6 to 30, with higher scores indicating greater acceptability; a commonly used threshold of 25.81 denotes high acceptability. An independent sample 2-tailed t test revealed a significant difference between waves (t_{25}=–3.28; P=.003), with higher acceptability observed in wave 2 compared to wave 1. Figure 5 illustrates the distribution of AES scores across the 2 experimental waves, showing the increase in mean acceptability from wave 1 to wave 2.

XSL•FO
RenderX

Figure 5. AES scores across the 2 experimental waves. AES: Acceptability E-Scale.



Usability Assessment

Overview

In wave 1, SUS scores ranged from 12.5 to 67.5, with a mean of 40.00 (SD 24.04). In wave 2, scores ranged from 2.5 to 92.5, with a mean of 60.42 (SD 23.11). The SUS ranges from 0 to 100, with 50.9 commonly cited as the minimum threshold for acceptable usability; scores below this indicate insufficient usability. An independent sample 2-tailed *t* test revealed a significant difference between waves (t_{25}=–2.14; *P*=.04), indicating greater perceived usability in wave 2 compared to wave 1. Figure 6 shows the increase in mean SUS scores between the 2 experimental waves, indicating improved perceived usability in wave 2.

Figure 6. SUS scores across the 2 experimental waves. SUS: System Usability Scale.

XSL•FO
RenderX

Associations Among Engagement, Outcomes, and User Characteristics

A Pearson correlation analysis was conducted to explore the relationships between user engagement (verbal, physical, and emotional), interaction outcomes, system evaluations, and participant characteristics (see Multimedia Appendix 2 for the full correlation matrix). Emotional and physical engagement were strongly positively correlated (r=0.63; P<.001), indicating that increased emotional expressiveness was closely associated with greater physical involvement. Emotional engagement was also positively associated with interaction success (r=0.28; P=.008), suggesting that successful interactions tended to elicit higher emotional responsiveness.

A moderate positive correlation was observed between physical and verbal engagement (r=0.23; P=.009), indicating that participants who were more physically expressive also tended to engage in more sustained or contextually responsive verbal behavior. Conversely, verbal engagement was negatively correlated with perceived acceptability (AES; r=–0.27; P=.002), suggesting that more frequent or proactive verbal contributions were associated with lower acceptability ratings.

Among participant characteristics, age showed a moderate negative correlation with physical engagement (r=–0.30; P<.001), indicating that older participants tended to be less physically expressive during interactions. Age was also negatively associated with acceptability ratings (r=–0.20; P=.03), suggesting slightly reduced system acceptability among older users. No significant correlations were found between cognitive functioning, as measured by MMSE scores, or socioeducational level, and the other engagement or evaluation measures.

Qualitative Analysis of Spontaneous Verbalizations

Overview

During the interactions, participants occasionally produced spontaneous comments in reaction to specific events, often triggered by the robot's conversational or technical errors. These remarks provide insight into how older adults evaluated the exchange, revealing patterns of frustration, adaptation, humor, and expectation management. Thematic analysis identified 5 recurrent themes (Table 5).

Table 5. Thematic analysis of participants' spontaneous verbalizations.

Theme	Description	Exemplar quotes
Silence, confusion, and humor as coping	Errors or nonresponses from the robot often led participants to react with humor, irony, or playful comments, softening frustration.	• "We're going round in circles here. [laughs]" [Wave 1]. • "Does it [the robot] have blocked ears? [laughs]" [Wave 1). • "Yet [the robot] understood (points to the screen with the transcript) but it [the robot] doesn't answer my question" [Wave 1].
Self-attribution of blame	Communication breakdowns were sometimes attributed by participants to their own speech, hearing, or contextual factors.	• "I can't hear very well, as I have a lot of trouble with my ears" [Wave 1]. • "It [the robot] is having trouble understanding me. Is it the mask?" [Wave 2]. • "Am I speaking loud enough [for the robot to understand]?" [Wave 1].
Expectation-response mismatch and technology comparisons	Participants noted discrepancies between expected and actual robot responses, sometimes comparing them to earlier or limited technologies.	• "Doesn't it understand anything? [the robot did not give an accurate answer]" [Wave 1]. • "We're not going to upset it [laughs]" [Wave 1]. • "It reminds me of when they first introduced voice word processing. We had some absolutely incredible things written down. It didn't make any sense at all" [Wave 2].
Seeking external guidance	Interaction difficulties prompted participants to turn to the experimenter for clarification or support.	• "How can I find out what questions I can ask the robot? [to the experimenter]" [Wave 2]. • "Do I have to talk to it [the robot]?" [Wave 2]. • "So now I can start again? Do I have to restart from zero or should I step out of the field and come back? [to the experimenter]" [Wave 2].
Positive reactions to robot-initiated exchanges	When the robot took initiative, participants expressed surprise or delight, highlighting novelty and engagement.	• "It's impressive [the robot]!" [Wave 2]. • "Oh! It [the robot] talks to me first, just like a person!" [Wave 2]. • "So if I don't say anything, it [the robot] will keep asking me things?" [Wave 2].

Silence, Confusion, and Humor as Coping

When the robot failed to respond or gave irrelevant answers, participants often reacted with a mix of confusion and humor. Some expressed mild frustration, "Well, yes, but it's not answering me" (Wave 1), while others turned to playful remarks, joking that the robot had "blocked ears" or even deserved a slap. Sarcasm and irony also emerged as ways to reframe disappointment, with comments like "[laughs] Wasn't that question planned [in the database]?" (Wave 1) or "We asked it a question it's not very good at" (Wave 1). Participants also relied on the robot's transcript display to make their point: "It

XSL•FO
RenderX

understood (points to the screen) but it doesn't answer my question." These responses show how older adults shifted between frustration and collaborative problem-solving. Some participants therefore chose humor rather than disengagement, demonstrating resilience when interacting with a new technology such as SAR.

In addition, participants recurrently described conversational "loops" when repeated prompts or ARI's lack of uptake brought dialogue to a standstill. The interaction frequently felt circular: the robot kept repeating information and failed to build on prior exchanges. This resulted in participants asking clarifying questions like "Shall I continue?" (Wave 2), signaling a breakdown in mutual understanding. Affect often shifted from amused to impatient, captured in remarks such as "We're going round in circles here [laughs]" (Wave 1) and "Wake up ARI!" (Wave 1), yielding interactional impasses marked by circularity, uncertainty about mutual understanding, and mounting frustration.

Self-Attribution of Blame

Instead of attributing breakdowns to the robot's limitations, participants often questioned their own role in communication difficulties. Comments such as "I can't hear very well, as I have a lot of trouble with my ears" (Wave 1) or "It's having trouble understanding me. Is it the mask?" (Wave 2) show how challenges were internalized, sometimes linked to environmental factors or speech clarity. This self-scrutiny extended to interaction etiquette, "Do I speak fast enough?" (Wave 1), "Am I speaking loud enough?" (Wave 1), and even basic rules, as in "Ah! Because I have to ask a question?" (Wave 2). Such attributions highlight how older adults often personalize technological breakdowns, with uncertainty toward novel systems manifesting as self-questioning rather than solely blaming the robot.

Expectation-Response Mismatch and Technology Comparisons

Participants at times noted a gap between their expectations and the robot's actual capabilities. Remarks such as "It's a catering robot, not a robot for guiding patients" or "Doesn't it [the robot] understand anything?" (Wave 1) revealed disappointment or confusion about its function. Others responded more playfully or with emotional distance, "We're not going to upset it [the robot] [laughs]" and "It [the robot] looks at me with strange eyes" (Wave 1). Some also drew comparisons with earlier technologies, as in "It [the robot] reminds me of when they first introduced voice word processing. We had some absolutely incredible things written down, it didn't make any sense at all" (Wave 2). Such expressions reflect a mix of critique and humor, showing how unmet expectations often evoked both skepticism and familiarity with past technological shortcomings.

Seeking External Guidance

When conversational flow was disrupted or when uncertainties about the interaction emerged, several participants turned to the experimenter for clarification or support. Requests like "Come along please [to the experimenter]" (Wave 2) and "How can I find out what questions I can ask the robot?" (Wave 2) point to participants' desire for guidance on possible actions or system boundaries. This tendency was also evident in more basic queries, "Do I have to talk to it [the robot]?" and logistical questions, for example, "So now I can start again? Do I have to restart from zero or should I step out of the field and come back? [to the experimenter]" (Wave 2). These excerpts highlight not only a search for reassurance but also the need for clearer cues and support mechanisms within the human-robot interface, especially in scenarios where expectations and interaction rules may not be fully explicit.

Positive Reactions to Robot-Initiated Exchanges

Participants sometimes reacted with surprise or curiosity when the robot initiated the conversation. Exclamations such as "It's impressive! [the robot]" (Wave 2) or "Oh! It [the robot] talks to me first, just like a person!" (Wave 2) show an appreciation for its apparent autonomy and proactive engagement. This behavior was perceived as a sense of dynamism to the interaction. The realization that the robot could sustain the exchange on its own, "So if I don't say anything, it will keep asking me things?" (Wave 2), further stimulated engagement.

Discussion

Principal Findings

This study evaluated the integration of a SAR into the routine activities of a geriatric hospital unit through a 2-wave, real-world comparative design. In both waves, older adults interacted freely with the robot within its functional domains (eg, hospital orientation, entertainment, and appointment assistance), without scripted prompts, in order to preserve the spontaneity. Quantitative measures included system performance indicators (error types and rates), user engagement (verbal, physical, and emotional dimensions), interaction success, and subjective evaluations of acceptability and usability; these were complemented by a thematic analysis of postinteraction interviews focusing on perceptions of robot errors.

Results showed that the introduction of an LLM between waves was associated with marked improvements in conversational performance, including a substantial reduction in verbal errors, an increase in error-free interactions, and higher rates of task success. These gains in system reliability were mirrored by higher acceptability (AES) and usability (SUS) ratings in the second wave. Yet, these gains, concerning HRI and user experience, should not be viewed as solely the product of the LLM; aspects of the study design (eg, different samples) and contextual factors (eg, the kind of questions users asked the robot in each wave) may also have shaped the outcomes.

On another level, qualitative analysis showed that participants' spontaneous reactions to the robot were shaped by both system performance and their own expectations. Breakdowns often prompted humor, self-blame, or requests for clarification, while successful or unexpected robot-initiated exchanges could elicit surprise and positive engagement. These findings suggest that emotional and behavioral responses in SAR-older adult interactions are influenced as much by expectation management and novelty by technical reliability.

These observations are consistent with prior work on how humans perceive and respond to erroneous robots. Mirnig et al

XSL•FO
RenderX

[47] found that user reactions to robot errors are not exclusively negative but often include adaptive strategies such as humor, indulgence, or self-attribution of blame. Minor errors may even strengthen engagement by rendering the robot more "human-like," provided that such errors remain occasional and do not critically hinder task achievement. In line with this, several of our participants coped with breakdowns through irony or laughter, suggesting that, in geriatric care contexts, error management is not only a technical challenge but also a social and affective process shaping the overall interaction climate.

The following discussion interprets these findings in light of existing literature, examining how the observed changes in performance, engagement, and user perceptions contribute to current knowledge on SAR deployment in geriatric care and highlighting implications for future system design and implementation.

LLM Integration and Conversational Reliability

The results suggest that the integration of the LLM, introduced between wave 1 (without LLM) and wave 2 (with LLM), enhanced the SAR's ability to process diverse user input and produce contextually relevant responses. This improvement was evident not only in lower rates of comprehension failures and incoherent replies but also in greater interactional fluidity, characteristics essential for sustaining user engagement. The marked improvement in interaction success across waves (wave 1: 9/36, 25% vs wave 2: 70/94, 74.5%) further underscores the practical benefits of LLM integration for enabling communicative goals to be achieved without breakdowns. These gains align with the observed reductions in verbal errors and the higher proportion of error-free interactions, indicating that technical reliability is closely tied to the system's capacity to support smooth exchanges. In addition, successful interactions were associated with higher acceptability (AES) and usability (SUS) ratings, reinforcing prior evidence that perceived system competence is a key determinant of user satisfaction and trust in SARs.

Such outcomes align with initial evidence from other domains, including customer service [48], museum guidance [49], and the use of SARs for education [50,51], where LLMs have been reported to improve language comprehension, contextual adaptation, and response coherence [52]. Compared to rule-based or task-specific systems, systems equipped with LLM seem to offer more fluid, adaptive, and context-sensitive interactions [53,54], which is consistent with our findings, showing a significant improvement in interaction success and perceived acceptability and usability after LLM integration.

Recent work with older adults further demonstrates the potential of LLM-powered systems to support health and well-being in real-life care contexts. For example, conversational agents have been used in home environments to monitor safety risks, verify symptoms, and initiate alerts during emergencies [55]. Other studies have leveraged LLMs to collect richer health information with less provider effort [56] or to deliver cognitive stimulation through structured dialogue, resulting in improved task performance, social engagement, and high acceptance among older adults [57].

System and User Constraints in LLM-Enhanced Older Adult-Robot Interaction

However, LLM-based applications, whether implemented in clinical or everyday settings involving older adults, also reveal limitations that can arise from both the system and the use. On the system side, latency from cloud-based speech recognition and LLM processing, as observed in Lima et al [57], can interrupt conversational flow and disrupt turn-taking, sometimes being perceived as inattentiveness. These challenges are consistent with broader observations in spoken dialogue systems for robotics, where developers must balance trade-offs between accuracy and latency [58]. While cloud-based systems often deliver higher accuracy, they introduce delays that can break the rhythm of interaction; conversely, on-premises systems avoid latency but are typically less accurate and more limited in vocabulary. Furthermore, pretrained recognizers are usually optimized on datasets that differ from the spontaneous, fragmentary, and context-dependent speech, common in real-world robot use, making adaptation resource-intensive. In our study, similar conversational breakdowns occurred in verbal-related errors, such as incomplete, irrelevant, or incoherent responses, which interrupted the exchange and occasionally led to repeated, circular interactions. We believe this might be due to a combination of several factors. First, even if we adapted the speech recognition model with French data, our on-premises solution has its limitations in terms of accuracy and confuses some words. Second, even if the LLM solution operated on a partner's cloud with sufficient resources, it could not always provide accurate and appropriate answers, even when the speech recognition worked flawlessly. Third, the system used a half-duplex audio, listening to the user only when the system was not speaking, which reduced interaction fluidity. Finally, even if these limitations are mild individually, their combination could cause misinterpretation on the robot's side and generate user frustration, which did not ease the next steps of the interaction.

A further system-related limitation is that current LLMs are not specifically trained for interactions with older adults. As noted by Diaz et al [59] and Chu et al [60], speech and interaction data from older adults are scarce in artificial intelligence (AI) training corpora, and existing datasets often contain age-related biases. As a result, characteristic features of older adult communication, such as changes in prosody, vocabulary, conversational pacing, and the presence of hesitations or fragmented discourse in noisy environments, are underrepresented. This underrepresentation may reduce the ability of LLM-based systems to accurately interpret older adult speech, anticipate their communicative needs, and adapt to their interaction style in real-world settings.

From the user perspective, common age-related factors such as slower speech tempo, pauses, and fluctuations in volume can pose difficulties for speech recognition, particularly in the presence of cognitive decline [61]. Beyond these physiological and cognitive aspects, there is also an expectation gap in how older adults perceive conversational systems. Mahmood et al [62] describe how older adults often approach such technologies through the lens of human conversational norms, anticipating richer and more contextually adaptive exchanges than the system

XSL•FO
RenderX

can actually deliver. This tendency is reinforced, as noted by Mahmood et al [63] and Liu et al [64], by two recurring influences: (1) the way many voice interfaces are designed and promoted to mirror human conversational styles and (2) the inherent affordance of speech as an interaction modality, which can implicitly suggest that open-ended, human-like dialogue is possible when, in practice, the system's scope is more constrained and task-oriented.

These perceptions can be resistant to change, even with repeated exposure, and may lead to frustration when the robot's responses fall short of these implicit promises [65,66]. In our study, this was evident in qualitative data: some participants persisted in treating the robot as a human interlocutor, even after repeated conversational errors. For example, one participant humorously asked, "Does it [the robot] have blocked ears?" (Wave 1), while another, after receiving no reply, remarked, "Well, yes, but it [the robot] is not answering me" (Wave 1). Others attributed breakdowns to their own performance, asking, "Am I speaking loud enough [for the robot to understand]?" (Wave 1) or "Do I speak fast enough [for the robot to understand]?" (Wave 1). In some cases, repeated failures prompted disengagement or the need for external guidance, as illustrated by the query, "How can I find out what questions I can ask the robot?" (Wave 2).

User Engagement and Its Relationship With Interaction Outcomes

Verbal, physical, and emotional engagement scores in our study remained relatively stable between waves, with no statistically significant differences. Although wave 2 showed an improvement in interaction success, acceptability, and usability, these gains did not directly translate into measurable increases in engagement behaviors.

Emotional engagement showed a modest upward trend from wave 1 to wave 2, potentially reflecting more fluid exchanges with the LLM-enhanced system, but this change did not reach statistical significance. Because participants in the 2 waves were different individuals, the pattern is unlikely to reflect individual-level adaptation over time and may instead be related to situational factors or differences in interaction dynamics. It is also possible that more pronounced differences in engagement were not detected because the observed interactions were brief (approximately 52 seconds on average) or because the 5-point coding scale used to assess engagement may not have been sufficiently sensitive to capture subtle variations. Moreover, many of the analyzed exchanges were primarily functional in nature, where high levels of observable emotional engagement would not necessarily be expected, even successful interactions can occur with minimal emotional display (eg, "Where are the toilets?" (User), "At the end of the corridor, on your left" (Robot)).

Our findings also revealed strong correlations between emotional and physical engagement, indicating that when users are emotionally responsive, they also tend to be more physically or behaviorally expressive. However, unlike system performance indicators, these engagement dimensions were not directly associated with interaction success. For instance, participants sometimes laughed or joked at robot errors.

Interestingly, verbal engagement was negatively correlated with acceptability, echoing findings by Mahmood et al [63] that higher verbal activity in older adult-robot interactions can sometimes stem from the need to overcome conversational breakdowns rather than from enjoyment. In our context, this may indicate that some users spoke more in an attempt to repair misunderstandings, potentially lowering their subjective evaluations of the system.

Accessibility Challenges in Multimodal Robot-Older Adult Interaction

Across conversational HRI with SARs in geriatrics, particularly those powered by AI-based dialogue models, key accessibility concerns span model-training quality (representativeness and bias), user diversity and inclusion (cognitive, linguistic, sensory, and cultural variability), and interface ergonomics (voice or visual or physical modalities and interaction load).

First, studies highlight the underrepresentation of older adults in generative AI training databases, leading to persistent generational, ethnic, and cultural biases and limiting the recognition of nicknames, idioms, or nonstandard expressions in HRI [67-70].

Second, age-related changes in voice, such as reduced intelligibility, rhythm fluctuations, or speech disorders (dysarthria and aphasia), further complicate dialogue quality and voice processing [71,72]. Although targeted adaptation of acoustic models can reduce error rates, most recognition systems remain unable to accurately integrate the modulation and heterogeneity of vocal productions related to age and pathologies [73].

Third, in terms of interfaces, using the ARI tablet to display transcripts is a way of compensating for hearing or cognitive impairments, but literature on sensory impairment shows that true accessibility requires multimodal support (visual, tactile, and auditory). This includes optimized font size and contrast, pictograms, and gestural instructions for different levels of visual impairment [74-76].

Finally, the study did not assess the impact of specific pathologies (eg, aphasia and Parkinson disease) on speech recognition or multimodal adaptation. Future SAR development should rely on more diverse datasets, advanced multimodal calibration, and adaptive features (volume, articulation, and gesture sensitivity) to enhance inclusion and responsiveness in geriatric care.

Limitations of the Study

This study has several limitations. First, it was conducted in a single geriatric hospital unit, which limits the generalizability of the findings to other care contexts or to community-dwelling older adults. The relatively small sample size may have reduced the statistical power to detect certain associations, particularly regarding user characteristics. In addition, the 2-wave, cross-sectional design, where different participants were recruited for each wave, limits our ability to isolate the impact of the LLM from potential differences in participant profiles. Because the individuals differed between samples, variations in their characteristics may partly explain the observed

XSL•FO
RenderX

differences in HRI quality. A within-subjects design would allow a more precise assessment of the LLM's specific contribution to the outcomes.

Second, this study focused on stationary, face-to-face interactions and did not explore the effect of robot mobility (eg, autonomous navigation) or expressive gestures on user engagement. Prior research has shown that these dimensions can significantly enhance social presence and interactional involvement in SAR-older adult encounters, particularly in stimulating physical engagement and sustained attention [30].

Third, the analysis focused on short-term, functional interactions. It did not capture the relational and identity-based dimensions of conversation, which are especially meaningful for older adults. For many older adults, dialogue is not only just about obtaining information but also about sustaining social ties and sharing narratives of lived experiences. By overlooking these deeper aspects, our findings may underestimate key factors influencing long-term engagement with SARs. Future work should explore how LLM-enhanced dialogue systems can use biographical cues, narrative prompts, and adaptive strategies to better reflect the relational nature of older adults' communication.

Finally, the short interaction duration (52 seconds) provided only a snapshot of spontaneous use, limiting conclusions about long-term engagement and sustained acceptance. Longitudinal deployments are needed to capture how perceptions, trust, and interaction patterns evolve over extended use.

Recommendations for Future Development and Implementation of Conversational SARs Using LLMs

This study highlights the potential of conversational SARs powered by LLMs to substantially improve conversational reliability with older adults. Future development should build on these gains while addressing key limitations and contextual needs observed in our findings.

Adapt AI Architectures for Older Adult Use, Including Future Vision-Language Model and Vision-Language-Action Model Applications

Beyond LLMs, future conversational SARs are likely to incorporate vision-language models and vision-language-action models, enabling richer multimodal understanding and more context-aware behaviors. However, all such models should be specifically adapted for older adults, particularly those with cognitive impairment, whose speech patterns, vocabulary, cognitive processing, and sensory capabilities differ from the datasets typically used to train general-purpose systems. Responsible adaptation must comply with regulatory and ethical frameworks to ensure safe, equitable, and trustworthy use in care settings.

Address the Limited Prior Experience of Older Adults With Conversational SARs Through Structured Familiarization Periods

Many older adults, particularly those without prior exposure to conversational agents, may require time and guided support to understand the robot's capabilities, limitations, and "rules of engagement." Future implementations should include a facilitator-led familiarization phase, where older adults can safely explore functions, interaction styles, and question formats without performance pressure. This early stage can build confidence, reduce uncertainty, and lay the groundwork for more meaningful and sustained engagement once independent use begins.

Strengthen the Facilitator's Role During Familiarization

For both novice and older adults with cognitive impairment, a human facilitator can play a critical role in bridging early HRI challenges. This includes demonstrating effective input styles, explaining the robot's capabilities and limitations, and supporting older adults during breakdowns. Incorporating a structured familiarization period may accelerate learning, reduce frustration, and foster more positive first impressions.

Implement Adaptive Error-Handling Strategies

Conversational SARs should detect and repair interaction breakdowns early, such as prolonged silences, repeated input, or off-topic responses, by offering clarifying prompts, rephrased questions, or multimodal alternatives (eg, visual selection and touch inputs). This can maintain engagement and reduce the negative emotional impact of errors.

Enhance HRI Personalization Across Sensory, Cognitive, and Motivational Dimensions

Personalization should include tuning speech recognition thresholds, adjusting interaction pacing, adapting vocabulary complexity, and aligning content with individual preferences and abilities. For older adults with varying cognitive, sensory, and mobility profiles, this is critical for both accessibility and engagement.

Integrate Proactive and Context-Aware Conversational Strategies

Initiative-taking behaviors, such as relevant follow-up questions, personalized activity suggestions, and reference to prior interactions, can help sustain older adult interest. Care should be taken to ensure that such behaviors remain contextually appropriate and nonintrusive.

Evaluate Future Systems With Multidimensional Frameworks

Assessment should combine technical measures (eg, error rates and latency), behavioral indicators (eg, engagement scores and turn-taking dynamics), and experiential outcomes (eg, trust and perceived usefulness). Such an approach ensures that improvements target both system performance and user experience in real-world contexts.

Promote Secure and Transparent Deployment

Beyond technical performance, deploying LLM-enhanced SARs in geriatric care requires attention to ethics and practice. In our study, only consenting participants were recorded, and all data were pseudonymized and securely stored in compliance with the General Data Protection Regulation. While these measures reduce privacy risks, future use will demand strict safeguards and transparency on secondary data use. Caution is also needed against overtrust, as older adults may attribute undue authority

XSL•FO
RenderX

to robots. Clear system limits, caregiver oversight, staff training, and assessment of costs are vital to ensure safe, equitable, and sustainable integration in care.

Conclusions

In this real-world, 2-wave study in a geriatric hospital day care unit, integrating an LLM into a conversational SAR improved interaction success, conversation quality, and perceived system performance. Comparing a baseline dialogue system (wave 1) with an LLM-enhanced system (wave 2) showed that advanced AI can produce more coherent, contextually relevant exchanges. These improvements were reflected in higher acceptability and usability ratings from older adults. Conducting the study in a naturalistic care environment was key to capturing spontaneous interactions and real-world constraints, factors often absent in laboratory settings.

Our findings confirm the potential of LLMs to enhance HRI in care contexts. However, they also highlight the need to better understand how interaction success relates to engagement quality and to user sociodemographic characteristics. To maximize these benefits, future systems should be tuned to older adults' speech, cognitive, and sensory profiles. Strategies such as structured familiarization periods, adaptive error recovery, and personalized interactions could help maintain engagement over time. Aligning technical capabilities with the needs and preferences of older adults will be essential for making conversational SARs trusted and effective tools for geriatric care.

Acknowledgments

The authors would like to sincerely thank all the participants who took part in this study as well as all the health care professionals whose involvement contributed to the successful conduct of the Socially Pertinent Robots in Gerontological Healthcare project.

Funding

This research was funded by the EU H2020 program (grant 871245) [77].

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Abstract

Background: Needleless access devices are essential for intravenous therapy but can be a source of contamination and catheter-related bloodstream infections (CRBSIs) if not disinfected properly. The BD PosiFlush SafeScrub (Becton, Dickinson and Company) is designed to support aseptic nontouch technique (ANTT) by incorporating a built-in reminder to “scrub-the-hub” before flushing. This feature can help improve compliance with disinfection practices and may reduce the risk of microbial contamination.

Objective: This study aimed to evaluate compliance with scrubbing before flushing using the BD PosiFlush SafeScrub in a simulated clinical environment compared with standard disinfection and flushing practices (alcohol swabs and prefilled saline syringes).

Methods: A cross-sectional, within-subjects, simulated-use compliance study was conducted with health care professionals familiarized with BD PosiFlush SafeScrub (a prefilled BD PosiFlush Syringe with an integrated disinfecting unit). Compliance was defined according to the disinfection procedure specified for each scenario; participants were considered compliant with standard practice if they followed their own institutional policy (ranging from 5 to 30 seconds or based on stroke counts), while compliance with BD PosiFlush SafeScrub required scrubbing for at least 10 seconds with a minimum of 8 clockwise and 8 counterclockwise rotations, in accordance with the instructions for use (IFU). Compliance with disinfection was monitored and recorded for both the BD PosiFlush SafeScrub and standard disinfection and flushing practice.

Results: Compliance with catheter hub disinfection was assessed among 60 participants for BD PosiFlush SafeScrub and 57 participants for standard practice. During preaccess procedures (Flush 1), BD PosiFlush SafeScrub achieved 46% compliance versus 21% with standard practice, representing an absolute improvement of 25% and a 119% relative improvement (P<.001). During the postmedication procedure (Flush 2), compliance was 22% with BD PosiFlush SafeScrub compared with 13% for standard practice, corresponding to a 9% absolute improvement and 69% relative improvement, although not statistically significant (P=.12). Overall, the compliance rate was 34% (81/240 interactions) in the BD PosiFlush SafeScrub group compared with 17% (39/228 interactions) in the standard practice group, representing an absolute improvement of 17% and a relative improvement of 100% (P<.001).

Conclusions: The BD PosiFlush SafeScrub, with its integrated disinfection unit, yielded approximately double the scrub-the-hub compliance (34%) before flushing compared to the standard practice of alcohol pads and prefilled saline syringes (17%), supporting its role in facilitating adherence to ANTT, which may reduce microbial growth.

Introduction

Background

Vascular access devices (VADs) and needleless access devices (NADs) are essential tools in modern health care, enabling the administration of medications, fluids, and nutrition. NADs—such as needle-free connectors, Y-sites, and stopcocks—are connected to the VAD hub or extension set to support intermittent or continuous infusion. These devices help maintain a closed system, reducing the risk of needlestick injuries and contamination, and are now considered integral to infection control practices [1,2].

Due to their routine use, safe disinfection and flushing practices are critical. Among the most significant complications associated with these devices are catheter-related bloodstream infections (CRBSIs) and central-line-associated bloodstream infections (CLABSIs), which are known to increase patient mortality, hospital length of stay, and health care costs. Recent data show that CLABSIs are associated with a 3.5-fold increased risk of mortality and can extend hospital stays by up to 24.9 days, with associated costs reaching as high as US $90,000 per case [3]. To mitigate these risks, updated guidelines strongly emphasize adherence to standardized insertion bundles, education, and site care and maintenance practices, including the use of antimicrobial NADs and active or passive disinfection [1].

The 2024 revision to the Infusion Therapy Standards of Practice recommends the use of active or passive disinfection to "disinfect the connection surface and sides of the needleless connector attached to any VAD" [1]. In addition, the standard recommends performing active disinfection by vigorous mechanical scrubbing containing 70% isopropyl alcohol or alcohol-based chlorhexidine suitable for use with medical devices. Buetti et al [4], emphasized the importance of hub disinfection using alcohol-based antiseptics for 15 seconds, recommending the use of disinfection caps or active scrubbing techniques to further reduce contamination and biofilm formation. These practices form an essential part of evidence-based bundles aimed at the prevention of CLABSIs.

Despite efforts to educate health care providers and improve disinfection agents, studies indicated that compliance with active disinfection of access ports remains low. A systematic review by Moureau et al [5], found that approximately 50% of central VAD infections stem from bacterial colonization of NADs due to a lapse in aseptic technique and inadequate disinfection. Despite this known risk, adherence to NAD disinfection protocols remains suboptimal, with observed compliance rates as low as 10%. Various factors have been identified that contribute to this noncompliance, including a lack of standardized protocols, high workload and time constraints, forgetfulness, and limited availability of necessary supplies, such as alcohol wipes at the bedside.

Devices like the BD PosiFlush SafeScrub (Becton, Dickinson and Company), which integrates disinfection and flushing into a single-use syringe, offer workflow efficiency and improved adherence to aseptic techniques. These innovations aim to reduce contamination risk and enhance patient safety through simplified, standardized practices. This study sought to evaluate health care providers' compliance with scrubbing practices when using the BD PosiFlush SafeScrub versus standard methods (alcohol wipes and prefilled syringes) to determine its effectiveness in promoting aseptic vascular access.

Problem Statement

This study investigated whether the BD PosiFlush SafeScrub can improve compliance with disinfection practice, before flushing compared to standard practice, which may reduce microbial growth.

Methods

Study Design

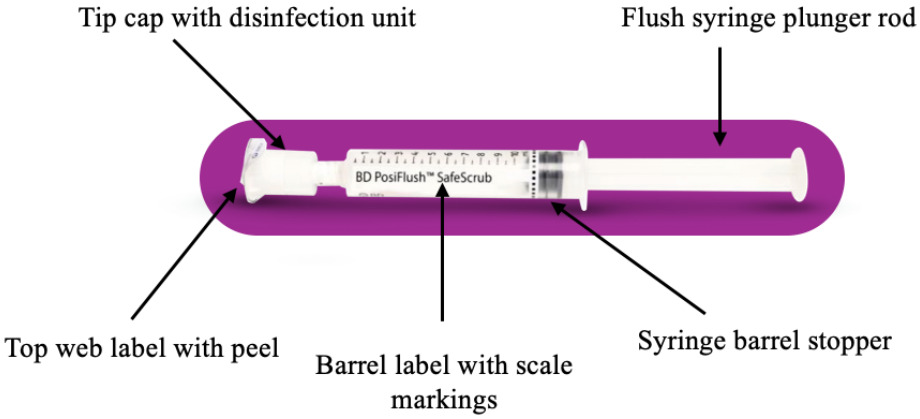
This cross-sectional, within-subjects, simulated-use compliance study aimed to evaluate compliance with disinfection protocols using the BD PosiFlush SafeScrub compared with BD PosiFlush prefilled saline syringes with alcohol swabs. "BD PosiFlush saline syringe with alcohol swabs" is hereafter referred to as the "standard practice." Sixty registered nurses from varied clinical specialties, including emergency department, intensive care unit (ICU), critical care unit, outpatient infusion, home health care, and medical-surgical units, were enrolled from acute care facilities. The recruitment and scheduling of participants for this simulation, survey-based study was done in a usability lab setting at Delve (Delve Research), a design consultancy and research services provider. The study was conducted in two geographical locations, Delve's Philadelphia office and Boston office, from June to July 2024.

Study Participants

All the study participants were healthy individuals. The registered nurses were from the emergency room, ICU, critical care unit, outpatient infusion center, home health care, and medical-surgical units. No participant had any hand injuries, latex sensitivity, or other conditions that might affect scrubbing behavior. The participants recruited for the study had prior experience with the care and maintenance of VADs and NADs.

Participants were recruited from acute care facilities with more than 50 beds. Inclusion criteria required participants to have experience with VADs and disinfection practices. Eligible individuals needed to be at least 18 years of age and proficient in understanding written and spoken English. Additionally, participants were required to have a minimum of 2 years of related nursing experience. They must not have participated in any usability studies related to flushing with prefilled syringes within 6 months of their participation in this study. This structured approach ensured that the study included a diverse and experienced group of health care professionals, providing a comprehensive evaluation of the BD PosiFlush SafeScrub in various clinical scenarios.

Materials



The materials used in this study included the BD PosiFlush SafeScrub Prefilled Saline Flush Syringe (Becton Dickinson and Co), standard alcohol swabs, and the BD PosiFlush Prefilled Flush Syringe (Becton Dickinson and Co). A mannequin was positioned in a simulated hospital bed or stretcher, with one

XSL•FO
RenderX

arm outfitted with a peripherally inserted central catheter (PICC; Becton Dickinson and Co) and the other with a peripheral intravenous catheter (PIVC; Becton Dickinson & Co). The study consisted of 60 simulated-use sessions, each lasting 60 minutes. Participants were observed through four simulated push medication scenarios, using both the standard practices and the BD PosiFlush SafeScrub. They were provided with all necessary materials typically found in a clinical setting, including gloves, alcohol swabs with 70% isopropyl alcohol, flush syringes filled with saline, prefilled simulated medication syringes (filled with colored saline), and other ancillary components. All participants were asked, before beginning the study, if the environment was similar to what they would see in their clinical areas of practice. This was done to ensure that the way they would respond to the scenario would be very close to what would occur in a real clinical setting.

The BD PosiFlush SafeScrub combines a prefilled saline syringe with an integrated disinfection cap, simplifying and streamlining the scrubbing and flushing workflow (Figure 1). It is a device designed to improve the disinfection process of NADs in vascular access systems. The dual-purpose design aims to simplify the disinfection process and improve compliance among health care providers with an all-in-one scrub and flush solution, ensuring consistent and effective disinfection before each flush. As a single-use product, it minimizes the risk of cross-contamination, making it a valuable tool in promoting aseptic nontouch technique (ANTT) in clinical settings [1]. By supporting consistent and effective disinfection, such devices play a vital role in reducing the contaminants that can cause bloodstream infections and enhance overall patient care.

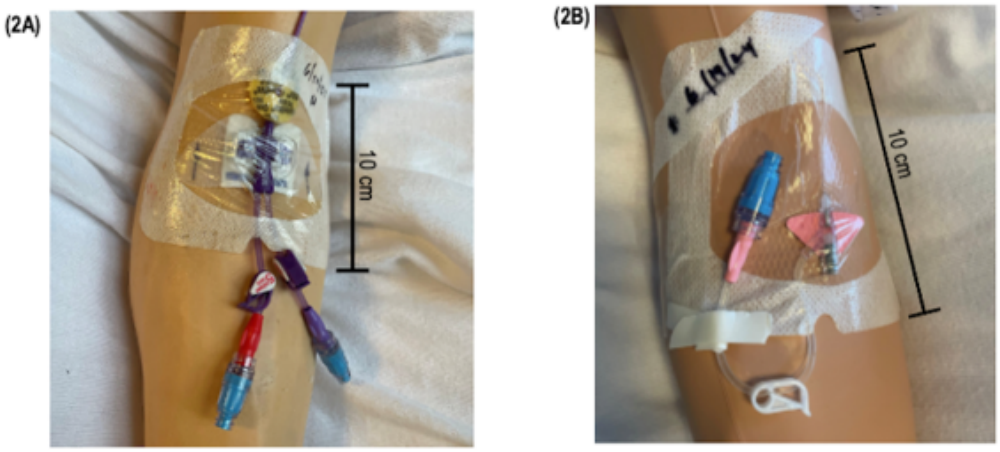
Figure 1. BD PosiFlush SafeScrub labeled image.

Study Protocol

Following consent and study enrollment, participants were informed that their hospital adopted a new catheter hub disinfection product. They were then asked, “What would you do?” Based upon their responses, participants either received the instructions for use (IFU) or were shown a demonstration video (along with the IFU), which were the only 2 training formats provided to ensure consistency. A total of 60 simulated-use sessions, each lasting approximately 60 minutes in duration, were conducted. They were instructed to follow aseptic technique throughout the medication administration process to minimize the potential for touch contamination. Each participant completed 4 simulated intravenous push medication scenarios, 2 using the standard practice and 2 using the BD PosiFlush SafeScrub. The order for using each syringe and scenario was randomized. The randomization determined both the sequence of device use (standard practice vs SafeScrub) and the catheter type (peripherally inserted central catheter [PICC] vs peripheral intravenous catheter [PIVC]) for each scenario. A 4-factorial forced randomization design was used. Participants were randomly assigned to one of the several pregenerated scenario sequences using a computer-based randomization algorithm. Each participant received their assigned sequence upon enrollment, ensuring a balanced distribution of scenario order and device type.

Each medication administration scenario included a flush before medication delivery and a flush postdelivery; however, the medication delivery step was solely for contextual purposes and not included in data analysis. The data were collected on compliance with scrubbing before flushing within the medication administration process. Throughout the study, the focus was on the scrubbing and flushing process, comparing the standard practice with that of the BD PosiFlush SafeScrub.

Three pilot studies were conducted to identify any potential issues and provide the most realistic setup and scenarios for the current study. The protocol, which was chosen after the pilot studies, included nonemergent clinical scenarios and no planned distractions for the participants. This protocol was then applied to the full data collection for all 60 participants.



These panels illustrate the simulated clinical environments developed for evaluating catheter hub disinfection practices. In each setup, the disinfection site (hub) is depicted to show the scrub-the-hub step performed before flushing. Incorporating both PICC and PIVC scenarios allowed the study design to reflect routine vascular access procedures and provided a standardized framework for assessing compliance with hub disinfection across intervention and control groups.

A study session was set up as follows, a mannequin was positioned in a simulated hospital bed or stretcher, with one arm outfitted with a PICC and the other with a PIVC. Both catheters were equipped with NADs. The arrangement and

XSL•FO
RenderX

location of the PICC line setup and the PIVC line setup on the mannequin are shown in Figure 2A and 2B, respectively. These images accurately represent a clinical PICC or PIVC setup, with both lines connected to a NAD. The NAD was not covered with a passive disinfecting cap, reflecting certain clinician practices that may not require scrubbing before accessing the NAD after a passive cap has been removed.

Figure 2. Simulated catheter set-ups demonstrating scrub-the-hub disinfection workflow. (A) Peripherally inserted central catheters. (B) Peripherally intravenous catheter.

The study protocol included several key steps outlined as follows:

- Flush 1: this was the intended scrub and flush before accessing the line for the medication delivery. It ensured that the line was free of occlusion before medication was delivered.
- Medication delivery: after Flush 1, the medication was administered. It is important to note that there was no compliance scoring for the scrubbing done immediately before this step.
- Flush 2: after the medication was delivered, there was a second scrub to disinfect the hub, followed by a flush step. This was intended to disinfect the hub before a final flush, which ensures no medication residue remains in the line.
- Compliance scoring: participants were evaluated based on their adherence to the protocols for Flush 1 and Flush 2. Absolute improvement in compliance was calculated as the difference in compliance rates between the BD PosiFlush SafeScrub group and the standard practice group, {(absolute improvement) = [(compliance of SafeScrub) – (compliance of standard practice)]}. Relative improvement in compliance was calculated as the absolute improvement expressed as a percentage of the standard practice compliance rate, {[relative improvement] = [(compliance SafeScrub) – (compliance standard) / (compliance standard)] times 100]}.

In summary, the protocol is designed to ensure proper disinfection or cleaning during the administration of flushing and medication administration via an intravenous line, with specific compliance measures for the disinfecting steps before and after the medication delivery. The study compared the standard practice with the BD PosiFlush SafeScrub.

Data Collection

Data collected during the simulation study included user demographics, current practices, and hospital policies on scrubbing and flushing. Specific metrics recorded were the frequency and duration of scrubbing before flushing for both the standard practice and BD PosiFlush SafeScrub, as well as the drying time allowed before accessing the NAD. For each location, a facilitator was in the room with the participant, and note takers and observers viewed from a separate room or remotely by way of streaming video or poststudy video review (Multimedia Appendix 1). Participants' overall impressions and reactions to each method were also collected. Data on compliance was collected through direct observation and video recording of the disinfection and flushing workflow process. For standard practice scenarios, participants were asked what their hospital policy was for scrubbing prior to flushing, and they were considered "compliant" if they followed their own individual hospital policy. Policies ranged from scrubbing 5-30 seconds, and some involved the number of times scrubbing back and forth rather than duration. For BD PosiFlush SafeScrub scenarios, participants were considered "compliant" if they scrubbed for at least 10 seconds, for a minimum of eight repetitions clockwise alternating with eight repetitions counterclockwise, in accordance with the IFU. The time was recorded using a stopwatch on a phone. We acknowledge that defining compliance according to the BD PosiFlush SafeScrub IFU (ie, ≥ 10-second scrub with at least eight clockwise and eight counterclockwise repetitions) while using institution-specific scrubbing policies for the standard practice arm introduces methodological asymmetry. However, this approach was intentionally chosen to preserve external validity and generalizability by reflecting the diverse, real-world practices of health care providers in different institutional contexts. In pragmatic study designs, such variation in comparator definitions is often embraced to capture how an intervention performs under routine operational conditions without artificially standardizing comparator practices [6,7].

Moreover, our goal was to assess whether the SafeScrub device promotes compliance beyond prevailing norms, rather than to apply a uniform compliance threshold across both conditions. By allowing participants to follow their own institutional standards in the comparator arm, we both minimized bias from

XSL•FO
RenderX

altering habitual workflows and maintained the relevance of our findings to everyday practice.

Thus, the differing compliance definitions enhance the external validity of our results and reinforce the practical utility of the BD PosiFlush SafeScrub device within diverse clinical settings.

Additional data collection methods included prestudy screener criteria, manual observations by note takers, video recordings and images for poststudy analysis, and reviews by data analysts to finalize results and uncover additional insights. After completing all 4 scenarios, participants were asked about their hospital policies and what they stated regarding scrubbing catheter hubs. After participants used the BD PosiFlush SafeScrub in the study, they were asked to complete a user acceptance survey, which was comprised of 15 questions. The survey incorporated both 1-5 and 0-10 Likert-type scales, intentionally selected based on the nature of the information being gathered. The 1-5 scale was used for most survey items to assess agreement with specific usability and compliance statements related to the device (eg, ease of use, learning curve, and reinforcement of guidelines). This scale is standard for capturing general attitudes and perceptions and satisfaction levels with sufficient sensitivity while minimizing respondent fatigue. The 0-10 scale was selectively applied to 2 questions that evaluated broader behavioral intentions–likelihood to recommend and inclination to use the device in clinical practice. These items benefit from greater granularity and are commonly used in health care research. The expanded range enables differentiation among high-positive responses (eg, 8 vs 10), which is important for assessing clinical acceptability and forecasting real-world implementation.

To aid interpretability and comparison across all survey items, responses were summarized using both average ratings (mean [SD]) and the percentage of respondents selecting a high response (defined as ≥4 for 1-5 scale items and ≥8 for 0-10 scale items).

Prior to enrollment, we conducted a priori power analysis based on the three pilot studies for a 2-tailed independent samples *t* test to determine the required sample size, targeting 80% power at α=.05 to detect a meaningful between-group effect.

Data Analysis

Data were analyzed using R version 4.3.0 (R Foundation for Statistical Computing). Descriptive statistics summarize the data, and inferential statistics, such as chi-square tests, were used to determine the significance of the differences observed. The results were considered significant for all analyses at a 5% level of significance (P<.05).

Ethical Considerations

No patient data were collected in this study, as patients were not included. In accordance with the ethical standards of the Declaration of Helsinki, written informed consent was obtained from all study participants before study initiation [8,9]. Participants were assured that all identifying information would remain confidential and would not be disclosed in any study-related publications. All data were deidentified before analysis to maintain participant anonymity.

Participants were informed of the potential risks associated with the procedure. Furthermore, the intervention involved a commercially available, marketed product containing substances already used in routine clinical practice, specifically isopropyl alcohol and 0.9% sodium chloride (normal saline). Although formal IRB approval was not required due to the nature of the simulation and the minimal risk posed to participants who were only exposed to the test device and preinserted catheters, this simulated use study was conducted in accordance with clinical and ethical best practices under the guidance of Delve (Delve Research).

Results

Study Participants

Sixty registered nurses participated in the study, representing a diverse clinical background and varying levels of professional experience. The demographics of the participants are shown in Table 1. All participants completed the simulation and provided complete demographic and clinical information. Participants were employed across multiple health care settings, including adult emergency departments (n=11), adult intensive care or critical care units (n=16), outpatient infusion centers (n=15), home health care (n=5), and medical-surgical units (n=13). The average overall clinical experience among participants was 15.87 years, with an average of 9.09 years of experience in their current primary department.

Table 1. Demographic and clinical background information of participants.

Participants number (N=60)	Variables
Primary department of occupation, n	
Adult emergency room nurse	11
Adult critical care nurse	16
Outpatient infusion center nurse	15
Home health care (HHC) nurse	5
Med-surg nurse	13
Overall years of experience (years), mean (SD)	15.87 (10.23)
Years of experience in the current primary department (years), mean (SD)	9.09 (7.17)

RenderX

Hospital Policy for Scrubbing Time

Participants reported a wide range of institutional policies related to catheter hub disinfection practices before flushing. Details on hospital policy counts and ranges are presented in Table 2. The most cited policy specified a scrubbing duration of 10 seconds, reported by 22 participants. A smaller number reported (n=9) scrubbing durations of 15 seconds, 15-30 seconds, and 20-30 seconds. One participant each reported scrubbing durations of 5-10 seconds, 5-15 seconds, or 25-30 seconds.

Variations in policy also included combined time and technique directives. Two participants noted a requirement of 10 scrubbing rotations, and one specified 10 rotations using 2 separate swabs. One participant reported different time-based policies for peripheral versus central lines (15 and 30 seconds, respectively), and another reported a general scrub for peripheral lines with a specified 15-second scrub for central lines. Three participants reported not knowing their hospital disinfection policy, with one stating that no disinfection policy was in place. A few participants (n=4) indicated policies in which only the initial flush required scrubbing, with no scrubbing required after medication administration.

Table 2. Reported hospital policies and ranges.

Reported hospital policy	Participants with hospital policy, n (%)
3-5 seconds first flush, no scrubbing second flush	1 (1.6)
5 seconds scrubbing time	1 (1.6)
10 seconds scrubbing time	22 (36.6)
15 seconds scrubbing time	9 (15)
15 seconds first flush, no scrubbing second flush	2 (3.3)
10 seconds first flush, no scrubbing second flush	1 (1.6)
30 seconds scrubbing time	6 (10)
5-10 seconds scrubbing time	1 (1.6)
5-15 seconds scrubbing time	1 (1.6)
10-15 seconds scrubbing time	2 (3.3)
15-30 seconds scrubbing time	2 (3.3)
25-30 seconds scrubbing time	1 (1.6)
20-30 seconds scrubbing time	2 (3.3)
10 rotations scrubbing time	2 (3.3)
10 rotations, 2 swabs	1 (1.6)
Peripheral just scrub, no time requirement Central 15 seconds	1 (1.6)
15 seconds peripheral, 30 seconds central	1 (1.6)
No requirement – as stated by the participant	1 (1.6)
Does not know – participants not familial with hospital policy	3 (5)

Compliance

Compliance with catheter hub disinfection protocols was assessed during both preaccess (Flush 1) and postmedication (Flush 2) procedures using either standard practices or the BD PosiFlush SafeScrub. For the BD PosiFlush SafeScrub scenarios, compliance was defined as scrubbing for ≥ 10 seconds with a minimum of 8 clockwise and 8 counterclockwise repetitions, as per the IFU. A total of 60 participants were evaluated in the SafeScrub group. In contrast, data from 57 participants were analyzed for standard practice due to incomplete hospital policy reporting from three individuals, rendering their standard practice compliance scoring invalid. Table 3 summarizes the compliance data for the participants using the standard practice and BD PosiFlush SafeScrub. Compliance was assessed across both the Flush 1 (preaccess) and Flush 2 (postmedication) procedures, and the total number of compliant interactions (overall compliance) was calculated for each method.

XSL•FO
RenderX

Table 3. Compliance data for the participants using the standard practice and BD PosiFlush SafeScrub.

Category	Standard practice (N=57)	BD PosiFlush SafeScrub (N=60)
Flush 1 (preaccess)		
PICC[a], n (%)	13 (23)	27 (45)
PIVC[b], n (%)	11 (19)	28 (47)

P value	—[c]	<.001

[a]PICC: peripherally inserted central catheter.

[b]PIVC: peripheral intravenous catheter.

[c]Not available.

Flush 1 (Preaccess)

The BD PosiFlush SafeScrub achieved a compliance rate of 46% (55/120), significantly higher than the 21% (24/114) observed with standard practice. This corresponds to an absolute improvement of 25% (*P*<.001) and a relative improvement of 119% in preaccess disinfection compliance when using the BD PosiFlush SafeScrub.

Flush 2 (Postmedication)

Post-medication compliance was also higher with BD PosiFlush SafeScrub, at 22% (26/120) interactions, compared to just 13% (15/114) interactions with the standard practice. This represents an absolute improvement of 9% and a relative improvement of 69%; however, the difference did not reach statistical significance (*P*=.12).

Overall Compliance

Across all interactions, the overall compliance rate was 34% (81/240) interactions in the BD PosiFlush SafeScrub group compared with 17% (39/228) interactions in the standard practice group, representing an absolute improvement of 17% and a relative improvement of 100% (*P* <.001).

An exploratory post-hoc analysis applying a 10-second threshold in participants using the standard practice and BD PosiFlush SafeScrub was also conducted. A 2-sample proportion test demonstrated a statistically significant difference between groups (*P*<.000) such that the BD PosiFlush SafeScrub group had a higher overall compliance when compared with the standard practice group.

Summary of Root Causes

Participants often thought that they followed the IFU for scrubbing the BD PosiFlush SafeScrub for at least 10 seconds, for a minimum of 8 repetitions clockwise alternating with 8 repetitions counterclockwise, and many noted that they were counting times back and forth rather than the seconds in their head. For BD PosiFlush SafeScrub and standard practice, most participants reported one of the following reasons for not following hospital policy or IFU.

- The participants believed that they were following their hospital policy.
- The participant reported that they knew they were in a study and that no actual patient would be at risk for infection if they did not scrub the entire required time (study artifact).
- The participant reported that clinicians generally do not follow the hospital policy for scrubbing.

User Acceptance Survey Results

The results of the user acceptance survey revealed consistently high levels of agreement with positive usability statements, indicating acceptance of the device within clinical practice. The user acceptance survey responses are summarized in Table 4.

XSL•FO
RenderX

Table 4. User acceptance survey results for the BD PosiFlush SafeScrub device.

Parameters	Agreement (respondents selecting ≥4 on 1-5 scale or ≥8 on 0-10 scale), %	Average rating, mean (SD)
SafeScrub Device (1-5 rating)		
Ease of use	96.6	4.6 (0.62)
Learning curve	96.6	4.7 (0.58)
Impact on patient safety	91.6	4.6 (0.64)
Compliance with best practices	88.3	4.4 (0.75)
Reinforcement of guidelines	96.6	4.7 (0.52)
Ease of compliance	93.3	4.6 (0.55)
Labeling and integration impact	85	4.5 (0.62)
Efficiency improvement	58.3	4.4 (0.83)
Frequency of distractions	86	3.1 (0.98)
Impact of distractions	85	4.1 (0.76)
Overall sentiment	91.6	4.4 (0.67)
Clinical acceptability/impact (0-10 rating)		
Inclination to use in practice	43.3 (≥8 on scale)	8.7 (1.93)
Likelihood to recommend	78.3 (≥8 on scale)	8.5 (1.75)

For ease of use and learning curve, a total of 96.6% of participants agreed that the BD PosiFlush SafeScrub device is easy to use, with an average rating of 4.6 on a 5-point scale. Similarly, 96.6% indicated that most clinicians would learn to use the device quickly, yielding an average learning curve rating of 4.7. These findings reflect minimal training burden and favorable ergonomics.

For the impact of safety and compliance regarding patient safety, 91.6% of respondents reported that the device contributed to reducing the risk of microbial growth and potential CRBSIs, with an average rating of 4.6. In terms of clinical compliance, 88.3% believed that the device improves adherence to evidence-based best practices—such as ANTT and “scrub-the-hub”—relative to their current practice, with a rating of 4.4. Furthermore, 96.6% reported that the device design reinforces compliance with “scrub-the-hub” guidelines (rating: 4.7), and 93.3% indicated that becoming compliant with its use would be easy (rating: 4.6).

Device labeling and integration features, including the peel tab and built-in disinfection unit, were positively received by 85% of participants, with an average rating of 4.5. A total of 58.3% of participants felt that the elimination of the need to search for alcohol wipes improved workflow efficiency (rating: 4.4), and 43.3% of participants indicated a high inclination to adopt the device in daily practice, with a mean rating of 8.7 on a 10-point scale. Upon further investigation, we observed that around 30% did not select a response, leading to a low inclination for adoption of the device. Notably, 86% of respondents acknowledged frequent distractions during catheter access tasks, and 85% agreed that such distractions may cause clinicians to rush the disinfection process, both rated at 4.1.

The overall sentiment toward the BD PosiFlush SafeScrub was favorable, with 91.6% of participants rating their experience 4 or above on a 5-point scale (mean 4.4, SD 0.67). Additionally, 78.3% expressed a high likelihood of recommending the device to colleagues, with a recommendation score of 8.5 out of 10.

These findings suggest that the BD PosiFlush SafeScrub is perceived as a user-friendly and effective tool that enhances compliance with infection prevention protocols and supports safer, more effective clinical workflows.

Discussion

Principal Findings

The purpose of this study was to evaluate compliance with scrubbing before flushing using the BD PosiFlush SafeScrub in a simulated clinical environment compared with standard disinfection and flushing practices (alcohol swabs and prefilled saline syringes). The results revealed that the BD PosiFlush SafeScrub, with its integrated disinfection unit, yielded approximately double the scrub-the-hub compliance (34%) before flushing compared to the standard practice of alcohol pads and prefilled saline syringes (17%). This improvement aligns with prior compliance-focused interventions. In adult acute care, Samanta et al [10] demonstrated that structured interventions, including daily audits, bedside teaching, and reinforced scrub-the-hub protocols, raised compliance rates for insertion checklists (83.3%), full barrier precautions (78.4%), and scrub-the-hub technique (65%), underscoring the value of both behavioral and system-based measures in high-risk environments [10]. A recent review reports that the Institute for Safe Medication Practices suggests that educational interventions are the easiest to implement, but they are the least effective approaches [11]. Further, the authors stated that the “‘forcing functions,’ which are safety design features that necessitate actions occurring in the same way each time, are the most e ective type of intervention, as they can eliminate the risk

XSL•FO
RenderX

of error (ie, a high leverage strategy based on system reliability), although they are more complex to introduce."

Bundle approaches have also been investigated to improve patient safety. Devrim et al [12], reported that implementation of a central line bundle—including split-septum devices, needleless connectors, and single-use prefilled flushing syringes—reduced CLABSI incidence in pediatric oncology patients by 59% with an estimated cost saving of approximately US $208,977 [12]. Similarly, Samanta et al [10], observed a 43% reduction in CLABSI rates in an adult polytrauma ICU, with 49 consecutive CLABSI-free days, reinforcing the link between compliance and infection prevention. In a neonatal ICU, another study demonstrated that routine scrubbing of catheter hubs reduced CLABSI incidence from 1.89 to 0.23 per 1000 central line days [13]. Collectively, these findings confirm that interventions ranging from bedside timing aids to institutional bundles and device-integrated solutions can deliver both clinical and economic benefits across diverse populations.

Compared with system-level programs that rely on continuous auditing and retraining, the BD PosiFlush SafeScrub offers a device-level behavioral nudge that integrates disinfection into the flushing step. By reducing reliance on memory, product availability, and accurate time estimation—factors vulnerable to erosion under workload stress—the device helps standardize practice in real-world, high-pressure environments such as emergency departments or ICUs. Its integrated design not only simplifies workflow but also encourages habit formation and consistent adherence, even when time is constrained.

These findings align with another study, which showed that implementing a universal disinfection cap program reduced CLABSI rates by over 40% with annual cost savings of US $282,840, reinforcing the association between disinfection compliance and economic benefits [14]. By embedding disinfection directly into practice, BD PosiFlush SafeScrub provides a low-barrier complement to larger institutional initiatives, helping to close the persistent gap between policy awareness and actual compliance.

According to the Infusion Nurses Society Infusion Therapy Standards of Practice (Ninth Edition, 2024), disinfection of the needleless connector is required before each access, including before flushing and locking after medication administration [1]. While this study found that the BD PosiFlush SafeScrub device improved preflush compliance substantially, the same effect was not observed following administration of medication (Flush 2 compliance). This endpoint was powered a priori to detect such differences, suggesting that improvements in post-medication scrub compliance may require interventions beyond device integration.

In addition, participant feedback further highlighted variability in adherence. Several participants believed they were following the BD PosiFlush SafeScrub IFU (at least 10 seconds with a minimum of 8 clockwise and eight counterclockwise repetitions) but admitted to counting motions rather than measuring time. In standard practice scenarios, deviations were often attributed to perceived protocol familiarity, low perceived risk during study participation, or inconsistent hospital policies ranging from 3 to 30 seconds. These observations emphasize the challenges of ensuring consistent adherence to disinfection protocols and reinforce the need for education, standardization, and behavioral support tools [11].

Impact Statement

This study demonstrated a clinically significant increase in disinfection compliance following the use of BD PosiFlush SafeScrub. Enhanced compliance with disinfection practices is critical for helping to reduce the microbial burden, which may lead to health care–associated infections, providing better health care, and lowering associated costs. By promoting a culture of accountability and standardizing device disinfection, this intervention could serve as a model for improving patient safety and quality of care in various health care settings.

Limitations of the Study

This study has several limitations. The simulated nature of the design, while valuable for the controlled exploration of device performance, cannot fully capture the complexities, time pressures, and interruptions present in real-world clinical environments across different health care settings. Simulated conditions may inadvertently inflate compliance rates due to factors such as the Hawthorne effect, simplification of tasks, scripted scenarios, and the absence of real patient risk, which could alter participant behavior. For instance, clinicians might demonstrate more meticulous disinfection in a simulation when no actual patient is in danger. These limitations affect ecological validity and underscore the need for further research to validate these findings under actual clinical conditions, where time pressures, competing priorities, and workflow disruptions are present.

In addition, the generalizability of results may be limited due to all participants being based in the United States. Further, not all aspects of compliance and disinfection were measured, leaving some critical elements unevaluated, and compliance improvement was only assessed over a limited time frame, preventing conclusions about long-term adherence. Another limitation is that the intervention group received structured training (via IFU or demonstration video), whereas the control group followed existing hospital procedures without equivalent refresher training. This methodological asymmetry introduces a confounding effect, as training alone can increase adherence regardless of device performance. Further studies should consider designs that isolate training effects, such as crossover trials or parallel group designs, to better determine device-specific impact.

Additionally, given the current health care environment, cost-conscious decision-making, and prevailing standard practices, we recognize that the unit cost of an alcohol swab and a prefilled flush may be lower than that of the study product, BD PosiFlush SafeScrub. However, the true value of the device lies in its ability to enhance compliance, as demonstrated in this study. Its integrated design serves as a visual and functional prompt for clinicians to scrub the access site prior to flushing, helping reduce the risk of introducing contaminants that could lead to CRBSIs. Further studies should therefore evaluate cost-effectiveness, implementation feasibility, and sustainability dimensions in real-world settings.

XSL•FO
RenderX

Finally, three pilot studies informed the main study design. Based on the clinician's feedback, the control group was evaluated against their own hospital policies rather than a ≥10-second threshold to preserve external validity by reflecting real-world practice. We acknowledge that this approach may introduce methodological asymmetry. To address this concern, we conducted an exploratory post hoc analysis applying a 10-second compliance threshold to both groups. This analysis demonstrated a statistically significant difference in favor of the intervention, indicating that the findings are robust regardless of the compliance definition applied.

Conclusions

The BD PosiFlush SafeScrub device approximately doubled the scrub-the-hub compliance before flushing compared to alcohol pads and prefilled saline syringes, simplifying workflow by embedding disinfection into the flushing step. Further real-world studies are needed to confirm cost-effectiveness and environmental impact across diverse health care settings.

Acknowledgments

We would like to acknowledge the staff at Delve for facilitation of the study, assisting with study design, collection of data, summarizing data, and data analysis. Corey Cook for obtaining quotes; securing funding, selecting a study partner; supporting the study protocol and methodology. Christophe Van Laethem for his supervision throughout clinical study. Sharath Kandhi for preparing the first draft of manuscript.

Funding

The funding of this study was provided by Becton Dickinson and Co (BD).

Authors' Contributions

KDB: writing – review & editing, conceptualization, data curation, funding acquisition, methodology, resources, supervision, validation. JS: writing – review & editing, conceptualization, data curation, funding acquisition, methodology, resources, supervision, validation. PS: writing – original draft, writing – review & editing, project administration, formal analysis, visualization. TJS: writing – review & editing, project administration, supervision, visualization.

Conflicts of Interest

The authors declare the following financial interest and personal relationships which may be considered as potential competing interests: KDB is an employee of and owns stocks in Becton, Dickinson and Company. JS reports that he is a committee member (alternate) of the AAMI standards group "HE - Human Factors Engineering Committee." He reports being an employee of and owns stock in Becton, Dickinson and Company. PS and TJS report that they are employees of Becton Dickinson. BD designed the study and interpreted the results. Delve independently conducted the study and statistical analysis of the data.

Abstract

Background: Despite the promise of digital therapeutics in providing scalable interventions for psychosis, translating them from clinical trials to routine care is challenging. SloMo is an evidence-based, digitally supported cognitive behavioral therapy for psychosis comprising a web-based therapy platform and mobile app. The therapy encourages individuals to slow down for a moment, to address fast-thinking habits fueling paranoia. SloMo has received a NICE Early Value Assessment recommendation for use in the National Health Service to address evidence gaps related to its use in the real world, and an implementation study is underway.

Objective: This study aimed to optimize the SloMo software for implementation by addressing limitations of the first release, reducing technology complexity, and improving user experience, to increase equitable outcomes.

Methods: An inclusive, human-centered design methodology was used to optimize SloMo. The redesign sought to reduce the technology's complexity and improve the user experience for diverse patients and therapists. The Double Diamond framework structured the iterative redesign, integrating insights from patient and public involvement consultants, therapists, and a transdisciplinary co-design team. The Double Diamond process was facilitated through 24 transdisciplinary workshops. These were supported by the following methods: identifying implementation barriers through desk research of SloMo's evidence and qualitative interviews with experts by experience (n=2); redefining user needs; iteratively developing solutions through user testing sessions with service user consultants (n=32); and validating the minimum viable product through think-aloud testing sessions with therapist (n=10) and service user (n=11) consultants.

Results: Users wanted a form of cognitive behavioral therapy for psychosis that was usable, trustworthy, enjoyable, personalized, normalizing, and memorable. The redesign, therefore, included a minimalist user interface, more diverse lived experience vignette content, enhanced agency over data, greater representation of protected characteristics and their intersectionality, and intuitive navigation. Feedback from a purposively sampled patient and therapist sample validated the redesign as it was associated with a strong user experience, particularly in relation to usability and usefulness.

Conclusions: The study produced a redesign of the SloMo software optimized for real-world use, whilst retaining fidelity to the therapeutic content of the previous version. Through an inclusive, human-centered approach, the optimized design of SloMo addresses barriers to adoption by reducing complexity and fostering accessibility. This study underscores the value of integrating lived experience involvement into digital therapeutics to support scalable, equitable, and sustainable mental health care solutions.

Introduction

Digital therapeutics present an opportunity for providing scalable, usable, and targeted evidence-based interventions for people with psychosis. Emerging evidence suggests digital technologies are acceptable and effective at addressing a range of treatment targets in this population [1,2]. With device ownership and levels of technology confidence on the increase, investment and interest in digital therapeutics for psychosis are growing. However, despite their promise, implementing digital therapeutics within real-world clinical settings following clinical trials is difficult, and a notable evidence-practice gap exists [3].

Successful implementation of digital technology in psychosis is multifactorial, with technology complexity being a particularly important barrier [4]. People from minoritized backgrounds are more likely to experience additional barriers to technology access and digital literacy, and if this is not given careful consideration, there is the risk that technology might inadvertently magnify health inequalities [5]. The National Health Service (NHS) Inclusive Digital Healthcare Framework [6] lists accessibility and ease of technology use as a key domain of digital inclusion. Inclusive, human-centered design (iHCD) is a method that seeks to ensure the design of a product aligns with the needs and capabilities of the people for whom it is intended [7]. iHCD uses ethnography to understand users and their contexts, with purposive recruitment to ensure representation across relevant user identities and characteristics (ie, gender, age, ethnicity, cognitive abilities, use of technology, and attitudes to therapy) and the inclusion of seldom-heard groups [8,9].

SloMo is a digitally supported psychological therapy targeting paranoia in psychosis. It was developed to address the limitations of conventional psychological therapies for psychosis; namely, issues in access, experience, and outcomes [10-12]. SloMo works by targeting fast thinking habits that fuel worries and supports people to slow down for a moment to find ways of feeling safer and living well. Specifically, SloMo adopts a causal-interventionist approach [13] to enhance belief flexibility (“slow thinking”) and build awareness of reasoning biases (“fast thinking”) that are characteristic of paranoia [14,15].

The technology comprises a web-based therapy platform that augments face-to-face individual therapy sessions. The platform offers interactive features such as animated psychoeducation videos, which encourage reflection, games promoting belief flexibility, and personalized content, including a psychological formulation, session summaries, and between-session task plans. Key content is synchronized with a mobile app that supports self-management in daily life. The mobile app supports users to notice worries and connect to alternative, safer thoughts through interactive features to promote slowing down, reminders of session content, and a record of between-session tasks. SloMo uses technology to support the visualization of thoughts and thinking habits. People can interact with their personalized SloMo thought bubbles, altering speed and size to reflect thinking habits and distress. SloMo tips support people to slow down and notice new information, helping to shrink fast-spinning gray, worry bubbles and grow colorful, slow-spinning helpful thoughts to promote well-being [16].

iHCD was used for the design of the first release of SloMo [16,17]. Ethnographic research insights indicated users with paranoia needed a form of cognitive behavioral therapy for psychosis (CBTp) that was usable, trustworthy, enjoyable, personalized, normalizing, and memorable, and the design solution was iteratively developed with them. The therapy design and usability of SloMo was validated by a comprehensive mixed methods approach [15,18-20]. Notably, although baseline technology use and confidence were lower in groups known to be disproportionately affected by the digital divide (Black people and older adults [21]), these baseline characteristics were not associated with differences in outcomes or user experience. This suggests the SloMo therapy design may bridge the “digital divide” and support accessibility, as intended.

In a multi-site randomized controlled trial (RCT) (N=362), SloMo demonstrated improved paranoia, self-concept, and well-being outcomes over 6 months compared with treatment as usual, with small to moderate effects [18]. SloMo received a NICE Early Value Assessment recommendation [22] for use in the NHS whilst real world data is collected to address identified evidence gaps, and accordingly is now being tested in a type II hybrid implementation-effectiveness study (ClinicalTrials.gov identifier: NCT06568081). McGinty et al [23] recommend that the evidence-practice gap be approached with a complexity science lens, including adaptation of the intervention to the implementation context. Consistent with this, we sought to optimize the SloMo therapy software for routine care prior to commencing our implementation-effectiveness study. The Non-adoption, Abandonment, Scale-up, Spread, Sustainability (NASSS) framework, an evidence-based implementation science framework for technologies, informed the work [24,25]. This mixed methods approach encourages the minimization of complexity in key domains (target problem, technology, adopters, organization, and broader system) to reduce the likelihood of nonadoption and abandonment, and increase the likelihood of scale-up, spread, and sustainability. The NASSS model has been used to plan and evaluate the implementation of SloMo and was chosen as it is an implementation science framework developed specifically for health care technologies. This paper reports on work focused on reducing complexity in the technology domain. Research to address other NASSS domains relevant to SloMo’s implementation will be reported separately. Intervention complexity has been identified as a key barrier to the implementation of digital technologies in psychosis and, therefore, warrants attention [4]. It is crucial we design digital technology to meet the needs of the end user, particularly in the

XSL•FO
RenderX

context of paranoia, where concerns about privacy and technology are often elevated [26].

In summary, the study aimed to optimize the SloMo software for implementation in routine care by addressing limitations of the first release, reducing technology complexity, and improving the user experience for service users and therapists, relative to the first version of the software. We anticipated that through iHCD methods, the likelihood of successful implementation would be enhanced. This will be evaluated further in an ongoing implementation-effectiveness study.

Methods

Design

Consistent with the design of the first version of SloMo [16,17] the Double Diamond [8], a human-centered design framework, was used to optimize SloMo for implementation, using inclusive design principles [9]. The Double Diamond is the most widely used co-design framework in the United Kingdom. This framework was selected because of its alignment with inclusive design principles and because it was used to develop the previous release of SloMo [16,17].

Ethical Considerations

This work was undertaken as a quality improvement project within South London and Maudsley NHS Foundation Trust and, according to institutional policy, did not require review or approval by a research ethics board. Participants provided verbal consent to participate in user-testing sessions and focus groups. Participation was voluntary, and all data were collected anonymously. No identifiable personal or health information was recorded, stored, or analyzed. The project was carried out in compliance with relevant ethical standards for quality improvement initiatives. Participants received gift vouchers for their contributions in line with National Institute for Health and Care Research payment rates [27].

Software

SloMo (release 1; R1) was self-certified as a class I medical device. We anticipate SloMo release 2 (R2) to be a Class I medical device under Rule 12 (All other active devices; MEDDEV Guideline 2.4/1 Rev 9), as the criteria for Rules 9, 10, and 11 for active devices are not met. The software was programmed by Bitam Ltd, which met ISO (International Organization for Standardization) 13485 and ISO14971 standards (ISO13485 is an international standard for medical device quality management systems; ISO14971 is an international standard for risk management of medical devices). The SloMo therapy platform architecture is compliant with ISO/IEC 27001:2022, 27001:201, ISO/IEC 27017:2015 and 27018:201.

Sample

To address the risk inherent in participatory design that the most willing, able, and vocal users are more likely to be involved, neglecting the needs of underserved groups, we purposively sampled people from a wide range of backgrounds (ie, across diverse gender, age, ethnicity, technology confidence, and attitudes to therapy). The group was representative of service users across the 3 NHS Trusts, with respect to ethnicity and age (Table 1). Confidence in using technology was self-reported by service user consultants at the start of testing sessions on a scale of “0” (not confident at all) to “100” (very confident). A wide range of technology confidence was self-reported, skewed towards people with higher levels. This is in line with recent literature indicating digital literacy is improving amongst people with psychosis [28].

Therapist patient and public involvement (PPI) consultants currently working with people with psychosis were purposively sampled in relation to gender, age, ethnicity, and experience of delivering psychological interventions for psychosis. Ten therapist PPI consultants participated in the deliver phase. The mean age was 34.9 years (range 26-54) and comprised 7 women and 3 men. One therapist identified as Bengali, 2 as Black British-African, 2 as Black British-Caribbean, 4 as White British, and 1 as White (other). Seven therapists were clinical psychologists or counseling psychologists, one was a high-intensity CBT therapist, two were trainee clinical psychologists, and one was an assistant psychologist. The mean technology confidence score was 86.2 out of 100 (range 70 to 100).

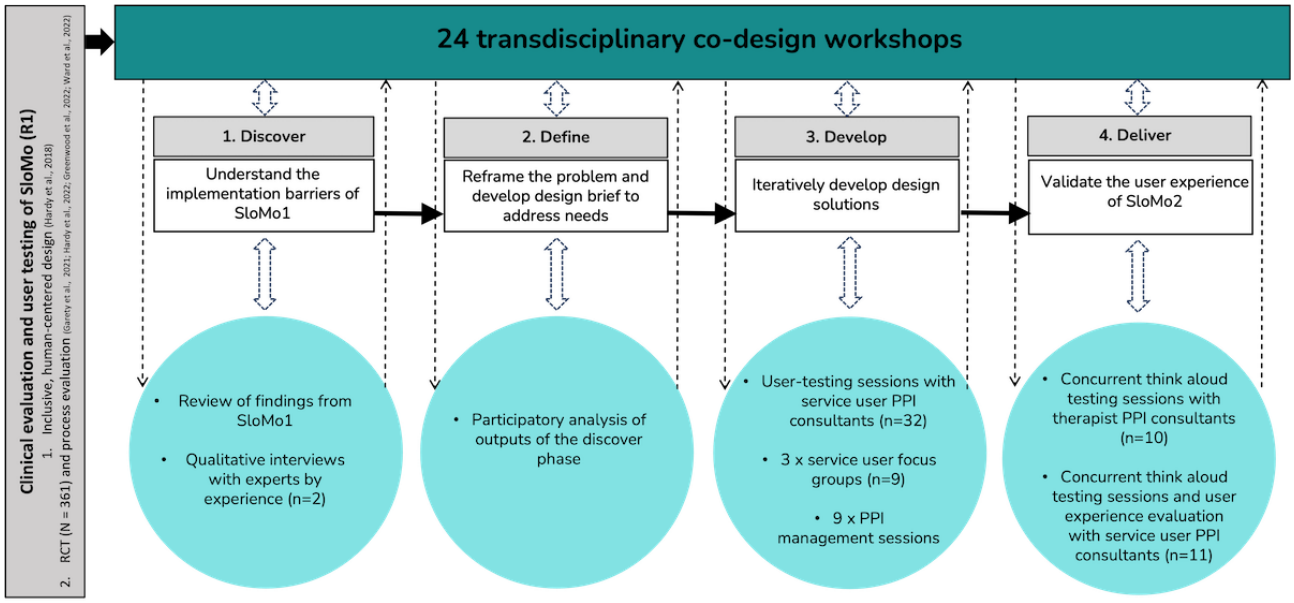
Table 1. Demographic characteristics of service user consultants for the develop and deliver phases (N=32).

Characteristics	Value
Gender, n (%)	
Man	18 (56.3)
Woman	13 (40.6)
Nonbinary	1 (3.1)
Age (years), n (%)	
18-25	1 (3.1)
26-35	12 (37.5)
36-45	5 (15.6)
46-60	11 (34.4)
60+	3 (9.4)
Ethnicity, n (%)	
Asian or Asian British	3 (9.4)
Black British, Caribbean or African	10 (31.3)
Mixed or multiple ethnic groups	3 (9.4)
White British	15 (46.9)
Any other White background	1 (3.1)
Technology confidence (0-100), mean (range)	82 (10-100)



Procedure

Transdisciplinary co-design workshops (referred to as "workshops" here forward) were central to the redesign of the new version of SloMo. Our project team included experts by experience (EBEs), designers, clinicians, academics, software developers, video producers, and illustrators (Multimedia Appendix 1 contains further details of the co-design team). Workshops were initially held in person (to support group cohesion), then switched to remote (to facilitate engagement of people from geographically diverse locations). Attendees were informed of the workshop's focus in advance of the meeting, which was prespecified according to the phase of development. Sessions were recorded so that the discussion could be reviewed, and members who were unable to attend could review and offer feedback via email. A PPI management team oversaw the project.

The Double Diamond is organized into 4 convergent and divergent phases: discover (understand the problem; divergent), define (reframe the problem and develop a design brief; convergent), develop (develop potential solutions; divergent), and deliver (test out solutions at a small scale and iterate; convergent). It should be noted that divergent phases were necessarily constrained by the previous version of SloMo and its clinical evaluation, and so we adopted a "waterfall-agile" approach [16]. Figure 1 provides an overview of the Double Diamond phases used to optimize SloMo for implementation, which are explained in more detail below.

XSL•FO
RenderX

Figure 1. Optimizing SloMo for implementation—design research methods used across the 4 phases of the Double Diamond framework. PPI: patient and public involvement.

Discover

The aim of the discover phase was to develop an understanding of possible implementation barriers for the SloMo software. This first involved reviewing the outputs of the SloMo RCT [15,18-20] in the transdisciplinary co-design workshops, to explore key technology problem areas that could potentially be targeted for the next release of SloMo. In addition, the designers conducted qualitative interviews with 2 EBEs who had received the first release of SloMo. Interviews focused on exploring what was required from a psychological therapy for psychosis, building on insights from Hardy et al [17], as well as exploring how SloMo could be improved.

Define

The define phase synthesized the insights gathered in the transdisciplinary workshops. The EBEs who provided feedback during the discover phase also took part in the next round of workshops to assist in synthesis. The information from the discover phase was sent to co-design group members to review ahead of time to allow for the opportunity to familiarize and reflect on the materials. Workshops involved reviewing the insights as a group, noting patterns, and sorting into themes, using a group consensus approach. Multiple workshops were run until a clear and workable design brief was developed, in line with identified user needs.

Develop

The develop phase aimed to generate potential design solutions that helped to address the redefined user needs outlined in the preceding phase. Guided by clinician and EBE recommendations, the designers initially explored content relevant to SloMo (ie, existing apps available on the market, including for mental health, as well as apps in parallel markets, such as meditation, nutrition, and habit-building). The designers fed back their design solutions in co-design workshops, and group consensus determined which ideas were taken forward for iterative development.

Low-fidelity digital prototypes of initial design concepts were developed (Multimedia Appendix 2). Preferred concepts, selected through workshops, were taken for one-to-one user testing with service user PPI consultants. Data from the user testing sessions informed the iterative development of design solutions, leading to the development of higher fidelity digital prototypes of adopted concepts. Prototypes were further iteratively tested and developed through one-to-one service user testing, focus groups with service user and clinician consultants, and workshops. Once a prototype had been validated, it was added to the optimized SloMo minimum viable product (MVP) software, which was taken forward to the deliver phase.

Deliver

The convergent deliver phase aimed to validate the user experience of the optimized version of SloMo. Given the redesign of SloMo focused on 2 software components (a web-based therapy platform and native mobile app), the deliver phase aimed to validate both through consultation with the applicable user groups. For the web-based therapy platform, therapist PPI consultants were chosen as this would be used by therapists to augment the face-to-face therapy sessions they deliver. Service user PPI consultants were chosen for mobile app feedback, as they were the main intended users of the app.

Concurrent think aloud testing sessions were carried out with therapist PPI consultants. This is a form of usability testing where participants are asked to verbalize their thoughts in real time as they interact with a user interface (UI; ie, modules on the SloMo web-based therapy platform) [29]. Following this, additional unstructured qualitative feedback was gathered. A similar approach was taken for the mobile app. Service user PPI consultants who were involved in the develop phase took part in think-aloud testing sessions. Service users were asked to complete different core functionalities on the app (eg, adding

XSL•FO
RenderX

a new worry, slowing down a worry, viewing session summary cards) whilst thinking aloud. Interactions were observed, and qualitative feedback was elicited. Following this, a user experience survey (UES) [19] was completed. This is a 10-item questionnaire (adapted from Lobban et al [30]) with subscales relating to enjoyment, usability, and usefulness. Each item is rated from 0 to 10 and summed for the subscale total scores, which were calculated as percentages, with higher percentages indicating a more positive experience. Following user experience validation, an MVP of SloMo, optimized for implementation, was finalized for release to Apple and Android app stores for piloting clinical use.

Results

SloMo Redesign Outputs

The key insights and outputs from each phase of the Double Diamond are presented in Table 2 and expanded on below. Additional details on participants, methods, and outputs can be found in Multimedia Appendix 3 [15,17-20].

XSL•FO
RenderX

Table 2. Summary of SloMo redesign using the double diamond framework.

SloMo (R1) RCT[a] original design solution	Discover: implementation barriers to design solution from SloMo (R1)	Define: design solutions for SloMo (R2) implementation	Develop and deliver: SloMo design outputs
Usable	Poorer usability in men compared with women [15]	UI[b] that is sufficiently visually appealing	• Minimalist redesign of UI • Character aesthetics made more realistic
Usable	Lower adherence with less tech confidence [15]	App navigation should feel intuitive	• App home screen limited to key functions • Embedded onboarding guidance
Usable	Participants disliked carrying 2 phones [20]	Convenient access to mobile app	• App availability through Android and iOS app stored
Usable	Therapists struggled pacing sessions[c]	Feedback available on session progress	• Session progress bar • Burger menu to support navigation
Usable	Difficulty generating goals and safer thoughts[c]	To feel supported in generating content	• Co-produced "community" goals and safer thoughts
Trustworthy	Lack of clarity on data transfer[c]	Greater agency over data sharing	• Notifications to accept/reject sharing content • Ability to select specific content to share/not share • "Lock thoughts" function to keep entries private
Enjoyable	Worries on home screen increased distress[c]	To feel supported when opening app	• Home screen displays safer thoughts as default • Active navigation required to view worries
Personalized	In session progress too slow for some [15,20]	Therapist to tailor sessions to person	• Burger menu to tailor navigation • Optional in session and between-session tasks
Personalized	Lack of diverse content in vignettes [20]	Manage more paranoia related worries	• Co-design of novel vignettes
Normalizing	Negative connotations of "slow" in SlowMo[c]	For SloMo to feel like a positive experience	• Therapy name updated to "SloMo"
Normalizing	Lack of intersectional diversity in videos[c]	To feel represented and normalized	• Videos conveying a range of protected characteristics • Customizable avatar representing the SloMo user
Memorable	Users wanted memory aides post-therapy[c]	SloMo journey to continue after completion	• Function to print a "therapy blueprint" • Catch-up screen at start of each session • Increased repetition of key learning messages

[a]RCT: randomized controlled trial.

[b]UI: user interface.

[c]Barrier identified by patient and public involvement (PPI) consultants in transdisciplinary co-design workshops.

Discover

Key implementation barriers in the technology domain for the first software version were identified through review of the SloMo RCT outputs and interviews with EBEs. This included reporting of poorer software usability by men and people with lower levels of technology confidence. In addition, qualitative data revealed service users disliked carrying 2 mobile handsets (the first release of SloMo was only available on a study handset). Therapists reported difficulties in pacing the sessions, as there were no signifiers indicating how much session content remained, which aligned with service user feedback indicating progress was at times too slow. Therapists and service users reported finding the content of psychoeducational vignettes

XSL•FO
RenderX

limited and instead used SloMo for a greater range of paranoia-related worries than was covered in the software. Other barriers included a lack of clarity around when data was being transferred between devices (ie, the web-based therapy platform and mobile app), an overemphasis on worries instead of safety on the app home screen, difficulties in generating personalized goals and safer thoughts, a lack of diversity across psychoeducational vignettes, and forgetting content covered in therapy sessions once these had ended. Outputs at the end of the discover phase included a list of technology-related implementation barriers. These barriers were reviewed during transdisciplinary workshops and taken forward to the define phase.

Define

The define phase reaffirmed the importance of SloMo's design brief of users needing a form of CBTp that was usable, trustworthy, enjoyable, personalized, normalizing, and memorable [17]. The problems identified during the discover phase were mapped onto these domains, indicating these were areas that could be targeted in the next iteration to further deliver on this design brief and enhance user experience.

The issues outlined in the discover phase were reframed as user needs through co-design workshops. Service users needed a visually appealing UI, an intuitive mobile app navigation, and convenient access to support usability. To foster a sense of trust, service users required greater agency over data sharing to and from the web-based therapy platform and mobile app. Service users needed to feel psychologically supported when opening the mobile app, for SloMo to feel like a positive experience, and to feel represented throughout. There was a need for learning ways of managing a wider range of paranoia-related worries, and for the SloMo journey to continue once face-to-face sessions had ceased. For therapists, it was important that they were provided feedback on session progress so they could pace sessions efficiently. There was a need for therapists to be able to use the web-based therapy platform flexibly, allowing them to tailor sessions to the client. The outputs at the end of the define phase included a design brief of the solution, which specified the user needs to be addressed in relation to the original design definition, which informed the subsequent development phase.

Develop

Thirty-two 1:1 service user testing sessions and 3 service user focus groups (n=9) were carried out. Initial user testing focused on design concepts, and later stages focused on interactive digital prototypes. Initial design concepts taken to 1:1 user testing sessions included (1) aesthetics of bubbles used to convey worry and safer thoughts, (2) design of the avatar representing the SloMo user on their journey, (3) SloMo character illustrations, and (4) aesthetics of physical tip cards used as a memory aid. Other concepts (eg, lived experience vignettes, UI changes, data transfer updates) were iteratively developed in co-design workshops. Multimedia Appendix 4 displays the updated concepts for the new version of SloMo compared with the previous one used in the RCT.

High-fidelity interactive digital prototypes developed and taken out for individual user testing included (1) user interactions with thought bubbles, (2) user interactions for building a customizable avatar, (3) character illustrations featured in audio-visual psychoeducational vignettes, and (4) the content of newly developed psychoeducational vignettes. User testing feedback in both the concept and prototype development phases was discussed in co-design workshops and iteratively developed until there was a group consensus that the prototype should be adopted. Figures 2 to 4 provide an overview of the development of specific SloMo features from the discover to deliver phase. Multimedia Appendix 5 provides additional data collected during the develop phase.

Outputs at the end of the develop phase included iteratively developed digital design solutions addressing the user needs and design brief from the define phase. In addition, early-stage demonstration and interaction testing of design solutions with user testing consultants provided preliminary validation of specific design solutions. These were then developed into the SloMo (R2) MVP during the deliver phase.

XSL•FO
RenderX

Figure 2. Development of SloMo characters featuring in psychoeducational vignettes. PPI: patient and public involvement.

Discover

- Lack of intersectional diversity in characters featuring in psychoeducational vignettes.

Define

- Service users need to feel represented across a range of protected characteristics.

Develop

- Low fidelity prototypes using different illustrations developed: semiabstract (A) and semirealistic, reflecting different sociodemographic realities.

A B

- User testing indicated preference was divided. Qualitative feedback indicated a majority would have opted for B If diversity in skin tones was shown.
- Co-design workshops determined subsequent user testing should focus on different shading styles:

A B C

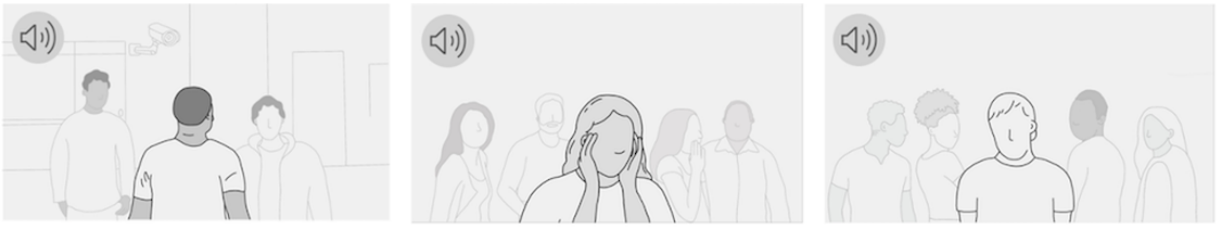
- There was a majority preference for C, with qualitative feedback indicating that this style promoted a normalising message, that these types of difficulties can impact anyone.
- High fidelity digital prototypes of our three SloMo characters were taken for user testing:

- Prototype testing indicated that the visual representation of the three characters worked well for a purposively sampled group of PPI consultants.
- Characters were added and taken forward to the deliver phase.

XSL•FO
RenderX

Figure 3. Co-designing psychoeducational vignettes on anomalous experiences and paranoia. EBE: experts by experience; MVP: minimum viable product; PPI: patient and public involvement.

Discover



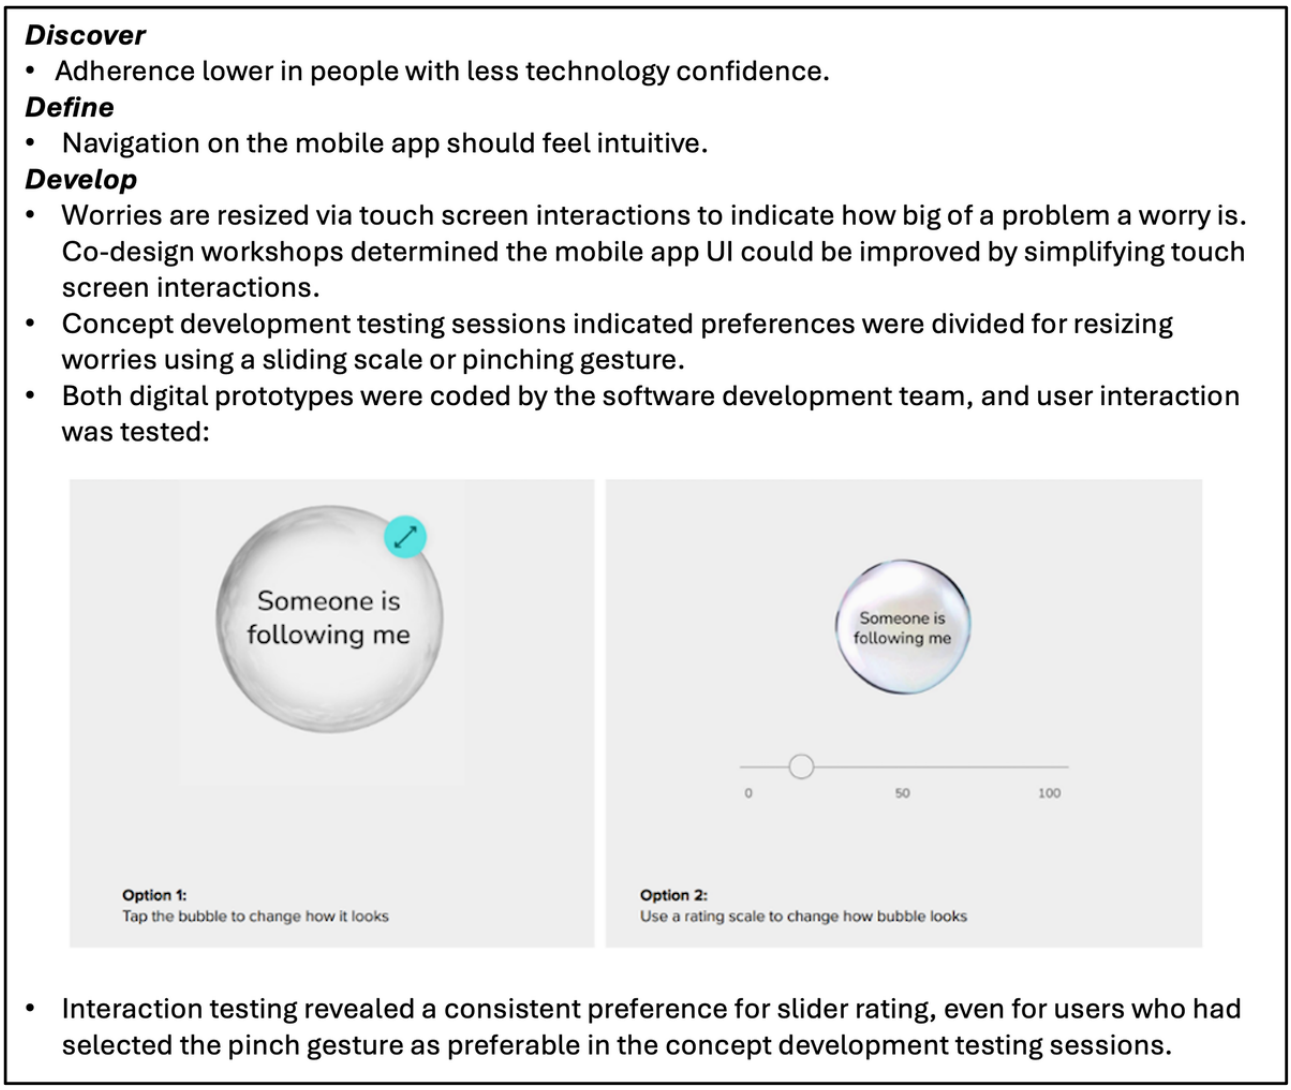
- Participants wanted more psychoeducational vignettes.

Define

- Learn ways of managing a wider range of paranoia-related worries.

Develop

- Audio recordings of initial vignettes developed in co-design workshops were taken for user testing feedback.



- Feedback indicated vignettes were interesting, understandable, and relatable.
- Some feedback suggested wording changes should be made to increase authenticity.
- During testing of audio recordings, several users commented that the module title (which was initially ”unusual experiences”) felt stigmatising. This was fed back in co-design workshops, where an EBE suggested “when the worlds doesn’t feel right”.
- This was taken for further user testing. Nine out of nine PPI consultants preferred this title.
- High fidelity audio-visual prototypes of vignettes adapted from previous feedback were taken out for further rounds of user testing.

- Feedback was sought on story content, illustrations, and narrators.
- The vignettes were well received and added to the optimised SloMo MVP.

RenderX

Figure 4. Bubble interactions on the mobile app to indicate levels of distress.

Deliver

Table 3 presents quotes from the therapist PPI consultants during the think-aloud testing sessions. Overall, the web-based therapy platform received positive feedback. Therapists appreciated the platform's simplicity and visual appeal, believing it would enhance the enjoyment and engagement of sessions. They noted therapeutic benefits, such as providing more structure to sessions and making therapy feel more personalized. Additionally, therapists found the platform engaging and flexible, allowing for adaptation based on various therapeutic needs. The addition of progress bars was positively commented on as a helpful feature for therapists to manage the session time more effectively.

During the think-aloud sessions, several areas for improvement were identified. Some therapists expressed hesitation about navigating back and forth due to concerns that personalized content entered into the platform might be lost. Others suggested that enjoyment could be further enhanced by incorporating more gamification elements, such as badges or achievements, to boost engagement. Additionally, there were recommendations to increase inclusivity by adding different languages, enabling access for users whose first language is not English.

Eleven service user PPI consultants who had previously taken part in user testing feedback sessions in the development develop phase took part in the concurrent think-aloud testing sessions for the deliver phase. Think-aloud consultants were purposively sampled to be representative of the psychosis population across the respective areas of the 3 trusts. The sample included 7 women and 4 men, whose ages ranged from 25 to 60 years, and 4 consultants identified as Black British, 1 as South American, and the remaining 6 as White British.

The UES findings for each subscale are presented in Table 4. The ratings suggest a good user experience of the SloMo demonstration, with a total UES mean of 83.4%. Notably, the mean score for enjoyment was around 10% lower than the domains of usability and usefulness, as well as showing a greater range of scores. This suggested that improved enjoyment may be an area requiring further development.

Table 5 displays qualitative feedback captured during think-aloud user testing sessions with service user PPI consultants. The feedback aligned with the UES ratings, indicating areas across the 3 domains of user experience that were well received. Interestingly, there were suggestions around how enjoyment could be enhanced, possibly providing insight into lower UES scores for this domain. For instance, haptic

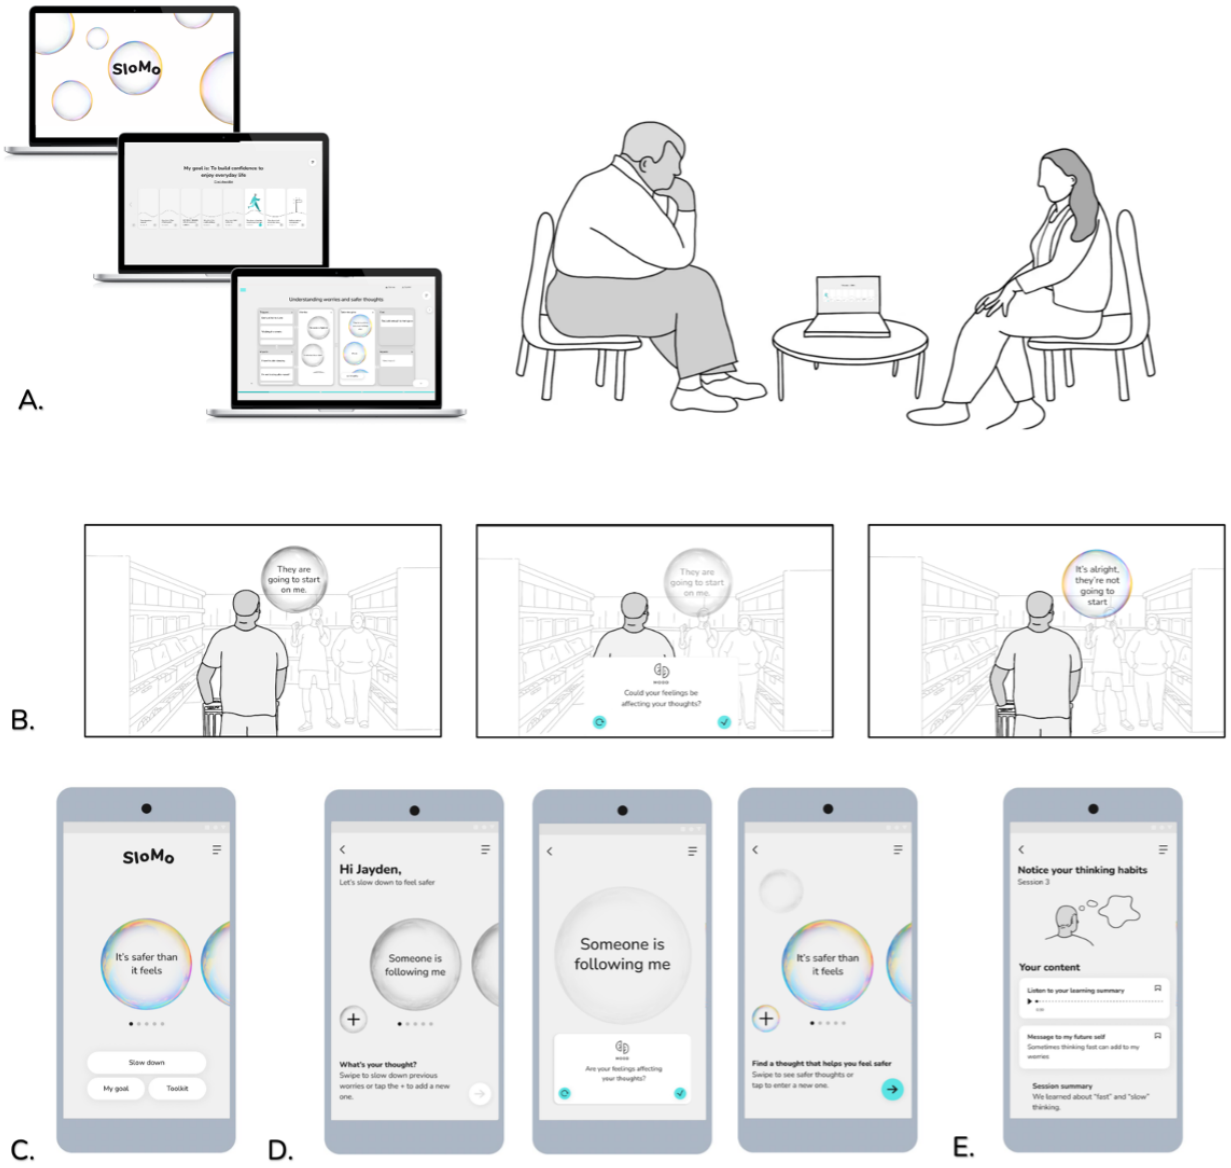
XSL•FO
RenderX

feedback was seen as a feature that could boost enjoyment, and improving touch screen interactions could further enhance usability. Outputs at the end of the develop phase included an MVP of SloMo (R2) that had received early-stage user experience validation from service users and therapist consultants. The user experience of the software will be further evaluated in an ongoing implementation-effectiveness study. Figure 5 [16,31] illustrates the prototype delivered from the develop phase.

Table 3. Quotes from the therapist consultants (n=10) during think-aloud testing.

Theme	Quote
Enjoyment	• I like the visuals… It is attractive to use • The gamified elements make it more enjoyable • This is definitely more enjoyable and accessible than conventional CBT for psychosis
Usability	• I like how simple it is… It's a nice scaffolding tool • I like the bar along the bottom to help with time management • I feel more confident to be flexible given my experience level... I worry that low intensity therapists would struggle to deliver in a flexible manner
Usefulness	• The structure scaffolds good CBT… you can be more focused on the person in the room • The formulation feels personalized • It gives such a clear focus for both therapists and client • I think it makes [the therapy process] less intense for people who struggle with conversations for an hour

Table 4. User experience survey (UES) ratings of SloMo from service user consultants (n=11).



UES variable	Values
Enjoyment	
Mean % (SD)	76.1 (17.3)
Range	47.5-100.0
Usability	
Mean % (SD)	85.8 (8.5)
Range	72.5-100.0
Usefulness	
Mean % (SD)	87.0 (8.5)
Range	67.5-100.0
Total UES	
Mean % (SD)	83.4 (9.7)
Range	69.2-95.8

Table 5. Quotes from service user consultants (n=11) during think aloud testing sessions.

Theme	Quote
Enjoyment	• I really liked the safer thoughts and the colours on the positive safer thoughts • Using haptics would be good… adds another layer • The swiping [screen interaction] is difficult in places. I would find this frustrating
Usability	• Ease of access is the biggest positive • It's not difficult to add worries and sometimes people are afraid of technology, but I think it's not difficult to use this app • I feel like I can navigate around it and haven't spent much time on in… It's pretty intuitive
Usefulness/Acceptability	• I like you don't need to share all of your thoughts with the therapist …sometimes you don't want to show your thoughts to other people • I like that it's really personalised, I can't count the amount of times that I have been given something that has not been in my own words in therapy

XSL•FO
RenderX

Figure 5. SloMo sessions with a therapist (in person or online) are supported by a (A) web-based therapy platform which promotes (B) understanding and managing worries through lived experience stories and interactive tasks. Personalized thought bubbles are visualized and synchronized with the (C) SloMo mobile app, (D) then "slowed down" to find ways of feeling safer. Additional mobile app features can be accessed via a toolkit, which includes (E) personalized learning summaries of therapy sessions (reproduced from Hardy et al [16], which is published under Creative Commons Attribution 4.0 International License [31]).

Discussion

Principal Results

This study optimized the SloMo therapy software for implementation in routine NHS care, through reducing technology complexity and boosting user experience [24,25]. An iHCD was used, involving transdisciplinary co-design workshops, focus groups, one-to-one user testing, and think-aloud testing sessions. From this research, we have produced an optimized MVP of SloMo, which is now being tested in the SloMo2 hybrid implementation-effectiveness study (ClinicalTrials.gov identifier: NCT06568081). User testing indicated that users need a form of CBTp that is usable, trustworthy, enjoyable, personalized, normalizing, and memorable, in line with earlier work from our team [17]. Design targets for improving the SloMo software were identified to deliver this design brief and address user needs. For reducing complexity, key targets included simplified app interfaces to highlight core functionalities, improved navigation, and, for boosting user experience, this included providing users with greater agency over data, and improving the representation of protected characteristics, including their intersectionality. The user experience of this optimized version of SloMo may be improved relative to the first version that was tested in the SloMo RCT, indicated by higher UES scores compared with those reported by Hardy et al [19].

A distinctive aspect of our product development approach is the integration of lived experience involvement in all stages of the design work. Traditional approaches to intervention development in clinical research often follow a convergent design process using existing theory and evidence to determine intervention content and structure. This approach can miss novel

XSL•FO
RenderX

opportunities to improve the user experience of therapies. In contrast, we adopted a "waterfall-agile" approach to facilitate the co-design of SloMo as an evidence-based digital therapeutic [16]. This allowed for agility in iterating specific features (eg, UI, psychoeducational vignettes) while maintaining fidelity to the previous UI and therapy protocol [18]. To support this, we embraced divergence, revisiting and challenging earlier design assumptions in line with iHCD principles. An example of this was the service user feedback that "unusual experiences" could be perceived as stigmatizing, despite this wording being widely used in CBTp [32] and the identification of a term describing these types of experiences, which felt more relevant and acceptable—"when the world doesn't feel right." Despite this divergent approach, we were necessarily constrained in certain respects. The need to build on a preexisting evidence base meant that some design decisions were necessarily limited by prior research findings and the parameters of the therapeutic model. For instance, some users suggested moving away from visualizing thoughts and thinking habits as bubbles, which was not possible, as this is a core component of SloMo and its previous clinical evaluation.

Limitations

Resource constraints restricted our ability to optimally develop this new version of SloMo. This included time pressure, as there was a need to produce an MVP in line with our implementation-effectiveness study milestones. Another constraint was workforce access, such as access to PPI consultants (therapists and service users), designers, and software developers. These limitations meant that pragmatic decisions had to be made for the redesign, for instance, regarding the types of software changes that could be made and what features were selected for user testing. Whilst decisions were made collaboratively within the transdisciplinary co-design workshops, it is possible that different design decisions may have been made with additional resources. These constraints may be viewed as a barrier to reducing complexity in the technology domain of the NASSS framework [24,25]. Ideally, future projects could be based in "living labs," whereby lived experience, clinical, technological, industry, regulatory, and research expertise is brought together in an organizational structure, with coproduction underpinning the co-design of digital health [33].

A limitation of the PPI consultant validation is that the service user and therapist experience of the optimized version of SloMo was based on a relatively brief exposure to the software, and so may not be directly comparable to the user experience findings from the SloMo RCT. Further, the PPI consultants involved in the delivery phase had been involved in the SloMo design work for an extended period and may have been less independent than the RCT sample. This may limit the conclusions we can draw from this early-stage validation. However, more rigorous data will be provided in our ongoing implementation study, examining SloMo when delivered by frontline therapists.

Validation of the SloMo (R2) MVP with service user consultants found enjoyment was rated lower than other domains on the UES [17], indicating an aspect of user experience that warrants attention in future development. Qualitative feedback highlighted specific areas for improvement, such as incorporating haptic feedback and improving user interaction. The digital therapy engagement literature could inform additional design strategies [34]. Nonetheless, lower enjoyment scores may reflect comparisons with nontherapeutic commercial apps, where higher levels of enjoyment are likely expected. It will be important to monitor this throughout the implementation-effectiveness study, and iterate on the software as needed; for example, monitoring engagement may act as a proxy for enjoyment.

Conclusions and Future Directions

This study demonstrates the value of using iHCD to optimize DMHIs for implementation in routine mental health care. By adopting an iterative, transdisciplinary approach that prioritized collaboration with service users, therapists, and technical experts, the SloMo redesign addressed critical usability barriers, fostered inclusivity, and enhanced the therapy's ability to meet the diverse needs of its target population. This methodology offers a valuable model for future mental health innovation, where the needs of diverse user groups are addressed, and therapeutic technologies are designed to be impactful and sustainable in routine care settings. We are now evaluating the implementation and effectiveness of the optimized version of SloMo when delivered by routine care therapists. We envisage SloMo will continue to be iterated based on learning from this work, in line with the principles of implementation science [35].

Abstract

Background: As more patients transition from hospital to home for postacute care, a growing interest exists in leveraging technology to support recovery, yet a limited understanding exists on how to design these tools to align with patient and caregiver needs and preferences.

Objective: This study aimed to explore the perceptions, attitudes, and beliefs of recently discharged patients to develop user-centered design principles for digital tools that support safe and effective transitions from hospital to home.

Methods: A vignette-based, mixed methods survey was conducted, grounded in the technology acceptance model, to explore patient perceptions of digital tools supporting postdischarge care. A random sample of 1000 recently discharged adult patients received a survey featuring validated vignettes and technology acceptance model–informed questions, with both quantitative and qualitative items. Open-ended responses were analyzed using grounded theory to derive design principles that inform the development and implementation of patient-centered digital health tools. Quantitative items were descriptive and are summarized as counts (n) and frequencies (%).

Results: Of the 967 eligible patients contacted, 116 completed the survey (response rate of 2%), with respondents having a median age of 71 (IQR 61-78) years, high rates of chronic illness, and access to smartphones (98/116, 84.5%) and in-home internet (111/116, 95.7%). Qualitative analysis revealed 6 key themes—connection to care, technical ease of use, solution usability, human connection, cost, and privacy—informing 3 patient-centered design principles focused on user experience, affordability, and transparent communication to guide future technology-supported hospital discharge interventions. Respondents reported the following factors as highly important: reassurance that a care team member would reach out if something seemed wrong (107/116, 92.2%), responsiveness to patient needs (95/116, 81.9%), ability to see their data (95/116, 81.9%), and out-of-pocket cost (94/116, 81.0%). Less important factors included duration of device use (22/116, 19.0%) and battery life (21/116, 18.0%).

Conclusions: Grounded in patient perspectives, this study identified the 3 core design principles of user experience and accessibility, cost and privacy, and communication and transparency that should guide the development and implementation of digital tools to support safe, effective, and human-centered transitions from hospital to home.

KEYWORDS

hospital discharge; technology; user-centered design; patient transitions; digital health; remote patient monitoring; ecological momentary assessments; accelerometers

Introduction

The quality of postacute care impacts both short- and long-term outcomes for patients discharging from the hospital [1,2]. In the United States, 2 in 5 hospital discharges of Medicare patients result in admission to a postacute care facility [1], despite evidence that most patients and caregivers have a strong preference for home-based postacute care [3]. In addition to patient preference for healing at home, limitations in hospital bed availability, restricted access to postacute care facilities, the high cost of care within these settings, and endorsement for in-home programs such as Medicare's Acute Hospital at Home have shifted rehabilitation and recovery to patient homes [4,5].

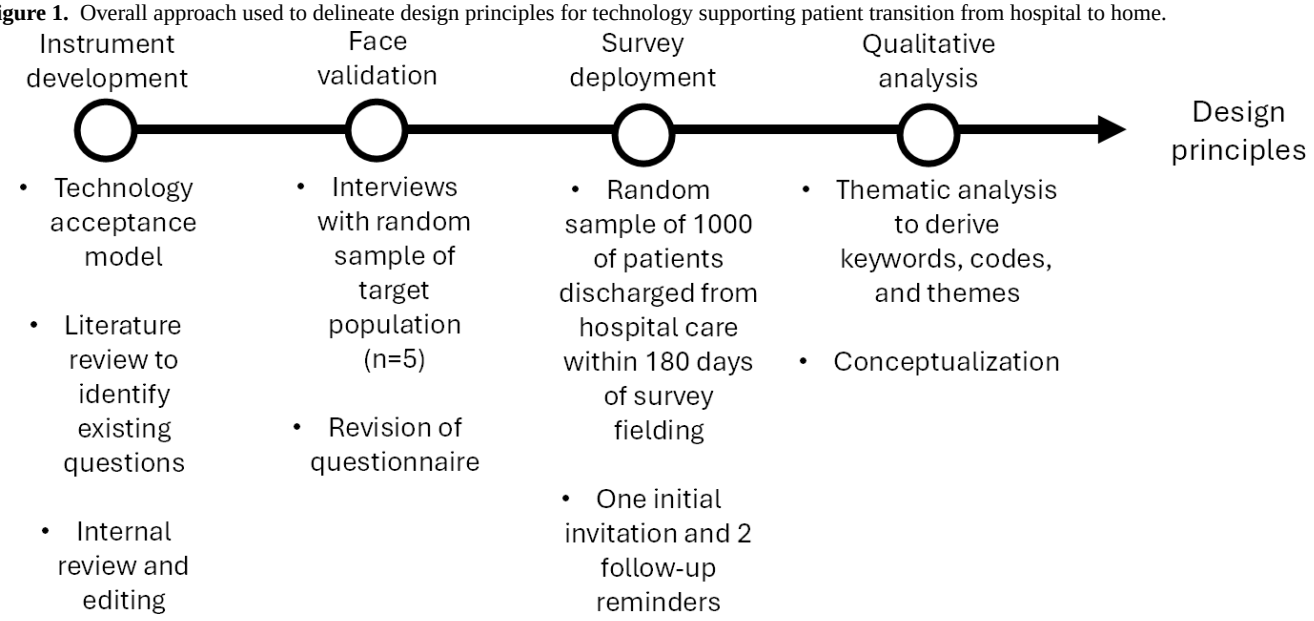
Although most patients feel relief returning home after hospital discharge, this relief is often accompanied by anxiety and confusion about managing recovery [6]. Telephone-based postdischarge outreach by primary care is recognized as a best practice for safe transitions of care and is supported by Medicare's transitional care management services, but can be limited due to the operational burden associated with nursing time and lack of longitudinal contact through the recovery period [7]. Technology can help facilitate patient transitions from

XSL•FO
RenderX

hospital care to home by addressing challenges experienced postdischarge, including continuity of care, patient adherence to therapy plans, patient and caregiver engagement, and timely escalation of needs to prevent adverse events or complications. Automated communications via standardized text messaging (eg, ecological momentary assessments) are the most widely reported upon technology, which can be used to schedule follow-up appointments, encourage treatment adherence, and monitor symptoms [7-9]. In addition to SMS-based text messaging, other active technology support for patient transitions from hospital settings to home includes remote monitoring of conditions such as acute kidney injury [10] and heart failure [11]. In these models, patients transfer daily vitals and patient-reported outcomes back to care teams, while interactive care plans guide them through discrete tasks to help stabilize a new or evolving medical condition [12,13]. Passive technology-based support, which is enabled without direct input from the patient or caregiver, is also emerging as an option to support patients transitioning from hospital care to home, but is less studied. Accelerometers and GPSs are common elements found in modern cellular phones and smartwatches and hold the potential to detect patient movement patterns, assessing for changes in physical activity levels, gait, or falls as proxies for recovery [14-16]. These passive modes of technology support are nascent and have only been studied in specific populations [14,16]. A gap exists in the scientific literature about how to design technologies to optimize patient and caregiver acceptability [9]. This will be increasingly important as intelligent monitoring systems based on Internet of Things technologies are being developed and proposed as possible health care solutions [17,18].

Hybrid models of technological connection between patients and care team members continue to evolve and be shared in the academic literature, while additional insights into implementation and scaling of successful interventions, and opportunities to address digital disparities experienced by patients, continue to emerge [7,19]. User-centered design (UCD) approaches can optimize the human experience with technologies, facilitating increased acceptance and uptake of new tools and thereby supporting implementation and scaling of successful interventions [20]. UCD focuses on a deep understanding of the needs, preferences, and barriers experienced by end users of design tools, services, and interventions addressing the needs of people [21]. Although major funding organizations and patient advocacy groups are encouraging participatory design for digital health interventions, the principles and approaches leveraging UCD relating to technology support for transitions from hospital care to home are uncommonly described in the academic literature. Design thinking can be deployed to create design principles in the build of new tools and services grounded in a patient-centered format. These design principles are critical constructs to inform product design and build, as well as implementation strategies to support adoption and sustainability.

The objective of our study was to elicit the perceptions, attitudes, and beliefs of patients recently discharged from the hospital to create design principles to enable the design and implementation of digital tools. We present our methodology, results of our vignette-based qualitative inquiry and survey-based quantitative findings, and propose a set of design principles to be used in technology design and clinical implementation.



Methods

Study Design, Setting, and Population

This study was a vignette-based, mixed methods survey design grounded in the technology acceptance model (TAM) to investigate patient-perceived barriers and facilitators to the use of digital tools to support patient connection back to care teams following hospital discharge. The TAM is a widely used theoretical framework for understanding when, how, and why individuals use technology [22]. Incorporating TAM constructs into the development of questionnaires ensures that all aspects known to influence technology use and acceptance are assessed within the survey instrument [22]. Vignette-based studies within the qualitative research landscape allow for an in-depth understanding of patient attitudes on potential changes to their health care environment and are commonly used in the human-centered design process to facilitate the development of design principles [23]. An overview of the approach is displayed in Figure 1. A Checklist for Reporting Results of Internet E-Surveys (CHERRIES) form is provided as Multimedia Appendix 3.

XSL•FO
RenderX

Figure 1. Overall approach used to delineate design principles for technology supporting patient transition from hospital to home.

Mayo Clinic is a multispecialty medical center with campuses in Rochester, Minnesota; Jacksonville, Florida; and Phoenix, Arizona, and a health care system spanning 44 communities in southern Minnesota, western Wisconsin, and northern Iowa. The Rochester, Minnesota, campus has 2 hospitals with over 2000 beds. The target population was 1000 unique patients discharged from either of the 2 campuses in Rochester, Minnesota. To ensure the relevancy and plausibility of our findings, we focused on patients discharged within 180 days before survey distribution. A simple random sample was performed among patients aged 18 years or younger at the time of discharge, residing within the hospital's catchment area, who had agreed to participate in research per state statute, were discharged to home, and were not deceased according to our medical records. The target sample size was 1000 patients to gain responses from at least 200 individuals, based on the 20% response rate typically observed in this population. The survey was tested, deployed, and managed by the Mayo Clinic Survey Research Center, as described in the later section "Instrument fielding."

Instrument Development and Testing

Instrument development involved a multistep process: development of vignettes, face validation, and survey development. Vignettes focused on 2 technologies under consideration for use by hospital practice: watch-based accelerometers intended to help hospital teams understand patient movement as a proxy for recovery, and text message–based ecological momentary assessments to check in on patients using short sets of questions. Initial vignettes were drafted by the principal investigator (LMP) in collaboration with the Mayo Clinic Center for Digital Health, responsible for the implementation of digital tools for patients as part of routine clinical care. The first review was performed by members of the research team (PR and REC) and internal medicine physicians specializing in hospital care (SBD and AS) and primary care (JOE).

Once initial vignettes were completed, they entered a phase of face validation, whereby 5 individuals fitting the criteria for our target population were interviewed one-on-one with a research team member (CMS) trained in qualitative research methods. A semistructured interview format was used, whereby each participant was provided an overview of the intent of the study and provided a printed copy of each draft vignette, as well as had the vignette read aloud by the interviewer (CMS). Each participant was asked about the clarity of the vignette through a semistructured interview. Participants were offered the option to be interviewed remotely (telephone or video) or in person, and all interviews were recorded for analysis purposes. Based on face validation, the technology vignettes were revised before launch. The interview guide is provided as Multimedia Appendix 1.

The complete survey instrument included the revised technology vignettes along with 2 open-ended questions: "What initial impressions do you have when thinking about (using an accelerometer/receiving ecologic momentary assessment) after a hospital stay?" and "What questions come to mind that you would want answered before agreeing to (wear an accelerometer/receive ecologic momentary assessment) after a hospital stay?" Following each vignette, respondents were asked to evaluate the level of importance of literature-derived or hypothesized design principles related to the use of each technology on a 5-point Likert scale. Questions grounded in the TAM that have been previously used and tested by the study team [24,25] were used to assess general use of technology such as the ability to access the internet at home or other locations, access to devices (eg, personal computers or laptops, and smartphones), and patient interest in and ability to use technology. Patient demographic factors, medical comorbidities, and patient-reported quality of life using the EuroQol 5-Dimension Scale (EQ-5D) [26] were also assessed. The survey instrument is provided as Multimedia Appendix 2.

Instrument Fielding

The finalized instrument was built by the Mayo Clinic Survey Research Center staff within Qualtrics survey software (Qualtrics LLC) for electronic deployment, sent to patient-provided email addresses. Pilot testing of the finalized

XSL•FO
RenderX

instrument led the study team to anticipate that respondents would need 20 - 25 minutes to complete the survey. Based on the inclusion criteria, 1000 patients were sampled to complete the online survey on Thursday, October 31, 2024. In total, 33 invitation emails bounced upon delivery. A total of 2 reminders were sent to nonresponders on November 3 and November 8, 2024, and the survey was closed on Wednesday, November 14, 2024, with 116 total responses.

Thematic Review and Derivation of Design Principles

Thematic review of participant-provided responses was completed using grounded theory. Open coding was performed to identify initial themes within the open-ended questions following the technology vignettes. Specifically, the input provided to the following questions was used: (1) "What initial impressions do you have when thinking about (using an accelerometer/receiving text messages) after a hospital stay?" and (2) "What questions come to mind that you would want answered before agreeing to (wear an accelerometer/answering questions from your care team via text message) after a hospital stay?" Keywords were derived from responses via close examination of responses, whereby recurring patterns and terms arose. Coding was performed to capture core messages provided by survey respondents, allowing the data to be transformed into generalizable, theoretical elements related to the main research questions. Design themes were derived from coded values, whereby design principles were created via the group's conceptualization of keywords, codes, and themes. The final design principles are shared as the final product to help inform the design of future technological tools to support patients transitioning from hospital to home. This process was conducted independently by 2 individuals trained in research methods with the following characteristics: Analyst A is a first-generation Asian American woman with training in public health science and epidemiology with extensive experience within health care delivery systems, while Analyst B is a White woman with training in human-centered design with experience in designing new products and services to enhance patient experiences with health care. Analyst A's experience navigating systemic barriers in health care for older family members informed her sensitivity to issues of access and equity, whereas Analyst B's 20-year experience designing digital solutions shaped her sensitivities to digital barriers. While Analyst A shares lived experience as a caregiver to the study population, she remains mindful of the varying challenges and psychosocial factors that patients of different ages, socioeconomic levels, and cultural backgrounds may face upon hospital discharge, thereby allowing her to approach data with a mindset open to understanding different perspectives. Analyst B, as a trained designer who is practiced in contextual inquiry and eliciting people's behaviors, goals, and motivations, approached this work with a trained perspective of understanding patient needs through qualitative research methods and analysis. The collaboration was grounded in mutual respect and critical dialogue, allowing us to challenge each other's assumptions and enrich our interpretations. The team recognized that positionalities are not fixed and committed to ongoing reflexivity throughout the research process.

Analysis of Quantitative Survey Responses

Quantitative survey response data were used to reinforce the design principles derived via our qualitative approach and were descriptive. Likert-based survey responses are described using frequency (n) and proportion. All data management and analyses were performed using SAS (version 9.2; SAS Institute). Response visualizations were created using R statistical software (version 4.1.2; R Foundation for Statistical Computing) and the ggplot2 package.

Ethical Considerations

This study was reviewed by the Mayo Clinic Institutional Review Board and deemed exempt from Institutional Review Board approval under 45 CFR 46.104(d), category/subcategory 2(i) (24 - 005650; principal investigator LMP). Confidential or identifying information was not collected for study participants, and all data were shared in aggregate form. Remuneration for study participation was not provided. As protected health information was not requested, written consent and Health Insurance Portability and Accountability Act (HIPAA) authorization were not required following 45 CFR 160.103.

Results

Overview

We had 116 completed responses to our vignette-based investigation (116/967, 12% response rate; excluding 33 bounced emails; Table 1). Our responding population had a median age of 71 (IQR 61-78) years, was predominantly of White race (112/116, 97%), and reported having chronic obstructive pulmonary disease (103/116, 88.8%), diabetes (87/116, 75.0%), cancer (65/116, 56.0%), osteoarthritis/chronic joint pain (63/116, 54.3%), and predominantly "good" (48/116, 41.4%) or "fair" (29/116, 25.0%) health. Most respondents reported having access to a smartphone (98/116, 84.5%), personal computer/laptop (85/116, 73.3%), and in-home internet (111/116, 95.7%).

Themes Associated With Technology-Supported Hospital Discharge

Several themes arose during qualitative analysis. The themes are outlined below with representative patient quotes.

Connection and Response

Most participants felt positively toward having a continuous connection with Mayo Clinic once discharged and thought they would benefit from sharing their data and receiving recommendations or other support to manage their health. One respondent wrote,

> *If it helps my providers gain needed information that can improve my overall outcome, I am in favor.*

while another stated,

> *I really like the idea. It would be able to track how a person is generally doing instead of relying 100% on the patient.*

Technical Ease of Use

Participants felt comfortable with the technology associated with these concepts, although some expressed concerns with management regarding difficulties if the technology proved challenging. One participant stated,

> *I am afraid I wouldn't understand how to use the device or if there was a glitch, I wouldn't be able to figure out how to fix it.*

and another less tech-savvy patient mentioned wanting "an alternative way to keep in touch because my techno skills are non-existent."

Solution Usability

Participants had questions or concerns with the wearability, simplicity, or frequency of use/interaction associated with the solution. This was the most popular theme, as participants recognized the impact of daily use. Several participants were wondering how long they would need to wear the device. One asked,

> *Do I wear it 24 hours a day?*

Regarding simplicity, another stated,

> *I don't look at my phone much sometimes 1 time a day.*

suggesting they may need to change their behavior if more frequent interaction is needed.

Human Connection

Participants mentioned a concern that these technologies could take away from the human connection, replacing it with an impersonal solution that might not recognize their specific needs. One participant mentioned,

> *It's okay but I feel it is better to talk to someone so I can express my feelings about my recovery.*

and another stated,

> *I would not want these text messages to replace the after-hospital discharge phone call from a hospital staff member.*

Cost

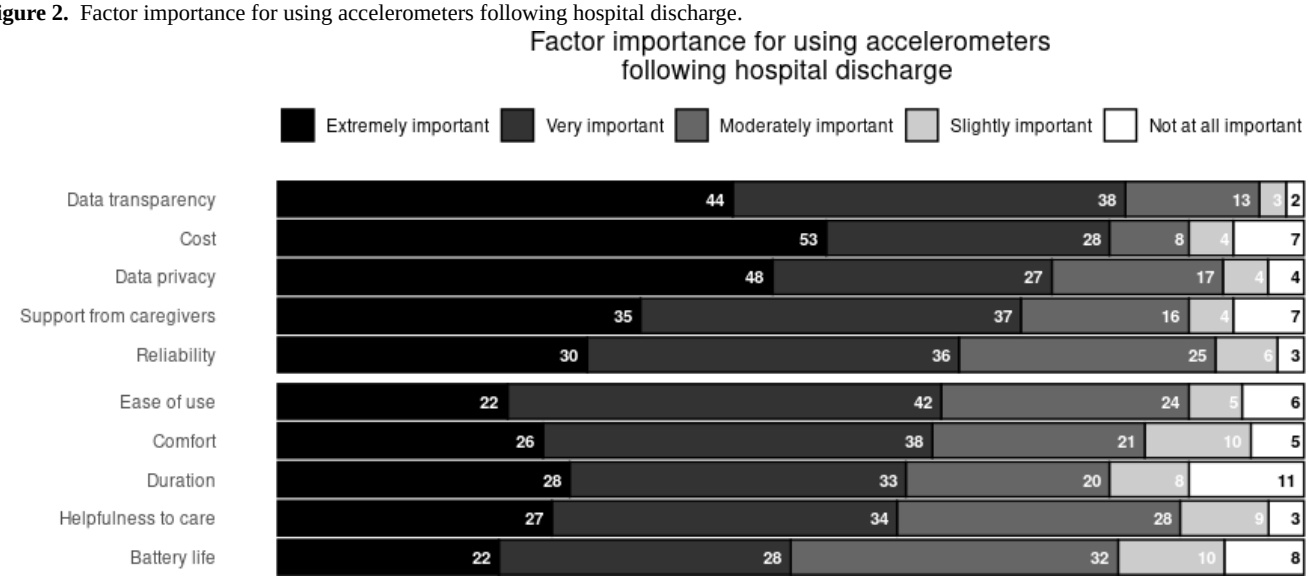
Participants were concerned about any costs associated with the product and expected not to incur any extra costs. One participant summed up the general feelings of the group by stating,

> *I would not expect to be charged for the device or access.*

Privacy and Security

Participants were concerned about data privacy and the security of the information shared. One participant mentioned,

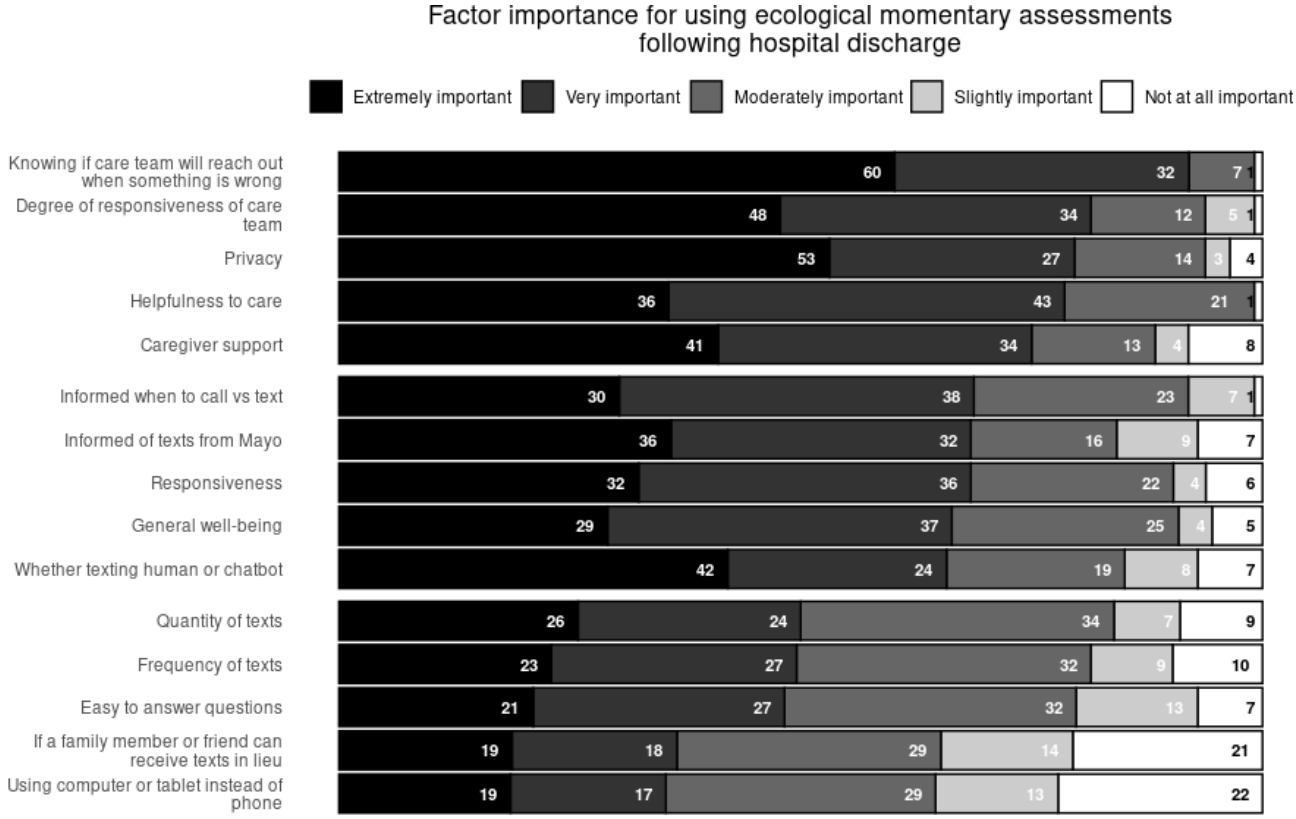
> *What exactly does it monitor and who has access to the data?*



Another stated, "I would want to make sure it is the doctor and not spam," and still another mentioned, "it seems a bit invasive."

Patient-Reported Technology Attribute Importance to Support Hospital Discharge

Regarding use of an accelerometer following a hospital stay, respondents reported that "the ability to see my own accelerometer data" (95/116, 81.9% rated as "Very important" or "Extremely Important") and "how much I would need to pay" (94/116, 81.0% rated as "Very Important" or "Extremely Important") had the highest cumulative levels of importance impacting willingness to use an accelerometer following a hospital stay. These were followed closely by "reassurance that my data is private between me and my provider team" (87/116, 75% rated as "Very Important" or "Extremely Important") and "how supportive my caregivers are to my use" (84/116, 72.4% rated as "Very Important" or "Extremely Important"). Respondents noted that "how long I would need to wear an accelerometer" (22/116, 19% rated as "Not Important at all" or "Slightly Important") and "How long the battery would last" (21/116, 18.1% rated as "Not Important at all" or "Slightly Important") were cumulative of least importance regarding willingness to use the device (Figure 2).

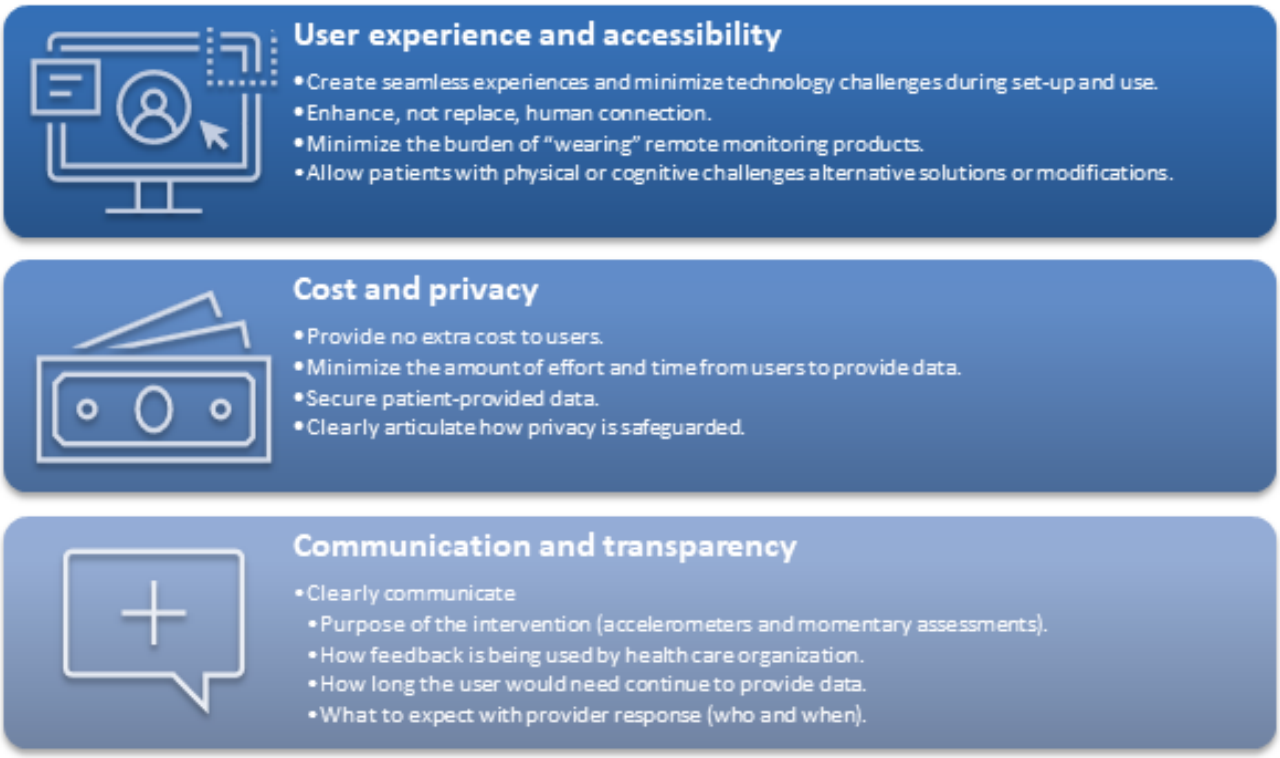


XSL•FO
RenderX

Figure 2. Factor importance for using accelerometers following hospital discharge.

When asked about factor importance in respondents' willingness to receive ecological momentary assessments following a hospital stay, the factors with the highest cumulative ranked importance were: "Whether a member of the care team would reach out if something was wrong" (107/116, 92.2% rated as "Very Important" or "Extremely important"), "How responsive the care team is to my answers" (95/116, 81.9% rated as "Very Important" or "Extremely important"), and "How helpful I feel the questions will be to my care" (92/116, 79.3% rated as "Very Important" or "Extremely important"; Figure 3). Respondents indicated "Whether I could have a family member or friend receive the messages instead of me" (24/116, 20.7% rated as "Not at all Important") and "Whether I can use my computer or tablet to answer instead of a cell phone" (25/116, 21.6% rated as "Not at all Important") had most responses indicating this factor was of no importance at all.

Figure 3. Factor importance for using ecological momentary assessments following hospital discharge.



Design Principles for Technology-Supported Hospital Discharge

Using the themes as guidance, 3 design principles were derived to highlight how concepts should perform (Figure 4). The first design principle describes user experience and accessibility by patients and includes constructs such as a seamless experience for end users (patients) during initial engagement with and use of the technology, how technology support should enhance the connection patients feel to care teams and not replace the human

XSL•FO
RenderX

connection, how technology needs to minimize the amount of effort needed by patients to enable the end goal of supportive healing at home following hospital discharge, and how modifications are needed to support patients with physical or cognitive limitations, such as patients reliant on wheelchairs or caregivers for cognitive support.

Figure 4. Design principles for technology to support patients during hospital discharge.

The second design principle derived focuses on consideration of cost to the patient when deploying new technology-based support for patients transitioning from hospital to home care. Cost is broadly defined as financial, including copayments and out-of-pocket costs, in addition to time and effort needed to participate in postdischarge, technology-based care models. Patients also identify the need for data security to ensure their information is private between the patient and the care team, and clear communication on how data privacy will be assured.

The third design principle emphasizes the need for communication about the purpose of the intervention and how the technology will be part of their care experience and used by the care team. Expectations regarding the duration of expected engagement with the technology were also important to patients, as was a clear understanding of which member of the care team would be interacting with the technology, and what the anticipated response content and timeline may be.

Discussion

Principal Findings

In this study, we derived 3 categories of design principles to aid in the design, development, and deployment of technology to support patients as they transition from hospital to home. We observed that patients value technology fitting seamlessly into their care experience, extending but not replacing human connection. Within our study, nearly every respondent indicated high importance that care teams be responsive to information received via technology, particularly if something seems to be going wrong. Patients were sensitive to additional costs that could be incurred based on use of these new technologies and placed high importance on data privacy and security in their willingness to engage with technology to support hospital discharge. Communication and transparency of the "why, what, who, and when" is important when engaging with technology to support transitions from hospital care to home. While the technical aspects of using technology are a consideration for patients, battery life, duration of use, and ability to use alternative mechanisms such as tablets or desktop computers for participation were of lower importance in patients' willingness to engage.

Comparison With Previous Work

Several studies have demonstrated a high degree of acceptance of digital technology to support hospital-to-home transition [7,9,27,28]. Studies deploying SMS-based text messaging had high patient satisfaction rates, and patients rated programs high on convenience and responsiveness during hospital-to-home transitions [7,27]. In addition, patients have reported appreciation for the flexibility enabled via automation and the asynchronous nature of technology solutions compared with traditional in-person care models [29]. Within our design exercise, we observed that patients value human connection supplemented by, but not replaced by, technology, building upon these aspects reported in the literature. Technology supporting human connection has been demonstrated in the hosting of virtual birthdays, funerals, and graduations, enabling shared human experiences across physical distances, which is particularly helpful for individuals experiencing physical

XSL•FO
RenderX

disabilities, frailty, or limited resources to support travel. In health care, technology has enabled human connection to mental health support that is accessible and practical, particularly for certain populations, such as adolescents [30] and those residing in areas with decreased availability of support services [31]. The multimodal delivery of mental health support, including video- and telephone-enabled care, mobile apps, and therapeutic gaming, supports the ability to foster human connection via technology [32].

Research has shown that bidirectional communication is considered more valuable than automated reminders by patients [9,19]. Both within our study and as reported elsewhere [33], patients indicate the desire to know that the interactions they are having with a device are being monitored or overseen by a human being, with the ability to escalate needs should a patient's condition warrant increased levels of care [34]. This reassurance has been reported to increase patient and caregiver confidence in the transition from institutionalized care to home care [34]. Use of technology to support hospital-to-home transitions is a mechanism to mitigate costs experienced by health care systems and payers alike via improved patient outcomes and decreased use [7,35]. However, the technology needed to support transitions from hospital to home may consist of personal computers, laptops, or tablets for inputting information, and in-home monitoring supplies such as glucose or blood pressure monitoring. Payment models to support these costs vary greatly, from coverage by payers to hospital systems to patients and families themselves. In addition to being cognizant of the costs associated with these new technologies, health care institutions need to address patient privacy and communicate those privacy considerations to patients upon consent for participation. Devices and platforms must be chosen that follow federal requirements (ie, HIPAA compliance within the United States), which require end-to-end data encryption, access controls, and audit trails. In addition, health care systems must require role-based access controls to ensure that only pertinent members of the care team can access patient information. All of these requirements must be supported by robust informed consent processes that ensure that patients understand how their data will be collected, used, and shared, and how patients and caregivers can protect themselves via secured network access, locking of personal devices, and avoidance of phishing.

The ability to incorporate supportive technology into transitions from hospital-based care to home as part of the care team, and not a separate entity, was emphasized as a need by our study participants. Technologies such as SMS-based text messaging, accelerometers, and other tools could be used to facilitate seamless transitions between our traditional care settings of hospital-based care, postacute care, and home with return to primary care. Patients with complex medical needs can experience frequent care transitions between our traditional care settings. However, care must be taken to ensure that safe and effective care is being maintained, particularly among those in a medically vulnerable state, such as following hospital discharge. Accuracy of supportive technology must be ensured so that care teams responding to in-home monitoring have reliable information, and devices must be usable by patients and caregivers. One opportunity is the movement toward "Bring Your Own Device" to help ensure usability; however, variability exists in the accuracy of direct-to-consumer monitoring devices, such as for blood pressure [36]. Health care systems may opt to designate a set of acceptable monitoring devices, allowing patients to use the device they choose within safety parameters outlined by health care providers. Grounding new tools in user experience and accessibility, cost and privacy, and communication and transparency can help clinical teams and developers improve the incorporation of tools into routine clinical care, thereby advancing seamless transitions during an anxiety-filled and uncertain time for patients.

Strengths and Limitations

Our study had limitations. Although our sample would be considered large for a qualitative assessment (n=116), the overall response rate was low (12%). We believe that lack of incentivization for study participation, use of patient-provided email as opposed to use of the clinic-provided patient portal, and survey availability in a single language (English) may have contributed to our low overall response rate. In addition, our response population was predominantly older adults (median age 71 years, IQR 61-78) and White (112/116, 97%) respondents from a single academic medical center, which may limit our ability to generalize to other populations. The older age of our participants may have influenced the digital literacy and access of our population, as research shows that older adults are more likely to experience decreased access to digital tools and services [37], and decreased digital literacy serves as an independent stressor to the well-being of older adults [38]. In addition, individuals of racial and ethnic minority groups are less likely to feel trust in the health care system and may be less willing to provide surveillance data directly back to their health care provider. Our response population was generally favorable about the use of movement tracking and text-based assessments following hospital discharge, but these results may not be consistent with other populations. Our investigation focused on 2 technologies (ecological momentary assessments via text message and accelerometers), which may not encompass the nuances of new tools that could be created to support all care transitions. One of the tools explored (accelerometers) is considered an emerging technology, which may not be validated for use in clinical settings. Our study had several strengths. First, this is one of the few investigations published to incorporate design thinking and UCD practices to help inform the design, development, and implementation of technology to support patients transitioning from hospital to home, focusing on the practical implications of new tools or services. Second, we used a vignette-based, mixed methods inquiry to derive open-ended feedback from a large qualitative sample of individuals who recently experienced hospital-to-home discharge. We used qualitative methodology to derive design constructs that can be used in multiple design settings and validate findings with quantitative assessment derived through the face validation exercise of patient interviews.

Future Directions

As health care systems increasingly rely on digital technologies to support transitions from hospital to home, future research must prioritize equity, inclusivity, and adaptability, building on

XSL•FO
RenderX

and testing the design principles presented here. One critical area for exploration is how these design principles perform across diverse cultural, racial, and demographic groups, given the limited diversity in our present sample. In addition, opportunities exist to evaluate emerging technologies—such as artificial intelligence–driven care coordination platforms, wearable sensors, and voice-assisted devices—for their usability, accessibility, and clinical impact. These innovations hold promise for improving postdischarge outcomes, but their success depends on aligning with patients' real-world needs, preferences, and capabilities. Finally, interdisciplinary collaboration among clinicians, social scientists, caregivers, and patients themselves will be essential to design and implement user-centered, culturally responsive digital solutions. By addressing these gaps, future work can help ensure that digital health technologies truly enhance recovery and reduce disparities as patients transition from hospital to home.

Conclusion

Our study identified key design principles for developing technology to support patients transitioning from hospital to home, emphasizing the importance of seamless integration into care, minimizing patient and caregiver burden, and ensuring data privacy and security. Patients value human connection supplemented by technology and prefer transparent communication about the use and purpose of these tools. Future efforts should focus on incorporating these principles to enhance patient experience and outcomes during postacute care transitions.

Acknowledgments

We thank the Mayo Clinic Survey Research Center for their help in planning, testing, and implementing the survey. This publication was made possible by the Clinical and Translational Science Award (CTSA; UL1 TR002377) from the National Center for Advancing Translational Sciences (NCATS), a component of the National Institutes of Health (NIH). Author (SBD) was also supported by the National Institute on Minority Health and Health Disparities (NIH; K23 MD016230). Abstract

Background: The Dutch acute health care system faces challenges with limited resources and increasing patient numbers. To reduce outpatient follow-up, direct discharge (DD) has been implemented in over 30 out of 80 Dutch hospitals. With DD, no routine follow-up appointments are scheduled after the emergency department (ED) visit for low-complex, isolated, and stable musculoskeletal injuries. This policy is supported by information leaflets, a smartphone app, and a telephone helpline with human support. Growing evidence shows that DD is satisfactory, safe, and effective in reducing secondary health care use, but thorough patient experiences are lacking.

Objective: The aim of this study was to explore the experiences of patients with DD to ensure durable adoption and to improve the treatment protocol.

Methods: A mixed method study was conducted parallel to the implementation of DD in 3 hospitals. Data were collected through a survey directly after the ED visit, a survey 3 months post injury, and semistructured interviews. Quantitative data were reported descriptively, and qualitative data used thematic analysis. Outcomes included the Bowen feasibility parameters: implementation, acceptance, preliminary efficacy, and demand. All patients who consented to the study face-to-face with one of the 12 low-complex musculoskeletal injuries were included in the study during the implementation period.

Results: Of the 429 patients who started the primary survey, 138 patients completed both surveys. A total of 18 semistructured interviews were conducted and analyzed. Patients reported a median treatment satisfaction score of 7.8 (IQR 6.6-8.8) on a 10-point scale of DD at the ED. Information quality was experienced as good (106/138, 77%), and most preferred DD over face-to-face follow-up (79/138, 59%). Patient information demands and app use varied among patients, with a median frequency of use of 4 times (ranging from 1 to 30).

Conclusions: This study shows that patients consider DD a feasible and safe alternative to traditional treatment, with a favorable perception of its acceptability, efficacy, applicability, and demand. Nevertheless, response rates were relatively low, and personal nuances and preferences must be considered when implementing DD. Clinicians and policy makers can use the insights to improve DD and work towards the integration of DD into clinical practice and future guidelines.

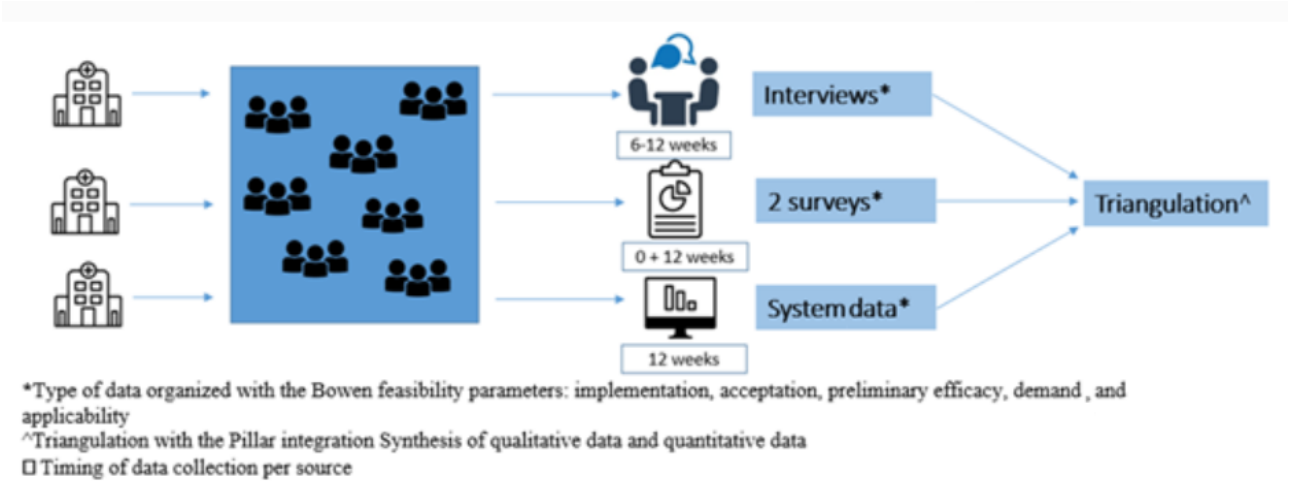
Introduction

The Dutch acute health care system faces substantial challenges due to limited resources and a rising number of patients requiring in-hospital care [1,2]. To alleviate this pressure, virtual fracture clinics have been introduced for Orthopedic and Trauma surgery patients [3]. Direct discharge (DD) is the most basic part of a virtual fracture clinic, concerning solely low-complex, isolated, stable musculoskeletal injuries. With DD, patients with these injuries are discharged directly from the emergency department (ED) without routine outpatient follow-up. Patients receive a removable orthosis or sling and are given information summarized in a mobile self-care app, the Virtual Fracture Care (VFC) app.

Growing evidence shows that DD is a safe and effective alternative to "traditional" care with routine follow-up [4,5]. DD reduces secondary health care use without causing a shift to primary health care use, while patient-reported outcomes (eg, functional outcome and satisfaction scores) and adverse outcomes (eg, complications and persistent complaints) are comparable [3,4]. These results and the usefulness of this method during COVID-19 social distancing measurements have led to a rapid uptake of DD in the Netherlands for 12 frequent injuries at the ED [6]. Since the first introduction in 2019, over 25 out of the 80 Dutch hospitals have implemented DD as the standard of care, adding to over 100 virtual fracture clinics and DDs worldwide [7]. While this reorganization of care has yielded beneficial outcomes in terms of reducing resources with comparable patient outcomes, there is a lack of research on the experiences of patients and their relatives with DD.



Performing an in-depth evaluation from an end user perspective deepens the insight into the quality of care by gaining a deeper understanding of user experiences and exploring reasons for nonadoption or abandonment, ensuring sustainable adoption of DD (inter)nationally. The aim of this study was therefore to explore the experiences of patients with DD to ensure durable adoption and to improve the protocol.

Methods

Design

An observational mixed method study was conducted among patients and parents of patients younger than 12 years who sustained low-complex, isolated, stable musculoskeletal injuries parallel to the implementation of DD in 3 Dutch level-2 trauma centers from September 2021 to July 2022 with an inclusion period of 3 months per hospital (Figure 1). Quantitative data and qualitative data were collected and analyzed separately by a quantitative team (GW and JS) and a qualitative team (WL and E Mathijsen). The Bowen feasibility framework was used to organize the data within the following parameters: implementation, acceptation, preliminary efficacy, and demand [8]. After separate analyses, quantitative data and qualitative data were triangulated with the Pillar Integration Process [9]. This study was reported according to the Good Reporting on a Mixed Methods Study (GRAMMS) criteria (Multimedia Appendix 1) [10], and according to the "Improving and Standardizing Evaluation Reports of Web-based and Mobile Health Interventions from the CONSORT-EHEALTH" [11].

Figure 1. Summary of study procedures and models used to evaluate the direct discharge protocol among patients.

Context

All participating centers were urban, level-2 trauma centers and teaching hospitals with up to 3 locations per hospital. All locations per hospital have an ED and implemented DD at the same time. Each hospital treats between 1200 and 1800 patients with low-complex, stable, isolated musculoskeletal injuries annually.

Traditional Treatment

Before DD was implemented, patients were treated according to local trauma protocols. These protocols consisted of immobilization or support with either a cast, sling, bandage, or splint and brief information about the injury at the ED. At least 1 outpatient follow-up appointment was scheduled at the plaster room or in the outpatient clinic within 2 weeks after the injury for review, extensive information, and definitive management planning.

XSL•FO
RenderX

Direct Discharge Protocol

This protocol was derived from the British model of a virtual fracture clinic and adapted to the Dutch health care setting in 2018. In its Dutch adaptation, DD includes 12 treatment protocols for low-complex, stable traumatic orthopedic injuries with additional injury-related criteria (Multimedia Appendix 2) [6]. Patients who met the injury-related inclusion criteria in Multimedia Appendix 2 and spoke Dutch or English fluently were included. No further predefined restrictions (eg, age or comorbidity) were used. Patients were excluded from the protocol if they had initial treatment in another hospital, follow-up in another hospital (eg, closer to home), multiple injuries, the reason for follow-up other than the injury (eg, social-care reasons), Eye/Motor/Verbal-score<15 at presentation, or intoxication. With DD, patients were discharged directly from the ED without routine outpatient follow-up. They receive a removable orthosis or a sling (eg, brace instead of a cast), and extensive information at the ED, summarized in a mobile self-care app, the VFC app. Apart from the criteria in Multimedia Appendix 2 and Dutch or English language skills (level B1), the protocols did not contain any predefined restrictions (eg, age or comorbidity). If, however, the ED staff believed physical follow-up was the most suitable treatment, outpatient follow-up was scheduled accordingly.

Patient eligibility for the protocol was re-evaluated on the next workday (within 24 h) by a team consisting of an (orthopedic) trauma surgeon and a radiologist. Patients who were incorrectly discharged directly were contacted by phone and scheduled for a face-to-face appointment.

VFC App

The VFC app provides self-care assistance through information, videos, and a helpline and can be downloaded for free at the Google Play Store and iOS App Store (Figure 2). Injury-specific leaflets with recovery information, treatment rules, and red flags were included. Furthermore, frequently asked questions, audiovisual exercise-, immobilization-, and analgesic instructions were included to assist patients. If patients required human contact in addition to the information, a helpline operated by an employee (eg, plaster technician) was available during working hours. The VFC app aimed to increase self-management and self-care during recovery and to substitute face-to-face follow-up. No reminders were sent, and use was voluntary. The app was developed by OLVG to reduce health care use and built by medical doctors with IT experience, usability testing was performed with peers. Due to its success, it was implemented in other hospitals. No major changes occurred during the study period.

XSL•FO
RenderX

Figure 2. English and Dutch in-app screenshots of the Virtual Fracture Care app used in the direct discharge protocol.

Study Population

Patients who met inclusion criteria and consented to participate in the surveys in the VFC app were included. Based on the annual number of patients (1200 - 1800 per hospital), and the inclusion time of 3 months per hospital, the estimated number of eligible patients was between 900 and 1350. Parents were asked to fill out the surveys if patients were 12 years or younger. If patients were between 13 and 16 years of age, patients and parents were allowed to complete the surveys. Patients older than 16 years could fill out the surveys alone. The exclusion criteria for this study were the same as the previously mentioned exclusion criteria for DD.

Sampling and Recruitment

Before discharge from the ED, in a face-to-face setting, eligible patients were asked to download and open the VFC app. An in-app pop-up asked for informed consent to participate in 2 surveys and an interview. After informed consent, patients were redirected to a Research Electronic Data Capture (REDCap) environment, a web-based survey system, to fill out the primary survey and were given an opt-out form by the treating physician, [12]. Additional information was given about the study and withdrawal methods. In the REDCap environment, all participants who started the survey were invited to participate in the interview by clicking a button and providing their email addresses. Age, sex, type of injury, and hospital were used to select a purposive sample among the quantitative population for interview patients. Eligible patients were contacted a

XSL•FO
RenderX

minimum of 6 weeks after injury to schedule a semistructured interview. During data collection, authors WDL and E Mathijsen considered whether the qualitative data had gained sufficient depth to perform a thorough analysis. Patients were reminded by email to complete the survey, and the second survey was sent 3 months post injury. Additional patient data were collected from electronic patient records.

Data Collection

Data were collected from surveys, semistructured interviews, and system data.

Surveys

Two surveys, 1 directly after the ED visit and one 3 months after the ED visit, with 63 questions, including close-ended questions, multiple-choice questions, 5-point Likert Scales, visual analog scales, and free-text questions, measured 5 Bowen feasibility parameters (Multimedia Appendix 3) [8]. As no golden standard for the evaluation of innovations exists, the surveys and topic list were developed by 4 researchers (JS, GW, BT, and THG) and checked by 2 experts on relevance: a professor in trauma surgery (JC Goslings) and an associate professor in-process evaluations of health care innovations (JCA Trappenburg). We pretested the survey with 5 patients to improve clarity.

Semistructured Interviews

Two independent researchers specialized in qualitative research, not involved in daily clinical practice or the VFC research team, conducted digital semistructured interviews to minimize social-desirability bias. The interviews were held within 6 and 10 weeks post injury to warrant an optimal recall. The interviews were guided by a topic list based on literature, including previously mentioned Bowen feasibility parameters (Multimedia Appendix 4) [8]. The research team piloted the topic list for clarity and completeness and modified it during data collection.

System Data

Quantitative data were extracted from the electronic patient record after 3 months of follow-up. The patient characteristics included compliance to therapy, complications (yes/no), type of complications, follow-up (yes/no), type of follow-up, and imaging. Downtime from the app was extracted from the log record of the VFC app.

Data Analysis

Quantitative data were analyzed using the SPSS (version 27; IBM Corporation) [13]. Baseline characteristics were reported descriptively using numbers and proportions for categorical variables and mean with SD or median with IQR as appropriate. The normal distribution of continuous data was assessed with visual analysis. Discrete variables were reported as numbers (percentages of the total population). The paired *t* test or the Mann-Whitney *U* test was used to determine the statistical significance of parametric variables for normally and nonnormally distributed data.

Qualitative data were analyzed according to the principles of the 6 phases of thematic analysis by Braun and Clark [14]. We have used an inductive, categorical approach because the triangulation process started after 4 phases. Data analysis started after the first 5 interviews. Interviews were audiotaped, transcribed verbatim, and analyzed using the software program NVivo (QSR International) [14]. One researcher (WL) independently analyzed the data, and another researcher (E Mathijsen) reviewed the analysis. Two researchers (WL and E Mathijsen) used several methods to ensure reliability and validity [15-17]. Discrepancies and remarks were discussed until they reached a consensus about data interpretations. Memos were made to track research decisions during analysis. Code saturation was reached when no new categories or themes emerged from the new raw data [15,16]. Instead of steps 5 and 6 according to Braun and Clark [14], we organized the data per theme during the triangulation session. The final themes were used to describe the value and feasibility of DD from the perspective of patients.

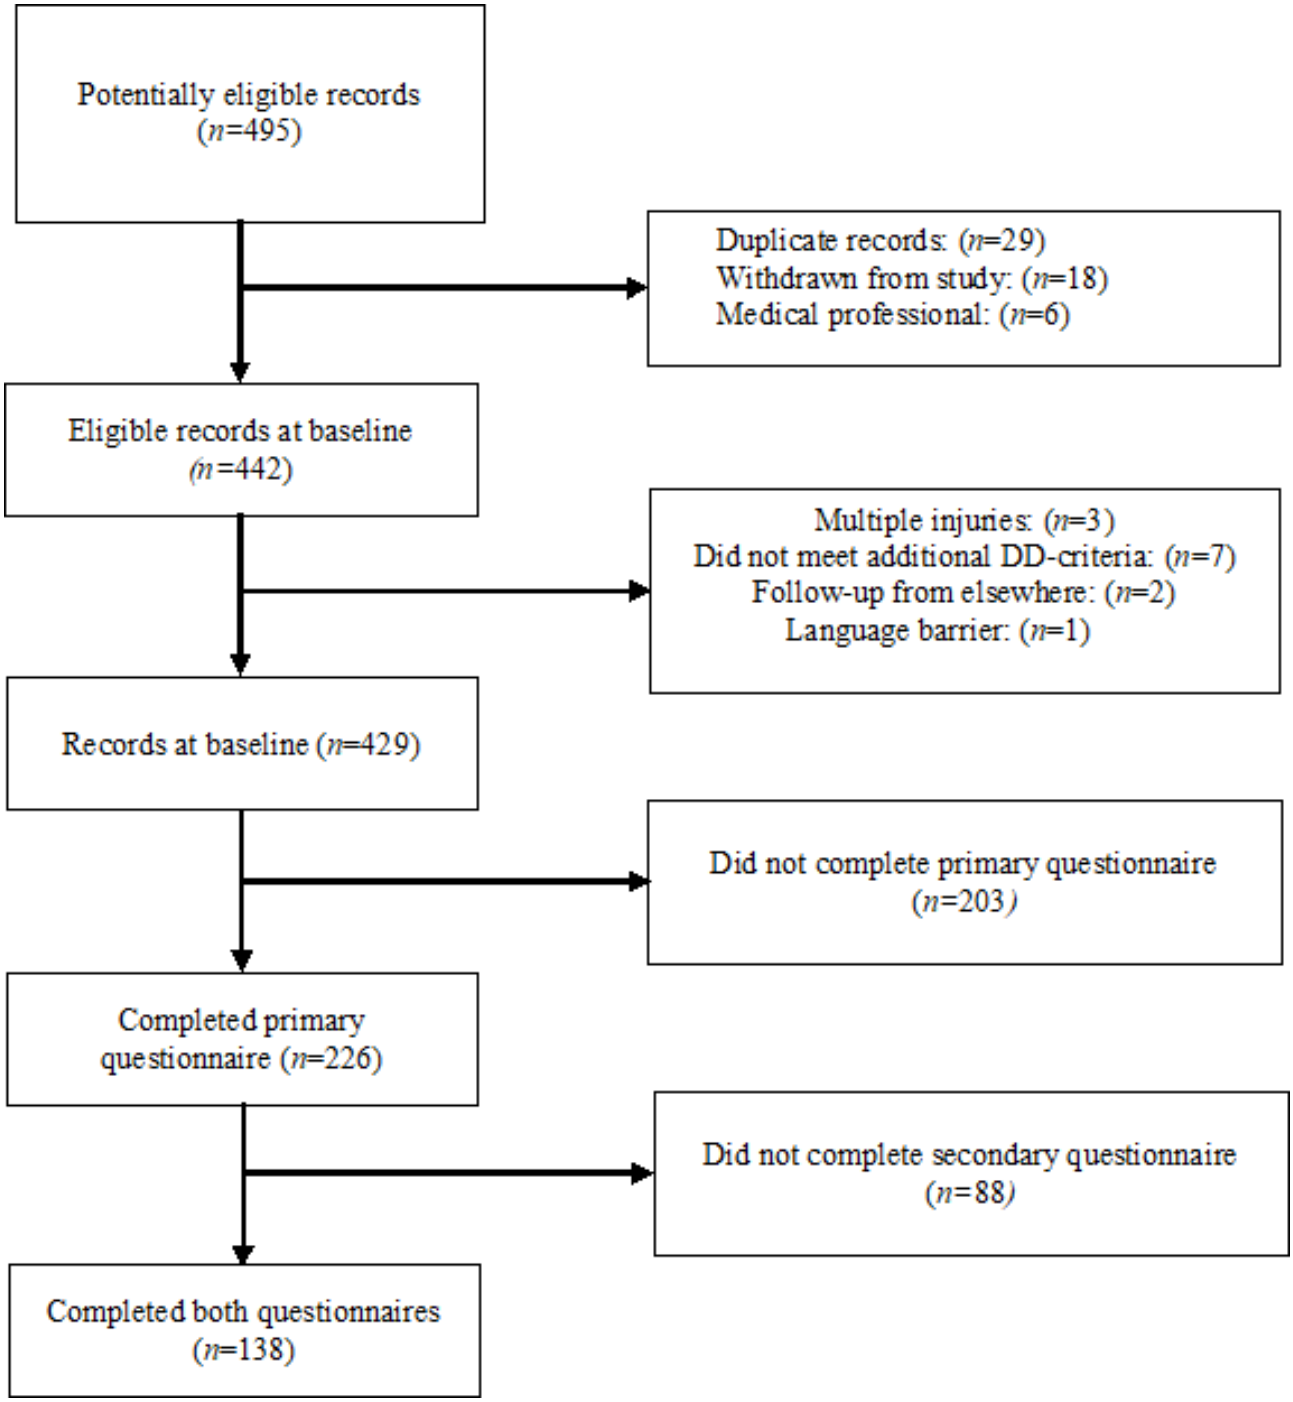
Triangulation

After the separate quantitative and partly qualitative analyses, findings were triangulated with a simplified approach of the Pillar Integration Process technique [9]. This approach uses a transparent and rigorous 4-stage technique for integrating and presenting qualitative and quantitative findings in a joint display Microsoft Excel, 2018 [18]. One of the researchers presented the quantitative findings (JS) per study parameter, and another the qualitative findings (WDL). (Dis)similarities and self-contained themes were objectified. One of the researchers (E Mathijsen) merged these themes into a meaningful narrative (the pillar), reviewed by researchers JS and WDL.

Ethical Considerations

This study, including the process analysis, was reviewed and approved by the Medical Ethical Committee of Utrecht, Netherlands (W21.261). Patients provided consent for participation in the research and could opt out at any time after request by email. The original consent and institutional review board approval covers secondary analysis without additional consent. A data key is stored at the local hospitals in a secured map and coded file. This is only accessible to JS and GW. The accessible data have been deidentified as far as possible (eg, age in years instead of the date of birth). Patients received no compensation to participate in this research.

Results



Demographics

Of the 429 patients who started the primary survey, 203 did not provide any data or contact details and did not complete the first survey and 88 did not complete both surveys (Figure 3). Of the 138 patients that completed both surveys (response rate: 138/429, 32%), 83 out of 138 (60%) were female, and the median age was 50 years (IQR 12 to 61) (Table 1). Patients who provided contact details at baseline varied significantly from responders regarding age (*P*=.01) but not sex (*P*=.14). Most patients were native Dutch speakers, who had attended primary school in the Netherlands (136/198, 98%), and over half had a minimum of a bachelor's degree (82/198, 59%) (Table 1). In addition, 18 patients sampled from the quantitative source participated in a web-based semistructured interview, of which

XSL•FO
RenderX

15 (83%) patients were female and 6 (33%) patients were parents of children (Table 2).

[a]Fx: fracture.

Implementation

Both data sources indicated that most patients were satisfied with their ED visit and the introduction of the app, despite some mentioning the hectic ED environment and difficulty downloading the app due to poor Wi-Fi connection. The physiological distress, and the hectic ED environment, resulted in an inability to recollect all the information provided by the ED physician. Several patients pointed out that the information in the VFC app was a valuable supplement to their ED visit (quote 1). Mobile app stability was excellent, with only 1 patient reporting issues accessing the app. The helpline could not be reached in 4 cases, resulting in 2 patients contacting the ED directly. The app was available 99.6% of the time, with the only downtime (5 hours in 3 months) caused by a software problem that was fixed by the app builder.

> *Because… it always goes quickly. It is always busy. But still, you know, this was completely clear; what I could expect and that I could download the app.* [quote 1; ID #10]

Acceptation

The median satisfaction with treatment was 7.8 (IQR 6.6-8.8) on a 10-point scale. Qualitative data complemented quantitative data, as most patients mentioned that they were satisfied with DD (quotes 2 and 3).

> *I would give DD a 7 or 8. Yeah, let's say 7, because I do feel that it might be difficult for older people. Especially because they don't always understand technology, you know.* [quote 2; ID #15]

> *To be honest, I think it's better. You know, often it's like, you go to a hospital, and it takes half a day just to get there, and come back, and all those things, and then it's just like: "O, it looks fine."* [quote 3; ID #5]

VFC App Acceptation

Most patients (106/138, 77%) reported that the quality of the information in the app was good and reported that the information answered the questions they had during their recovery (82/138, 58%). Additionally, 59% (79/138) would prefer the app over face-to-face follow-up if they were to have a similar injury. However, in qualitative data, some patients expressed concerns that the app may not be suitable for people with limited digital skills. Even though none of the patients identified themselves as "vulnerable," many reported that the app may not be appropriate for vulnerable individuals. Patients expressed that DD should not be mandatory for all in order to protect potentially vulnerable patients for whom DD would not be suitable.

Brace Acceptation

A total of 122 patients out of 138 (89%) used the brace for the prescribed period. Most patients (116/138, 84%) removed the brace or the sling during showering, at night (118/138, 86%), and (72/138, 52%) during non–weight bearing exercises. Most patients (97/138, 71%) found the brace comfortable, and 94 out of 138 patients (68%) found the brace convenient for these types of injuries (Multimedia Appendix 5). These findings were

XSL•FO
RenderX

complementary to the qualitative data. Patients preferred the brace to a cast as it allowed for better mobility because it was less bulky and less rigid compared with a cast (quote 4). However, the increased mobility made it tempting to overexert oneself, resulting in increased pain and insecurity for some patients (quote 5). The smaller size of the braces made some injuries seem less serious and burdensome, reportedly leading to social pressure to return to work earlier than advised by the doctor or app. Additionally, the less rigid nature of the brace resulted in increased skin friction, causing a superficial ulcer in 1 patient in the qualitative data.

> *I really like the brace because it allowed me to move. So, I was not stuck with a bulky cast on my leg, but rather, I had a lot of flexibility. I could actually determine what I wanted to do or not. So, I found that very enjoyable.* [quote 4; ID #2]

> *The brace was sometimes the reason I went over my limit. I could move more and was in the process of moving to a new home. But then the pain came back. I found it very difficult to 'guard' my limits.* [quote 5; ID #18]

Helpline and Perceived Safety

Most patients found the helpline important (116/138, 84%) and that the helpline offered them a sense of security (86/138, 62%). For some patients, the helpline was a way of checking if their recovery was still on track (quote 6). Most patients (94/138, 68%) in both data sources expressed that treatment with a brace and a helpline is safe for these types of injuries. However, some expected that if injuries were more severe, they would need more assistance than a brace and a smartphone app (quote 7).

Self-Empowerment

An increase in perceived self-empowerment was reported in 67 out of 138 (49%) of all patients, 51 (37%) patients reported neutral results, and 20 (14%) patients reported no increase. Enhanced treatment engagement was reported in 58 (42%) patients, while 50 (36%) patients reported neutral results, and 31 out of 138 (23%) patients reported no enhanced engagement (Multimedia Appendix 6). In the qualitative data, some of the interviewed patients stated that this type of treatment provided more self-empowerment and therefore, more control in their recovery (quote 8).

> *After about a week or three, I had a setback. I couldn't find this in the app, so I decided to call the helpline. The pain came back, and I was afraid I had broken something or something like that. They reassured me that it could not happen so quickly and that I just needed to rest for 24 hours h. They were right! It was nice to be able to check this.* [quote 6; ID #11]

> *Yes, I believe it is safe, given the circumstances. Because it wasn't that serious. Yes. I do have the confidence that if it is something serious I won't receive this type of treatment.* [quote 7; ID #17]

> *It was nice that I could read what I was allowed to do and what I was not. I think that gave me more control over my recovery. I knew what I could do myself in terms of exercises, and that was very helpful.* [quote 8; ID #2]

Preliminary Efficacy

Secondary Health Care Use

A total of 10 out of 138 (7%) patients had a face-to-face follow-up, and 9 (7%) patients by phone. Two patients attended the ED again after discharge due to anxiety and pain at the fracture site and were scheduled for outpatient follow-up. Two patients received follow-up for a wound check and 2 received follow-up as decided by the medical specialist due to severe pain complaints at the ED.

Functional Outcome

More than half of the patients had fully recovered 3 months after injury in terms of daily activities, sports, and work (84/138, 61%). Between 31% and 40% of patients were limited in functional outcomes once or twice a week. Approximately one in 10 patients were limited in physical activities more than 3 times a week. (Multimedia Appendix 7).

Pain

Most (92/138, 67%) patients have used painkillers in the first 3 weeks of recovery. Of these patients, 70 out of 92 (76%) patients have used acetaminophen, 17 (12%) patients have used nonsteroidal anti-inflammatory drugs, and 5 (4%) patients have used other undefined analgesics. Few patients (7/92, 5%) used cooling of the injury site to reduce pain. Analgesic use in the second week was lower (35/92, 38%) and further declined in the third week (9/92, 10%) and in the fourth week or after (9/92, 10%). Qualitative data showed limited pain complaints after immobilization of the initial trauma. Pain complaints in the first weeks were treated with analgesics. After the immobilization, a few patients had persistent pain symptoms. Most of these patients sustained a Weber A ankle fracture or ankle distortion. Those patients were most limited in their daily activities, specifically during more intense physical activities (eg, labor and sports) (quote 9).

> *The eight weeks of recovery are over, I believe. So now I should be able to start exercising again, well I do karate but I'll wait a little longer for that.* [quote 9; ID #4]

Demand

Almost all patients used the app during recovery (133/138, 95%) with a median of 4 times (IQR 2-6.5, range 0 - 30). Reasons to use the app included checking recovery exercises (91/138, 68%), treatment rules (69/133, 51%), the phase of recovery (68/133, 51%), seeking helpline information (57/133, 42%), and analgesics (10/133, 8%). Qualitative data supported the quantitative data. App use was focused on the first weeks post injury, and parents consulted the app more than children. They occasionally showed it to their child, predominantly if the information contained photos and videos (quote 10). Among the interviewed patients, almost all patients reported not requiring face-to-face follow-up for these types of injuries. The biggest advantage of DD is that it is time-saving on a personal level. Nevertheless, a few patients expressed a preference for outpatient follow-up. Especially if they had persistent complaints

XSL•FO
RenderX

or when the recovery was slower than expected. Patients expressed that this led to insecurity, which was also expressed by patients who used the app more frequently or later in the recovery phase (quote 11).

A minority of patients reported a lack of human contact and the physicians' reassurance of adequate recovery. Subsequently, as a minimal substitute, these patients suggested a feedback system (eg, pain scores or communication tools) to assist them further.

> *As for the app, he did see it, but you know, whatever! The only thing they find really interesting are pictures. What I liked that in the app is that they actually showed what was going on and what it looks like.* [quote 10; ID #17]

> *I was constantly looking for confirmation in the app, online, or at the fracture helpline.* [quote 11; ID #11]

Discussion

Principal Findings

This study shows that patients consider DD a feasible and safe alternative to traditional treatment, with a favorable perception of its acceptability, efficacy, applicability, and demand. Nevertheless, response rates were relatively low, and personal nuances and preferences must be considered when implementing DD.

Comparison With Literature

Patient satisfaction and perceived safety with DD aligned with previous studies [3,19,20]. Most patients responded positively to the introduction of DD at the ED, brace treatment, and assistance with the VFC app and helpline. The VFC app proved valuable in overcoming low recall of verbal information due to the chaotic ED environment and psychological distress. This finding is consistent with a systematic review highlighting the benefits of additional visual and written information in enhancing recall and injury knowledge [21]. Adequate understanding of the injury is crucial for properly following self-care protocols and monitoring red flags, this aligns with the finding that almost all patients used the app at least once. The braces used with DD were well-received, offering advantages such as easy removal (eg, during or at night), and improved daily living activities due to the early weight bearing. Braces seem to affect patients positively, as the lack of these advantages has been reported as most burdensome during cast immobilization [22]. However, the perceived decreased severity of the injury may pose a risk of overexertion and require further research.

Preliminary efficacy results align with previous research, demonstrating low complication rates, secondary health care use, comparable functional outcomes, and patient satisfaction with treatment [4,5,23]. Most patients preferred the VFC app over face-to-face follow-up for these injuries. While using apps in orthopedic and trauma surgery is not new, adding a self-care app to DD and virtual fracture clinics is a novel approach [24-26]. Patients found the information quality good and appreciated the time-saving component (eg, reducing work absenteeism). However, in the case of more severe injuries with wounds or complex fractures, some patients would prefer face-to-face interaction for additional reassurance. As previously suggested, digital self-care could be combined with face-to-face follow-up or used for preappointment education in patients with more severe injuries [27,28].

Although a good fit for most, some (young) patients noted that the app might not be suitable for older individuals or those with limited digital skills, potentially increasing health inequities in an already digitally oriented world [29,30]. However, it is important to note that DD targets relatively young patients, who are considered capable by the treating physician.

While previous studies have highlighted the potential for increased self-empowerment and patient engagement with eHealth, this study did not explicitly confirm it [31-33]. Despite positive study results, individual nuances in patients and injury types require a continuous assessment to ensure personalized patient care.

Information demand and app use varied among patients, implying different levels of demand among users. A minority of patients expressed a desire for more human contact and reassurance. A possible suggested solution was developing an in-app numerical feedback system, such as a questionnaire or communication tool.

Strengths and Limitations

This study has several strengths. To our knowledge, it is the first to provide in-depth interviews with patients treated using DD, providing valuable insights. Second, the research team's multidisciplinary involvement ensured a comprehensive evaluation and analysis of the data from multiple perspectives. Thirdly, the mixed method approach, including the separate collection of both data sources until data saturation, combined with the triangulation, increased the likelihood of realistic and rigorous results. Additionally, using a validated framework provided a structured insight into each feasibility parameter.

However, limitations include potential responder and selection bias due to a younger sample of patients with higher education levels and Dutch literacy rates than the general Dutch population. This age difference could be caused by the 12 selected injuries, of which half only occur in pediatric patients. Furthermore, the response rate of this study was 32%. Response rate, literacy, and education may limit the generalizability of the findings to a broader Dutch population, especially those with lower health literacy or digital skills. Furthermore, the timing to measure functional outcomes might have been suboptimal in these patients, as for some injuries (eg, mallet finger injuries), the immobilization period had just ended, resulting in limitations in daily activities.

Implications for Clinicians and Policy Makers, and Future Perspectives

DD has emerged as a promising approach to reduce outpatient follow-up while maintaining positive effects on primary health care use, patient satisfaction, complications, and functional outcomes [4,5]. By delivering follow-up care close to home, associated health care costs and societal costs decrease [34]. In addition, it limits unnecessary patient travel to the hospital thereby reducing the environmental impact of health care.

XSL•FO
RenderX

Including patients' perspectives in evaluating new care pathways, whether digitally assisted or not, is crucial for sustainable adoption and quality of care. Clinicians, researchers, and policy makers should prioritize patient involvement throughout the design, prototype, pilot, and evaluation phases. "Design thinking," a validated approach widely recognized in user experience and implementation literature, can be used to design these pathways. For example, replacing hospital care with DD involves changes in location and care deliverers, which presents new needs, challenges, and opportunities suitable to solve with design thinking. This study has identified areas for improvement of DD in terms of functions and features, and adjusted language to lower literacy. Future studies should focus on co-designing in-app feedback systems that address patient and health care professional needs for reassurance and monitoring like communication tools or questionnaires.

Conclusion

Patients consider DD a feasible and safe alternative to traditional treatment, with a favorable perception of its acceptability, efficacy, applicability, and demand. Nevertheless, response rates were relatively low, and personal nuances and preferences must be considered when implementing DD. Clinicians and policy makers can use the insights to improve DD and work towards the integration of DD into clinical practice and future guidelines.

Acknowledgments

The authors wish to thank Dr JCA Trappenburg, associate professor at the Julius Center from the University Medical Center of Utrecht, and Drs WL and E Mathijsen from the Healthcare Innovation Center (THINC) for the assistance in the development of the surveys and collecting and analyzing of the qualitative data. The institutions of the authors affiliated with St Antonius Hospital and OLVG Hospital have received funding to support this work through an unrestricted grant from the Dutch organization for health care sciences and health care innovation, ZonMw, the Hague, the Netherlands (grant 516012524).

The Colloboration Group is: Dr N Sosef, Dr T L Groenesteege, and Dr J G Ten Brinke.

Abstract

Background: Ward rounds are an essential component of inpatient care. Patient participation in rounds is increasingly encouraged, despite the occasional complicated circumstances, especially in acute care settings.

Objective: This study aimed to evaluate the effect of real-time ward round notifications using SMS text messaging on the satisfaction of inpatients in an acute medical ward.

Methods: Since January 2021, a service implementing real-time ward round notifications via text messaging (WR-SMS) has been operational at a tertiary-care medical center in Korea. To assess its impact, we conducted a retrospective cohort study of patients admitted to the acute medical unit who participated in a patient experience survey. Patient satisfaction was compared between patients admitted in 2020 (pre–WR-SMS group) and 2021 (post–WR-SMS group).

Results: From January 2020 to December 2021, a total of 100 patients were enrolled (53 patients in the pre–WR-SMS group and 47 patients in the post–WR-SMS group). Compared with the pre–WR-SMS group, the post–WR-SMS group showed significantly greater satisfaction about being informed about round schedules (mean 3.43, SD 0.910 vs mean 3.89, SD 0.375; $P<.001$) and felt more emotionally supported during admission (mean 3.49, SD 0.800 vs mean 3.87, SD 0.397; $P<.001$). Regarding other questionnaire scores, the post–WR-SMS group showed an overall, although statistically insignificant, improvement compared with the pre–WR-SMS group.

Conclusions: Real-time round notifications using a user-friendly SMS may improve inpatient satisfaction effectively.

(JMIR Hum Factors 2025;12:e57470) doi:10.2196/57470

KEYWORDS

rounds; round-time notification; text messaging; patient experience assessment; patient experiences; patient-centeredness; patient participation

Introduction

Inpatient ward rounds constitute a salient core activity of the daily care of hospitalized patients and present a critical opportunity to deliver patient-centered care [1,2]. Ward rounds are a complex process that involves organizing the clinical care of inpatients, including diagnostic assessment and therapeutic planning by the care team [3]. For the patient, inpatient ward rounds provide an opportunity for direct patient-clinician communication, sharing of information, and participation in their own care planning [3,4]. Despite the widely recognized importance of ward rounds, an environment conducive to conducting such rounds and effectively communicating with patients is not always achievable, resulting in ineffective communication with and dissatisfaction of patients [5]. Especially in acute care settings, the participation of patients in ward rounds is likely to be limited not only due to their acute illness and fatigue [6] but also by the acute care context itself and time constraints of the ward staff [7,8].

With the emphasis on patient-centeredness, the Korean Ministry of Health and Welfare (MOHW) and the Health Insurance Review and Assessment Service (HIRA) developed the Korean Patient Experience Survey, to gain insight into the needs of inpatients and improve inpatient care quality. This survey has

XSL•FO
RenderX

been conducted biennially by telephone since 2017 among patients discharged from hospitals, and the results have repeatedly revealed that patients remain least satisfied with inpatient ward rounds [9,10]. In line with global trends, studies from the United States and the United Kingdom highlight the importance of improving patient communication and providing clear, predictable information to enhance patient satisfaction [11-13]. Furthermore, evidence suggests that interventions focusing on real-time communication [14], such as the use of SMS text messaging, can help alleviate patient dissatisfaction by improving the timeliness and transparency of ward rounds.

As part of the efforts to improve patients' satisfaction, Seoul National University Bundang Hospital (SNUBH), a 1300-bed tertiary referral hospital in the Republic of Korea, has implemented the real-time ward round notifications via text messaging (WR-SMS) service since January 2021 to inform the patients and their carers about the start of daily ward rounds, and thereby alleviating arbitrary waiting for rounds.

In 2015, a hospitalist-run acute medical unit (AMU) was established to enhance patient safety and care efficiency for patients with acute medical conditions. Although the AMU improved patient outcomes and efficiency of care [15,16], patients' perceptions of inpatient care were found to be inconsistent, which could be attributed to the acuteness and complexity of clinical conditions, the hectic hospital environment, and heightened levels of anxiety.

As mobile devices continue to advance, SMS text messaging has been suggested to enhance clear and efficient communication in various clinical contexts [14,17]. However, there remains a gap in research regarding the potential impact of informing patients about round times via SMS text messages on communication effectiveness and patient satisfaction. This study aimed to determine the effect of real-time WR-SMS service on the satisfaction of AMU inpatients.

Methods

Study Design and Clinical Setting

This retrospective cohort study was conducted at the AMU of SNUBH, a hospitalist-run 46-bed ward caring for patients with acute medical conditions, who were admitted from the emergency or outpatient departments for active acute medical care, unless being hemodynamically unstable requiring invasive monitoring and critical care or terminally ill with cancer requiring only palliative care. After receiving active acute care, patients were either discharged or transferred to a specialty ward for further treatment. The AMU was operated 24 hours a day and 7 days a week by 10 board-certified medical hospitalists on a weekly rotation basis.

The SNUBH patient-experience survey has been routinely performed by telephone since 2006. Patients eligible for the survey were randomly selected within 2 to 56 days (8 wk) after discharge. Patients unable to communicate effectively due to conditions resulting in severe cognitive or communication impairments were excluded from the survey. Following the introduction of the official Korean Patient Experience Survey developed by the Korean MOHW/HIRA in 2017, the SNUBH patient-experience survey used the very same questionnaire to assess patients' hospital experiences.

Study Participants

Adult patients ≥19 years of age who were admitted to the AMU of SNUBH between January 2020 and December 2021 for ≥1 day and who participated in the SNUBH patient-experience survey after discharge were included. Their demographic data were retrospectively collected from the electronic medical record system, and their satisfaction was assessed based on the SNUBH patient-experience survey results. To determine whether patient satisfaction improved, we compared the scores from 2020 (before the implementation of the WR-SMS, pre–WR-SMS group) with those of 2021 (after the implementation of the WR-SMS post–WR-SMS group).

Real-Time Ward Round Notification Service With Text Messaging

The WR-SMS service was first developed in September 2020. It was actively implemented in January 2021, after an introductory period of 3 months (October to December 2020) during which the staff was educated about and encouraged to use the service via campaigns and email or SMS notifications.

The WR-SMS service was embedded into the SNUBH electronic health record system, enabling the doctors to send short text messages (80 to 160 bytes; ie, SMS) to their inpatients directly from the electronic health record system with a few clicks. From their patient list, doctors were able to select or deselect the patients who would receive the SMS text message. The default content of the SMS text message read, "Ward rounds by Dr. OOO will begin shortly. Visiting times may vary depending on the room." Further adjustments to the content of the message could be made as needed by the doctor. The notification could also be sent simultaneously to other relevant medical staff. The doctors were encouraged to send this WR-SMS to their patients just before starting their ward rounds, usually right after reviewing the patients' records.

Patient-Experience Survey

The SNUBH patient-experience survey questionnaire, which uses the same questions as the official Korean Patient Experience Survey developed by the Korean MOHW/HIRA, comprises 19 questions organized into 5 domains about the patients' hospital experience (4 questions pertaining to "Services from nurses," 4 pertaining to "Services from physicians," 5 pertaining to "Medication and treatment processes," 2 pertaining to "Hospital environment," 4 pertaining to "Ensuring patients' rights", and 4 assessing patients' demographic characteristics) (detailed questionnaire is presented in Multimedia Appendix 1). Each question was scored on a 4-point Likert scale (1=very dissatisfied, 2=dissatisfied, 3=satisfied, and 4=very satisfied) to assess patients' subjective satisfaction with the quality of inpatient services. Except for the question about providing information about plans after discharge, answers were either "Yes" or "No." For this study, the responses to the "Services from physicians" and "Medication and treatment processes" domain, which are closely related to inpatient ward rounds, were considered.

XSL•FO
RenderX

Statistical Analysis

Data reflecting patients' baseline characteristics were expressed as a median with ranges for continuous variables and as frequencies and percentages for categorical variables. Data from Likert scales were expressed as means and SDs, as well as median with ranges (IQRs). Comparisons were performed using the Mann-Whitney *U* test, Student *t* test, and χ^2 test. All tests were 2-sided and performed at a significance level of .05. Statistical analyses were performed using IBM SPSS v. 21.0 (IBM Corp).

Ethical Considerations

The study was conducted in accordance with the Declaration of Helsinki, revised in 2013. The SNUBH institutional review board approved this study design and waived the need for obtaining informed consent from the participants due to the retrospective design (B-2203-746-101). Participant confidentiality and anonymity were strictly maintained throughout the research process, and data were handled in a secure manner to protect their privacy. In addition, the study ensured that no undue harm or burden was placed on participants and that their rights, safety, and well-being were prioritized at all times.

Results

Baseline Characteristics of the Participants

A total of 100 patients were enrolled from January 2020 to December 2021 (53 in the pre–WR-SMS group before WR-SMS implementation and 47 in the post–WR-SMS group after WR-SMS implementation). The median age of the patients was 59.5 (range 25 - 81) years, and of the total, 59 were female. A total of 74 patients were hospitalized because of malignancy and 26 patients were admitted for non-cancer illnesses. A total of 44 and 56 patients were admitted from the emergency and outpatient departments, respectively. The median length of hospital stay was 7 (range 3 - 30) days. No statistically significant difference of patients' baseline characteristics between the pre- and post–WR-SMS groups was observed (Table 1).

Table . Baseline demographic and clinical characteristics of study participants.

Characteristics		Pre–WR-SMS group[a] (n=53)	Post–WR-SMS group[b] (n=47)	*P* value
Age (year), median (range)		58 (25-81)	60 (38-76)	.90
Sex, n (%)				.36
	Male	19 (36)	22 (47)	
	Female	34 (64)	25 (53)	
Disease, n (%)				.43
	Malignancy	37 (70)	37 (79)	
	Non-cancer illness	16 (30)	10 (21)	
Hospitalization route, n (%)				.94
	Emergency department	24 (45)	20 (43)	
	Outpatient department	29 (55)	27 (57)	
Education, n (%)				.25
	≤High school	29 (55)	32 (68)	
	≥College	24 (45)	15 (32)	
Length of stay (days), median (range)		7 (3-30)	7 (3-23)	.76

[a]Pre–WR-SMS group: patients hospitalized at the acute medical unit in 2020, before the implementation of ward round notifications via text messaging service.

[b]Post–WR-SMS group: patients hospitalized at the acute medical unit in 2021, after the implementation of ward round notifications via text messaging.

Effects of Real-Time Round Notification on Satisfaction of Hospitalized Patients

After the WR-SMS implementation in 2021, the score for the question pertaining to whether the patient had received information about round schedules improved significantly compared with 2020. Differences in the Likert scale for this question are illustrated in Figure 1. The proportion of patients who assigned a rating of 4 points (very satisfied) increased from 66% (35/53) in the pre–WR-SMS group to 92% (43/47) in the post–WR-SMS group, while the proportion of those who assigned a rating of 1 point (very dissatisfied) decreased from 6% (3/53) in the pre–WR-SMS group to 0% in in the post–WR-SMS group.

Figure 1. Changes in Likert scale scores regarding the provision of patient information on round schedules before and after the implementation of ward round notifications via text messaging. Pre–WR-SMS group: patients hospitalized at the acute medical unit in 2020, before the implementation of ward round notifications via text messaging service; Post–WR-SMS group: patients hospitalized at the acute medical unit in 2021, after the implementation of ward round notifications via text messaging service.

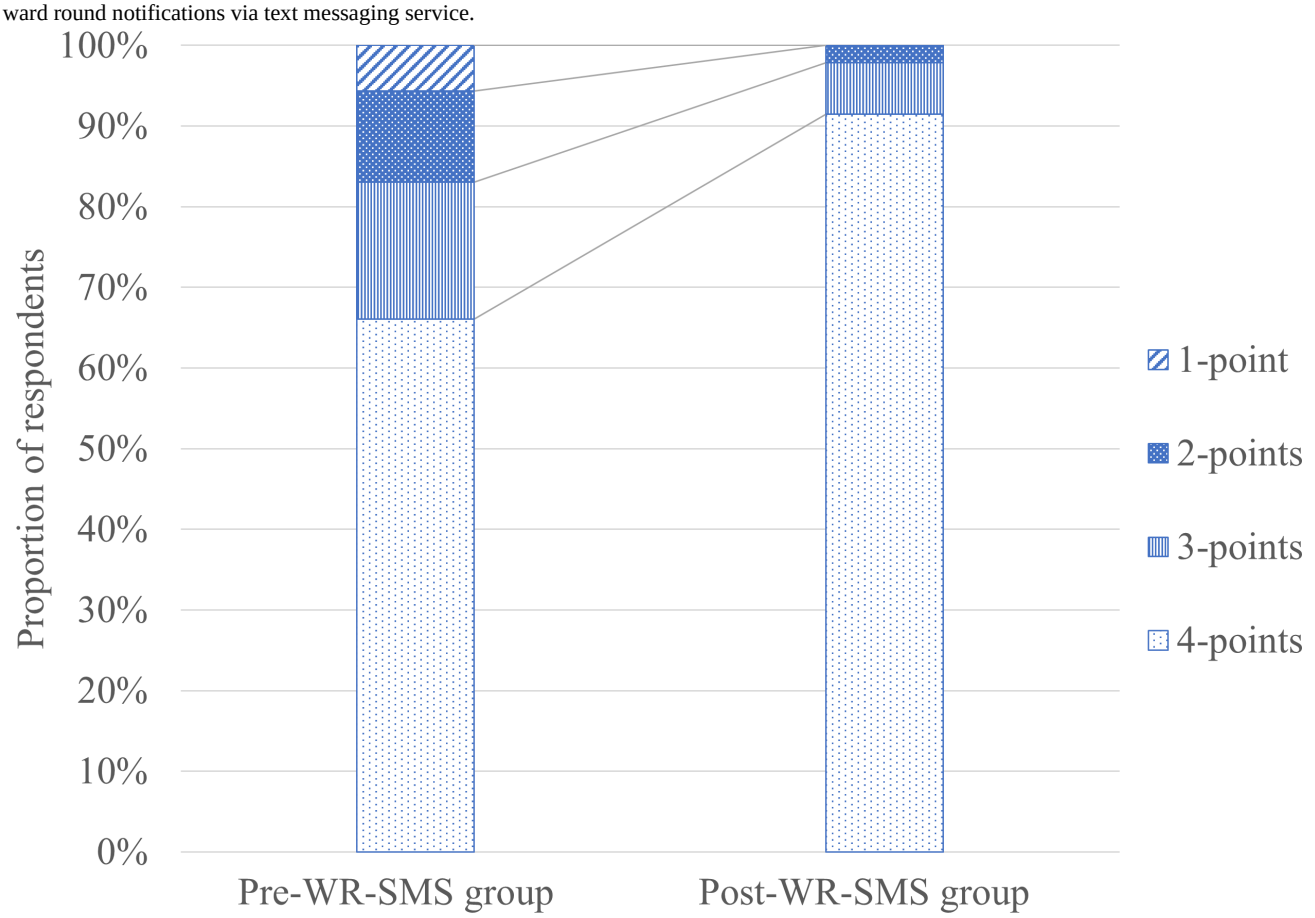

Table 2 summarizes the responses for the "Services from physicians" and "Medication and treatment processes" domains. Naturally, patients in the post–WR-SMS group showed significantly higher satisfaction about being informed about round schedules (mean 3.43, SD 0.910 vs mean 3.89, SD 0.375; *P*<.001) compared with patients in the pre–WR-SMS group. Interestingly, patients in the post–WR-SMS group also demonstrated significantly higher satisfaction with the emotional support (comfort and empathy) they received during admission (mean 3.49, SD 0.800 vs mean 3.87, SD 0.397; *P*<.001). Although not statistically significant, they were also satisfied with the description of the treatment processes (mean 3.62, SD 0.713 vs mean 3.83, SD 0.481; *P*=.09) and the explanations of possible side effects during treatment (mean 3.60, SD 0.743 vs mean 3.85, SD 0.465; *P*=.05). For all other questions in the "Services from physicians" and "Medication and treatment processes" domain, the post–WR-SMS group recorded a higher overall score compared to the pre–WR-SMS group, although it was not statistically significant (Multimedia Appendix 2).

Discussion

Principal Findings

The WR-SMS implementation resulted in significant improvement of inpatient satisfaction among patients hospitalized in the AMU. Besides the direct improvement in scores pertaining to the receipt of round schedule information (mean 3.43, SD 0.910 vs mean 3.89, SD 0.375; *P*<.001), patients felt more emotionally supported and involved in the care process (mean 3.49, SD 0.800 vs mean 3.87, SD 0.397; *P*<.001), and also expressed higher satisfaction with the explanations provided

XSL•FO
RenderX

about treatment side effects (mean 3.60, SD 0.743 vs mean 3.85, SD 0.465; *P*=.047). These significant findings emphasize the value of real-time communication on both procedural and emotional aspects of care. Our results indicate that by enabling patients to participate more actively in routine ward rounds, WR-SMS fosters a greater sense of involvement and satisfaction, reaffirming the critical role of patient-centered communication in inpatient care.

Patient-centeredness is an essential component of high-quality health care, contributing to improved experience and clinical outcomes [18]. It is defined by the Institute of Medicine as the establishment of a partnership between the patient and health care providers to ensure that the wishes, needs, and preferences of the former are respected in the shared decision-making process [19]. Since the early 2000s, many countries have implemented patient-reported experience measures (such as standardized surveys) at the national level. The data are publicly reported, in order to assess and monitor patients' health care experiences and improve the quality of care [11,12]. For example, the United States Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS) survey, first implemented in 2006, measures patients' perspectives on the quality of care they receive during their hospital stay, with its scores influencing hospital payment [13]. The United Kingdom and the Netherlands also conduct national-level surveys to assess patient satisfaction, which are used for various purposes related to improving health care services [20,21]. Previous studies revealed that quality improvement activities were initiated after patient care performance data were publicly released [22], with even hospitals that exhibited high levels of patient satisfaction delivering higher-quality clinical care [13].

In South Korea, the Korean Patient Experience Survey has been regularly conducted by HIRA biennially since 2017 by telephone among patients discharged from hospitals. It was developed based on the American HCAHPS, but further modified to suit the Korean context and to promote improvement of current Korean health care service quality [23]. A 2015 survey by the Korea Institute for Health and Social Affairs revealed that 30.5% of hospitalized patients claimed not to have been adequately informed about ward rounds and 20.4% reported not being included in the care process [24]. Furthermore, qualitative research during the Korean Patient Experience Survey development process revealed that inpatients were frequently unsatisfied with the communication with their doctors, especially regarding the lack of advance notice and unpredictability of ward round times [23]. To gauge these concerns, a direct question about whether the patient has been informed about the ward round time was included in the official Korean Patient Experience Survey.

Despite the increasing emphasis on patient-centeredness, patients are often still excluded from their own care process [5,6]. The results of the previous Korean Patient Experience Surveys (first to third, conducted from 2017 to 2021) reveal that the scores for the "Ensuring patients' rights" and "Services from physicians" domains remain lowest [9,10,25], suggesting that communication between patients and doctors remains unsatisfactory and patients do not feel sufficiently involved in the care process. Among several factors influencing patient participation and communication, such as the ward staff's attitude, time constraints [7], and health literacy [26], the care environment context itself has been identified as critical [8]. Previous Korean patient surveys revealed that patients felt dissatisfied and even frustrated by the medical staff's impolite, indifferent, or authoritarian attitudes and faced difficulties in communicating with their doctors who always appeared busy, and took issue with unpredictable and irregular round times [23]. Particularly in acute care environments, the patients' ability to participate is further diminished by their vulnerability, illness, and anxiety; furthermore, even the ward atmosphere is often disorderly and far from suitable for effective communication. In such situations, patient involvement is notably infrequent [6].

Patients in our AMU were mostly afflicted with complex, acute illness and frequently in need of interventional procedures, imaging studies, and even surgical procedures. Therefore, these patients and their carers often missed routine ward rounds during planned procedures or did not notice that ward rounds were taking place. Furthermore, the acuteness of the patients' conditions and lack of awareness about ward rounds likely led to frustration, anxiety, and dissatisfaction of patients and their carers toward their care. Real-time notifications provided through the WR-SMS addressed these issues by increasing awareness and predictability of ward rounds, which may help mitigate the emotional burden associated with the uncertainty of acute care. This aligns with studies suggesting that structured and predictable communication mechanisms, such as SMS notifications, create a more conducive environment for patient participation in care processes. A study conducted by Redley et al [6] at an acute inpatient ward indicated that only 18% (20/52) of rounds involved patient participation in clinical decisions, although even the patients who participated in rounds indicated low preferences for participation upon arrival at the hospital. The authors suggest that the patients' preferences for participation could change during the course of their hospital stay and it is also likely that passive participation may have been driven by limited opportunities to participate [6]. Similarly, Walton et al [27] revealed that familiarity with the hospital environment tended to positively affect participation in ward rounds, with several participants highlighting the uncertainty regarding the timing of rounds as a source of difficulty and anxiety.

With the development of communication devices such as cellular phones and smartphones, text messaging via SMS is increasingly used to enhance effective communication with patients and carers [14,17]. In our institution, the WR-SMS was developed and introduced to inform inpatients about the start of ward rounds in real time to improve their opportunities to participate in them. As physicians typically review their patients' medical records right before they begin ward rounds, the WR-SMS was embedded into our electronic health record system to enhance its use instead of using a separate platform. Following its implementation in January 2021, its utilization rate rapidly increased with long-term promotional activities, reaching an average of 65% in 2021. With its use, although only a statistically insignificant increase in patients' perceptions of opportunities to meet their doctors was noted (possibly owing

XSL•FO
RenderX

to the small sample size and the nature of the ward, which is staffed by hospitalists who are primarily based within the unit), inpatient satisfaction significantly improved with regard to "providing information about round-time" and the "Medication and treatment processes" domain. However, scores for other aspects in the "Services from physicians" domain did not improve significantly, suggesting that while real-time SMS notifications enhance patients' involvement and satisfaction with specific aspects of care, they may need to be supplemented with other interventions to address broader communication gaps.

Limitations

To our knowledge, this is the first study to investigate the effect of real-time round notification via SMS on inpatients' satisfaction. Nevertheless, it has some limitations. First, it was conducted at a single referral center in South Korea. As of 2019, the penetration rate of mobile phones in South Korea was 100%, with smartphones accounting for 95%. Therefore, our results may not be reproduced in other countries with lower mobile phone penetration rates. Second, as we used information from subjects who participated in the SNUBH patient-experience survey, instead of conducting a new survey, the number of patients included in this study is relatively small, precluding further adjustments and analyses based on clinical characteristics or comorbidities. However, the clinical setting remained constant throughout the study period and the subjects for the SNUBH patient-experience survey were randomly selected, which should minimize bias. Third, since this study included only patients capable of communication as survey respondents, it was not possible to assess the impact of WR-SMS on caregiver satisfaction.

Conclusion

Effective communication between physicians and patients, particularly during inpatient ward rounds, is a crucial aspect of inpatient care. This study proposes that real-time round notifications delivered through a user-friendly SMS service could improve inpatient satisfaction, likely by providing predictability and fostering an improved perception of emotional support. In the contemporary landscape, with personal communication devices becoming increasingly ubiquitous, the strategic utilization of such devices is anticipated to significantly influence patient satisfaction.

Abstract

Background: The World Health Organization anticipates a shortage of 14 million health workers by 2030, particularly affecting the Global South. Community health workers (CHWs) may mitigate the shortages of professional health care workers. Recent studies have explored the feasibility and effectiveness of shifting noncommunicable disease (NCD) services to CHWs. Challenges, such as high attrition rates and variable performance, persist due to inadequate organizational support and could hamper such efforts. Research on employee empowerment highlights how organizational structures affect employees' perception of empowerment and retention.

Objective: This study aims to develop Scripted Medicine to empower CHWs to accept broader responsibilities in NCD care. It aims to convey relevant medical and counseling knowledge through medical algorithms and ThinkLets (ie, social scripts). Collaboration engineering research offers insights that could help address the structural issues in community-based health care and facilitate task shifting.

Methods: This study followed a design science research approach to implement a mobile health–supported, community-based intervention in 2 districts of Lesotho. We first developed the medical algorithms and ThinkLets based on insights from collaboration engineering and algorithmic management literature. We then evaluated the designed approach in a field study in the ComBaCaL (Community Based Chronic Disease Care Lesotho) project. The field study included 10 newly recruited CHWs and spanned over 2 weeks of training and 12 weeks of field experience. Following an abductive approach, we analyzed surveys, interviews, and observations to study how Scripted Medicine empowers CHWs to accept broader responsibilities in NCD care.

Results: Scripted Medicine successfully conveyed the required medical and counseling knowledge through medical algorithms and ThinkLets. We found that medical algorithms predominantly influenced CHWs' perception of structural empowerment, while ThinkLets affected their psychological empowerment. The different perceptions between the groups of CHWs from the 2 districts highlighted the importance of considering the cultural and economic context.

Conclusions: We propose Scripted Medicine as a novel approach to CHW empowerment inspired by collaboration engineering and algorithmic management. Scripted Medicine broadens the perspective on mobile health–supported, community-based health care. It emphasizes the need to *script* not only essential medical knowledge but also *script* counseling expertise. These scripts allow CHWs to embed medical knowledge into the social interactions in community-based health care. Scripted Medicine empowers CHW to accept broader responsibilities to address the imminent shortage of medical professionals in the Global South.

Introduction

Background

The World Health Organization projects a health worker shortage of 14 million by 2030 [1]. Many countries struggle to train and retain enough medical professionals [1], with the Global South disproportionately affected by this shortage [2]. In response to this situation, community health workers (CHWs) have been integral in alleviating the consequences of staff shortages and extending the health systems in many countries [3]. CHWs are laypeople residing within their communities who receive basic medical training to provide essential health services in their communities and to link patients to professional facility-based health care [3]. Whereas physicians are often rare, expensive, and concentrated in urban hubs, CHWs are available in vast numbers and comparably inexpensive. While CHWs have traditionally focused on maternal, neonatal, and infectious disease services, recent studies have investigated the feasibility of expanding CHWs' responsibilities to tackle the rapidly growing noncommunicable disease (NCD) pandemic [4,5]. In task shifting, specific tasks are shifted from medical professionals to CHWs [6,7]. For example, many community-based health programs in the Global South shift screening and monitoring tasks for infectious diseases, such as HIV and tuberculosis, from medical professionals to CHWs. Task shifting may be a cost-effective approach to increasing the reach of health care delivery systems. It may reduce important access barriers by allowing for more decentralized health care delivery while freeing medical professionals' resources [8].

Despite the increasing popularity of community-based health programs, attrition rates among CHWs are generally high, and studies often report high variability in CHW performance [9-13]. These persisting challenges are linked to inadequate organizational support [12-14], including insufficient training and economic opportunities [15,16] and a lack of appreciation and support from supervisors [9,14]. Further, CHWs reported other social challenges, such as a lack of support from their families and insufficient trust, linked to low uptake rates of services by the community [14].

Empowering CHWs to Accept Broader Responsibilities

The empowerment literature reported high attrition rates and performance variability due to a lack of organizational support, especially in nurses [17-19]. Studies show that an organization needs to transfer power from supervisors to employees to create ideal work conditions. This transfer of power is called structural empowerment [20,21]. It emphasizes the necessity of providing employees with a work environment that enables them to carry out their work. Structural empowerment is achieved by providing employees *access to information*, *resources*, *support*, and *opportunities* [21,22]. The act of empowerment positively influences the perception of empowerment. Psychological empowerment builds on the idea that perceived control increases intrinsic motivation. It draws on prior research on self-efficacy [23] and self-determination [24] and is measured through the perception of *meaning*, *competence*, *autonomy*, and *impact* [25]. Empowering employees increases retention rates and job satisfaction and decreases job strain [18,22,26]. Employees feel disempowered when lacking access to critical information (eg, through training), resources (eg, adequate pay), or support from peers and supervisors. Disempowered employees are less productive and more likely to change jobs.

Unsurprisingly, CHW empowerment is a growing topic of interest. However, CHW empowerment is a poorly defined concept despite its recent popularity. Researchers often use empowerment as a synonym for facilitating or enabling CHWs to carry out specific tasks without diving into the depth of its meaning. For example, CHWs are empowered to treat diabetes [27] or provide counseling for family planning [28]. Consequently, they often miss addressing the persisting challenges of inadequate organizational support that lead to high attrition rates and performance variability. Only a few articles introduce CHW empowerment conceptualizations that consider the sociotechnical aspects of community-based health care. They highlight how the lack of organizational support disempowers CHWs with social, economic, and cultural consequences [29-32].

Mobile Health for CHWs

Mobile technologies often play a central role in efforts to empower CHWs in their work [33-35]. Recent studies demonstrate the potential of mobile health (mHealth) to address the challenges in CHW retention and performance [36], for example, through decision support [11,37-39]. Clinical decision support systems provide CHWs with the necessary clinical knowledge through medical algorithms to ensure the proper implementation of guidelines [37,40-42]. These explorations in empowering CHWs with decision-support tools align well with the premise of algorithmic management. Algorithmic management is a growing research topic in human-computer interaction and information systems research. It argues that management becomes a process embedded in technology rather than a human routine [43,44]. Studies have shown how algorithmic management can increase productivity without increasing job strain by managing the user's work process [45,46].

The 5RSM framework describes 7 forms of algorithmic management for process restriction: *algorithmicrecommending*, *restricting*, *requiring*, *rating*, *rewarding*, *sanctioning*, and *monitoring* [47]. Table 1 provides the original definition for each form of algorithmic management from Hirsch et al [47]. We complement the table with CHW-related examples.

XSL•FO
RenderX

Table 1. Forms and definitions of algorithmic management [47], with community health toolkit (CHT)–related examples.

Form	Definition (how the algorithm aligns worker behavior with organizational goals)	Example (CHT application)
Recommending	The algorithm automatically suggests specific behavior to the worker that takes the form of either explicit recommendations for action or implicit forms (such as nudges).	Medical algorithms propose a task prioritization that CHWs[a] can adopt to organize their workflow.
Restricting	The algorithm withholds information or limits the scope of action for the worker.	Medical algorithms hide recommendations for a drug prescription in case of reported intolerance.
Requiring	The algorithm instructs workers to perform specific actions that they cannot reject without negative consequences.	Medical algorithms require CHWs to perform tasks by a specific due date.
Rating	The algorithm ranks workers or allows third parties to rate work behavior and outcome.	Medical algorithms display leader boards comparing the number of clients CHWs have counseled.
Rewarding	The algorithm assigns rewards for work behaviors that align with organizational goals.	Medical algorithms issue nonmonetary (eg, digital badges) and monetary rewards (eg, performance-based compensation).
Sanctioning	The algorithm issues penalties for work behaviors that do not align with the organizational goals.	Medical algorithms reduce performance-based compensation if tasks are not completed in due time.
Monitoring	The algorithm enables supervision of the work process by the worker or a third party by collecting, aggregating, and displaying data on working behavior.	Medical algorithms provide performance dashboards with performance indicators such as the number of delayed task completions per month.

[a]CHW: community health workers.

While algorithmic management offers valuable tools for empowering CHW with mHealth, we believe 2 dimensions require specific consideration for community-based health care. *Recommending* might only be applied in areas where patient safety is not at stake. For example, algorithms must *require* instead of *recommending* CHWs to perform specific tasks such as distributing medication on time to ensure patient safety. Work termination, the strongest form of *sanctioning*, should not be performed by algorithms. Work termination has far-reaching consequences as communities would temporarily be left without their CHW.

Digital CHW empowerment is associated with the improvement of patient knowledge and attitude [48], disease surveillance and health coverage [33], and identification of health priorities in the communities [49]. These efforts often aim to address the root causes of CHW disempowerment [35]: the lack of organizational support and appreciation (eg, by supervisors) [9,14]; inadequate training and learning opportunities [15]; and insufficient monetary compensation [16].

However, the growing CHW empowerment literature mentioned earlier criticizes the unilateral focus on clinical knowledge to capacitate CHWs [29,30,50]. Research often abstracts from the context in which the clinical knowledge is applied [51]. It studies how technology *empowers* CHWs to become better and more reliable at diagnosing and monitoring diseases in the field. Consequently, the importance of a functioning CHW-client interaction is often omitted [52,53]. A recent study highlights the persisting, often implicit, view of CHWs as sensors for the health system because of this unilateral consideration [54]. CHWs are often deployed to *sense* the health status of their community by diagnosing and monitoring specific diseases (eg, HIV). However, they are not autonomous actors who offer treatment services. This perception stands against the proclaimed active role CHWs should claim to address predicted staff shortages [4,50]. Consequently, research lacks a comprehensive approach that embeds clinical knowledge in its application context to empower CHWs to accept broader responsibilities.

Collaboration Engineering

Current research often abstracts from the social interactions—the collaboration between CHWs and patients—in community-based health care. However, we argue that community-based health care is not the outcome of an individual's effort (ie, CHW) or technology. It is a collaborative process between CHWs, their clients, and the health system. Seen as a collaborative process, community-based health care would likely benefit from insights from collaboration engineering research. Collaboration engineering originates from research on group support systems (GSSs) [55]. This research studies how technology enhances group collaboration by reducing process losses, such as conformity pressure or the conversation domination of 1 or a few collaborators [56]. Despite the substantial benefits, GSS adoption struggled as they require professional facilitators who design and conduct GSS-supported group collaborations [56,57]. However, facilitators are a rare and expensive resource, requiring extensive training and experience [58].

The premise of collaboration engineering is to drastically reduce costs and training efforts by enabling virtually anyone to design and conduct group collaboration. Briggs et al [59] described this as the "facilitator in a box." The core assumption is that high value and recurring tasks can be predesigned to empower nonexperts through process restrictiveness [57,60]. This restriction quickly allows nonexperts to carry out expert tasks without extensive training and experience. However, collaboration engineering stresses that they must benefit users and offer adequate flexibility to avoid adverse effects [59,60]. The literature describes enabling nonexperts to fruitfully collaborate by restricting them in the process through (1) a carefully designed series of activities, (2) the configuration of technology to support behaviors within each activity, and (3)

XSL•FO
RenderX

guidance on the behaviors (including constraints) they should perform in each activity [59]. Collaboration engineering research proposes ThinkLets to guide the behaviors in these activities. ThinkLets are tools to "codify expertise such that it would be easy for [nonexperts] to learn and reuse." Similar to a cooking recipe, they consist of explicit instructions on collaboration behaviors, including instructions on configuring and using support tools [57]. ThinkLets formalize the required expertise for nonexperts to reach predictable and repeatable outcomes, increasing collaboration performance and outcomes [61].

On the basis of these insights, we argue that collaboration engineering is a promising approach for CHW empowerment as its underlying premise closely resembles global struggles in health care. The fundamental problem that collaboration engineering aims to resolve is that of scarce, valuable resources. Facilitators are replaced with inexpensive and plentiful nonexperts, who receive tools to facilitate collaboration in a specific context successfully. Collaboration engineering breaks processes into repeatable and formalized pieces, preconfigured technology, and guidance on required behaviors. From this perspective, collaboration engineering and community-based health care adopt a similar approach. Medical professionals facilitate their medical consultations based on their formal training and a repertoire of scripts grown by experience. This training is time-consuming and expensive. Likewise, CHWs are the nonexpert collaborators in medical consultations. They are available in large numbers and at comparably low costs. They lack critical knowledge and expertise that must be compensated through process restrictions. Thus, medical professionals are trained facilitators, and CHWs are nonexperts facilitating health care within a limited domain.

Following this analogy, we claim collaboration engineering offers efficient and effective task shifting tools that "standardize the performance and interpretation of certain tasks" [6]. Consequently, CHWs could be empowered to accept broader responsibilities and perform tasks beyond diagnosing and monitoring patients. In turn, empowered CHWs might be retained longer, reducing attrition rates. Despite this potential value, there is a lack of research studying how collaboration engineering can formalize crucial knowledge to facilitate task shifting from medical professionals to CHWs.

Research Objective

This study addresses this research gap by developing Scripted Medicine, an approach for CHW empowerment inspired by research on collaboration engineering and algorithmic management. The insights from algorithmic management align well with restricting collaboration processes through (1) a carefully designed series of activities and (2) the configuration of technology to support behaviors within each activity. In community-based health care, mHealth combines both principles as medical algorithms represent the series of activities and provide the user with the functionalities required to perform these activities. Collaboration engineering offers ThinkLets as a tool to guide CHWs' behaviors throughout the activities. They convey expert knowledge in predictable and repeatable recipe-like scripts that make the knowledge easily accessible for nonexperts. Accordingly, we formulate the design goal and solution objectives demonstrated in Textbox 1.

Textbox 1. Design goal and solution objectives.

Design goal

- Empower community health workers with Scripted Medicine to accept broader responsibilities in noncommunicable disease care

Solution objectives

- "Medical Knowledge"
  - Convey medical knowledge through a carefully designed series of activities and preconfigured technology by drawing on insights from algorithmic management
- "Counseling Knowledge"
  - Convey knowledge through guidance on specific behaviors in the activities in ThinkLets

Methods

Overview

We followed the design science research methodology proposed by Peffers et al [62] to develop the Scripted Medicine approach for CHW empowerment. Design science research is especially suitable as it aims to create artifacts that address a practical problem [63]. Such artifacts include software designs, theoretical models, or approaches [62]. While originating from information systems and computer science, design science research is increasingly applied in medical informatics to study emerging phenomena and generate new knowledge through a design approach [64-68]. The following subsections introduce the ComBaCaL (Community Based Chronic Disease Care Lesotho) project and describe our implementation of the design science research methodology. This manuscript focuses on the diabetes pilot of the ComBaCaL project.

Ethical Considerations

The pilot is approved by the Ministry of Health Research and Ethics Committee Lesotho (ID 176-2021). All participants gave verbal informed consent to participate in the study. The obtained data was de-identified. The participants did not receive any compensation for participating in the study.

ComBaCaL: Community-Based NCD Care

ComBaCaL is an innovative initiative to address the escalating NCD epidemic in Lesotho. The 5-year project used a community-based model, leveraging CHWs and mHealth to enhance NCD prevention, screening, diagnosis, and care.

One key aspect of ComBaCaL is its emphasis on empowering CHWs to play a pivotal role in delivering NCD care at the community level. Lesotho successfully decreased HIV transmission and AIDS-related deaths mainly due to the broad rollout of HIV testing and antiretroviral treatment. Previous studies explored the potential of decentralized, home-based service delivery for HIV care in the setting [69-71]. The project aimed to continue expanding the responsibilities of CHWs horizontally (ie, other diseases) and vertically (ie, offer treatment).

ComBaCaL is among the first projects to expand CHWs' responsibilities to provide treatment for NCDs through task shifting. The project strategically focuses on 2 critical NCDs: type 2 diabetes and hypertension, with a comprehensive care package beyond screening and monitoring. ComBaCaL follows a more comprehensive approach to community-based care that includes lifestyle counseling and prescription of first-line treatments for uncomplicated type 2 diabetes and hypertension. The goal was to provide accessible NCD care within the community, thus minimizing the need for travel to the often distant health care facilities without compromising patient safety and care quality.

To achieve this goal, ComBaCaL used mHealth, specifically a community health toolkit (CHT), to capacitate CHWs. These tools guide CHWs through clinical algorithms on tablets, enabling them to effectively screen and monitor NCDs, prescribe first-line treatments, and provide necessary care within the community.

The CHT is an open-source toolkit for community-based health care that reflects the needs of the local context [72]: a community-based perspective, an offline-first approach, and flexibility in configuring medical algorithms. These tools should streamline CHW activities and facilitate decision support based on entered data, ensuring effective and accurate care provision.

ComBaCaL is a multidisciplinary implementation research project that aims to improve care for chronic diseases in rural Lesotho by developing and implementing innovative community-based health service delivery models. The project consortium includes SolidarMed, a local nonprofit organization; the Division of Clinical Epidemiology at the University Hospital Basel; the National University of Lesotho; the Lesotho Ministry of Health; and the Department of Informatics at the University of Zurich.

Design and Development

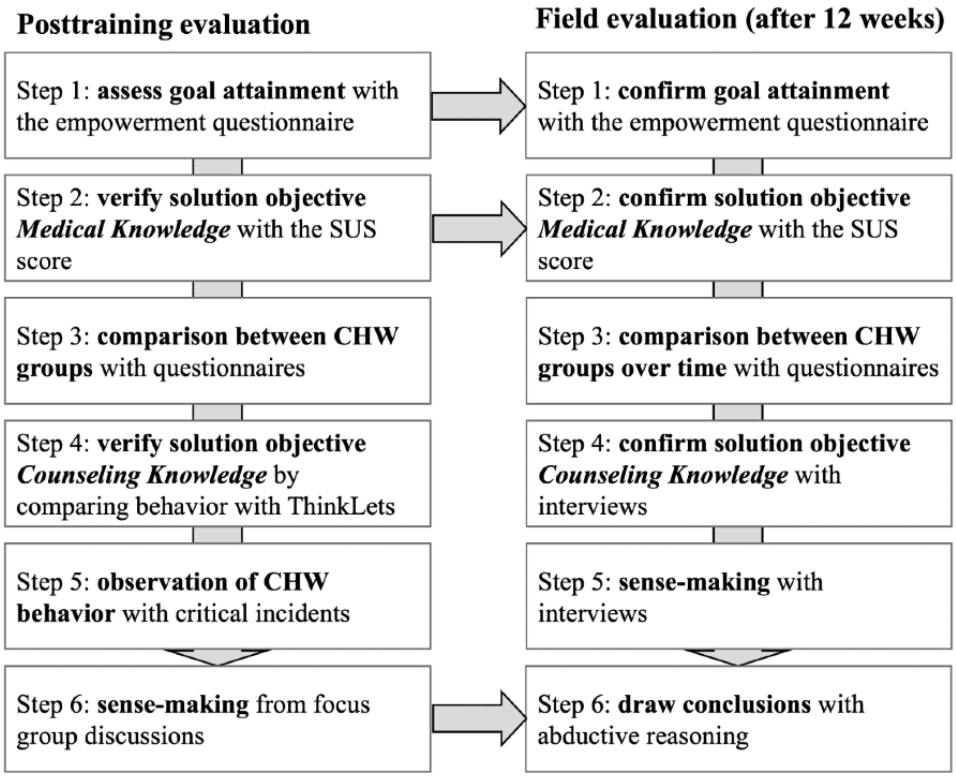
An interdisciplinary and multicultural project team adopted a human-centered approach to gather extensive requirements for the envisioned community-based health program with support from students in Lesotho and Switzerland [73,74]. This approach allowed the project team to include all relevant stakeholders and their needs. The program was developed in 2 streams between February 2021 and April 2022. In the first stream, the project team developed medical algorithms instantiated in the CHT, named the ComBaCaL app. In collaboration with medical experts, informatics students from a university in Switzerland build medical algorithms that contain step-by-step guidance in registering, screening, diagnosing, and (if necessary) treating clients for diabetes. The algorithms were developed using agile methods and tested before the intervention. In the second stream, a group of 4 researchers iteratively codeveloped ThinkLets. The researchers developed 9 ThinkLets covering the social interactions associated with the medical algorithm's guidance. They especially considered the interrelation between medical procedures and social interactions between CHWs and their patients. The ThinkLets were revised and finalized after the CHW training to incorporate learning from practice sessions.

Demonstration and Evaluation

The concept was evaluated with 10 newly recruited CHWs in 2 districts in Lesotho in Spring 2022. The communities elected the CHWs according to the Lesotho Village Health Policy. The scope of the evaluation covers 2 weeks of training and approximately 12 weeks of field experience, during which CHWs provided diabetes counseling in their community.

The first week of training focused on clinical knowledge. Medical experts educated CHWs on diabetes risk factors, pathophysiology, diagnosis, and treatment. Practical sessions on medical procedures, such as capillary blood glucose measurement, complemented the lectures and allowed CHWs to practice with peers. The second training week focused on embedding the gained clinical knowledge into the interactions between CHWs and their clients. The practice-oriented counseling training was organized in modules along the counseling process. Each module was built on the previous one to cover the whole interaction when combined. The modules all followed the same approach. First, the trainers introduced the relevant ThinkLet to the plenum. They explained the aim, reason, and process of each ThinkLet and answered questions. A trainer demonstrated how a ThinkLet intends to support the CHWs in handling the medical algorithm on a tablet app and their interaction with clients. A total of 2 CHWs then applied the ThinkLet in a roleplay, with the remaining CHWs watching and asking questions. Second, the CHWs practiced on each other in groups of 5 by applying the clinical knowledge in the algorithms in its social context supported by ThinkLets. Third, the groups met again in the plenum to discuss what they had learned and to answer open questions. This approach was repeated until the CHWs counseled their peers, from welcoming to saying goodbye. The training concluded with 2 days in a nearby village where the CHWs applied their knowledge and skills in a real-world setting with people closely resembling their future clients.

Data Collection and Analysis



Overview

We followed an abductive approach to study how Scripted Medicine empowers CHWs to accept broader responsibilities in NCD care. Deductive and inductive approaches aim to test a theory objectively (ie, deductive) or generate a theory from

XSL•FO
RenderX

interpretation (ie, inductive). Compared to these approaches, abductive research balances empirical data and existing theory [75]. This balance makes abductive reasoning suitable for design science research and this study as it considers a theory (ie, empowerment) and empirical data to generate new knowledge [76]. We conducted our abductive approach in 2 rounds, as depicted in Figure 1. Throughout the data collection, the CHWs always could speak Sesotho to express themselves in the best way possible. Native speaking Basotho either participated in the focus group discussion or conducted the interviews if preferred. Questionnaires were in Sesotho and English languages.

Figure 1. An abductive analysis approach for the posttraining and field evaluation. CHW: community health worker; SUS: System Usability Scale.

Posttraining Evaluation

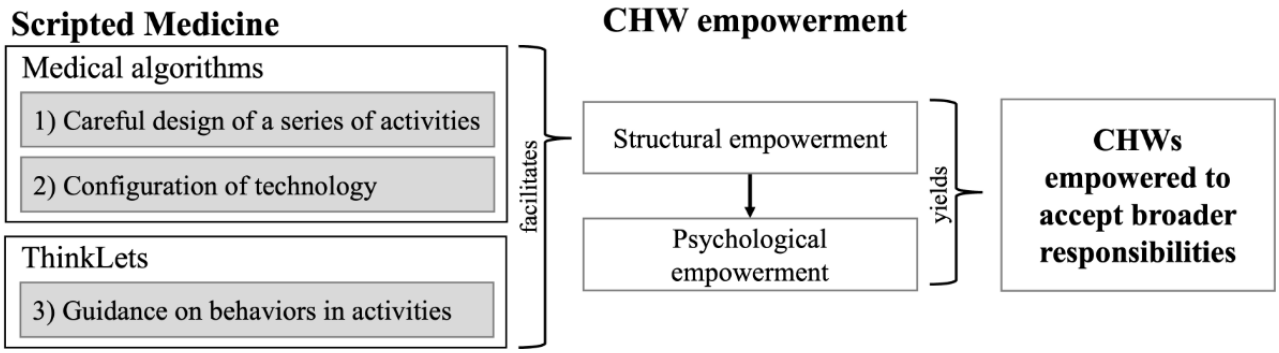
We collected data during the CHWs' training. We captured video recordings during the training sessions to study the CHWs' learning curve. At the end of the training, the CHWs participated in a focus group discussion to reflect on their training experience and expectations toward their new role. We divided the CHWs into 2 groups of 5 to give each CHW enough space to speak. Finally, each CHW completed a questionnaire on structural and psychological empowerment [17,25] and rated the ComBaCaL app on the System Usability Scale (SUS) [77] (see Multimedia Appendix 1 [17] and Multimedia Appendix 2 [77] for the questionnaires).

We conducted the data analysis in 6 steps. First, we began our analysis by focusing on the questionnaire data to assess goal attainment regarding the CHWs' perception of structural and psychological empowerment. We calculated the median and mean for each item and item group (where applicable). Second, we calculated the SUS score for the ComBaCaL app. The SUS evaluates the quality of the process restrictions instantiated in the ComBaCaL app through (1) the designed sequence of activities and (2) the configuration of the app, and, therefore, verifies solution objective 1. Third, we compared the results between the Mokhotlong and Butha Buthe groups (5 CHWs each). This step elicited interesting insights to guide the subsequent observation and interview data analysis. We then analyzed the observations (ie, video recordings). In the fourth step, we compared the CHWs' behaviors with the counseling ThinkLets to assess their adoption (solution objective 2). Fifth, we applied the critical incidents technique to identify outstandingly effective or ineffective behaviors [78]. Finally, we analyzed the 2 focus group discussions following a theory-driven coding approach based on the empowerment literature [20,25] paired with in-vivo coding for emerging themes. Analyzing the focus group discussions allowed us to understand the insights from the previous steps. The initial codes were *access to information*, *support*, *resources*, and *opportunities* (structural empowerment) and *meaning*, *impact*, *competence*, and *autonomy* (psychological empowerment).

Field Evaluation

We collected a second round of data after the CHWs worked in the field for approximately 12 weeks. The CHWs again completed the same questionnaire on empowerment and system usability. Further, they provided insights into their work through semistructured interviews (individual interviews).

We first analyzed the empowerment questionnaire and SUS score (steps 1 and 2). In step 3, we calculated changes between the initial and second questionnaires in addition to the median and mean. These changes yielded interesting insights into the dynamics of empowerment that we further explored in the interviews (step 5). We analyzed the interviews based on the



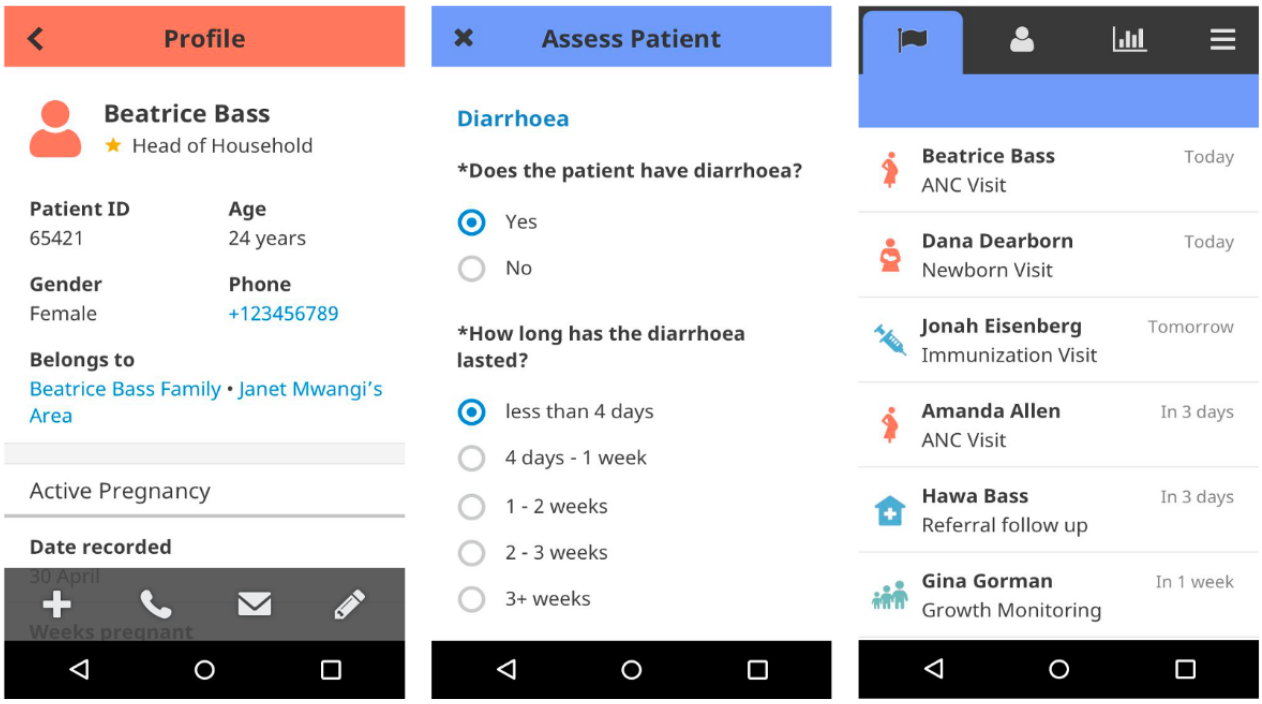
XSL•FO
RenderX

same coding approach to find explanations for the identified changes. We further analyzed the interviews regarding the continued use or adaptation of the ThinkLets (step 4). Finally, we combined survey data, interviews, and field observations to draw our conclusions. We could generate a rich and multidimensional understanding of Scripted Medicine through careful triangulation. Our abductive approach sensitized us to balance the empirical findings and theoretical grounding in collaboration engineering, algorithmic management, and empowerment. Finally, we formulated design principles as proposed in a study by Gregor et al [79] to synthesize our contribution and inform designers.

Artifact Description

Scripted Medicine was developed based on the 3 principles of process restriction proposed in collaboration engineering: (1) careful design of a series of activities; (2) configuration of technology to support behaviors within each activity; and (3) guidance on the behaviors (including constraints) performed in each activity [59]. Insights from algorithmic management guided the design of the series of activities and the configuration of technology, while ThinkLets formalize the behaviors in the activities. Scripted Medicine interlinks medical and counseling expertise conveyed by algorithms and ThinkLets to structurally and psychologically empower CHWs. The act and perception of empowerment allow CHWs to accept broader responsibilities in NCD care. Figure 2 depicts this conceptual model for Scripted Medicine.

Figure 2. A conceptual model for community health worker (CHW) empowerment with Scripted Medicine based on process restrictions through medical algorithms and ThinkLets.



Formalizing Clinical Knowledge in ComBaCaL

Medical algorithms formalize the clinical knowledge necessary to offer diagnosis, monitoring, and treatment services for NCDs. These algorithms represent a carefully designed series of activities that follow existing medical guidelines. They constrain CHWs in their actions to ensure the proper application of care procedures for patient safety. These constraints facilitate the expansion of CHWs' responsibilities and have been shown to empower CHWs [35]. For example, they offer step-by-step guidance to support CHWs in implementing the proper medical procedures in the correct order. Further, mHealth automates documentation, which frees up time for CHWs. Finally, such tools give CHWs access to relevant medical history information collected previously.

The medical algorithms were implemented in CHT and called the ComBaCaL app. The toolkit offers a "shell" with basic functionalities and allows for rapid deployment of medical algorithms. The ComBaCaL app is structured in 3 tabs: tasks, care guides, and profiles (Figure 3 [72]). The medical algorithms influence each tab by defining open tasks and their due date, storing, and displaying information in patient profiles, and providing step-by-step guidance in the care guides. For the study, the medical algorithm covered medical procedures for (1) *patient and household enumeration* (ie, registration and obtaining informed consent); (2) *screening for diabetes*, using capillary blood sugar measurements after prescreening using age and body mass; (3) *diagnosing diabetes*; and (4) *initiating treatment* (ie, medication and lifestyle advice, if applicable). In a diagnosis, the medical algorithm would initiate screening for signs and symptoms of advanced disease and other criteria that would require a referral of the patient to a health facility. In an uncomplicated disease, the algorithm would start a treatment cycle with regular follow-ups to adjust medication until an acceptable blood glucose level is reached. If acceptable blood glucose levels cannot be reached through the treatment provided by the CHW, the algorithm would then suggest referral to the health facility for further care. Guidelines for medical professionals are confined to essential clinical information. More guidance is required in community-based health care as CHWs do not have this formal education. In ComBaCaL, the medical algorithms contained relevant clinical questions, notes on preparations (eg, to ensure that all necessary materials, such as protective gloves are available), information to provide to clients (eg, possible side effects of medication), and alerts, if a client must be sent to a medical professional. However, not all relevant knowledge can be conveyed in algorithms, as they would become cluttered and overly lengthy.

XSL•FO
RenderX

Figure 3. The community health toolkit structure in the tabs: (A) profile; (B) care guides; and (C) tasks. ANC: antenatal care.

Formalizing Counseling Knowledge in ComBaCaL

Accordingly, Scripted Medicine formalized counseling knowledge in ThinkLets. Medical scripts (ie, medical algorithms) guided the CHWs through a series of activities. This way, they offered the information basis for the social interactions (eg, a diagnosis a CHW must explain to the patient). ThinkLets formalized counseling expertise to guide CHWs in these social interactions throughout the consultation process. While initially developed to guide behaviors in large group collaboration, ThinkLets are not limited to such collaborations. They have been successfully applied in dyadic collaboration. For example, ThinkLets can empower service providers to use technology to adapt work practices for value cocreation in service encounters [80]. They can also facilitate knowledge transfer between expert advisers and nonexpert clients in burglary prevention [81].

In Scripted Medicine, they contained the counseling knowledge required to interact meaningfully with clients and build quality relationships. Counseling ThinkLets embed the clinical knowledge instantiated in algorithms into social interactions. Such ThinkLets can range from high-level steps to microinteractions. For example, a ThinkLet could provide instructions on approaching new clients and introducing the health program to start counseling. Another ThinkLet on comforting clients could offer CHWs a tool to handle patients' emotional reactions after a diagnosis.

In ComBaCaL, social interactions along the medical algorithm's guidance were scripted in 9 ThinkLets. The ThinkLets covered the steps of *greeting and consent*, *enumeration*, *screening*, *confirmation*, *counseling*, *referral*, *medication*, *dosing*, *closing with diabetes*, and *closing no diabetes*. These high-level steps are intended as a proof-of-concept that should be broken down into more nuanced ThinkLets with growing experience and insights. Table 2 shows the *greeting and consent* ThinkLet as an example. Italicized texts indicate posttraining adaptations made due to insights from the training. For example, Basotho customs require people entering the property to announce themselves with "Koko." The ThinkLets indicates the inputs required and expected outputs for the interaction. The setup includes instructions, for example, on how to position oneself or organize the working space. The steps and "say this..." offer guidance on how to structure the interaction. In the subsequent example, the ThinkLet also refers to additional materials to be used (ie, "according to the introduction cheat sheet"). Finally, notes offer insights for CHWs and others into the context and mechanisms of a ThinkLet.

XSL•FO
RenderX

Table 2. An example ThinkLet greeting and consent, with posttraining adaptations in italics.

Dimension	Description
Name	• Greeting and consent
Inputs	• None
Outputs	• Signed informed consent form and client who knows the CHW[a] and ComBaCaL[b]
Setup	• *Say loudly "koko" while entering the property and repeat until you can be certain that the owner heard you if they are around*
Steps	1. Greet clients 2. Briefly present yourself 3. Briefly present ComBaCaL cohort study 4. Wait for permission to take a seat or ask for it (outdoor or indoor) 5. Take tablet and the *introduction cheat sheet*
Say this	1. *According to the introduction cheat sheet:* • present yourself • present ComBaCaL • explain informed consent form 2. Let all clients sign the informed consent form (including children) 3. *Start creating the household in the app* 4. *Answer all required questions while creating the household* 5. *Submit*
Notes	• Basotho houses in rural areas differ from houses in western countries in that you already enter a more private part of the property, even if you have not yet stepped through a front door. Because many houses consist of only 1 room, one already enters the bedroom when entering the house interior. The properties are fenced and when you pass through the fence gate, however, you cannot knock. The observations during the trainings have shown that the CHWs replace the ringing or knocking at the door with a loud "Koko." This should be loud enough so that it can he heard over the entire property and the owner will be aware of it if they are home.

[a]CHW: community health worker.

[b]ComBaCaL: Community Based Chronic Disease Care Lesotho.

Results

Overview

In this section, we report on the evaluation outcomes of Scripted Medicine in the field study in ComBaCaL. We evaluated the attainment of the design goal (ie, empower CHWs to accept broader responsibilities in NCD care) in 2 rounds. First, we examined Scripted Medicine's effect on CHW empowerment directly after the training. Second, we highlighted changes in the CHWs' perception after approximately 3 months in the field.

CHW Empowerment After the Training

The video recordings captured the CHWs' application of the counseling ThinkLets. While the interactions in practice sessions at the beginning appeared artificial, the CHWs felt noticeably more comfortable interacting with clients in the nearby villages. The analysis showed that most CHWs closely followed the ThinkLets. However, they had already started adjusting the scripts to their liking. For example, instead of enumerating a household with everyone present, they opted to enumerate each member individually and asked others to leave. Later, the CHWs explained that due to the personal questions in the general health questionnaire (eg, HIV status), they wanted to create a more secure environment.

The medical algorithms in the ComBaCaL app scored 74.25 on the SUS. This indicated that the CHWs perceive the medical algorithms and the ComBaCaL app as useful in counseling clients. The analysis of the video recordings supports this indication. Most CHWs navigated the app without difficulties at the end of the practice-oriented training.

The empowerment questionnaire showed that the training empowered the CHWs. On average, the CHWs rated their structural empowerment at 4.5 on a 5-point Likert scale (Table 3; Multimedia Appendix 3 provides further details). In the focus group discussions, many referred to the clear structure provided by the medical algorithms and ThinkLets. One CHW said the following:

> *I thought it's going to be hard to go through [all the procedures]. But then, when we proceeded, everything became clearer. The app reminds me, and things come easy.*

XSL•FO
RenderX

Table 3. Evaluation results of community health worker empowerment on a 5-point Likert scale and System Usability Scale (range 0-100).

Measure and dimension	After training	After field experience	Trend
Structural empowerment (5-point Likert scale)			
Access to opportunities	4.5	4.6	↑
Access to information	4.6	4.6	—[a]
Access to support	4.3	4	↓
Access to resources	4.6	4.3	↓
Psychological empowerment (5-point Likert scale)			
Meaning	4.9	4.8	↓
Competence	4.6	4.5	↓
Autonomy	4.1	4.2	↑
Impact	3.8	4	↑
System Usability Scale (range 0-100)			
Total score	74.25	76.5	↑

[a]Not available.

The training approach also resonated well with the CHWs. They could make mistakes in a safe environment, where they received feedback from trainers and peers. Further, the Butha Buthe CHWs agreed in the focus group discussion that the last days in the nearby village greatly benefited them in interacting with strangers. Back in their community, their clients mostly will not be strangers but people they already know to a certain degree, which would make the interactions even easier. However, some CHWs, particularly those from Mokhotlong (ie, the more rural district), raised infrastructure concerns such as the lack of electricity to charge their tablets. Consequently, the Mokhotlong CHWs rated their access to resources as 14% lower (4.27 compared to 4.87) and access to support as 17% lower than their Butha Buthe colleagues (3.93 compared to 4.6).

The CHWs also felt empowered as they rated their combined psychological empowerment at 4.35 out of 5. Notably, impact is the only dimension rated <4, at 3.8. Again, the Mokhotlong CHWs rated the perceived impact noticeably lower (26%, 3.33 compared to 4.2). In the focus group discussions, some feared that people might refuse their services due to skepticism, as NCDs "are for the rich people" and would only affect "people who are older."

Conversely, both groups perceived an exceptional meaning in their future work (4.9 out of 5), which one CHW explained with this:

> *We don't want to see an increased number of patients diagnosed with diabetes and hypertension, and also, we don't want to see people who already have hypertension or diabetes die due to complications of those diseases.*

Another CHW highlighted the benefits of the counseling ThinkLets. She described herself as shy, "but this time, I've seen that I'm not shy anymore, and I can speak freely to everyone." The Mokhotlong CHWs all rated meaning with the maximum score and, thereby, slightly higher than the Butha Buthe CHWs. Further, all CHWs felt confident with their new skills and roles. One CHW said the following:

> *I don't think there will be challenges. The people in my village are waiting for me.*

However, the CHWs also raised some initial concerns. The concerns were primarily related to their acceptance, as community members might not be willing to accept their services. Both groups would prefer a project representative to introduce them to their village to gain initial credibility. Some mentioned that weather conditions influencing their ability to travel were a concern, especially in winter. These concerns often evolved around the loss of control, which could explain the CHWs' lower perception of autonomy compared to the other dimension (4.1 out of 5 on a 5-point Likert scale).

When asked what they expect upon returning, one CHW emphasizes the collaboration with patients as follows:

> *We're expecting to work hand in hand with patients. And being kind to them, to speak to each other. I think the most important thing is the idea of ComBaCaL to come through, and this is going to happen by the way we'll be working. We are going to be sure that each and everyone will be happy with our services.*

Despite raising some concerns, the CHWs felt well-prepared for their new responsibilities when returning to their communities after the training.

CHW Empowerment After Field Experience

After approximately 12 weeks in the field, the CHWs still felt empowered and ranked the ComBaCaL app slightly higher at 76.5 points on the SUS (Table 3).

Over the 3 months, CHW empowerment showed some minor changes. As the CHWs are distributed across 2 districts in Lesotho, they appeared to perceive less access to support (from 4.3 to 4 out of 5). During the training, they had access to supervisors, experts, and peers to ask questions and receive feedback. After returning to their communities, the CHWs

XSL•FO
RenderX

mainly worked alone. In the interview, one CHW proposed adding "a chatting platform, where people are ready to help in case of seeking for help; on which our instructors are able to communicate with us." Further, they had fewer opportunities to acquire new skills than during the training (from 4.6 to 4.3). Some mentioned in the interview that adjusting from a training setting to working back in their community took some time.

The CHWs perceived the same or even slightly better access to information (from 4.5 to 4.6) and resources (remained at 4.6) compared to the training. One CHW refers to the tablet as the source of information and resources as follows:

> *It helps a lot since it shows all the activities we were taught in training. It shows which people to attend the following day and how many people I have offered services to. It...helps me to keep track of people who are served and others to be served. If I happen to make a mistake in my activity, it reminds me because it shows that something is wrong.*

The CHWs' psychological empowerment also underwent some changes. Despite their high confidence in their skills, most CHWs report challenges they encountered in their community. Accordingly, perceived meaning and competence slightly decreased. A CHW mentioned convincing young adults as a challenging task as follows:

> *The main challenge is that the youngest adults refuse to agree when we test for them. But after talking to them about the importance of this, then they agree.*

Interestingly, most CHWs reported similar experiences of persuading reluctant clients when asked about their greatest success so far. For example, another CHW said: "what made me happy is the joy of being able to convince a person, or generally making a person have interest in matters of health." They could persuade clients to accept their services despite the initial skepticism. This success might have increased perceived autonomy and impact, as "those one I helped are very impressed since ComBaCaL is taking care of their lives door to door, and they even gained some information on how to take care of themselves." After translating their training into practice, the CHWs could see the impact of their work. This gave them confidence in their capabilities and resulted in more trust from their patients, as one CHW summarized:

> *Most of my clients see the confidence in me when I walk; when I touch anything. So, when you enter the door of the household, you should look confident and say clear things so clients are able to trust you. [The training] was basic because it helped me overcome my fear. That was my first action when I started; to see how to work with a patient. So, I learned there, and I was able to move forward with the knowledge.*

Interestingly, the interviews showed that medical algorithms dominated the perception of structural empowerment. However, psychological empowerment is often attributed to the ThinkLets that embed clinical knowledge in client interactions. As in the example earlier, the CHW refers to "work with a patient" and their confidence in their interactions with the patient. Hence, combining medical and counseling knowledge empowered CHWs to accept their responsibilities in ComBaCaL.

Discussion

Principal Findings

This study aimed to design Scripted Medicine, which is an approach to empower CHWs to accept broader responsibilities in NCD care. We grounded the approach in research on collaboration engineering and algorithmic management. Restricting CHWs in the process facilitated the transfer of power (ie, structural empowerment) that led to psychological empowerment. As hypothesized, the empowered CHWs could accept the broadened responsibilities and offer more holistic NCD care to their community. These results allow us to make a 2-fold contribution.

Scripted Medicine

Scripted Medicine is a novel approach inspired by existing research on collaboration engineering and algorithmic management. It is the product of scripting the necessary medical and counseling expertise. Scripted Medicine combines previously separated knowledge spheres to create significant empowerment potential in community-based health care. Process restrictions empower CHWs by conveying the relevant knowledge required for their work.

Medical algorithms empower CHWs to perform medical procedures [40-42]. Scripted Medicine broadens the perspective on medical algorithms by drawing on algorithmic management literature [43,44,47]. The 5RSM framework provides a nuanced distinction of algorithmic management forms that influence how researchers design and study medical algorithms [47]. For example, our evaluation highlights the necessity for carefully considering algorithmic requiring and recommending. CHWs might feel disempowered when requiring noncritical activities instead of providing certain flexibility in work planning. On the contrary, previous research reports seemingly contradictory observations in CHW empowerment. CHWs perceived algorithmic restricting as empowering instead of a loss of autonomy [54]. This observation aligns with collaboration engineering research [59,60]. Accordingly, Scripted Medicine explains how restricting CHWs in the process (eg, restricting unsafe actions) while allowing enough flexibility for users to adapt to their context is empowering rather than disempowering. It also emphasizes the "well-designed" when instantiating clinical knowledge in mHealth tools. Consequently, we formulate the design principle of scripted medical activities (Textbox 2 [79]).

XSL•FO

Textbox 2. The design principle of scripted medical activities following the study by Gregor et al.

Title

- Design principle of scripted medical activities

Aim, implementer, and user

- For designers and researchers (implementers) to efficiently and effectively convey medical knowledge (aim; solution objective [SO] medical knowledge) by drawing on the algorithmic recommending, restricting, requiring, rating, rewarding, sanctioning, and monitoring (5RSM) framework to guide community health workers (CHWs; users) through carefully designing a series of medical activities

Context

- Community-based health care heavily relies on medical algorithms to enable CHWs to perform medical procedures (eg, diagnostics) safely and independently [40-42]. While requiring CHWs to follow a specific path creates more reliability, it ignores the individual preferences of CHWs and might lead to conflicts with other responsibilities (eg, families). This could result in dropouts [13,14].

Mechanism

- Provide medical knowledge to CHWs through scripts based on algorithms (eg, decision trees), allowing them to have agency over noncritical medical activities

Rationale

- Collaboration engineering allows nonexperts to perform activities by restricting their process flexibility [59]. While this has an empowering effect, certain forms of algorithmic management (ie, recommending and requiring) can have opposite effects [47]. Our results have shown that requiring a specific order in which tasks are completed feels too restrictive. Allowing CHWs to plan their work independently, within limits, offers them an agency that is perceived as empowering. Accordingly, the 5RSM framework offers more nuanced forms of algorithmic management that acknowledge the need for reliability and safety as well as independence and agency.

Scripted Medicine further argues that formalizing clinical knowledge alone is insufficient for sustainable community-based health care. While medical algorithms provide the foundation to expand CHWs' responsibilities, they do not adequately address all relevant aspects of empowering CHWs. Medical algorithms cater to 2 out of 3 aspects of process restrictions as follows: (1) careful design of a series of activities and (2) configuration of technology to support behaviors within each activity. However, they lack the final ingredient that translates the clinical knowledge into its application context: (3) guidance on the behaviors performed in each activity to maneuver CHWs and their clients through the counseling process.

Scripted Medicine addresses a significant shortcoming in current research that often assumes that medical algorithms alone empower CHWs. This limited perspective results in unilateral solutions that solely focus on the technical dimension of CHW empowerment [29,30,54]. However, CHW acceptance and overall health outcomes also depend on the quality of the social interactions between CHWs and their clients [52,53]. Yet, counseling knowledge is seldom in scope in community-based health programs. Scripted Medicine extends the existing work on CHW empowerment as it embeds clinical knowledge into the context where it is applied. Our evaluation indicated differences between Mokhotlong and Butha Buthe CHWs. These differences highlight the importance of considering the social context. Both CHW groups received the same scripted expertise and training but showed different perceptions of structural and psychological empowerment. While the survey only offered indications, our observations and interviews allow us to argue that the slightly different contexts between the 2 districts cause the indicated differences. People in Mokhotlong might be more skeptical of Western medicine in general. Hence, CHWs might believe the community will be reluctant to accept their services and perceive less impact of their work. Further, Mokhotlong CHWs raise the issue of lacking access to electricity or cellular signals, while their Butha Buthe colleagues do not. Infrastructure differences also alter empowerment perceptions. Mokhotlong CHWs perceive less access to resources (ie, the tablet could run out of battery) and support (ie, no means to call or text a supervisor). Scripted Medicine obliges designers and researchers to consider the context within which they operate carefully.

Counseling ThinkLets serve multiple purposes in Scripted Medicine. First, ThinkLets were useful training modules for counseling clients with the support of medical algorithms. Trainers can structure training along ThinkLets to maintain a logical order. ThinkLets can first be discussed and demonstrated in the plenum before moving to practice-oriented training sessions. In these sessions, CHWs apply ThinkLets to build expertise in a safe environment and receive feedback from trainers and peers. Second, ThinkLets are individual learning modules beyond official training sessions. CHWs can always revert to them in case they feel insecure. For example, CHWs might not perform specific tasks regularly and want to refresh their memory before counseling clients. Third, ThinkLets are intended to provide a foundation for social interactions in counseling. While the medical algorithm provides continuous constraints for care procedures, ThinkLets should "kickstart" the CHWs' counseling practices that they adapt over time as their expertise grows. Finally, ThinkLets allow designers and researchers to study the evolving routines of individual CHWs when performing their work. These insights can be formalized and shared with other CHWs to make knowledge accessible within the program.

Scripted Medicine emphasizes the sociotechnical context, which is often lacking in existing literature on technology-supported

XSL•FO
RenderX

community–based health care. It allows research to go beyond medical outcomes and consider CHWs' difficult position at the margin of different communities (eg, their families and the health system), often without fully belonging to any of them [29]. In combination, counseling ThinkLets and medical algorithms facilitate the structural empowerment of CHWs as they gain access to information, resources, support, and opportunities. Scripted Medicine postulates a more comprehensive view of structural empowerment, as optimizing one aspect might not cater to all dimensions. For example, medical algorithms might reduce or even prevent access to opportunities. CHWs cannot deviate from the algorithm's predetermined workflow to ensure patient safety. On the other hand, counseling ThinkLets open plenty of opportunities for CHWs to develop their personal way of interacting with clients. They empower CHWs to transfer medical procedures from isolation into the social interactions of health services. On the basis of these insights, we formulate the design principle of scripted counseling (Textbox 3 [79]).

Textbox 3. The design principle of scripted counseling following the study by Gregor et al.

Title

- Design principle of scripted counseling

Aim, implementer, and user

- For designers and researchers (implementers) to efficiently and effectively convey counseling knowledge (aim; solution objective [SO] counseling knowledge) to support community health workers (CHWs; users) in the creation of their own, culturally adapted counseling practices

Context

- Digital health tools for community-based health care primarily convey medical knowledge to CHWs [29,30,54]. While medical knowledge is crucial, health care is always an interaction between people. Accordingly, existing research does not support CHWs enough to transfer this medical knowledge into action.

Mechanism

- Provide counseling knowledge to CHWs through ThinkLets (ie, communication scripts), allowing them to scaffold their advice and to develop their counseling practices in accordance with their preferences and the cultural context

Rationale

- CHW acceptance and health outcomes significantly rely on social interactions [52,53]. Counseling ThinkLets require designers to consider the context for which they design and allow CHWs to develop their own practices that suit their preferences and strengths. Further, it allows tailoring to nuances within specific cultural contexts. Our findings indicated differences between the CHWs from the more urban Butha Buthe and the rural Mokhotlong.

Scripted Medicine is more than stringing together medical and counseling scripts. These scripts are interdependent. Explicating medical knowledge in the form of guidelines has long been established. Counseling knowledge, as established in the introduction, is often implicit and gained with years of training and experience. Accordingly, guidelines for medical professionals focus on essential clinical information. They assume medical professionals possess the counseling experience to translate clinical information into the consultation context.

The literature often neglects that CHWs require more guidance than medical professionals. Scripted Medicine is an approach to formalizing both areas of expertise, as clinical knowledge alone is insufficient. For example, CHWs can counsel people if they can rely on proper medical guidance and access relevant clinical information about patients and medical procedures. However, access to that data and being able to implement the medical procedures depends on a good working relationship with patients. Establishing and maintaining such a relationship requires guidance on counseling practices.

Scripted Medicine considers the symbiosis of medical and counseling knowledge and their interdependence. Accordingly, it is more than merely a combination of clinical and counseling guidance. For example, medical algorithms might include different media types for CHWs to educate patients about their condition after a diagnosis. Further, ThinkLets must consider the process restrictions implemented in algorithms to avoid unnatural interactions. This combination of formalized knowledge in Scripted Medicine is the foundation for psychological empowerment. While clinical knowledge itself might enable CHWs to conduct medical procedures, CHWs perceive the embedding in social interactions as empowering. It allows CHWs to see the meaning in their work, feel competent in counseling clients, autonomously plan their work, and observe their work's impact on their community. Thus, we formulate the design principle of Scripted Medicine (Textbox 4 [79]).

XSL•FO
RenderX

Textbox 4. The design principle of Scripted Medicine following the study by Gregor et al.

Title

- Design principle of scripted medicine

Aim, implementer, and user

- For designers and researchers (implementers) to meaningfully intertwine formalized medical and counseling knowledge (aim) to empower community health workers (CHWs; users) to accept broader responsibilities in noncommunicable disease care

Context

- On one side, CHWs depend on medical algorithms to offer health services. On other side, medical algorithms depend on the data inserted by CHWs during consultations. Thus, CHWs require a tool that carefully aligns the designed medical activities with counseling practices to carry out more complex tasks successfully.

Mechanism

- Integrate formalized medical and counseling knowledge visually and algorithmically to empower CHWs

Rationale

- Collaboration engineering is an approach that carefully considers the effects of restricting and guiding users through activities and interactions [57,59]. IT-supported community–based health care is a sociotechnical system in which people, tasks, systems, and organizational structures (communities) are inherently interdependent [54]. Thus, CHWs require access to information, resources, support, and opportunities that consider the social and technical dimensions of community-based health care.

Becoming Agents of Social Change

Existing research provides in-depth insights into the design of mHealth to capacitate CHWs to perform actions they could not perform otherwise, such as diabetes screening [5,34,37,41]. While this work is fundamental for expanding CHWs' responsibilities, it fosters a unilateral focus on conveying medical knowledge through mHealth. It has been argued that most studies view CHWs as sensors of the health system, leading to a reductionist perspective on community-based health care [54]. In other words, existing research almost exclusively focuses on the technical domain in a sociotechnical system and omits the social dimension. This situation was mentioned in a critique by Engel [82] on biomedical medicine as follows:

> *The crippling flaw of the [biomedical] model is that it does not include the patient and [their] attributes as a person, as a human being. Yet, in the everyday work of the physician, the prime object of study is a person.*

Similarly, existing research does not consider community-based health care as a collaborative process between CHWs and their clients. However, multiple studies highlight the importance of social interactions in community-based health care for patient experience and treatment adherence [52,53]. Scripted Medicine offers a lens that emphasizes the collaborative nature of community-based health care. While the immense benefits of community-based health care are undoubted, we criticize the often reductionist consideration of health outcomes only. mHealth might increase CHW performance and retention or capacitate them to perform more complex tasks guided by medical algorithms [36]. However, they do not necessarily address the root causes of low performance and high attrition (eg, lack of organizational support and appreciation [9,14]). Accordingly, mHealth could even worsen the situation for CHWs. Their responsibilities continuously broaden and become more complex, while their work conditions do not necessarily improve at the same rate. From an empowerment perspective, current research focuses on shifting responsibilities and often forgets shifting power. This could lead to CHWs feeling more disempowered and increase instead of decrease attrition rates over time.

Scripted Medicine aims to address such structural issues. It accentuates the interdependence between the 2 dimensions of health care: the medical and outcome-oriented procedure (health) and the interpersonal, collaborative character (care). For example, existing reports on health outcomes of community-based health initiatives are limited to people willing to accept CHWs' services. Reluctant people do not benefit from improved access to health care and, consequently, are usually not considered in such studies. Our evaluation indicates that Scripted Medicine might empower CHWs to better persuade this population to accept their services. By considering both dimensions of health care, we believe CHWs become better service providers and become the "agents of social change, beyond their role as links between the community and the health system." [50]

Conclusions and Limitations

Task shifting to CHWs is a promising remedy to the imminent shortage of medical professionals in the Global South [4,5]. However, community-based health programs often face performance variability and high attrition rates [9-13]. As a result, task-shifting efforts might be built on unstable foundations if the root causes of the existing challenges are not resolved.

Scripted Medicine provides a more comprehensive perspective to empower CHWs to accept broader responsibilities in NCD care. Scripted Medicine "scripts" clinical and counseling knowledge that promises to quickly empower CHWs to accept broader responsibilities and become active members of the

XSL•FO
RenderX

health system. It draws on research on collaboration engineering and algorithmic management to restrict CHWs in the counseling process in a way that empowers them to offer more complex health services, such as first-line treatment for uncomplicated type 2 diabetes and hypertension.

Scripted Medicine positions CHWs as active members and not sensors of the health system. Scripting medical and counseling knowledge transfers the power necessary to offer high-quality health services to CHWs. In turn, CHWs feel empowered to accept new responsibilities and, thereby, increase the accessibility of health care. Scripted Medicine highlights the need for a deeper understanding of the local context and the design of contextually adapted community-based health programs to support CHWs in their work.

However, this study does not come without limitations. Scripted Medicine broadens the unilateral focus on the technical dimension by emphasizing social interactions. However, more research is needed to study other potential dimensions influencing CHW empowerment. Empowerment is a dynamic concept that requires a longitudinal assessment of changing CHW demands [35]. Finally, the rich dataset allowed us to triangulate Scripted Medicine from empirical data. Future work is needed to validate these empirical observations at a larger scale.

Acknowledgments

This study is part of the Community Based Chronic Care Project Lesotho (ComBaCaL). The ComBaCaL project is funded by the TRANSFORM grant of the Swiss Agency for Development and Cooperation (project 7F-10345.01.01) and a grant by the World Diabetes Foundation (WDF-1778) to SolidarMed. The authors would like to thank the CHWs interviewed in this study and all involved ComBaCaL staff members, especially Thabo Lejone, who organized the community health workers' training and assisted with the interviews.

Abstract

Background: Knowledge sharing in medical imaging departments is driven by the need to improve health care services, develop health care professionals' skills, and reduce repetitive mistakes. It is considered an important step in the implementation of knowledge management solutions. By following a maturity model of knowledge sharing, knowledge-sharing practices can be improved.

Objective: This study aimed to develop a maturity model for knowledge sharing in the medical imaging department to help managers to assess the level of maturity of knowledge-sharing practices. In modern health care institutions, improvements in health care professionals' skills and health care services are often driven through practicing knowledge-sharing behaviors. Managers can follow the indicators of maturity model of knowledge sharing and its measurements to identify the current level and move to the next level.

Methods: This study was conducted in 4 stages: an *overview stage* that highlighted the factors that affect knowledge-sharing practices in medical imaging departments; an *analysis factor stage* that was designed to assess the factors that affect knowledge sharing using a concurrent mixed methods approach (questionnaires and semistructured interviews) in 2 medical imaging departments; *a structuring maturity model knowledge sharing stage*, where a maturity model of knowledge sharing was developed based on the findings of the first and second stages; and finally, an *assessment of reliability and validity stage*, where a modified Delphi method was used to obtain consensus among experts on model components to be ready for implantation.

Results: The model presented in this study includes 17 indicators, divided into 11 components. Those components were derived from the findings of the questionnaires and semistructured interviews that were applied in the medical imaging departments. It consisted of 5 maturity levels: initial, aware, defined, managed, and optimized. In each level, measurements were included to help managers assess the current level by answering the questions. On the basis of reliability, the experts reached a consensus agreement on the model's components in 2 rounds with SD <1.

Conclusions: This maturity model of knowledge sharing in medical imaging departments allows managers and policy makers to measure the maturity level of knowledge sharing in those departments. Although the model has been applied to medical imaging departments, it could easily be modified for application in other institutions.

Introduction

Background

Knowledge is an essential asset in achieving successful institutional practices, and sharing knowledge gives a sustainable competitive advantage to modern institutions [1,2]. Accessing knowledge is the main step in problem-solving and decision-making [3]. Knowledge is a mixture of experiences, thoughts, ideas, values, and information. In the context of institutions, knowledge can be shared and transformed among employees within institutions to create new experiences and information that did not exist before [4]. It consists of 2 main categories: tacit and explicit knowledge [5]. Tacit knowledge is any knowledge that exists in human minds, such as thoughts and ideas. This kind of knowledge is difficult to document and share. In contrast, explicit knowledge is the knowledge that exists in policies, letters, documents, and manuals. This kind of knowledge is easy to document and share with others using several mechanisms [6]. Both kinds of knowledge are not separate from each other. The dynamic process between tacit and explicit knowledge helps share knowledge efficiently [5,7].

Health care institutions, for example, hospitals and specialized centers, must apply a knowledge management system to build a proper and effective network among all health care providers [4]. The reasons for implementing a knowledge management system are mainly the complexity and huge number of knowledge-based resources that need to be managed [8]. Implementing knowledge management depends on understanding its processes (knowledge creation, knowledge capture, knowledge sharing, and knowledge applications). Moreover, identifying a clear framework to follow is vital to targeting any weaknesses in each step and creating a good environment for health care professionals. As a result, health care services and patient outcomes can be improved [8].

Knowledge sharing is considered an important step in implementing knowledge management. Without a knowledge-sharing process, knowledge management will be difficult to implement because it relies on the dynamic process of tacit and explicit knowledge sharing among employees. Therefore, creating a culture of knowledge sharing among them, and understanding the resources and factors that affect knowledge sharing, are important for any knowledge management system. Looking at health care services, knowledge sharing is an essential step for successful knowledge management within institutions, as it can lead to improved health care settings performance, save them time, reduce costs, and increase health education levels [9]. It plays an important role in providing great accountability and establishing good practices in health planning and policy making. Abzari et al [10] stated that knowledge sharing is considered an essential factor in successful institutional performance. It refers to the act of sharing both tacit and explicit knowledge, such as thoughts, ideas, and experiences from one person, group, or institution to another to formulate new knowledge [11]. Knowledge sharing is one of the challenges for health care institutions due to the variety of resources and knowledge. Health care institutions are complex environments given the variety of specialties in each department and who operates institutional resources in each department [12].

Medical imaging departments are essential in any health care institution due to the importance of performing important procedures for the pretreatment plan and interpreting results. On the basis of the observation at the cancer center, there are several problems facing knowledge-sharing practices in the medical imaging department, such as a lack of awareness of the importance of knowledge sharing, difficulty in sharing knowledge among health care professionals, and a lack of implementation of information and communication technology (ICT) [13]. Creating a communication environment is important to control the amount of knowledge shared among health care professionals in their institutions [14]. In addition, dealing with health care institutional issues is directly related to human capital [15]. Sharing knowledge among health care professionals is critical to apply that knowledge in their daily work and allow them to create new knowledge that is needed for developing the institutional process. Both tacit and explicit knowledge are important to enhance the knowledge-sharing process among health care professionals, because they are directly related to the health care professional's experience and skills [16]. Therefore, identifying a clear maturity model (MM) for knowledge sharing in medical imaging is important to help policy makers and managers use it to enhance knowledge-sharing practices among health care professionals.

An Overview of the MMs

Maturity in this context refers to the degree to which technology, institutional process, or frameworks evolve over time [17,18]. In institutions, an MM can be methodically used to define operations and identify stages, which can lead to policy plans [19]. The concept of the MM was developed in the early 1970s [20]. It is increasingly applied in information systems [21] and is established in many fields, such as knowledge management, information management, and software performance and management [22-25]. The purpose of MMs is to provide a clear model based on an institution's capabilities in a certain managerial area using a set of criteria and related evaluation methodologies [26]. It can be a powerful tool that helps identify strengths and weaknesses in a specific area [27]. Bititci et al [28] indicated that MMs have a positive impact on improving institutional performance and respond to many challenges by describing each step and stage properly.

Health care institutions face challenges in achieving best practices in knowledge management system implementation [29]. Maturity in knowledge management is defined as the degree to which knowledge assets are effectively managed and controlled within institutions [30]. There have been several MMs for evaluating and describing these areas of management that have been proposed in different studies [17-19,31-33]. Some other applications of MMs have been applied to health care intuition information systems [34].

On the basis of the definition of maturity in knowledge management, there is a strong link with the knowledge-sharing definition, which is sharing experience and knowledge with each other within an institution. This knowledge, either tacit or explicit, needs to be managed to be able to be shared. In

XSL•FO
RenderX

addition, to share any kind of knowledge, it should be managed by human experience; this kind of management is required for implementing the knowledge management process because it is *dynamic and active* [35]. Therefore, there is a strong relationship between the 2 definitions, as both deal with the assets that need to be managed to obtain the objective. To share the knowledge, they must understand the types of knowledge and the factors that control the process of knowledge sharing, all of which need to be managed and controlled within institutions. On the basis of this context, to improve the knowledge management process, we need to improve the process of sharing the knowledge.

There is a continuing need to structure and develop a new knowledge sharing MM (KSMM) for enhancing knowledge-sharing practices among employees in the medical imaging departments [36]. Structuring a KSMM helps decision makers to achieve institutional tasks and improve the quality of patient outcomes [37]. There are several models of knowledge sharing [38-41]. Despite the variety of these models, few of them focus on knowledge sharing in health care in general and in the medical imaging department in particular [42]. There are several factors that affect knowledge sharing among health care professionals, including the MM of multidisciplinary team (MDT) meetings, community of practice, ICT, social media networks, picture archiving and communication system (PACS), telemedicine, and digital library [43-49]. Creating a MM for knowledge sharing that consists of all factors that affect their behaviors is vital to implementing a knowledge-sharing environment among health care professionals. The KSMM should be an umbrella that covers all the factors.

To date, there is no MM to assess knowledge-sharing practices among health care professionals in general hospitals, or in medical imaging departments specifically, covering all the factors that affect knowledge sharing in medical imaging departments. Ipe [50] represented the model for the relation of the knowledge sharing between individuals, factors, and the relation between them. Therefore, developing an MM to evaluate the level of maturity of knowledge-sharing behaviors is a challenge due to the interactions of health care professionals' behaviors with each other on the one hand and with ICT on the other. In addition, this model is dependent on human beings, cultural environments, and technological facilitators [50].

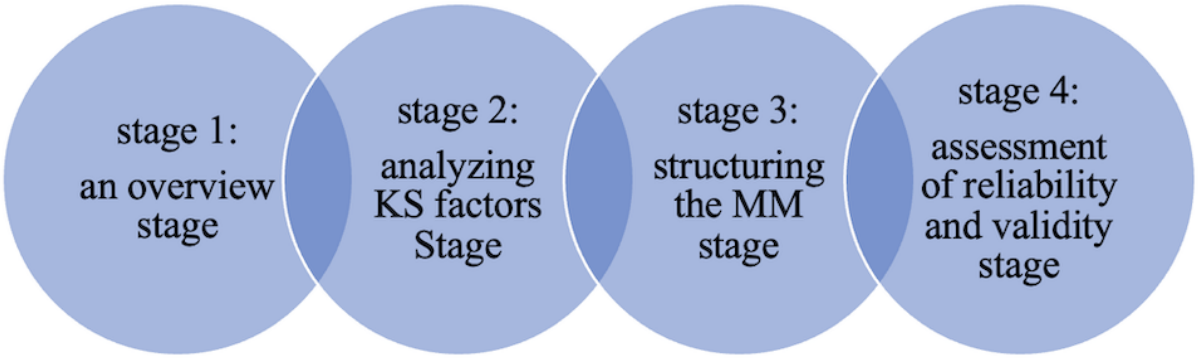
Aim and Research Questions

The aims of this paper were to present the steps of the development of a KSMM for understanding how health care professionals share their knowledge; define the proper stages of achieving the best knowledge practices among health care professionals in medical imaging departments; and use the Delphi method to examine the reliability and validity among experts on that model [51].

Therefore, the key research questions were as follows: (1) what are the main components that structure the KSMM? (2) what are the stages of MM that managers in medical imaging departments need to follow to evaluate and enhance knowledge-sharing practices among health care professionals? (3) what are the indicators that control the KSMM, and how can managers measure them? and (4) how to evaluate the proposed KSSM regarding validity and reliability?

Objectives

This paper had various objectives. The first objective is to identify the main stages and components that relate to the KSMM. The second objective is to explain the main characteristics of each stage involved in the MM in depth. The third objective is to create a proposal for an MM that includes the knowledge-sharing influencing indicators that affect knowledge-sharing practices among health care professionals in medical imaging departments, and to present the measurements for each indicator that form the components of the KSMM. Finally, the last objective is to generate consensus among the experts in knowledge management and senior managers of the medical imaging departments in the United Kingdom and Kuwait on the components of the MM along with its indicators and measurements to be implemented in all departments.



Methods

Overview

This paper illustrates the development of an MM for knowledge sharing in medical imaging departments. There were four stages conducted in this study, as shown in Figure 1: (1) an *overview stage*, consisting of a review of previous literature that identified factors that affect knowledge-sharing practices in health care institutions in general and medical imaging departments specifically; (2) the *analysis of factors* stage, which consists of applying several methodologies to examine those factors; (3) the *structuring the MM* stage; and (4) the *assessment of reliability and validity* stage. Hence, the initial MM for knowledge sharing in the medical imaging department was developed.

XSL•FO
RenderX

Figure 1. The 4 stages conducted in this study. KS: knowledge sharing; MM: maturity model.

Ethical Considerations

This study followed the ethical guidelines outlined by the Christie hospital and the Kuwait Cancer Control Center (KCCC). Stage 1 was a systematic review, which did not require ethics approval. Stage 2 assessed potential factors with the involvement of health care professionals, and stage 3 analyzed the data from previous stages. The Christie hospital, following the University of Manchester regulations, did not require ethics approval for these two stages because no sensitive or personal question were asked; the KCCC, following regulation from the Ministry of Health, Kuwait, provided the approval (3797). Stage 4 used the Delphi method, which also does not require ethics approval because all information based on the respondents will be kept anonymous.

All respondents were asked to fill out the consent form electronically, as a mandatory request on the Qualtrics survey tool, before participating in the study. A brief description of the study was provided at the start of the electronic survey, followed by the consent form. Additionally, participants had a right to withdraw at any point of the survey based on the consent form provided. All the data are stored in the University of Manchester Qualtrics platform and kept anonymous, only accessible by the authors for the purposes of this study.

Stage 1: An Overview

An overview stage illustrated the factors that affect knowledge sharing in medical imaging departments at the general hospital and cancer centers specifically. There were several studies that identified knowledge-sharing factors, which were divided into 3 categories: individual factors, administrative factors, and technological factors [42,52-64]. Any factors that have a positive impact on enhancing knowledge sharing are called facilitators. In contrast, any factors that hinder knowledge-sharing practices are called barriers.

Stage 2: Analysis of Factors

In this stage, to examine and analyze those factors, mixed methods were used in this study. The mixed methods consist of questionnaires and semistructured interviews [65]. A concurrent, cross-sectional, triangulation, mixed methods design was used in this study in 2 cancer centers (the Christie hospital and KCCC). The questionnaire was structured based on the previous studies, and the semistructured interview questions were formed based on the factors in the previous stage to examine those factors by distributing questionnaires and conducting semistructured interview among health care professionals who are working in the medical imaging department at the 2 cancer centers [66-68]. We used self-selection sampling for the questionnaires and snowball sampling for the semistructured sampling techniques. The questionnaire was divided into 3 parts: the demographic section, knowledge-sharing practices, and factors that affect knowledge-sharing practices in the medical imaging departments. Multimedia Appendix 1 shows the survey questions. The questionnaires were distributed electronically using the Qualtrics (Qualtrics International Inc) survey tool. For the health care professionals working at the KCCC, a WhatsApp group (Meta Platforms) was used for distributing questionnaires, whereas the internal page was used as an official web-based tool for those questionnaires. The semistructured interviews were conducted via Microsoft Teams for the health care professionals in the medical imaging department of 2 cancer centers: the Christie hospital and KCCC.

The collection of the data was conducted between February 2023 and July 2023. After collecting the data, an analysis for the quantitative data were performed using Qualtrics Experience Management software package. The duration of the semistructured interviews was approximately 25 to 45 minutes. The thematic analysis was conducted to analyze the transcripts. All the codes and themes were analyzed using the NVivo software (Lumivero).

Stage 3: Structuring the MM

In this stage, an MM for knowledge sharing was developed. On the basis of the identification and evaluation of factors that affect knowledge-sharing practices in medical imaging departments in previous rounds, a clear vision was developed to build a KSMM in a proper manner, helping the managers and policy makers to follow these steps and understand how these factors are related to each other in different stages. Furthermore, it helped them either to implement a knowledge-sharing environment or to identify the weak points of knowledge-sharing practices.

Stage 4: Assessment of Reliability and Validity

In this stage, after the KSMM was developed, it was further assessed for reliability to validate the model. Without validation, the KSSM lacked reliability in its components. To apply this

XSL•FO
RenderX

model, experts and senior managers should agree on its use. Therefore, this stage aimed to generate consensus among the experts in knowledge management and senior managers of the medical imaging departments in the United Kingdom and Kuwait on the components of the MM along with its indicators and measurements to be implemented in all departments. Consensus on the model contributes to updating and correcting missing information before reaching out to whom it concerns.

Our target was to recruit 7 to 10 participants (experts in knowledge management and senior managers in the medical imaging department). This is the minimum number of participants required to conduct this kind of study [69,70]. In addition, Cyphert and Gant [71] illustrated that the best results might be obtained by a homogenous group of 10 to 15 experts. There are no rigid rules in the Delphi method regarding selecting the size of the expert's panel. However, the number of experts depends on the purpose of the study [72]. Delphi studies often use a sample size adjusted to the topic. By selecting experts with comparable broad understanding of the subject, a smaller sample size can be used [73]. We used the following four ways to choose participants: (1) we searched for the experts of knowledge management through the official university websites to find the senior lecturer in that field, especially at Kuwait University and the University of Manchester; (2) we searched through LinkedIn (Microsoft Inc) to find stakeholders for the National Health Service who have a role in knowledge management practices; (3) throughout the previous literature in knowledge management, there were several potential articles in this field with the authors name and contacts details, so we contacted them through this information to request their participation in this study; and (4) we asked the senior managers in the medical imaging department at the Christie hospital and KCCC to participate and help us to add their perspectives based on their professional experience. All participants remained anonymous during the research.

The modified Delphi method survey questions were generated based on the indicators and the measurements that structured the KSMM. The experts who participated in this study were informed of the aim, methods, and main components that structured the model to give them an overview of the study. The consensus survey questionnaire consisted the consent form (5 statements) and 3 sections: demographic questions (7 multiple-choice questions), a Likert scale with 5 points (disagree to agree) for the 17 indicators, and open-ended questions for it measurements to allow the experts to add their comments for updating the model. Study data were collected electronically using the Quartics survey tool and distributed via email. The use of email has a potential benefit in making it easier to maintain the anonymity of the respondents. Delphi studies ensure the anonymity of suggested comments and assessment to prevent group dynamics, strong personalities, or group conformism from influencing personal relationships between participants [74]. Descriptive statistics were used to analyze the Delphi studies, including SD, mean, and the intraclass correlation coefficient (ICC). We computed the mean, ICC, and SD based on the Likert scale of each indicator, where 1 indicates the least agreement and 5 indicates the highest agreement. In Delphi studies, IQRs are widely used to identify the level of group censuses [75,76]. However, we used mean, ICC, and SD in this study as they might be enough to identify the level of agreement for a model that was already structured.

Results

Stage 1: An Overview

On the basis of the previous literature, the factors that affect knowledge sharing in medical imaging departments are the same whether in a general hospital or a cancer center. However, they are different in terminology because the nature of the cancer center is mainly concerned with treating cancer cases, which require more than one specialty to end up with an appropriate protocol to treat specific cases [77]. Therefore, documenting the factors that affect knowledge sharing in medical imaging departments from the previous literature is important to test these factors in the next stage [77]. These factors are shown in Table 1 [77].

XSL•FO

[b]MDT: multidisciplinary team.

[c]ICT: information and communication technology.

[d]PACS: picture archiving and communication system.

Stage 2: Analysis of Factors

A total of 85 responses were received (56 from the KCCC and 29 from the Christie hospital), and the response rate based on Quadrics was 100%. Qualtrics Experience Management software was used to analyze the quantitative data. The factors were divided into 3 categories based on the systematic review: individual factors, departmental factors, and technological factors [77]. The demographics characteristics of the 2 centers are shown in Table 2. The results of the questionnaires for the 2 cancer centers are provided in Multimedia Appendix 2.

The semistructured interviews were conducted online using Microsoft Teams with 13 health care professionals who were working in the medical imaging departments at the 2 cancer centers: 11 (85%) were from the KCCC and only 2 (15%) were from the Christie hospital. Thematic analysis was used to analyze the qualitative data. Codes were organized using NVivo software. This was done to validate the quantitative methods, understand their views, understand how knowledge-sharing practices were going on in these centers, and assess if there was a clear policy to adopt knowledge-sharing practices. Multimedia Appendix 3 shows the interview questions and consent form. All these methods were applied according to the ethical considerations at both canters.

[a]KCCC: Kuwait Cancer Control Center.

The results revealed that there were 11 components derived from 5 categories, as shown in Table 3. These categories started with awareness, which is considered the main step to adopting knowledge-sharing practices in the department. Awareness of the importance of knowledge sharing in developing health care professionals' skills and improving health care services is important to increase their willingness to share their knowledge. The results of the quantitative method showed that health care professionals in both cancer centers have a high level of awareness of the importance of knowledge sharing. The second category was related to the types of knowledge sharing. It is divided into 2 categories: tacit and explicit knowledge. Tacit knowledge is the most dominant type of knowledge in the medical imaging department because several meetings and specialized meetings (MDT meetings, community of practices, and community of oncologists) occur in these departments. In contrast, explicit knowledge exists in the endorsed documents, protocols, policies, and procedures manuals. Therefore, understanding both types of knowledge and organizing them is important to increase knowledge-sharing practices.

The third, fourth, and fifth categories were related to the factors that affect knowledge-sharing practices: individual, departmental, and technological factors. The mean scores of the factors fell between somewhat agree and strongly agree, which reveals that health care professionals believe in the importance of these factors in enhancing knowledge-sharing behaviors. The individual factors consisted of 2 components: communication among health professionals, and personality and positive attitudes. Building trusting relationships among health care professionals is important to allow them to share their experiences. In addition, most of the respondents agreed that intrinsic motivation has a positive impact on sharing knowledge by increasing their self-efficacy and self-esteem by giving them opportunities to practice their abilities and experiences. There is a strong relationship between personality, positive attitudes, and increased knowledge-sharing practices. The respondents indicated that knowledge-sharing behaviors occur among individuals. Each indivdual has a specific personality and attitude toward knowledge-sharing practices. Some of them like to share their knowledge in large groups, while others prefer when they share it in small groups.

Table 3. Categories, components, and indicators that build maturity model of knowledge sharing for the medical imaging departments.

Categories and components	Indicators
Awareness	
• Awareness and willingness	• (1/17) Awareness and willingness toward KS[a]
Types of knowledge sharing: tacit knowledge and explicit knowledge	
• Understanding and organizing a knowledge-sharing repository	• (2/17) Structured and collected both types of knowledge
Individual factors: trust, positive attitudes, experience, intrinsic motivation, personality, self-esteem, and self-efficacy	
• Communication among HCPs[b]	• (3/17) Building trust among HCPs and sharing their experience • (4/17) Increased intrinsic motivation (self-efficacy, and self-esteem)
• Personality and positive attitudes	• (5/17) Personality and communication among HCPs
Departmental factors: MDT[c] and community of oncologists, leadership; culture, teamwork, extrinsic motivation, learning and training, physician rounds, and departmental arrangements	
• Leadership and culture	• (6/17) Structured leadership and creating culture • (7/17) Handover policy
• Achieving departmental tasks	• (8/17) Creating teamwork
• Continuous education and develop HCP skills	• (9/17) Organizing (learning lectures, workshops, training sessions, physician rounds, and participation in conferences)
• Decision-making	• (10/17) Regular meeting • (11/17) MDT and CoP[d] decision-making
• Infrastructure and workforce	• (12/17) Meeting room and office layout • (13/17) Enhanced extrinsic motivation • (14/17) Organized work process
Technological factors: ICT[e] (PACS[f], social media, intranet, extranet, telemedicine, and teleradiology), network, and digital library	
• Stored and shared patient data electronically	• (15/17) Strong network • (16/17) Implementation information, communication technology, and maintenance
• Access to the electronical databases	• (17/17) Digital library

[a]KS: knowledge sharing.

[b]HCP: health care professional.

[c]MDT: multidisciplinary team.

[d]CoP: communities of practice.

[e]ICT: information and communication technology.

[f]PACS: picture archiving and communication system.

The departments have a big responsibility to enhance knowledge sharing based on respondents' thoughts. Departmental factors consisted of 5 components: leadership and culture, achieving departmental task, continuous education, decision-making, and infrastructure and workforce. The participants agreed that a leader has a responsibility to create a culture of communication that allows health care professionals to practice knowledge-sharing behaviors. Developing health care professionals' skills require setting a clear plan for practicing continuing education activities, such as attending conferences, lectures, training sessions, and workshops. Offering them space and time is vital for allowing them to practice knowledge-sharing activities by organizing tasks among them and giving them empty spaces. To achieve departmental tasks, working within a team is crucial to increase the number of tasks achieved. Decision-making regarding patient treatment is one of the important tasks in the department, which is usually undertaken in highly specialized meetings, such as MDTs and communities of practices.

Technological factors consisted of several technological modalities, such as PACS, social media, the intranet, the extranet, telemedicine, and teleradiology, that require high-speed networking. These factors consisted of 2 components: storing and sharing electronic data electronically, and access to electronic databases. The respondents illustrated that using

XSL•FO
RenderX

technology requires skills for using it efficiently. Moreover, accessing the databases is vital to expanding health care professionals' knowledge about up-to-date treatment plans that are used to treat patients with cancer.

Stage 3: Structuring the MM

The development of the MM was derived from a systematic review that identified the factors affecting knowledge-sharing behaviors in the medical imaging department, as well as concurrent mixed methods that evaluated those factors in 2 cancer centers. The nonprobability sampling technique was used for mixed methods: the self-selection sampling technique for the quantitative method and the snowball sampling technique for the qualitative method. The results indicated that the KSMM consisted of 17 indicators divided into 11 components. These components represented the following 5 main categories: awareness, knowledge-sharing repository, individual factors, departmental factors, and technological factors. Table 3 shows the details of the MM indicators for knowledge sharing. Knowledge sharing is a dynamic process among health care professionals to manage the institutional process and interaction with ICT infrastructures. As a consequence, these components were incorporated into the 5 maturity levels. The levels were adopted from the work of Pee and Kankanhalli [19] that indicated that there are 5 levels of maturity in knowledge management (initial, aware, defined, managed, and optimized) based on people, process, and technology. The KSMM for the medical imaging department is presented in Multimedia Appendix 4. For each indicator, there are measurement questions that help managers and policy makers assess each indicator.

Stage 4: Assessment of Reliability and Validity

A total of 9 different participants were recruited in this study: 9 in the first round and 9 in the second part. They were from 2 countries: the United Kingdom and Kuwait. Table 4 shows the demographic characteristics of the participants. Most of respondents were female (n=7, 78%), and they were mainly from Kuwait (n=7, 78%). Most (n=6, 67%) of the respondents had a doctorate degree and the rest (n=3, 34%) had first degree.

Table 4. Demographic characteristics of the participants in the Delphi method (N=9).

Demographic characteristics	Participants, n (%)
Gender	
Female	7 (78)
Male	2 (22)
Age group (y)	
40-50	7 (78)
50-60	2 (22)
Highest education level	
First degree	3 (33)
Doctorate degree	6 (67)
Background	
Senior lecturer in knowledge managements	3 (33)
Senior manager in medical imaging departments	6 (67)
Experience (y)	
<10	1 (11)
10-20	4 (44)
20-30	4 (44)
Country	
United Kingdom	2 (22)
Kuwait	7 (78)

In the first round, most of the indicators and their measurements that formed the KSMM reached consensus with a narrow SD (<1); Multimedia Appendix 5 shows the level of consensus in both rounds. In contrast, indicators 1 (SD 1.25) and 17 (SD 1.15), which were about awareness and the digital libraries, respectively, did not reach to the consensus level with a large SD (>1). Therefore, the SD was more obvious and sensitive for this study to assess the level of consensus, compared to other measurements [74,78,79]. Awareness is the first component that forms the KSMM because it has a crucial role in enhancing knowledge-sharing practices among health care professionals. On the basis of their comments, there is a difference between the willingness to share knowledge and awareness. The willingness to share their knowledge comes from an awareness of the importance of knowledge sharing and believing in the value and benefits of their shared knowledge [80]. To increase awareness about knowledge sharing, the managers should set a clear policy to identify the benefits of sharing practices in

XSL•FO
RenderX

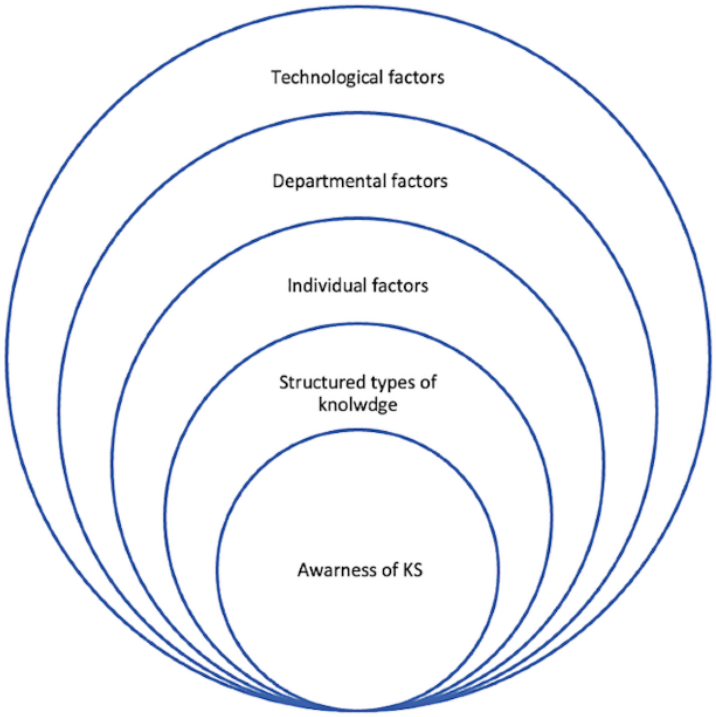
their daily work to increase patient outcomes and reduce medical errors. In contrast, their willingness to share knowledge is directly related to their personality and how their intrinsic and extrinsic motivations encourage them to share their knowledge among other peers. On the basis of indicator 17, most (4/9, 44%) of the respondents indicated that the digital resources are more comprehensive among those indicators. The digital resources include digital databases that contain libraries that play an important role in enhancing their knowledge in any field and therefore increasing knowledge-sharing practices. Regarding other measurements, they showed less sensitivity compared to the SD because they did not indicate any disagreements compared to the SD. Therefore, the SD is a more sensitive measurement compared to others [79].

Besides the analysis of the Likert scale, we received an important comment that helped to update the KSMM based on their experiences. Multimedia Appendix 6 shows the comments of the participants and our response to update the model.

In round 2, all the components of KSMM met the consensus SD level (<1.0). This indicates that all the respondents agreed with the updated version of the model that kept all their comments and considerations. Therefore, there was no follow-up round for this study because consensus on all the indicators along with their measurements of the KSMM was met. The final KSMM in the medical imaging department is presented in Multimedia Appendix 4.

Discussion

Principal Findings



Despite the considerable attention given to knowledge management in health care institutions and the significance of the MM in managing health care resources, knowledge sharing in hospitals has been less focused on developing the MM as a tool for assessing knowledge-sharing practices or a road map to adopting knowledge-sharing behaviors. This is the essence of this work. This study aimed to develop a KSMM in the medical imaging department by assessing the factors that affect knowledge-sharing practices. Several MMs have been developed for social media, health systems, digital libraries, ICT, PACS, and telemedicine [43,45,47-49]. These models were used to assess each factor that affects knowledge-sharing practices in benchmarking efforts and to develop progressive strategies that might improve its activities. In addition, Liu et al [46] shed light on a MM for multidisciplinary cancer teams. Their model consisted of 17 indicators that were used to measure health care professionals' performance and monitor the quality of performance at cancers centers over time.

Figure 2 highlights the 5 components that affect the KSMM in the medical imaging department and classifies each component in terms of its influence on knowledge-sharing behaviors. Awareness of the importance of knowledge management is one of the core components that contribute to the adoption of knowledge-sharing practices among health care professionals. Most of the respondents showed a high level of awareness of the importance of knowledge sharing in developing their skills, increasing health care services, and reducing medical errors. Therefore, results showed that more than half of respondents in both cancer centers (the Christie: 17/29, 59%; KCCC: 32/56, 57%) participated daily in knowledge-sharing activities that were available in their department. In addition, one of the articles showed that without awareness of the importance of knowledge sharing, there were no knowledge-sharing practices in the medical imaging department [13]. The next step was structuring the types of knowledge (tacit and explicit). Understanding the types of knowledge available in the department and how to capture, document, and share it is vital to accelerating knowledge-sharing practices in the department. Tacit knowledge appears in the medical imaging department as a dominant type among health care professionals that is considered a tool for sharing knowledge in lectures, conferencing, and meetings. In contrast, explicit knowledge takes several forms, such as documents, policies, procedures, and manuals. This form allows workers to reach it anytime in an easy way [81]. From the third to the fifth step, factors that affected knowledge sharing were divided into 3 categories: individual factors, followed by departmental factors, and finally technological factors [13,42,52-55,57,59-62].

The structure of the KSMM relies on the deep interpretation of several methods. The KSMM was built based on the interpretation of the systematic review and the concurrent mixed methods. That model is lacking in validation. Applying the modified Delphi method helps to validate this model by involving experts. In the first round, the results revealed that indicators 1 and 17 had a large SD (>1).

XSL•FO
RenderX

Figure 2. Schematic description of the 5 components that affect the knowledge sharing maturity model in medical imaging departments. KS: knowledge sharing.

The first round provided several comments and suggestions to modify the model. There were significant comments that needed to be considered and updated before being shared with the participants in the second round. Some of the respondents (R6 and R7) indicated that tacit knowledge is different from explicit knowledge in optimization, so the updated model indicated the way to optimize tacit knowledge in a significant way. Tacit knowledge is intangible, which is difficult to codify and capture [82]. To optimize and capture tacit knowledge, it needs to be part of an externalization process that focuses on transforming the tacit knowledge into explicit knowledge [83]. There are several methods of externalization, for example, recording the meeting and writing a summary note to make it easy to share it with health care professionals. On the basis of indicator 3, the respondents (R1, R6, and R7) illustrated that there are 2 types of trust that we should be aware of. Trust in their abilities and other expertise helps them perform more tasks in the working area, and benevolent trust helps to reduce conflicts among them and, therefore, increases knowledge sharing. The trust itself among group members might be increased throughout social activities more than task communication [84]. In addition, Chen and Hung [85] illustrated that both types of trust help increase the desire to share their knowledge, resulting in enhancing the level of positive outcomes in shared groups. Therefore, leaders and managers should be aware of social activities that help increase their trust, which is defined as a level of confidence among members. Regarding individual facilitators, a respondent (R7) illustrated that there is a difference between self-efficacy and self-esteem. Chan and Hung [85] have defined knowledge-sharing self-efficacy as an individual's confidence in their knowledge, abilities, and experience to achieve several tasks that might be helpful for other peers. A high level of self-efficacy is directly related to a higher level of performance on tasks [85]. In contrast, self-esteem is defined to play a key role in emotional and behavioral adjustment, as well as academic achievements [86]. Leaders and senior managers should encourage their employees to share their knowledge, helping them to understand the importance of sharing knowledge among them and how it has direct positive outcomes—by understanding their abilities and increasing their awareness of knowledge sharing, and not by forcing them. Giving them positive feedback on their abilities directly increases their self-efficacy and self-esteem [80,87].

Regarding applying knowledge-sharing practices, the respondents (R1, R5, R6, and R7) indicated that the senior managers and leaders should be aware of the knowledge-sharing models. There are several models for knowledge sharing, and each of them has a certain characteristic [36,88-90]. In addition, they must be able to create a knowledge-sharing model based on the resources that are available in the department. On the basis of the indicator 7, a respondent (R5) indicated that the handover policy should be applied and used not only when health care professionals decide to leave the department. They must share their knowledge with other peers in routine work to allow them to cover their work when they are absent. Such behavior helps to make knowledge-sharing practices more active in daily work. On the basis of teamwork, a respondent (R7) illustrated that to maximize the level of knowledge sharing, leaders and managers should be aware of the diversity of the teamwork in the workplace and the diversity of the member professionals in one teamwork [91]. The diversity is directly related to the individual differences in their knowledge and the abilities that make them unique from other peers [91]. The diversity of the member professionals in one teamwork helps to increase their performance by bringing new knowledge and experiences. However, diversity in one teamwork has several

XSL•FO
RenderX

challenges, such as increasing conflicts and a lack of trust. In contrast, the diversity of teamwork who are performing the task has a positive impact on sharing knowledge.

On the basis of indicator 10, which illustrates meetings, the respondents (R1, R5, R6, and R7) indicated that there are formal and informal meetings in the department, and informal meetings have a significant role in increasing knowledge-sharing behaviors. Hutchinson and Qunitas [92] have defined informal meetings as meetings that indicate knowledge-sharing practices without focusing on the task and the target that is directed by the organization. However, the leader should be aware of the difference between formal and informal meetings and strike a balance between them to enhance knowledge-sharing practices.

Indicator 15 illustrated the strong network. A strong network plays a vital role in enhancing knowledge sharing by introducing new technology to store and share data, anytime and anywhere. A respondent (R7) identified that artificial intelligence (AI) is an important technology, playing an important role in increasing efficiency, effectiveness, and productivity, and therefore increasing knowledge sharing [93]. It is defined as a set of ICTs that mimic human intellect with the goal of enhancing jobs, increasing efficiency, and boosting economic growth [94]. In addition, Arakpogun et al [94] indicated that the benefit of using AI is limited, because new knowledge needs to be introduced as part of the AI learning process, and therefore, more effective collaboration with knowledge-sharing systems is needed.

The Delphi method has limitations, including the use of nonrandomized samples; subjectivity and bias from expert panel composition; and a lack of consensus recommendations for the number of participants, rounds, and reporting criteria [69]. In this study, a significant limitation was the small size of the panel in 2 rounds and only in 2 countries. Despite these limitations, the modified Delphi method is an effective tool for validating several models.

Through this study, the key research questions were answered. The model can be used as a scoring tool to assess knowledge-sharing practices, with each MM scoring 1, 2, 3, 4, and 5, respectively. Moreover, this model can help managers and policy makers find opportunities for improvements and ways to achieve them. In addition, applying the KSMM helps health care institutions increase health services and patient outcomes, reduce errors, and solve the problem in a practical way. The Delphi study identified several comments and suggestions that helped in improving the KSMM. All these comments were kept in consideration for updating the model because they were based on participants' experiences in the workplace as either a senior manager in knowledge managements or a lecturer in the knowledge management field. Multimedia Appendix 4 shows the new KSMM with its updates.

Conclusions

Knowledge sharing is considered a core step in the implementation of knowledge management. Health care institutions have a responsibility to adopt knowledge-sharing practices to manage knowledge that is either tacit or explicit. A medical imaging department is crucial to any health care institution. Therefore, creating the KSMM is important to develop knowledge-sharing practices. The model proposed in this study allows managers to measure the maturity level of knowledge sharing in the medical imaging department. By providing the road map, the KSSM allows policy makers and managers in health care to appraise knowledge-sharing practices and adopt a culture of knowledge sharing to achieve departmental tasks and improvements. In addition, it could help managers assess knowledge-sharing practices in the medical imaging department and find the weak points that have a negative impact on those behaviors. A range of factors were addressed in our previous work, and we then evaluated those factors in 2 medical imaging departments in 2 cancer centers. The factors were further divided into 5 categories. Therefore, the KSMM consisted of 17 indicators that were divided into 11 components and presented in 5 categories. The most important of these indicators is awareness of the importance of knowledge sharing, presumably because it allows health care professionals to develop their skills and perform several tasks. The KSMM went through 2 rounds to ensure consensus among the experts who participated in the Delphi method. Regarding the measurements, all the indicators reached the consensus level with SD <1. Therefore, the model is ready to be applied in the medical imaging departments, and with minor modifications based on their resources, it might be applied in any institution. The model presented might also be used as a reference for improving knowledge-sharing practices. The measurement of each indicator helps the managers assess what level they are at. If the answer to the first level is no, then they must work on their current level until they achieve it and then move on to the next level. It enables them to share their experience in knowledge-sharing practices and serve as a lesson learned for another department with lower KSMM results. In the future, we are looking forward to comparing knowledge-sharing practices before and after implementing the KSMM in the medical imaging department. In general, knowledge-sharing practices are important in health care institutions to avoid repetitive errors, improve health care services, improve collaboration and communication among staff, and therefore encourage them to come up with new ideas together.

Acknowledgments

This study was completed as a part of doctoral studies funded by Ministry of Health, Kuwait, and University of Manchester, United Kingdom.

The authors would like to acknowledge all the professionals who participated in this study.

Abstract

Traditional medical education encounters several challenges. The introduction of advanced facial expression recognition technology offers a new approach to address these issues. The aim of the study is to propose a medical education–assisted teaching and student evaluation method based on facial expression recognition technology. This method consists of 4 key steps. In data collection, multiangle high-definition cameras record students' facial expressions to ensure data comprehensiveness and accuracy. Facial expression recognition uses computer vision and deep learning algorithms to identify students' emotional states. The result analysis stage organizes and statistically analyzes the recognized emotional data to provide teachers with students' learning status feedback. In the teaching feedback stage, teaching strategies are adjusted according to the analysis results. Although this method faces challenges such as technical accuracy, device dependency, and privacy protection, it has the potential to improve teaching effectiveness, optimize personalized learning, and promote teacher-student interaction. The application prospects of this method in medical education are broad, and it is expected to significantly enhance teaching quality and students' learning experience.

medical education; facial expression recognition; auxiliary teaching; student assessment; teaching innovation

Introduction

Under the traditional mode of medical education, although rich teaching experience and knowledge system have been accumulated for a long time, some inherent problems have gradually emerged with the advancement of technology and changes in social needs [1,2]. First, in terms of teaching methods, traditional medical education generally adopts a teacher-led teaching mode, which often neglects students' initiative and participation, and limits the cultivation of their independent thinking and practical abilities [3]. Second, in terms of evaluation mechanism, traditional medical education mainly relies on written examinations and clinical internships, but this evaluation method often cannot fully and accurately reflect students' learning outcomes and abilities. Especially in nonacademic evaluations, such as emotions, attitudes, and values, traditional methods seem inadequate [4]. In addition, with the continuous updating of medical knowledge and the rapid development of technology, traditional medical education often lags behind the latest scientific research achievements and practical experience in teaching content and methods, which makes it difficult for students to adapt to the rapidly changing medical environment after graduation. Therefore, it is necessary to introduce new teaching methods and technological means to make up for the shortcomings of traditional medical education and improve the quality and effectiveness of medical education.

Facial expression recognition technology is a technique that recognizes and understands an individual's emotional state by capturing and analyzing facial expressions [5-8]. The development history of facial expression recognition technology can be traced back to the 1970s when American psychologists Ekman and Friesen pioneered the definition of 6 basic human expressions and established the Facial Action Coding System, laying the foundation for subsequent research on facial expression recognition [9-11]. This milestone work not only clarifies the framework for facial expression classification but also provides standardized analytical tools for subsequent research [12].

Entering the 21st century, with the vigorous development of computer vision and artificial intelligence technology, facial expression recognition technology has ushered in new opportunities for development. In early research, researchers mainly relied on traditional image processing and machine learning algorithms such as support vector machines (SVMs) and principal component analysis to process and analyze facial expressions [13,14]. However, the recognition accuracy of these methods is limited by manually designed feature extraction methods and limited training data [15-17].

In recent years, the rise of deep learning technology has brought revolutionary changes to the field of facial expression recognition. Deep learning models such as convolutional neural

XSL•FO
RenderX

networks (CNNs) and recurrent neural networks have achieved significant results in facial expression recognition [18-20]. For example, AlexNet proposed by Krizhevsky et al has made breakthrough progress in ImageNet image classification tasks, providing strong support for the application of deep learning in expression recognition [21]. Subsequently, researchers began to apply deep learning models to facial expression recognition tasks, continuously improving the accuracy and robustness of facial expression recognition by constructing deeper network structures and introducing attention mechanisms and other methods.

In specific research work, there are several aspects that deserve special attention. First, multimodal fusion technology has become a research hotspot in recent years. Researchers have found that in addition to facial expressions, a person's emotional state can also be expressed through other modalities such as speech, posture, and physiological signals. Therefore, integrating information from multiple modalities can further improve the accuracy and reliability of facial expression recognition. For example, some studies have achieved more accurate emotion recognition by integrating facial expressions and voice information [22].

Second, the application of self-supervised learning in facial expression recognition is gradually receiving attention. Due to the high cost of obtaining labeled data, researchers have begun exploring the use of unlabeled data for pretraining to improve the model's generalization ability. This self-supervised learning method can fully use a large amount of unlabeled data resources and extract useful feature representations by designing appropriate pretraining tasks. For example, some studies have achieved significant performance improvements by designing self-supervised learning tasks based on facial movements to pretrain models [23].

In addition, with the continuous development of computer vision technology, some new technologies have also been introduced into facial expression recognition. For example, 3D facial expression recognition technology can more accurately recognize facial expressions by capturing 3D information of the face. This technology can overcome issues such as lighting and posture in 2D images and improve the robustness of facial expression recognition. In addition, some researchers have also explored expression synthesis techniques based on generative adversarial networks, which can generate facial images with specific expressions, providing more training data and testing samples for expression recognition [24-26].

Introducing facial expression recognition technology to assist teaching and student assessment in medical education can bring significant advantages [27]. First, this technology can capture students' facial expressions in real time, providing teachers with intuitive and immediate feedback, thereby helping them more accurately grasp students' learning status, adjust teaching strategies in a timely manner, and improve teaching effectiveness. Second, facial expression recognition technology can help students better understand teaching content. Through students' facial feedback, teachers can promptly answer students' questions and enhance students' learning motivation and participation [28]. In addition, facial expression recognition technology can also help achieve personalized teaching. Based on the emotional reactions of different students, teachers can develop more targeted teaching plans to meet their personalized needs [29].

Facial expression recognition technology has unique advantages in solving traditional medical education problems. Traditional medical education often relies on written examinations and clinical internships to evaluate students' learning status, but this evaluation method is difficult to comprehensively and accurately reflect students' learning outcomes and abilities. Especially for nonacademic evaluations of students' emotions, attitudes, and values, traditional methods seem inadequate. Facial expression recognition technology can capture students' emotional reactions, providing teachers with a more comprehensive evaluation basis, thereby more accurately assessing students' comprehensive qualities and potential. In addition, traditional medical education often adopts a teacher-led teaching mode in teaching methods, lacking student participation and interaction. Facial expression recognition technology can obtain real-time feedback from students, making teaching more interactive and targeted and improving students' learning outcomes.

Facial Expression Recognition Technology and Its Application in Medical Education

Principles of Facial Expression Recognition Technology

Facial expression recognition technology is a technique that uses image processing and analysis to recognize and understand human facial expressions. It is mainly based on algorithms, such as machine learning and deep learning, and achieves automatic recognition and classification of facial expressions through training and learning on a large number of facial expression images [30-33]. The facial expression recognition technology mainly relies on computer vision and pattern recognition technology and achieves automatic recognition and classification of facial expressions through feature extraction and classification of facial images [34]. This process can be summarized as the following steps:

- Image input: first, an image containing facial expressions needs to be input. These images can come from various sources, such as real-time video streams captured by cameras and static image libraries.
- Facial detection: using facial detection algorithms to accurately locate facial regions in the input image. This is one of the key steps in facial expression recognition technology, as only by accurately detecting the face can facial expression features be further extracted.
- Image preprocessing: preprocessing the detected facial images, including grayscale, normalization, denoising, and other operations. These preprocessing steps help eliminate redundant information and interference factors in the image, improving the accuracy of subsequent feature extraction.
- Feature extraction: in the preprocessed image, use feature extraction algorithms to extract key features that can characterize facial expressions. These features can include geometric features of the face (such as the shape and

XSL•FO
RenderX

position of the eyes and mouth), texture features (such as skin texture and wrinkles), and dynamic features (such as the movement of facial muscles). Feature extraction is one of the core steps in facial expression recognition technology, and the quality of the extracted features directly affects the accuracy of subsequent facial expression recognition.

- Pattern classification: after extracting facial expression features, machine learning or deep learning algorithms are used to classify these features. These algorithms can automatically recognize different facial expression categories by training and learning from a large number of labeled facial expression images. Common machine learning algorithms include SVM, decision tree, and random forest; deep learning algorithms include CNN, recurrent neural networks, and so on. These algorithms continuously optimize model parameters during the training process to improve the accuracy and generalization ability of facial expression recognition.

Potential Applications of Facial Expression Recognition in Medical Education

In medical education, facial expression recognition technology can be applied in 2 aspects: assisting teaching and student assessment [35]. First, teachers can analyze students' facial expressions to understand their understanding and mastery of the teaching content and adjust teaching strategies and methods accordingly. Second, student assessment can also achieve more objective and accurate evaluation results through facial expression recognition technology. For example, students' participation, interest, and learning status can be evaluated by analyzing their facial expressions during classroom discussions, experimental operations, and other processes.

Auxiliary Teaching: Optimizing Teaching Strategies Through Facial Expression Recognition

In medical education, teachers can observe students' facial expressions to understand their understanding and mastery of the teaching content [36]. Facial expression recognition technology can provide effective support for this. By analyzing students' facial expressions in real time, teachers can quickly identify their emotional states such as confusion, interest, or fatigue. Based on this information, teachers can adjust teaching strategies and methods in a timely manner to better meet students' learning needs.

Specifically, when teachers find that students are confused about a certain knowledge point, they can pause the explanation and clarify it through questioning or giving examples; when students show a strong interest, they can further expand their relevant knowledge points to stimulate their learning interest; and when students show fatigue, they can adjust the teaching pace appropriately and relieve their fatigue through rest or small games.

Student Assessment: Achieving Objective and Accurate Assessment Through Facial Expression Recognition

In addition to assisting teaching, facial expression recognition technology can also be used for student assessment. Traditional student assessment methods often rely on students' self-reports or teachers' subjective judgments, which have certain subjectivity and errors. Facial expression recognition technology can evaluate students' participation, interest, and learning status by analyzing their facial expressions, providing more objective and accurate evaluation results.

For example, in classroom discussions, teachers can evaluate students' engagement by analyzing their facial expressions. When students actively participate in discussions, they usually show a positive and focused expression; when student engagement is low, they may exhibit expressions of boredom, fatigue, or confusion. By collecting and analyzing these facial expression data, teachers can more accurately evaluate students' classroom performance.

In addition, facial expression recognition technology can also be used to evaluate students' learning status in experimental operations. When students encounter difficulties or challenges, they usually show expressions of tension, anxiety, or confusion; when students successfully solve problems, they will show excited and satisfied expressions. By analyzing these facial expression data, teachers can understand students' learning status during experimental operations and provide timely guidance and assistance.

Auxiliary Teaching and Student Evaluation Methods Based on Facial Expression Recognition in Medical Education

Overview of Methods

The auxiliary teaching and student evaluation method based on facial expression recognition in medical education proposed in this section mainly include the following 4 steps: data collection, facial expression recognition, result analysis, and teaching feedback.

Data Collection

In the medical education–assisted teaching and student evaluation method based on facial expression recognition, the data collection process is the foundation and key of the entire process. The primary task of data collection is to obtain high-quality video and image data, which mainly comes from the facial expression records of students during the teaching process. To ensure the comprehensiveness and accuracy of data, multiple high-definition cameras are usually installed in the classroom to capture students' facial expressions from different angles. These cameras need to have good resolution and frame rate to ensure clear and detailed images. In addition, portable devices such as smartphones and tablets can be used for supplementary shooting to meet the flexible data collection needs in special situations.

The collected data should not only include static facial images but also dynamic video recordings. This is because the changes in facial expressions are often continuous, and a single static image may not fully reflect the emotional state of students. Therefore, the collection of video data is crucial, as it can capture the changes in students' expressions at different time points, providing richer information for subsequent expression

XSL•FO
RenderX

recognition and analysis. At the same time, video data can also record classroom interactions, including scenarios such as students' questions, answers, and discussions. These behavioral data also have important reference value for evaluating teaching effectiveness.

During the data collection process, special attention should be paid to privacy protection and data security. Due to the personal privacy involved in the collected facial expression data, it is necessary to strictly comply with relevant ethical norms and laws and regulations. Prior to data collection, informed consent from students should be obtained, clearly informing them of the purpose, scope of use, and protective measures of the data collection. At the same time, encryption technology is used in the process of data storage and transmission to prevent data leakage and ensure that student privacy is not violated. In addition, in order to further improve the confidentiality of the data, anonymization can be performed on the collected data, that is, personal identity information can be separated from facial expression data through technical means, thereby ensuring the effectiveness of data analysis while maximizing the protection of student privacy.

Finally, in order to ensure the high quality and practicality of the data, detailed standards and specifications need to be developed in the data collection process. These standards include the installation position and angle of the camera, control of lighting conditions, and selection of shooting time. For example, cameras should be installed at angles that can clearly capture students' faces and avoid adverse lighting conditions such as backlighting. The shooting time should cover the entire teaching process, including explanations, interactions, and breaks, to comprehensively reflect the changes in students' expressions at different stages of teaching. By formulating and implementing these standards and specifications, the accuracy and reliability of data collection can be maximized, providing a solid foundation for subsequent facial expression recognition and result analysis.

Facial Expression Recognition

In medical education–assisted teaching and student evaluation methods based on facial expression recognition, the facial expression recognition process is a key step in converting the collected raw data into meaningful emotional information. The process of facial expression recognition first relies on advanced computer vision and machine learning technologies, which can automatically detect and analyze key feature points of students' faces. Specifically, facial detection algorithms locate facial regions by processing video frames or images and further extract key feature points including eyes, eyebrows, nose, and mouth. The precise localization of these feature points is the foundation for facial expression recognition, ensuring that the algorithm can accurately capture subtle changes in the face.

After extracting key feature points, the expression recognition system will use the trained classifier to recognize different expression categories. Common classifiers include SVM and CNN. These classifiers can learn and distinguish feature patterns corresponding to various expressions by training on a large amount of labeled data. Especially, CNNs have shown superior performance in facial expression recognition, as they can automatically extract high-level feature representations, significantly improving the accuracy and robustness of facial expression recognition. In the recognition process, the system not only needs to distinguish basic expressions, such as happiness, sadness, and surprise, but also needs to combine contextual information to recognize complex emotional states, such as confusion, focus, or boredom.

To further improve the accuracy of facial expression recognition, multimodal fusion is usually required, which combines multiple sources of information such as facial expressions, speech emotions, and posture changes. Multimodal fusion can make up for the limitations of a single mode and provide more comprehensive and accurate emotion recognition results. For example, when students write with their heads down, their facial expressions may not fully capture their emotional state. In this case, combining speech intonation and body movement information can enhance the accuracy and reliability of emotion recognition. Through the fusion processing of multimodal data, the system can better understand the true emotional state of students and provide rich emotional data for subsequent result analysis.

In addition, the accuracy of facial expression recognition also depends on the personalized modeling of different individuals. Due to individual differences in facial features and expressions among students, a unified recognition model may not be able to adapt to all individuals. Therefore, introducing personalized modeling mechanisms into facial expression recognition systems and establishing personalized facial expression recognition models for each student can significantly improve recognition accuracy. This process typically involves learning and adapting individual features, dynamically updating the model using previously collected data to continuously optimize recognition performance.

The final output of the facial expression recognition process is a detailed record of the emotional state of each student throughout the entire teaching process. These records include time series data of emotional states as well as emotional fluctuations in different teaching stages. By organizing and analyzing these emotional data, comprehensive emotional feedback can be provided, laying a solid foundation for subsequent result analysis and teaching feedback. The facial expression recognition stage is not only the initial processing stage of emotional data but also the core stage of the entire auxiliary teaching and student evaluation method. Its accuracy and effectiveness directly affect the final quality of teaching feedback.

Result Analysis

In the medical education–assisted teaching and student evaluation method based on facial expression recognition, the result analysis stage plays a bridging role, which is a key step in transforming the identified emotional data into a deep understanding of teaching effectiveness and student learning status. The result analysis first involves the organization and preprocessing of emotional data, including smoothing of time series, detection and removal of outliers, and statistical analysis of the distribution of different emotional categories. Through preliminary processing of emotional data, the emotional change

XSL•FO
RenderX

curves of each student at different time periods can be obtained, which provides a foundation for further in-depth analysis.

Based on the organized emotional data, statistical analysis and data mining techniques are further used to reveal the relationship between students' emotional states and teaching activities. Specifically, through regression analysis, correlation analysis, and other methods, the impact of different teaching stages, content, and methods on students' emotional states can be explored. For example, analyzing the changes in students' concentration, confusion, and participation in different teaching stages, such as teacher lectures, interactive questioning, and experimental operations, in order to evaluate the teaching effectiveness of these stages. In addition, through cluster analysis and pattern recognition, student groups with similar emotional change patterns can be identified, providing a basis for personalized teaching and hierarchical guidance.

To gain a deeper understanding of the teaching significance behind students' emotional data, result analysis should also be combined with the specific context of classroom teaching and the teacher's teaching design. By synchronously analyzing emotional data and teaching videos, it is possible to identify which specific teaching behaviors have caused students' emotional fluctuations. For example, when students exhibit general confusion or anxiety at a certain point in time, it is possible to trace back to the teaching content and the teacher's explanation during that period and identify the difficult issues or unclear explanations that may have caused confusion for students. This situational analysis not only helps diagnose problems in teaching but also provides specific reference suggestions for teachers to improve their teaching.

In the result analysis stage, special attention should be paid to the handling of individual differences. Due to significant differences in emotional performance and learning styles among each student, a unified analysis method may not fully reflect an individual's learning status. Therefore, the result analysis should be combined with personalized emotional data for targeted analysis. For example, by longitudinal tracking and comparative analysis of a student's emotional change data, it is possible to evaluate their emotional response under different courses and teaching methods and identify the most suitable teaching strategy for their learning style. In this way, not only can it improve the accurate assessment of individual learning status, but it can also provide a scientific basis for personalized teaching.

Finally, the output of the result analysis stage is a comprehensive evaluation report of the entire teaching process and students' emotional state. These reports include statistical results of emotional data, trend analysis of emotional changes, emotional feedback in teaching processes, and personalized teaching recommendations. Through these detailed analysis reports, teachers can comprehensively understand the teaching effectiveness and students' learning status, adjust teaching strategies and methods in a targeted manner, and thus achieve continuous improvement in teaching quality. Result analysis is not only a simple processing of emotional data but also a data-driven teaching improvement process, and its accuracy and scientificity directly affect the effectiveness and operability of teaching feedback.

Teaching Feedback

In the medical education–assisted teaching and student evaluation method based on facial expression recognition, the teaching feedback link is the terminal link of the entire process, aiming to transform the conclusions drawn from the result analysis into specific teaching improvement measures. Teaching feedback is not only feedback on students' learning status and teaching effectiveness but also guidance for future teaching design and strategies. Medical education has its unique characteristics, including highly specialized knowledge content, rigorous practical skills training, and comprehensive requirements for students' overall quality, which makes the teaching feedback link particularly important in medical education.

First, in the teaching feedback stage, the emotional data and behavioral patterns identified in the result analysis need to be fed back to the teacher. This process not only includes the aggregation and presentation of emotional data but also requires providing detailed explanations and analysis reports in conjunction with specific teaching contexts and classroom activities. For example, in the result analysis, it is found that some students exhibit obvious confusion or anxiety in specific teaching stages. Teaching feedback should provide a detailed explanation of the possible reasons for these emotional changes and provide corresponding teaching improvement suggestions. For medical education, this meticulous feedback helps teachers to explain complex medical concepts or skill operations in a more targeted manner in subsequent teaching, improving teaching effectiveness.

Second, the teaching feedback process should also focus on providing individual feedback and guidance to students. Students in medical education not only need to master a large amount of theoretical knowledge but also need to possess solid clinical skills and good professional ethics. Personalized feedback can help students understand their weak areas in learning and provide specific improvement suggestions. For example, through facial expression recognition and emotion analysis of students in simulated clinical operations, feedback can point out the possible tension or lack of confidence that students may have during the operation process and suggest that they improve their operational skills and psychological qualities through more practice or psychological counseling. Such personalized feedback not only helps students make progress in their studies but also assists them in better coping with various challenges in their future careers.

In addition, the teaching feedback process should also take into account the characteristics of team learning and collaborative practice in medical education. Medical education not only focuses on individual learning but also emphasizes the importance of teamwork and collective decision-making. Therefore, teaching feedback should include emotional and behavioral analysis of student teamwork, identifying potential communication barriers or collaboration issues within the team. For example, through facial expression recognition technology, analyzing students' emotional states during team discussions

XSL•FO
RenderX

or collaborative tasks can identify which members may have issues with insufficient participation or poor communication and provide suggestions for improving the team's collaboration methods. In this way, not only can it improve the efficiency of team learning, but it can also cultivate students' cooperation ability and team spirit, which are key qualities in medical education.

Finally, the teaching feedback process should focus on long-term effectiveness evaluation and continuous improvement. Medical education is a long-term process, and the cultivation of students' learning outcomes and professional qualities requires continuous attention and improvement. Through regular emotional data analysis and teaching feedback, teachers can dynamically adjust teaching strategies and continuously optimize teaching content and methods. For example, regularly reviewing and summarizing students' emotional data and learning performance, evaluating the effectiveness of teaching improvement measures, and proposing new teaching improvement plans based on this. In this way, teaching feedback is not only a reflection and improvement of current teaching activities but also a continuous and dynamic process of improving teaching quality.

In summary, the feedback loop in teaching is of great significance in medical education–assisted teaching and student evaluation methods based on facial expression recognition. Through meticulous analysis of emotional data and personalized feedback, not only can teaching effectiveness be improved and students overcome learning difficulties, but also team collaboration and long-term improvement of teaching quality can be promoted. The particularity of medical education requires that the teaching feedback process pays more attention to individual differences, teamwork, and continuous improvement in order to comprehensively enhance the quality of medical education and the comprehensive quality of students.

Advantages and Limitations of the Method

Advantages of Methods

The medical education–assisted teaching and student evaluation methods based on facial expression recognition have multiple advantages, which are particularly significant in the special context of medical education. First, through real-time facial expression recognition technology, it is possible to objectively and instantly capture and analyze students' emotional states in the classroom. This real-time data acquisition and analysis enables teachers to timely understand students' emotional changes during the teaching process, especially their understanding of complex or abstract medical concepts. When students show negative emotions, such as confusion or anxiety, teachers can immediately adjust teaching strategies, such as providing more detailed explanations or adding interactive elements, to alleviate students' emotions and improve teaching effectiveness. This real-time feedback mechanism significantly enhances the dynamic adjustment ability of classroom teaching, ensuring that every student can keep up with the teaching progress.

Second, methods based on facial expression recognition can provide refined personalized teaching feedback. The content of medical education is complex and covers a wide range of professional knowledge, and students' understanding and mastery vary greatly. By analyzing students' facial expression data in different teaching stages, specific difficulties and emotional fluctuations of individuals in the learning process can be accurately identified. For example, when studying anatomy, if a student shows persistent confusion in a specific chapter, the facial expression recognition system can capture and record this phenomenon and provide targeted learning suggestions for the student in teaching feedback. This personalized feedback mechanism can not only help students overcome obstacles in learning but also improve their learning efficiency and effectiveness, thereby achieving the goal of teaching according to their aptitude.

In addition, this method has unique advantages in cultivating students' clinical practice skills and comprehensive qualities. Medical education not only emphasizes the mastery of theoretical knowledge but also pays more attention to the training of clinical skills and the cultivation of professional qualities. Through facial expression recognition technology, students' emotional states can be monitored and analyzed in real time during simulated clinical operations and actual clinical training. For example, during simulated surgical procedures, the system can capture students' emotional changes, such as tension, anxiety, or confidence, and use these data to evaluate their proficiency and psychological resilience. This evaluation method is more objective and comprehensive than traditional manual observation, which helps teachers to strengthen students' practical training and psychological development in teaching feedback and improve their clinical and emergency response abilities.

In addition, the evaluation method based on facial expression recognition has also demonstrated significant advantages in cultivating teamwork and communication skills. Many tasks and projects in medical education require students to collaborate as a team, and effective communication and collaboration among team members are key to success. Facial expression recognition technology can monitor and analyze the emotional states of team members during collaboration, identifying potential communication barriers or collaboration issues. For example, in team discussions or collaborative tasks, if the system detects insufficient participation or low mood among certain members, it can promptly provide feedback to the teacher or team leader, prompting them to take measures to improve the team's collaborative atmosphere. This team evaluation and feedback based on emotional data not only improves the efficiency of team learning but also cultivates students' communication skills and teamwork spirit.

Finally, the teaching evaluation method based on facial expression recognition has the advantage of continuous improvement. Medical education is a long-term and dynamic process that requires continuous adjustment and optimization of teaching strategies. By regularly collecting and analyzing emotional data, teachers can continuously evaluate teaching effectiveness and identify and improve deficiencies in teaching. For example, by tracking students' emotional changes and learning performance over the long term, evaluating the effectiveness of different teaching methods and content, and

XSL•FO
RenderX

continuously optimizing and adjusting them in subsequent teaching. This data-driven continuous improvement mechanism ensures the high quality of medical education and the efficiency of student learning, meeting the needs of modern medical education for refined and personalized teaching.

Limitations of the Method

Although facial expression recognition–based methods for medical education auxiliary teaching and student evaluation offer significant advantages, such as real-time feedback and objective assessment, their limitations, including issues related to data privacy, cross-cultural recognition accuracy, and the complexity of emotional interpretation, cannot be overlooked. First, the accuracy and reliability of facial expression recognition technology face challenges in practical applications. Facial expressions are influenced by various factors, including lighting, shooting angle, and facial occlusion, which may result in inaccurate recognition results. In addition, there are significant differences in facial expressions and emotional expression styles among individuals, which limits the applicability of universal expression recognition models in personalized applications. Especially in medical education, students may have more subtle emotional expressions when faced with complex professional content, which further increases the difficulty of facial expression recognition.

Second, the dependency of facial expression recognition technology is an important issue. This technology relies on high-quality video data and advanced computing devices, and in practical teaching environments, especially with limited resources, it is difficult to ensure that every classroom is equipped with sufficient cameras and computing power. This not only increases implementation costs but may also lead to incomplete or low-quality data collection, thereby affecting the accuracy and reliability of evaluation results. In addition, prolonged video surveillance may cause students' resistance and affect their natural performance, thereby interfering with the authenticity of emotional data.

Furthermore, facial expression recognition technology mainly focuses on facial expressions, and emotions and psychological states are complex and multidimensional. Relying solely on facial expression data is difficult to fully reflect students' true emotions and learning status. In medical education, students' stress, anxiety, and cognitive load are often complex and varied, and these internal states may not be fully expressed through facial expressions. Therefore, relying solely on facial expression recognition for emotional assessment has limitations and may lead to a one-sided understanding of students' learning status. In addition, the interpretation of emotional data is also subjective, and different teachers may have different interpretations of the same emotional data, which affects the consistency and effectiveness of teaching feedback.

In addition, privacy protection and ethical issues are major challenges based on facial expression recognition technology. Collecting and analyzing students' facial expression data involve personal privacy and must strictly comply with relevant laws, regulations, and ethical guidelines. In practical operation, how to ensure the security, anonymity, and transparency of data use is a complex and sensitive issue. If not handled properly, it may cause concerns for students and parents and even lead to legal disputes. In addition, long-term monitoring and data analysis may bring psychological pressure, affecting students' learning experience and mental health.

Finally, there is uncertainty in the application effectiveness of facial expression recognition–based evaluation methods in actual teaching improvement. Although emotional data can provide some reference, improving teaching effectiveness involves multiple factors, including teaching content, teaching methods, and teacher quality. Relying solely on emotional data is difficult to comprehensively improve teaching quality. Therefore, in the application process, it is necessary to combine other evaluation methods and means and comprehensively analyze and improve teaching strategies to ensure the comprehensiveness and scientificity of teaching feedback.

Conclusions and Prospect

In this paper, we explore the application of facial expression recognition technology in medical education and its potential in assisting teaching and student assessment. Through in-depth research and practical application analysis of facial expression recognition technology, we have found that this technology can significantly enhance teacher-student interaction, improve teaching effectiveness, and provide strong support for personalized education. Specifically, facial expression recognition technology can capture and analyze students' facial expressions in real time, helping teachers understand students' emotional states and understanding in a timely manner, thereby adjusting teaching strategies and providing more targeted guidance.

In addition, facial expression recognition technology can also serve as an effective student assessment tool, providing detailed feedback data for teachers by quantitatively analyzing students' emotional reactions and participation in the classroom. These data can not only be used to evaluate students' learning outcomes but also to improve curriculum design and teaching methods, thereby achieving a comprehensive improvement in educational quality.

Looking ahead to the future, with the continuous development and improvement of facial expression recognition technology, its application prospects in medical education will be even broader. We foresee that future medical education will become more intelligent and personalized, and facial expression recognition technology will be combined with other advanced technologies such as artificial intelligence and big data analysis to jointly build a comprehensive and dynamic education ecosystem. At the same time, with the popularization of technology and the accumulation of application experience, we also need to pay attention and solve the ethical and privacy issues that technology may face in practical applications, ensuring the sustainable development of technology in the field of education.

In short, facial expression recognition technology, as an innovative tool, can not only improve the teaching effectiveness and evaluation efficiency of medical education but also provide new ideas and directions for the future development of medical

XSL•FO
RenderX

education. We believe that with the deepening of research and the promotion of application, facial expression recognition technology will bring more innovation and change to medical education and help cultivate more outstanding medical talents.

Abstract

Mental health services face a multitude of challenges, such as increasing demand, underfunding, and limited workforce capacity. The accelerated digital transformation of public services is positioned by government, the private sector, and some academic researchers as the solution. Alongside this, human-centered design has emerged as a guiding paradigm for this transformation to ensure user needs are met. We define what digital transformation and human-centered design are, how they are implemented in the UK policy context, and their role within the evolving delivery of mental health services. The involvement of one of our coauthors (DP) in the design and delivery of these policies over the past 5 years provides unique insights into the decision-making process and policy story. We review the promises, pitfalls, and ongoing challenges identified across a multidisciplinary literature. Finally, we propose future research questions and policy options to ensure that services are designed and delivered to meet the mental health needs of the population.

Introduction

Background

Mental health services are under strain in the United Kingdom [1,2]. Demands for assessment, diagnosis, and treatment are increasing [3], while funding and infrastructure struggle to keep up and are widely seen to be in crisis [4]. Waiting lists and prolonged referral times are commonplace, with disastrous consequences for the well-being of service users [5]. Frontline organizations struggle to recruit, retain, and train staff, with the mental health of those in position already at risk [6,7]. The United Kingdom and others across Europe and the Organisation for Economic Cooperation Development countries are seeking innovative and ambitious policy solutions [8].

Digital transformation is widely touted as the answer to these challenges, promising affordability, accessibility, and rapid scalability [9,10]. In the United Kingdom, widely regarded as a leader in digital transformation across policy domains [11,12], a digital-first delivery model is now embedded in the long-term policy for the health service [4,13,14]. Special attention is placed on the expansion and reform of mental health care [15,16], with a view to supporting financial cuts. Globally, the digital delivery

XSL•FO
RenderX

of mental health services is viewed as vital to meet demand [17-20], especially for the poorest and the hardest-to-reach populations, whether culturally, geographically, or economically [21,22].

Despite national and international enthusiasm from policy constituencies and academic researchers, digital transformation remains an ambiguous concept [23] and is poorly defined on the ground. Digital transformation has been ongoing in health care for decades as various information and communication technologies (eg, emails, mobile phones, and electronic health records) were integrated into service delivery, at times through professional and patient discretion. Still, recent calls for acceleration and increased policy discourse demand a robust definition moving forward. Furthermore, despite optimism, digital transformation risks being an inequitable and ineffective process if it fails to meet the needs and requirements of service users, health care providers, and professionals [24]. In response, service-user involvement is increasingly advocated in the form of human-centered design (HCD) [17,25,26].

Outline

We begin by defining digital transformation and HCD for mental health services. We contextualize these ideas and processes in a personal view section, including a case study of the Mental Health Act (MHA) in UK policy. These policy insights draw directly from our experiences implementing HCD digital transformation in the UK Department for Health and Social Care (DHSC).

In the second half of the paper, we integrate academic knowledge on these themes, bringing researchers and practitioners together on policy and research developments. We first discuss opportunities and challenges in digital therapeutics before emphasizing the need for service-user involvement in therapeutics. We then move to digital transformation of services more broadly. We argue that HCD is essential to the digital transformation of mental health. In so doing, we warn against technosolutionism in digital transformation [17]. Finally, we summarize ongoing service challenges, avenues for future research, and policy recommendations. Overall, the paper contributes to an ongoing debate on the digital transformation of essential public services.

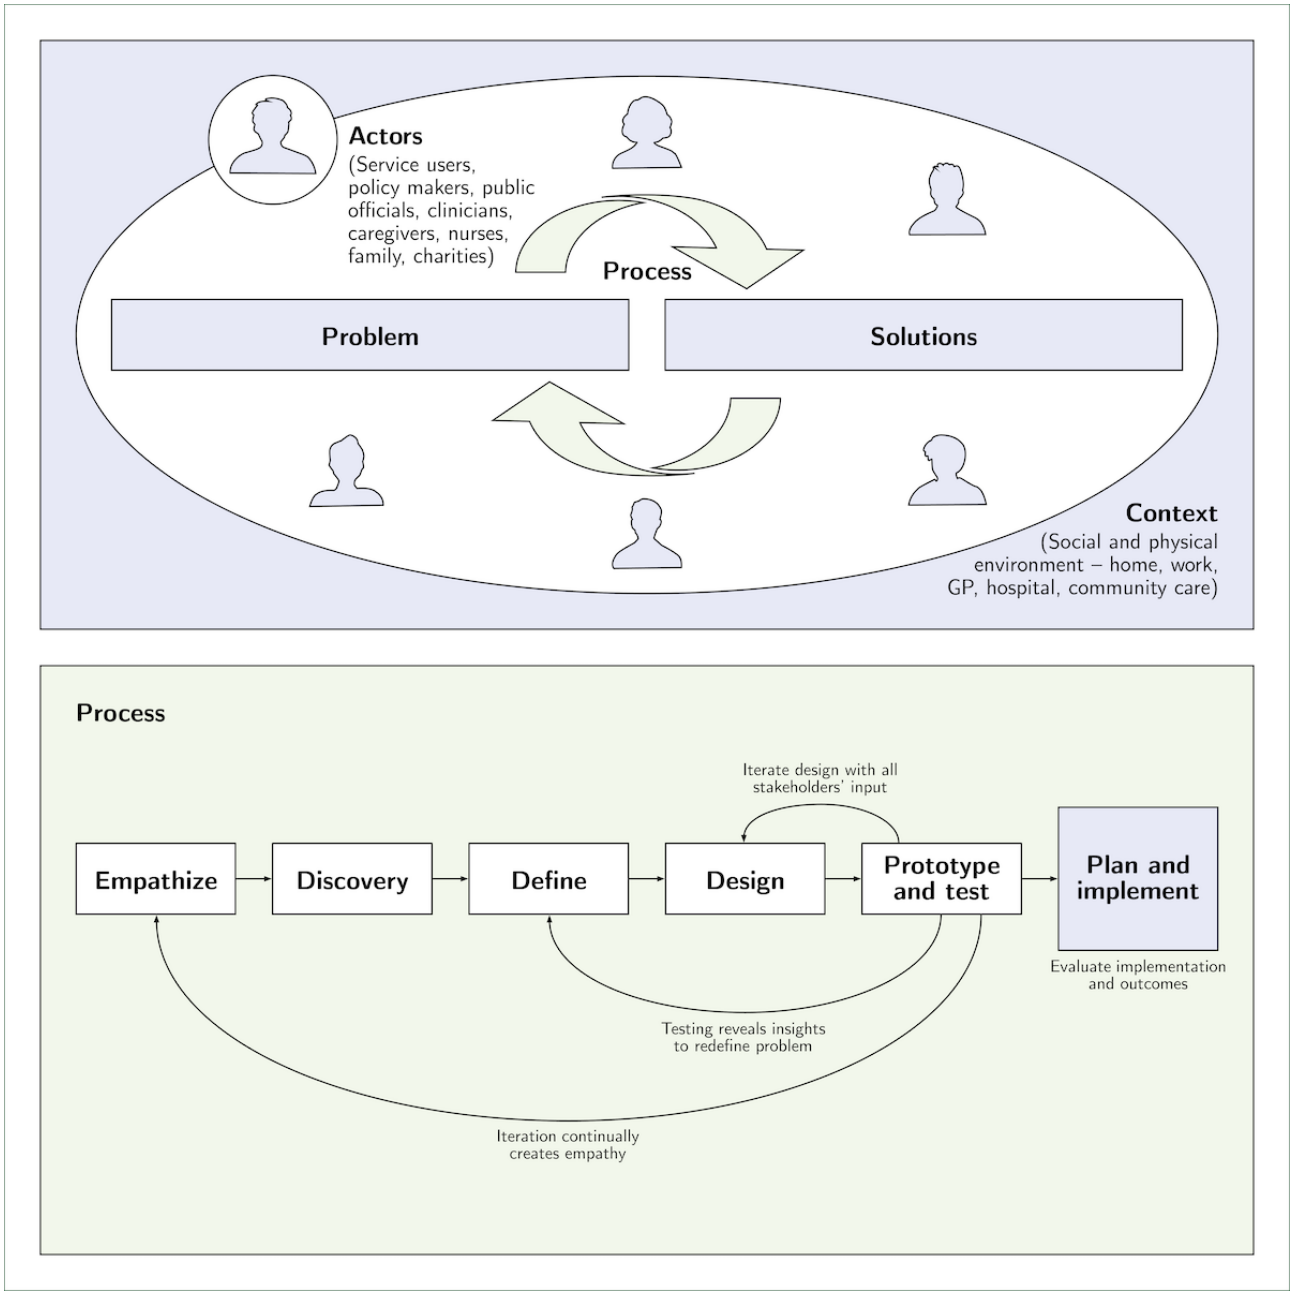
This review is a product of a National Institute for Health and Care Research Applied Research Collaboration East of England project, which holds knowledge exchange to be central. We brought together researchers, service delivery experts in the DHSC, the National Health Service (NHS), the Office for Health Improvement and Disparities, as well as local coordinators and frontline staff in the east of England. The review is informed by the ongoing exchange, including interviews with practitioners and a training workshop we hosted on "human-centered design for mental health services" [27]. Among frontline professionals we found enthusiasm for HCD, alongside many practical constraints to implementation. The search strategy and selection criteria are as follows: we identified relevant articles in English through structured searches on Web of Science and unstructured searches on Google Scholar using key terms, such as "mental health," "human-centered design," "co-production," "digital," and "services." Our disciplinary focus was journals in psychiatry and public health as well as relevant literature from public policy and design. We also searched the key terms in *The Lancet Psychiatry*, the *Journal of Medical Internet Research*, and *JMIR Mental Health*. Relevant policy gray literature is included to define the context, sourced from professional networks, and project stakeholder engagement.

Defining Digital Transformation

Digital transformation is a poorly defined concept, with multiple uses found across practitioner and academic literature. For example, the UK DHSC does not offer any definition in their policy paper "A plan for digital health and social care" [13], despite central claims that "the long-term sustainability of health and social care is dependent on having the right digital foundations in place, and so digital transformation must be the linchpin upon which all of these reforms are based." Ambiguity is repeated in government guidance for UK NHS trusts [28] and in global settings, with the World Health Organization neglecting to define digital transformation, despite its "Global strategy on digital health 2020-2025" [18].

In a systematic review of the digital transformation literature, Vial [23] offers a synthesized definition: "a process that aims to improve an entity by triggering significant changes to its properties through combinations of information, computing, communication, and connectivity technologies." In the context of increased discourse around the digitalization of mental health and the need to understand implementation and outcomes, a domain-specific definition of digital transformation is required. We adapt and define mental health digital transformation as "a process that aims to improve the provision of mental health services by triggering significant changes to its administration, coordination, treatments and therapeutics, through combinations of information, computing, communication, and connectivity technologies."

Defining HCD



The concept of HCD originated in the fields of computer science, engineering, and ergonomics. The technical origin is captured in the International Organization for Standardization definition of HCD [29], but the emphasis in early technology-oriented definitions centers the relationship between individual users and physical objects. The conceptual scope of HCD expanded as the social potential was realized: "today's human centred design is based on the use of techniques which communicate, interact, empathise and stimulate people involved, obtaining an understanding of their needs, desires and experiences" [30]. HCD principles can guide value and well-being creation in the delivery of products, systems, and services. We define HCD in mental health services and research as "a practical, iterative approach to the design, development and reform of mental health systems, services and products that is achieved through communication, interaction and empathy with users' needs, desires and experiences."

Figure 1 summarizes the HCD approach. HCD is applied in an iterative process and includes 4 dimensions: the problems and coevolving solutions (*objects*), social and physical environment

XSL•FO
RenderX

(*context*), structure and dynamic of the activity (*process*), and those involved (*actors*) [30,31]. In the process, HCD deploys a range of qualitative techniques, such as service logic modeling, semistructured interviews, focus groups, and ethnographic research. This qualitative view creates *empathy* in the *discovery* phase to *define* the issue, including identifying user needs, the interdependencies and interactions between different user groups, and how users navigate and interact with services and products. The aim is to understand the overall context and provide a map of pathways through which a service or product user moves. The new qualitative understanding then guides the *design* of the product and service to be *tested* iteratively in a prototype phase, continuing to redefine the issue and provide new insight. Final *implementation* is enacted while quantitatively evaluating processes and outcomes.

Figure 1. Human-centered design process for mental health services. GP: general practitioner.

Accompanying the expansion of HCD is increasing conceptual confusion, with related terms such as user-centered design, user experience design, stakeholder-centered design, design thinking, and participatory design [17,31-33]. HCD is the most theoretically developed and commonly applied in policy. We propose HCD can be used as an umbrella term for iterative end user involvement in product and service delivery that emphasizes empathy, discovery, and testing. Synonymous terms can be understood as types of HCD, deployed in different contexts with varying aims.

Coproduction is a crucial related idea that dominates discussion of user involvement in public services. Coproduction is a broader umbrella concept that also entails citizen and user involvement to varying degrees [34-37]. In contrast to HCD, coproduction emphasizes sharing power (decision-making) and collaboratively delivering a service or product. With HCD,

XSL•FO
RenderX

decision-making and delivery remain with the service or product provider while strongly involving user input in the iterative process outlined above. HCD is a lighter approach to citizen involvement. Figure 1 visualizes the HCD process and demonstrates the underlying principles, which are more important than semantic debates [37,38].

Personal View: Untold Stories From the United Kingdom

Overview

In the United Kingdom health care system, digital transformation methodologies were formally enacted with the creation of "NHSX" [39]. However, the origins and design of the "whole of government" approach were first articulated by the review by Lane Fox [40]. The report emphasized the need for a user-centered digital transformation and a policy culture that is "putting the needs of citizens ahead of those of departments" [40].

The Government Digital Service (GDS) unit within the Cabinet Office was created with the mandate to digitally transform the whole of government and public services more broadly, while introducing new ways of working, such as agile delivery and HCD [41]. While GDS standards, resources, and practices offered a baseline, fragmented governance, dispersed responsibilities, and split accountability among multiple agencies in the health care system often led to inefficient transformation and processes losing sight of the end user.

NHSX was embedded with the mandate of user-centered design, with "X" standing for "user experience." NHSX was the convening body between DHSC (which designs policy), NHS England (which currently designs policy implementation but is soon to be subsumed in DHSC), and NHS Digital (which delivers technology), alongside arm's-length bodies of the NHS [42]. In the June 2021 health ministerial transition, an independent review was conducted to assess progress in digital transformation, how to build on what had already been delivered under NHSX's mandate, and to inform future structuring and investment decisions for NHSX as well as its consequences for other NHS institutions [43]. Therefore, NHSX was dissolved, and a new transformation directorate was created, hosted by NHS England.

Digitizing the MHA

An example of an "untold story" [44] on an NHSX project is the application of HCD and digital transformation to reforming the MHA. The HCD discovery phase was conducted internally in the UK government and until now has not featured publicly in academic or policy debate.

The MHA is the main legislation covering the assessment, treatment, and rights of people with mental health disorders. As the review of the MHA was being commissioned, the intention was to "make sure those suffering from mental health issues are treated with dignity and respect, with their liberty and autonomy respected" [45,46]. MHA reform began following recommendations arising from another independent review, "Modernising the Mental Health Act" [47]. The recommendations, accepted by the DHSC [48], were to modernize the act, digitize processes, and design a more human-centered system, ensuring "a person's wishes and preferences will have much more impact and be harder to ignore than before" (47: 186).

DHSC commissioned and delivered a series of discoveries on the act. Discovery is the first qualitative stage of exploratory work, outlined earlier, to identify problems and user needs. One area of focus was advance choice documents (ACDs) [49], which allow a person to set out preferences on future care and treatment, especially in cases of detention. This exploratory work examined the various service pathways people experience the application of the MHA, such as the psychological state that people are in at engagement and where "pinch points" are for service users and staff. Through HCD methods, different users of the ACD system were identified [49]. Discovery primarily involved semistructured interviews with these users, including service users or those at risk of detention, their support network, approved mental health professionals, responsible clinicians, charge nurses, and care coordinators. Exploration also included questionnaires, secondary research, and further focus groups with mental health professionals. The findings provided several recommendations and insights for all types of users.

From the user research conducted, we learned that in moments of acute crisis, there is often no time to meaningfully incorporate patient preferences. People with lived experience described feeling that the most distressing part of being detained is the absence of agency in decision-making. They expressed the need to feel listened to, treated with respect, and "not just a number." From professionals' perspective, user involvement emphasized the importance of understanding why a patient would or would not seek specific treatments. Approved mental health professionals we spoke to also expressed concerns about the practical limitations they face in accessing up-to-date medical information and about the crucial challenge of ensuring ACDs reflect the most up-to-date picture of a patient's needs and circumstances. Nurses also shared concerns about how staff-to-patient ratios directly affect the ability to engage in person-centered care.

Further noted challenges were the lack of information interoperability between care coordinators' systems and external health care professionals. Overall, the process was felt to have created empathy and illuminated implementation barriers as well as specific challenges and contexts from different users' perspectives. This HCD process emphasized the crucial role of human relationships in improving care, rather than specific needs for digital services and tools. The follow-up recommendations from the study were to test prototypes for ACDs through a pilot program designed to understand uptake, ease-of-use, and effectiveness across a range of roles and to identify challenges and improvements. Unfortunately, government prioritization decisions meant that recommendations were not put into action.

Digital Mental Health Research

Digital Therapeutics

In most discussions of digital mental health, the emphasis is on "apps, social media, chatbots, and virtual reality" [50]. Digital interventions like these are seen as the solution for growing demands for mental health support. Benefits appear to be affordability, accessibility, quick response times, potential integration of resources, and creation of large amounts of data [26,50-53]. The largest benefits are expected for young people who are digitally native [50,51], underrepresented racial and ethnic minority groups [54-56], and low- to middle-income countries where mental health care is minimal to absent [21]. Digital interventions are viewed as especially helpful during acute personal crisis such as suicide prevention [56,57], and external crisis, such as pandemics and natural disasters [58-60]. Researchers are generally positive about the promise of these digital therapeutics [57,61,62], especially through self-help [57,63-65]. However, there are difficulties for the practical widespread adoption, with several reviewers unwilling to recommend adoption and expansion of digital interventions, judging the current evidence inadequate [66,67]. Claims that digital transformation will address health inequalities are also yet to be substantiated, with existing evidence for health care broadly indicating they can exacerbate inequalities through unequal access and outcomes [24].

There are further difficulties for digital interventions. There are a vast number of digital mental health tools, with, for example, estimates of over 15,000 mobile mental health apps [68,69]. Therefore, continued use of the apps is low, with high attrition [68,70,71]. Preventing uptake and upkeep are concerns around data transparency, lack of regulation, and inadequate links with existing services for both patients and clinicians [50,53,69,71]. There is a polarization between low-use, evidence-based practices and high-use, less substantial platforms, accelerated by overcommercialization reducing the quality of products [72]. Furthermore, transplanting digital interventions from trial settings into real-world contexts is a major hurdle [73]. Other difficulties are known too, such as little engagement from those with severe mental illness [74], supply-side technical issues, and a lack of personalization [75]. Clinician involvement in design and implementation is found to produce better effects, but this is not always practiced [76].

Some of these problems arise from limitations in underlying research, resulting in researchers, practitioners, and policy makers being unable to make clear judgments. Trials often target less complex mental illnesses with more standardized solutions, such as generalized anxiety disorders and cognitive behavioral therapy (CBT), acceptance and commitment therapy, and mindfulness [61]. Witt et al [67] state that "most studies are biased" and "it is unclear whether reductions would be clinically meaningful."

As one of the more controversial examples, chatbot "conversational agent" therapies can exemplify the difficulties. Chatbots are one artificial intelligence–driven therapy enthusiastically proposed as cheap and effective [77]. Reviewers have argued that trials are of low-quality study design overall, with small samples, high attrition, negligible effects, and a high risk of bias [78]. However, new evidence is frequently published, pointing to the benefits of generative artificial intelligence therapeutic solutions for clinical depression [79]. Further user involvement is needed for assessing efficacy [17].

While chatbots exemplify the need for user engagement where therapeutic efficacy is not assured, the same is cited for proven digital interventions. Togetherall is an illuminating example of a prominent peer support platform for mental health [80,81]. Across multiple studies, partnered researchers show that service can address gaps in provision, offer support for those on waiting lists, and provide self-management opportunities. These studies indicate positive signs but reveal an ongoing need for rigorous and independent evaluation.

HCD and the Need for User Involvement

As in policy reviews, academic commentators continually call for more user involvement in the design and implementation of digital interventions [25,26,51,82], proposing coproduction as the "standard way of working" in digital mental health research [83]. This desire is echoed by practitioners and patients as well [84], all recognizing the need for co-designed solutions for effective and ethical care [85]. Therefore, it should not be surprising that HCD emerged as a guiding paradigm alongside digital transformation. Indeed, commentators in the design literature cite the digital transformation of public services as the reason why HCD has become so popular [86,87].

Vial et al [31] review the prevalence of HCD principles in the development of digital mental health interventions. They find 22 studies mentioning HCD or specific design methods, offering some promise for the integration of these ideas into digital mental health products. Since then, other interesting case studies have been published. The best example is perhaps from Creswell et al [88]. The "digitally augmented" platform they co-designed with users [89,90] provides online training and therapist support for parents to deliver themselves in-person CBT treatment for their child's anxiety. They find this parent-led, real-world application to be as effective as regular therapist-delivered CBT and more cost-effective. The strengths of the intervention stem from their HCD approach, ensuring fit with all user needs and professional support throughout. Our examples show that digital technologies can support the improvement and expansion of mental health services, with HCD principles enhancing development to meet service-user needs. These results suggest that social interactions remain key to effective treatment, while people can be supported with digital tools in the delivery rather than replaced.

Digital Mental Health Services

Overview

Within digital mental health research and policy, there is an overwhelming focus on the delivery of therapeutic interventions. This can be seen across many of the systematic reviews [63] and policy documents on the topic. However, this limits the potential of digital transformation and hinders the stated aim of improving the effectiveness, affordability, and scalability of mental health services for all. Further uses are evident in the studies by Naslund et al [91] and Stein et al [92].

XSL•FO
RenderX

Data Collection and Sharing

Digital technologies offer opportunities for the collection, communication, and analysis of patient data. Internal electronic health records are an early example of digital transformation in health services. A more recent patient-focused avenue is patient-accessible electronic health records (PAEHRs). In recent years, health services in North America and Europe have allowed patients to view health data and clinical notes (eg, the NHS App). The aim is to improve transparency, patient engagement, patient-clinician communication, and health literacy [93,94]. Service-user involvement in the design of PAEHRs shows that different mental illnesses reveal different attitudes toward the practice. Those with more severe and chronic mental concerns decline open PAEHRs more often and are more critical of systems, and in cases of severe mental illness, records are often concealed [95]. Systems can be more equitable with HCD applied in the development and ongoing improvement of services [94,95].

Linkage and interoperability are ongoing data challenges, highlighted in our discussion of the MHA [96,97]. Data sharing is vital for the delivery of services, with overlapping policy domains of health, employment, housing, and education. In our stakeholder engagement we learned of difficulties faced by asylum-seekers and refugees in the United Kingdom who would be "bounced" between immigration, housing, health, and employment systems with minimal communication or knowledge sharing between organizations [27]. Considered adoption of HCD could develop these insights for improving information sharing.

Assessment

Assessment and diagnostics appear fruitful for the implementation of digital technologies [51]. Multiple studies propose digital screening in general practice offices to identify mental health issues [98,99], alleviating resource constraints on professionals. While promising, there have been too few attempts to seriously involve those being assessed in the design of digital screening tools. One exception is the depression monitor by Nickels et al [100], which correlated electronic pulse surveys with smartphone data to explore its applicability in place of targeted questionnaires. Another radical form of assessment is the use of smart home sensing by Tiersen et al [101] for those with dementia, finding HCD enhanced applicability and relevance.

Promotion and Primary Prevention

Mental health promotion is frequently proposed as a fruitful domain for digital transformation [10,17,102-104]. Assessment and diagnostics is a key component of prevention to develop early intervention, but promotion and prevention can take on a variety of forms. Some interventions include education (to follow), mood management, diaries, peer support, or community engagement. Some level of co-design is almost always argued in the development of prevention interventions to ensure either underrepresented voices are included [103], engagement with products is maintained [102,104], or there is trust generally between users, designers, and health professionals [102].

Education

Digital transformation and HCD can come together on a smaller scale than full system change. Education is one such area where research shows digitalization can assist and be effectively designed for information provision for either clinicians or citizens [105,106]. For example, Manning et al [107] show a digital training program for nurses can improve professional effectiveness when co-designed by young people who have self-harmed. Digital learning can also benefit communities through mental health literacy, especially in contexts with previous low levels [108].

Rehabilitation

Finally, digital technologies may help with the rehabilitation process. Engdahl et al [109] show that their co-designed, digital return-to-work scheme is an effective way of supporting those with common mental illnesses. "mWorks" operates as a supplementary self-management tool for existing return-to-work services to prevent relapse. The participatory aspects were central to the success of the platform. Such an initiative shows that successful digital mental health tools may supplement rather than replace core services.

"The Solution May or May Not Be Digital": HCD in Mental Health Services

We have highlighted areas that indicate benefits from HCD in digital mental health. However, by only considering HCD principles in the design of digital therapeutic tools, researchers, practitioners, and policy makers would fail to embody the ideals of evolving services to meet citizen needs. HCD promotes solutions tailored to user needs discovered through qualitative engagement. It may be that appropriate solutions are not digital but instead other service reforms or improved financial, staffing, and technical resources. An implicit "technosolutionism" [17] in discussions of HCD in psychiatry can be seen by the emphasis placed on using it to enhance acceptability of these technologies [110]. Similarly, assuming digital transformation will aid co-creation methods risks ignoring that they may instead be used to bypass democratic oversight and citizen involvement [111]. These contradictions demand a more thorough integration of HCD principles into the design of mental health services as a whole.

HCD appears beneficial for the reform of health services—digital or not digital [87,112]—while lessons can be learned from the previous application of HCD in the public sector outside of mental health. HCD and coproduction are proposed by public policy scholars as ways to create public value in services, enhance trust in the face of democratic deficit, create active citizens and communities, and enhance the legitimacy and communication of science [35,36]. Bason and Austin [113] review various service and policy redesigns in areas such as family services, housing, and education, finding multiple advantages in HCD projects, including the ability to identify previously unknown barriers and iteratively improve services. They suggest HCD can produce a model of public governance that is more relational, networked, and reflexive. Several commentators outline these same empowering benefits

XSL•FO
RenderX

in health and care services but cite several challenges for embedding HCD as best practice [114,115].

The value of HCD for service delivery is demonstrated beyond academic research teams. One case highlighted through stakeholder engagement was conducted by the mental health charity, Mind. They co-designed perinatal support for Muslim women in the east of England [116], a population that is typically considered difficult to reach. Mind also publicly detailing their commitments to human-centered service design and offering guidance for others who are interested in these methods [117]. The charity Mind shows that HCD is relevant for third-sector actors as well as for public policy, academics, or commercial developers.

Ongoing Challenges: Directions for Research and Policy

Research

Digital transformation and HCD ideals can offer great potential for expanding and improving mental health services. However, we see several ongoing challenges for researchers, practitioners, policy makers, and service users.

First, many of the ideas within HCD principles are not new to health care delivery, with elements found in, for instance, “no decision about me, without me” [118], patient and public involvement, triangle of care, and person-centered care. HCD brings with it structured and working methodologies as well as more expansive considerations, but progress from previous citizen involvement agendas must not be forgotten or lost amid calls for the latest trending policy paradigm.

As discussed, technosolutionism can limit the impact of HCD if digital transformation is assumed to be the required resource for meeting needs. Next, a common concern in HCD and coproduction is continued power asymmetries [119,120]. For many, “the gap between principles and practice is challenging” [121], with dangers of practitioners, researchers, and designers acting “as if” power boundaries are blurred [122], when in reality the resources of current and future users of service are not enhanced [123]. Relatedly, service-user involvement must cover underrepresented populations [124]. This is most likely to be those with more severe mental conditions, exposed to multiple deprivations, and from discriminated groups. Difficulties, including the hardest-to-reach populations, emphasize that HCD will not guarantee success in the delivery of mental health services.

In addition, there are tensions between medical models of health care and the person, patient, or citizen emphasis of HCD. Traditional models of health care assume that expertise lies with professionals who have extensive training and clinical experience. Indeed, this is especially relevant in severe cases of mental illness; for example, following our discussion of the MHA, a person may be detained against their wishes. Mental health care generally requires classification and standardized protocols such as the MHA. In contrast, HCD assumes that the user is the expert [125], and in the case of mental health, where the experiences are intensely subjective and often context-specific, it poses domain-specific difficulties for developing universally or nationally appropriate services. This epistemic and political incompatibility is a common challenge elsewhere in coproduction, leading to the ideal of coproduction being undermined, proving tokenistic or “pretend” [122,126,127]. In HCD, where the ultimate delivery remains with the service provider, these limitations are less crucial. Service provision can be designed with strong involvement of service users, without appearing to dispense with professional health expertise. Nevertheless, as with all involvement practices, a central challenge remains which is achieving successful, meaningful engagement with service users [126,128,129].

To evaluate these challenges, HCD digital transformation must embed implementation evaluation and success metrics from the start and include user involvement in this design process [31,68,130]. This includes developing theories of change [81,131], identifying process mechanisms, and safeguarding those who may be negatively impacted by interventions [67].

Finally, thorough HCD can be time intensive, requires staffing commitments and funding, and can be difficult to standardize [131]. New policy structures, regulatory and commissioning practices, and funding are needed if HCD is to be a long-term solution [115,131], especially when facing the need for cost-effectiveness of digital solutions. Recent regulation of digital mental health technology from government agencies is a welcome protection against these latter harms [132]. In our own stakeholder engagement, the cost and time for co-designing were cited as limitations, but so too was the feeling that these ideas and digitalization were a top-down policy approach putting pressure on service delivery instead of providing funding. We learned of the gaps between, on one hand, those designing policy plans for digital transformation and ideals of HCD, and on the other, the realities of underresourced services. The future research agenda is given in Textbox 1.

XSL•FO
RenderX

Textbox 1. Future research agenda.

- How effective is large-scale digital transformation for meeting service-user needs and health outcomes?
- What are the barriers to engagement in human-centered design (HCD) and coproduction processes?
- How can user involvement be better integrated into data sharing, linking, and interoperability systems?
- How are government digital transformation policy mandates received by practitioners in health service delivery and local authorities? How are HCD ideas translated and received across levels of governance?
- How does prospective regulation of artificial intelligence and other emergent technologies link to digital mental health?
- What is the political economy of digital transformation and HCD in mental health services, including political and economic incentives at multiple levels, funding arrangements, and private capital involvement?
- Where do "policy ideas" on mental health emerge from?

Policy Recommendations

Overview

Our review of the literature reveals many opportunities, but also challenges, for the digital transformation of mental health services, and especially the contradictory promise of HCD. We urge caution on technosolutionism, with increased institutional support and attention to the tensions between technocratic and HCD models as well as implementation and evaluation.

Similarly, insights from various NHSX projects, in the personal view section, reveal systemic issues that hinder the design and provision of HCD: the absence of agency for patients, staff shortages, operational pressures that prioritize risk-based approaches, fractured data systems, lack of systems' interoperability, and outdated data and digital infrastructure. These realities highlight the need for structural, policy, and capability reforms that go beyond individual behavior change to reshape decision-making systems.

The recent political decision to abolish NHS England marks a significant shift in UK health care, offering a unique opportunity to redesign the system for greater efficiency and responsiveness. The elimination of duplicative governance structures and clearer decision-making pathways bring modernization possibilities for operations and realignment with user needs.

Therefore, in conclusion, we advance several policy recommendations for mental health in the United Kingdom, developed from our review, stakeholder engagement, and professional experience of digital transformation and HCD.

Independent and Cross-Departmental Digital Transformation Commission

The digital transformation directorate currently within NHS England should be externalized to establish an autonomous unit tasked with leading digital transformation across the health care ecosystem. A common strength of GDS and NHSX lies in their external positioning vis-à-vis "existing routines" and political constraints [11]. An external directorate would provide more effective convening powers, enabling better collaboration and system-wide alignment of incentives, efforts, and decisions across national and local public institutions and arm's-length bodies.

Agreed Definitions of Methodologies and Outcomes

In the course of this paper, we have developed definitions of digital transformation and HCD with respect to mental health services, and these should be incorporated into the digital transformation directorate. We hope and intend for these to be used in future policy work. Further research is needed to agree on the criteria for successful transformation, standardized processes, cost guidelines, capability assessment and needs guidance, and impact evaluation methods.

Digital Standards Collaboratively Defined

Similarly to the first recommendation, HCD approaches should be leveraged to develop data standards and operability with collaboration across systems for common terminologies, protocols, and exchange standards, as recommended by DHSC [133] and NHSX [134]. Standards and operability must function across policy domains and government departments, linking NHS mental health services with other government departments.

Integrate HCD in Other Public Policy Domains and at Both Local and National Levels in Health Services

Health care is viewed as the most promising and important avenue for the adoption of HCD principles [112,135]. Still, HCD and coproduction have been shown to be beneficial in an array of policy settings [36,113]. To facilitate the success of HCD in mental health, extending the application of HCD across public services and at multiple policy levels will normalize and strengthen the relevant social and operational systems required for success. Widespread use of HCD can bring standardization and capacity building and connect it to other models of involvement to ensure meaningful service-user engagement.

Conflicts of Interest

None declared.

Abstract

Background: Rhinolaryngoscopes are one of the most widely used tools by otolaryngologists and speech-language pathologists in current clinical practice. However, there is limited data on adverse events associated with or caused by the use of rhinolaryngoscopes.

Objective: In this study, we used the Manufacturer and User Facility Device Experience (MAUDE) database with the aim of providing insights that may assist otolaryngologists in better understanding the limitations of these devices and selecting appropriate procedures for their specific clinical setting.

Methods: We characterized complications associated with the postmarket use of rhinolaryngoscope devices from the US Food and Drug Administration MAUDE database from 2016 through 2023.

Results: A total of 2591 reports were identified, including 2534 device malfunctions, 56 injuries, and 1 death, from 2016 through 2023. The most common device problem with rhinolaryngoscopes was breakage (n=1058 reports, 40.8%), followed by fluid leaks (n=632 reports, 24.4%). The third most common problem was poor image quality (n=467 reports, 18%). Other device issues included contamination or device reprocessing problems (n=127 reports, 4.9%), material deformation or wear (n=125 reports, 4.8%), and device detachment (n=73 reports, 2.8%). Of the 63 reported adverse events, the most common patient-related adverse event was hemorrhage or bleeding, accounting for 18 reports, with the root causes including material deformation or wear, breakage, wrinkled rubber, or improper operation.

Conclusions: Our study offers valuable insights for endoscopists and manufacturers to recognize potential issues and adverse events associated with the use of rhinolaryngoscopes. It emphasizes the need for improving device reliability, training, and procedural protocols to enhance patient safety during diagnostic procedures.

Introduction

Rhinolaryngoscopes are currently available in various forms, including rigid, flexible, and video versions. They are essential tools routinely used by otolaryngologists and speech-language pathologists [1,2]. Given the substantial proportion of patients who require a rhinolaryngoscopic procedure as part of a head and neck examination, rhinolaryngoscopy has become an indispensable diagnostic procedure in otolaryngological practice [3]. Modern rhinolaryngoscopes can have a distal diameter as small as 2 mm, are equipped with lighting, are flexible, and have photo and video capabilities, enabling direct visualization of the nose, throat, and airway in diverse clinical settings, including emergency, inpatient, and outpatient scenarios. The range of indications for rhinolaryngoscopy includes visualizing polyps, tumors, and sources of epistaxis in the nasal cavity and aiding in the identification of suspected tumors or adenoidal hypertrophy [4]. In the oropharynx or laryngopharynx,

XSL•FO
RenderX

rhinolaryngoscopy can be instrumental in evaluating foreign bodies and potential airway obstructions from etiologies such as neoplasm and epiglottitis, obstructive sleep apnea, dysphagia, dysphonia, tonsillar hypertrophy, glossoptosis, laryngomalacia, and vocal fold lesions [5,6]. Rhinolaryngoscopy may also assist in assessing the severity of angioedema. An alternative visualization tool is the flexible fiber-optic laryngoscope [7]. While laryngoscopes may be less expensive and simpler to use than rhinolaryngoscopes, fiber-optic rhinolaryngoscopy provides clearer visualization and better access to the larynx anatomy. In general, imaging quality, including illumination, color fidelity, resolution, and accurate length representation, plays a pivotal role in visualizing abnormalities. Therefore, the choice of instrument is often determined by clinician preference or equipment capabilities [8].

Rhinolaryngoscopes are classified as a moderate-risk medical device and require a 510(k) submission for premarket review by the US Food and Drug Administration (FDA; regulation number 21 CFR 874.4760). Although rhinolaryngoscopy is considered a generally safe procedure with rare serious adverse events, complications such as mucosal tearing, damage to anatomic structures (particularly with rigid scopes), bleeding, and laryngospasm have been reported [9]. However, there is limited data regarding device failures for both rigid and flexible rhinolaryngoscopes, incidence rates, and adverse events associated with these devices. The FDA's Manufacturer and User Facility Device Experience (MAUDE) database serves as a repository for adverse events and malfunction reports related to medical devices, and it has been used as a data source to study device-related adverse events [10,11]. In addition, capturing user experiences and integrating them into the design during medical device development has become an essential component for ensuring patient safety and device effectiveness. In this study, we used the MAUDE database to characterize postmarket complications associated with the use of rhinolaryngoscope devices from 2016 through 2023, with the aim of providing insights that may assist otolaryngologists in better understanding the limitations of these devices and selecting appropriate procedures for their specific clinical setting.

Methods

Search and Selection

MAUDE, a comprehensive postmarket surveillance database from the FDA, was chosen because of its extensive collection of medical device reports (MDRs) from both mandatory and voluntary reporters related to FDA-cleared medical devices [11]. Mandatory reporters comprise manufacturers or device user facilities, whereas voluntary reporters include physicians, patients, or other device consumers. The MDRs from MAUDE include device malfunctions and potential patient harms associated with device failures during procedures. Therefore, the event classifications used in this analysis include device malfunctions and adverse events among patients.

The MAUDE database was queried by searching for the product category "rhinolaryngoscope (Flexible or Rigid)," which included MDRs from January 2016 through December 2023. This search encompassed terms such as "rhino-laryngo videoscope," "rhino-laryngo fiberscope," "telescope," and "single use endoscope." Each MDR was then logged in a Microsoft Excel spreadsheet. Among the reports, items that may have been incorrectly classified, such as cystoscopes and arthroscopes, were manually removed. These misclassifications accounted for only a small portion of the reports and resulted from errors made by the reporters. The MDRs underwent manual review, including assessment of the date of the event, event type (device malfunction, injury, or death), and the root causes of the adverse event. Device failures were defined as reported instances of rhinolaryngoscopes not functioning as expected during a procedure.

Data Extraction

The device failure problems were classified as (1) breakage, (2) fluid leakage, (3) poor image quality, (4) contamination, (5) material deformation, (6) device detachment, (7) unintended movement, (8) mechanical problems, (9) unidentified device or use problems, (10) device overheating, (11) improper or incorrect procedures, (12) moisture damage, (13) packing problems, and (14) electrical shorting. To minimize potential bias and ensure consistency in categorization, 2 reviewers (SHC and DC) independently screened and categorized the reported events. Adverse events among patients included all reported complications resulting in injury, harm, or death during procedures associated with rhinolaryngoscopes. Following the categorization of the failure problems and adverse events, statistical analysis was conducted. The frequency of each failure type and adverse event was calculated, and the results were expressed as the number and percentage of occurrences within each category.

Additionally, to assess the context of these device failures in clinical practice, we analyzed the US Medicare population using *Current Procedural Terminology* (*CPT*) codes associated with rhinolaryngoscope diagnostic procedures (excluding surgeries). Specifically, we selected *CPT* codes 31231 (nasal endoscopy, diagnostic; unilateral or bilateral), 31575 (laryngoscopy, flexible; diagnostic), and 92511 (nasopharyngoscopy with endoscope), which may correspond to diagnostic procedures involving rhinolaryngoscopes. The data were accessed under the "Research, Statistics, Data & Systems" section. The Centers for Medicare and Medicaid Services Part B National Summary Data File was used to obtain annual procedure data based on *CPT* codes 31231, 31575, and 92511. These codes were used to compare the number of procedure claims with the number of device failure reports, allowing us to explore the relationship between the frequency of rhinolaryngoscope use (as indicated by procedure billing) and the reported failure incidents. This comparison provide a picture of the relative incidence of device failures in clinical practice compared to the frequency of procedures conducted, shedding light on potential areas for improvement in device performance or clinical training.

Ethical Considerations

This study involved querying the FDA MAUDE database and US *CPT* codes. These activities did not involve direct interaction with human subjects, nor did they involve the collection or analysis of personal health data. Therefore, such data queries typically do not require approval from an institutional review

XSL•FO
RenderX

board. Publicly available databases like the FDA MAUDE and *CPT* codes generally do not raise ethical concerns. We analyzed publicly available data and did not collect personal data or perform clinical trials, so institutional review board approval was not required.

Results

Device-Related Problems

A total of 2591 reports were identified, including 2534 device malfunctions, 56 injuries, and 1 death among patients from 2016 through 2023. The number of reports submitted significantly increased in 2021, 2022, and 2023 (n=347, n=1147, and n=918 reports, respectively), constituting greater than 90% of all reports submitted during the study period. Device malfunctions and their incidence rates are presented in Table 1. The most common device problem with rhinolaryngoscopes was breakage (n=1058 reports, 40.8%), followed by fluid leakage (n=632 reports, 24.4%). The third most common problem was poor image quality (n=467 reports, 18%). Other device issues included contamination or device reprocessing (n=127 reports, 4.9%), material deformation or wear (n=125 reports, 4.8%), device detachment (n=73 reports, 2.8%), and unintended movement (n=55 reports, 2.2%), with the remaining issues each accounting for less than 1%. Mechanical problems, device overheating, packaging issues, and electrical shorting were relatively infrequent problems, as summarized in Table 2.

Table . Event types reported to the US Food and Drug Administration Manufacturer and User Facility Device Experience (MAUDE) database for rhinolaryngoscopes per year.

Year	Deaths (n=1), n (%)	Injuries (n=56), n (%)	Malfunctions (n=2534), n (%)
2023	0 (0)	14 (25)	918 (36.2)
2022	1 (100)	7 (12.5)	1147 (45.3)
2021	0 (0)	2 (3.6)	347 (13.7)
2020	0 (0)	10 (17.8)	37 (1.5)
2019	0 (0)	14 (25)	38 (1.5)
2018	0 (0)	2 (3.6)	21 (0.8)
2017	0 (0)	5 (8.9)	13 (0.5)
2016	0 (0)	2 (3.6)	13 (0.5)

Table . Device problems reported for rhinolaryngoscopes.

Device problems	Reports (n=2591), n (%)
Breakage	1058 (40.8)
Fluid leakage	632 (24.4)
Poor image quality; optical distortion	467 (18)
Contamination; device reprocessing problem	127 (4.9)
Material deformation; wear	125 (4.8)
Detachment of device	73 (2.8)
Unintended movement	55 (2.2)
Mechanical problem	12 (0.5)
Unidentified device or use problem	11 (0.4)
Overheating of device	10 (0.4)
Improper or incorrect procedure	6 (0.2)
Moisture damage	6 (0.2)
Packaging problem	5 (0.2)
Electrical shorting; flare or flash	4 (0.2)

We conducted a comprehensive analysis of device failures, examining variations across specific manufacturers, including Olympus, Storz, Pentax, and Gyrus. A high incidence of breakage and fluid leakage reports was associated with Pentax. In comparison, Olympus devices showed a breakage rate of 4.8% (50/1028). However, Olympus devices were also associated with the highest frequency of contamination reports, followed by Pentax. These higher failure rates could be linked to the relatively larger market share of these manufacturers. Additionally, we scrutinized the frequency of nasal endoscopies performed in the US Medicare population using *CPT* codes 31231, 31575, and 92511. In 2022, a total of 1,196,520

XSL•FO
RenderX

procedures were performed. Meanwhile, the MAUDE database reported 1155 device failures. This results in an estimated failure rate of approximately 1 per 1000 procedures.

Patient-Related Adverse Events

Adverse events or complications associated with device problems were evaluated based on the MAUDE database. Adverse events in patients in reports included all instances of complications resulting in injury, harm, or death associated with the use of rhinolaryngoscopes. Adverse events in patients were categorized as (1) hemorrhage/bleeding, (2) a foreign body in the patient, (3) burns or thermal burns, (4) discomfort or pain, (5) anaphylactic shock, (6) edema, (7) laryngospasm and dyspnea, (8) unspecified tissue injury, (9) allergic reaction, and (10) death. The specified root cause of the adverse event included material and mechanical problems, device chemical contamination, improper operation, fluid leakage, overheating, and display issues, among others.

The adverse events in patients and their specified root causes are presented in Table 3. A total of 63 reported adverse events were identified, including hemorrhage/bleeding (n=18 reports, 28%), a foreign body in the patient (n=12 reports, 19%), discomfort/pain (n=10 reports, 16%), thermal burns (n=9 reports, 14%), anaphylactic shock (n=4 reports, 6%), edema (n=3 reports, 5%), laryngospasm and dyspnea (n=3 reports, 5%), unspecified tissue injury (n=2 reports, 3%), allergic reaction (n=1 report, 2%) and death (n=1 report, 2%). The most common patient-related adverse event was hemorrhage/bleeding, accounting for 18 reports, with the root causes including material deformation or wear, breakage, wrinkled rubber, or improper operation. One death was reported, with an unspecified cause. Material breakage, material wear, and improper operation were identified as the major root causes for the reported adverse events. In 2019, 1 case of edema was attributed to improper reprocessing and device contamination with chemicals. The manufacturer's investigation determined that the customer had insufficiently wiped phthalaldehyde-based disinfectants off the endoscope during reprocessing, resulting in the possibility of anaphylactic shock. Table 4 displays the numbers of adverse events from 2016 through 2023, including thermal burns, foreign bodies in patients, and discomfort, reported in 2023.

Table . Adverse events in patients from rhinolaryngoscope device problems.

Adverse event	Root cause	Events (n=63), n (%)
Hemorrhage/bleeding	Material deformation or wear; breakage; rubber wrinkling; improper operation	18 (28)
Foreign body in patient	Detachment of device or device component; breakage; material fragmentation; wear; improper operation	12 (19)
Discomfort/pain	Material wear; breakage; material invagination; mechanical problems	10 (16)
Burns/thermal burns	Scratched material; cut or torn material; burst battery; device overheating; use of device problem	9 (14)
Anaphylactic shock	Material perforation; material cracks or holes	4 (6)
Edema	Unidentified device or use problem; allergic reaction due to improper reprocessing and device chemical contamination	3 (5)
Laryngospasm and dyspnea	Display problem/poor image; unspecified issue	3 (5)
Unspecified tissue injury	Fluid/blood leakage; material wear	2 (3)
Allergic reaction	Reprocessing agent	1 (2)
Death	Unspecified issue	1 (2)

XSL•FO

Table . Number of adverse events based on year and type.

	Events, n							
	2023	2022	2021	2020	2019	2018	2017	2016
Hemorrhage/bleeding	0	0	0	2	12	0	3	1
Foreign body in patient	4	0	0	0	2	0	5	1
Discomfort/pain	5	2	0	1	2	0	0	0
Burns/thermal burns	3	1	1	1	0	1	1	1
Anaphylactic shock	0	0	0	4	0	0	0	0
Edema	0	0	0	0	1	0	2	0
Laryngospasm and dyspnea	0	0	0	0	3	0	0	0
Unspecified tissue injury	0	2	0	0	0	0	0	0
Allergic reaction	0	0	1	0	0	0	0	0
Death	0	1	0	0	0	0	0	0

Discussion

Principal Findings

This study examined adverse events associated with the use of rhinolaryngoscopes based on the MAUDE database, analyzing 2591 common device issues and 63 patient-related adverse events from January 2016 through June 2023. Breakage (40.83%) was the most common device issue, whereas hemorrhage (28.57%) was the most common patient-related adverse event, primarily attributed to material deformation or breakage. These findings underscore the overall low occurrence of adverse events associated with the use of rhinolaryngoscopes. Previous studies have highlighted mucosal tearing and bleeding as the most common complications, with laryngospasm occurring in less than 1% of procedures [12-14]. To prevent these complications, adequate nasal decongestion and limited force are recommended. However, our results show that improper operation or use problems frequently contributed as the root cause of adverse events, including hemorrhages, foreign bodies in patients, thermal burns, pain, and edema. Operator experience with the device may also influence the occurrence of adverse events. One customer reported a broken eyepiece on a rigid scope (report number 9610773-2023-03626). Following investigation, the manufacturer attributed the issue to wear and tear coupled with excessive force. Similarly, another report detailed a damaged lens at the distal end of a scope (report number 9610773-2023-02419). Upon examination, the manufacturer concluded that this damage stemmed from user error, improper handling, and the application of excessive force. Therefore, considerations of usability and ergonomics are imperative to enhance patient care [15-17].

Despite gathering 125 reports of material wear from the MAUDE database, which accounted for one-ninth of the total breakage reports, it is noteworthy that the majority of the reported failures were not attributed to routine wear and tear, as determined by the manufacturer's investigation. This observation underscores the importance of scrutinizing reported failures to distinguish between typical wear-related issues and potentially more serious underlying concerns. It is evident that device failures may arise from various root causes beyond routine wear and tear, which manufacturers may not consistently highlight in their manuals. For instance, in the manual for the TJF-Q180V (Olympus) endoscope, there is an acknowledgment that repeated use and reprocessing of the endoscope and its accessories can lead to gradual wear and tear. This underscores the importance of thorough understanding of and adherence to manufacturer instructions, as well as recognizing potential factors contributing to device failures, beyond typical wear-related issues.

Moreover, it was observed that many cases of device failure could be linked to improper reprocessing practices. In this study, 127 device failures caused by rhinolaryngoscope contamination were reported. Although manufacturers provide recommendations for product use and reprocessing, Biadsee et al [18] reported that less than 20% of physicians adhere to the recommended decontamination process outlined by manufacturers. Another study, from Jiang et al [19], of rhinolaryngoscope device failure due to contamination using the MAUDE database from 2013 to 2019 revealed associations with laryngeal edema, rather than infection, highlighting 1 injury resulting from improper reprocessing procedures (insufficient disinfectant removal from the endoscope). Anaphylaxis resulting from the use of phthalaldehyde-based disinfectants has been reported in cases involving the cleaning of rhinolaryngoscopes and cystoscopes [20,21]. In this case (report number 9610877-2019-00238), the risk of injury from microbial

XSL•FO
RenderX

infection may be less than the potential harm caused by the disinfectant solution itself. In response to this incident, 5 members of the otolaryngology department were identified and retrained as the personnel at the hospital did not properly reprocess the endoscope. Regarding the compatibility of disinfectants, the manufacturer of the endoscope recommends that facilities adhere strictly to the instructions provided by the disinfectant manufacturer, including specific parameters such as concentration, temperature, and exposure time. Furthermore, it is crucial to ensure thorough rinsing of internal channels, external endoscope surfaces, and components with clean water to remove any residual detergent solution, thereby minimizing the risk of adverse reactions or complications associated with disinfectant use. Our results identified 1 allergic adverse event associated with a reprocessing agent, and 3 cases of edema due to improper reprocessing or device use, confirming previous literature regarding rhinolaryngoscope contamination [22,23]. Compared to other endoscope types, such as bronchoscopes and duodenoscopes, the contamination rate of rhinolaryngoscopes is less commonly associated with patient harm or death [18]. This indicates a comparatively lower risk associated with rhinolaryngoscopes in contrast to other endoscopic examinations.

This study reviewed the MAUDE database and identified 9 cases of thermal burns in patients who underwent rhinolaryngoscope examinations over 8 years. Scope overheating was reported as a root cause, likely because of prolonged procedure times with the light source on or the brightness setting of the lamp. Several studies assessed the heat effects of endoscopes in otorhinolaryngology and recommended keeping light sources at the lowest effective intensity [24-26]. MacKeith et al [27] evaluated the amount of heat produced by endoscopes and showed that larger-diameter endoscopes attain a higher temperature. Chitnavis [28] demonstrated that even momentary proximity could cause a thermal burn to a patient's skin, without generating smoke or fire. The risk of thermal injury may be associated with the light source, endoscope caliber, and angulation [25,27,29,30]. Consequently, available cameras are often equipped with a regulation system capable of automatic gain control in poor lighting situations [31].

Furthermore, it is noteworthy that the number of MDRs underwent a significant surge in 2021, 2022, and 2023, with 347, 1147, and 918 reports, respectively. This notable increase underscores the importance of continued vigilance and thorough investigation into the factors driving these trends to ensure the safety and efficacy of medical devices. The growth in frequency can be attributed to several major factors, including the increased prevalence of laryngeal diseases, heightened use of laryngoscopes in airway management, guideline recommendations, elevated demand for respiratory products, and the impact of the COVID-19 pandemic. However, there was no significant rise in the number of nasal endoscopies performed in the US Medicare population with *CPT* codes 31231, 31575, and 92511 from 2016 to 2022. Another plausible explanation for the increased MDRs could stem from new product launches and strategic activities by manufacturers, which have had a moderate impact on the laryngoscope market, influencing the growth in the frequency of MDRs.

The statistical analysis conducted using the FDA's MAUDE database carries significant implications for clinical practice. These data not only help identify trends and patterns in device failures but also provide critical safety information for clinical health care. By analyzing the MAUDE data, we can identify failure types and frequencies associated with specific devices, such as rhinolaryngoscopes, thereby understanding their potential impact on patient safety. The data reveal the sources of device failures, including variations across manufacturers and models, which can aid clinical decision-makers in selecting devices based on more informed criteria. Furthermore, by examining the time trends of device failures in the MAUDE database, we can correlate these trends with medical policies or other external factors. This trend analysis can assist health care institutions in adjusting operational processes and training programs to address the growing issue of device failures, especially during times of infectious disease outbreaks or when new devices are introduced. The data derived provide empirical evidence that can help in developing more effective clinical guidelines and training plans, ultimately contributing to improved quality of health care services [32]. These findings highlight the importance of timely adjustments to clinical operational processes and training programs to address the growing issue of device failures and provide guidance for future device improvements and clinical recommendations.

Limitations

A major limitation of this study is its reliance on reports from the FDA's MAUDE database, which may not account for comorbidities involved in reported device failures. Furthermore, the information may be incomplete or limited because MDRs can be submitted by health care professionals, patients, or manufacturers. Reporting variations between private-practice clinics and large academic medical centers may also affect data accuracy and which brands are used. Therefore, establishing causative associations for some reported adverse events is challenging. However, it is important to note that manufacturers are required to investigate reported adverse events and device failures, and their findings or follow-up reports are included in the MAUDE database. The manufacturer reports help to mitigate potential bias arising from self-reported data. Since the MAUDE database primarily focuses on device-related issues, we recognize the possibility of underreporting or inconsistent reporting practices. Nonetheless, the inclusion of both user-reported and manufacturer-investigated information adds a level of rigor to the analysis, allowing for a more nuanced understanding of the issues related to device failures. Despite these limitations, our study provides important insights for endoscopists and manufacturers to recognize potential issues and adverse events associated with the use of rhinolaryngoscopes, emphasizing the importance of patient safety.

Conclusions

Although our findings underscore the overall low occurrence of adverse events associated with the use of rhinolaryngoscopes, the results indicate that improper operation frequently contributed to adverse events, including hemorrhage, foreign bodies in patients, thermal burns, pain, and edema. Operator

XSL•FO
RenderX

experience with the device may also influence the occurrence of adverse events. Results from this study will be important for endoscopists and manufacturers to have a thorough understanding of the equipment and its limitations. Future research should assess the broader organizational impact, including otolaryngology teams, documentation practices, clinician training, and patient perspectives.

Abstract

Background: The collection of dietary behavior data is crucial in childbearing populations. In addition to observed inequities in perinatal dietary intake and quality, burdensome assessment methods (eg, 24-h dietary recall) may limit research participation for some groups. Ecological momentary assessment (EMA) is associated with reduced recall bias and participant convenience, but there is a dearth of studies with diverse cohorts.

Objective: Our aim is to describe participant completion of food intake items in EMA surveys, overall and across individual characteristics (eg, prepregnancy BMI).

Methods: Using secondary EMA data from participants in a longitudinal study, we report average completion rates of survey items regarding dietary behavior (eg, number of meals eaten in a day) across individual demographic variables (eg, age) and combined strata (eg, race+age) during late pregnancy and throughout 12 months post partum.

Results: In our analytic sample (N=310), the average completion rate was 52.4% (SD 27.8%) during pregnancy, rising to 59.1% (SD 22.0%) after giving birth. Participants who were older (>30 y), overweight before pregnancy, self-identified as White, working, or earning higher annual income (>US $50,000) had higher average completion rates than their counterparts. Examining combined strata, we found some variation in survey completion within racial groups. Black participants using a study phone had higher average completion rates during pregnancy and post partum, but this relationship was reversed for White participants.

Conclusions: Our secondary analysis showed relatively stable engagement with EMA surveys in a childbearing cohort across 15 months. Increased completion rates among privileged groups (eg, White, higher income) may demonstrate the impact of socioeconomic advantages on individual health behaviors. Investigators should consider how intersections between race and other factors (eg, employment) may impact participation and data collection.

(JMIR Hum Factors 2025;12:e67081) doi:10.2196/67081

Introduction

The collection of dietary behavior data is integral to understanding how diet and eating patterns shape health for individuals and communities [1,2]. In childbearing populations, studies show that dietary intake patterns during pregnancy are critical to the health of both the mother and infant [3]. Inadequate nutrition during pregnancy can increase the risk of cardiometabolic comorbidities (eg, hypertension disorders of pregnancy and gestational diabetes) during pregnancy and of

XSL•FO
RenderX

low birthweight from fetal growth restriction and neurodevelopmental delays [4,5]. Additionally, research shows significant disparities in perinatal diet quality across social determinants of health (education, food security, income) [6-9], obliging studies to examine dietary behaviors across these strata. Racial inequities also exist, where Black birthing populations report higher food insecurity [6] and lower-quality diets [7-9] and increased prevalence of perinatal and postnatal comorbidities compared to White populations [10].

Commonly used dietary assessment methods include 24-hour dietary recalls, food frequency questionnaires, and food diaries, each presenting advantages and disadvantages in their administration and the quality of data collected [11]. The 24-hour dietary recall provides detailed information on dietary intake and has proven to be acceptable across diverse populations including pregnant individuals [12-15]. The major disadvantages of the 24-hour dietary recall measure are that it is prone to recall bias, it is limited by its reliance on an individual's episodic memory, there is potential for intentional misreporting, and it requires the greatest amount of time to complete [11,13]. Food frequency questionnaires also rely on participants' memory and lack detailed collection of specific food intake. Food diaries and the 24-hour dietary recall are similar in recording detailed food intake, increasing the burden on study participants and potentially influencing their eating behavior on the days being recorded [16].

Ecological momentary assessment (EMA) is a sampling method used to repeatedly collect information in "real time" [17] and in one's natural setting; it has been used to understand eating behaviors and food intake, typically via digital devices (eg, smartphones) [18]. EMA reduces retrospective bias and promotes reliability and ecological validity. Compared to more time-intensive methods, EMA reduces the burden of reporting and often the time lapse between a behavior and its recording. Furthermore, the repeated sampling design facilitates a broader behavioral assessment over time [17-22]. Recent research using EMA to assess dietary behaviors has been conducted in different populations, including children [23,24], adolescents [25,26], mother-child dyads [27-29], individuals with eating disorders [30], and postbariatric surgery patients [31]. The few EMA studies examining dietary behavior in perinatal populations report homogenous samples and poor adherence to EMA completion, making a strong case for more demographically diverse cohorts in evaluating the usability of these assessment tools [32,33].

Since EMA is a novel approach to collecting dietary data, particularly over long periods of time (eg, >3 mo), it is critical to assess participant adherence to the EMA protocol for reporting food intake. It is important to note that EMA surveys are designed to be briefer, making them ideal for studying the context of eating behaviors, rather than nutritional content, which may be measured more precisely in recalls and diaries. Leveraging EMA data from a diverse childbearing cohort within a longitudinal, observational investigation (approximately 15 mo), this secondary analysis aimed to describe participant completion of dietary intake items in EMA surveys, overall and across individual characteristics (eg, prepregnancy BMI).

Methods

Study Design

This secondary analysis uses participant-reported data regarding dietary intake from the Postpartum Mothers Mobile Study (PMOMS), a longitudinal, observational investigation [34] designed to examine factors associated with racial disparities in postpartum weight retention and cardiometabolic health. Pregnant people were recruited between 18 and 32 weeks' gestation and followed through 12 months post partum. Participants completed daily EMA surveys via smartphones, weighed themselves weekly using Bluetooth-enabled scales, and attended follow-up visits for anthropometric measurements and biospecimen collection. The study applied EMA methods to better understand participants' experiences and exposures in their natural environment via real-time measurements of psychosocial (eg, stress, discrimination), behavioral (eg, eating behavior, consumption of foods with added sugars, physical activity), and contextual (eg, geographic location) factors.

Brief EMA surveys were administered at the beginning of day (BOD) and end of day (EOD), representing time-contingent responses, and at random times throughout the day (signal-contingent responses). Participants selected times for receiving BOD and EOD surveys, with at least 9 hours between the 2 surveys. Links for BOD and EOD surveys were active for 30 minutes (60 min for random surveys) to ensure that participant-reported data reflected real-time information. Each participant contributed approximately 15 months of EMA data during the pregnancy and postpartum periods. The protocol for PMOMS is described in more detail in a previous publication [34].

Ethical Considerations

The study was approved by the institutional review board within the University of Pittsburgh Human Research Protection Office (#PRO16100117).

Participants and Recruitment

PMOMS was an ancillary study to a randomized clinical trial, the Comparison of Two Screening Strategies for Gestational Diabetes (GDM^2) [35,36], conducted at a women's hospital in southwestern Pennsylvania. The clinical trial visits provided 2 in-person opportunities for our staff to approach and recruit potential participants and determine eligibility between 18 and 32 weeks' gestation. Participants were recruited this way between December 2017 and March 2019. After the GDM^2 study ended recruitment, PMOMS staff directly recruited participants from December 2019 to March 2020, when study activities were interrupted by the COVID-19 pandemic.

After providing their written, informed consent at a baseline visit (between 18 and 32 weeks' gestation), participants completed demographic questionnaires and anthropometric measures. At this same visit, a research assistant facilitated setting up participants' smartphones for receiving daily EMA surveys, which were scheduled to begin the following day [34]. Individuals using their own phone for study participation were compensated US $35 each month for using their data (up to US

XSL•FO
RenderX

$525 throughout the study). For those without a suitable device for participating in the study, PMOMS offered a smartphone with a paid, unlimited data plan for the duration of the study. Upon completing the study, these participants had the option of keeping the smartphone provided by the study as an additional incentive.

All participants were compensated monthly if their EMA completion rate reached 60% or more during that month. Those who reached a completion rate of 80% or higher were entered into a monthly drawing for additional compensation. In addition, PMOMS staff conducted routine check-ins (via phone or text) with all participants falling below the 60% threshold to identify and address any barriers to increasing their completion rate.

Pregnant individuals were excluded from participating in PMOMS if they indicated any of the following: plan to deliver at a different hospital from the study recruitment site, multiple pregnancy, plan to move from the area before 12 months post partum, history of type 1 or type 2 diabetes diagnosis, gestational diabetes diagnosis before 20 weeks' gestation in current pregnancy, consumption of oral glucocorticoids in last 30 days, history of "dumping syndrome" following gastric bypass surgery, hypertension diagnosis or medication for high blood pressure, and diagnosis of severe liver disease (eg, cirrhosis). Further details about the PMOMS protocol can be found elsewhere [34].

Measures

Although EOD surveys were delivered to participants every day, eating habits and intake of added-sugar foods were only assessed in these surveys on 10 randomly selected weekdays and 4 randomly selected weekend days for every 28-day block of time after EMA prompts began [34]. Participants were asked to report the number of meals and snacks they ate during the day. They were also asked to report whether they had any food or drinks with added sugar. If they answered yes to either, they were asked to report the number of foods with added sugar in 4 categories (cookies, cake, pie, and donuts; candy; ice cream and frozen treats; and other sugary foods), as well as the number of drinks with added sugar in 4 categories (regular soda pop, juice drinks, coffee shop drink and frozen treats, and other sugary drinks). These EMA survey items, along with dozens of others, were developed for the purposes of our study and were tested in a pilot study [37]. All EMA surveys were designed to be brief (1 - 2 min in duration), and those including dietary intake items did not ask participants to specify sizes or types of added sugar items consumed.

Upon enrollment, we collected data on maternal age, education, race, ethnicity, employment status, marital status, and annual household income. We dichotomized some demographic variables for descriptive statistics: age as ≤30 years and >30 years (based on the sample median), employment status as working (part-time or full-time) versus not working (unemployed or on disability), and annual household income as ≤US $50,000 per year versus >US $50,000 per year (based on the sample median). In this study, we also examined EMA completion between participants using their own phone and those using a smartphone provided by PMOMS. Study staff measured participant height at the first clinical trial visit, and participants self-reported their prepregnancy weight at the second clinical trial visit. We calculated prepregnancy BMI by dividing participants' weight in kilograms by their height in meters squared and categorized participants as normal/healthy (BMI 18.0 - 24.9) and overweight (BMI≥25.0) [38].

Data Analysis

We determined our final sample for this secondary analysis (N=310) after excluding participants only if they were determined to be ineligible for PMOMS (n=3) at the study enrollment phase because they withdrew from either PMOMS or GDM^2 (parent study). We report frequencies and percentages for all demographic and anthropometric variables.

Completion rates were calculated for all participants included in the analytic sample by dividing the number of responses to dietary intake questions by the number of EOD surveys delivered during both pregnancy and postpartum periods. Given the sampling design described above, we only considered EOD surveys with the dietary intake questions in these completion calculations. We then stratified the study sample across demographic and clinical measures, describing average completion rates for each pair. In addition to the subgroups described above (by age, employment status upon study enrollment, household income), we examined average completion rates for participants by prepregnancy BMI (healthy: 18.0 - 24.9 vs overweight: ≥25.0), study phone usage, and race (Black vs White). Lastly, we looked at average completion rates across combined sample strata (eg, by race and age). We focused specifically on Black/African American and White participants in describing completion rates in subgroups due to sample size limitations in other racial groups.

Results

Table 1 provides an overall description of the analytic sample (N=310), which attempted a total of 36,687 EOD surveys that included dietary intake items, with a mean of 121.5 (SD 70.7) EOD surveys attempted per person (median 2128.0, IQR 60.3-185.8) and a range of 1.0 - 243.0 EOD surveys attempted per participant over the study period. Only 3 participants were excluded from these analyses due to being deemed ineligible to participate in PMOMS after enrolling in the study (eg, withdrew from parent study).

periods (up to 12 mo after giving birth), as well as across sample strata (eg, study phone vs own phone). We note that values are missing for 6 (1.9%) participants during pregnancy and 11 (3.5%) participants post partum, due to no EOD surveys being delivered to these participants during that time. Rate calculations for the 4 dietary intake items in EOD surveys did not vary between the items, so the completion rates for just 1 item (meals) are presented as proxy rates for overall completion of these items.

Table . Average completion rates for dietary items during pregnancy and post partum in the overall cohort (N=310), as well as by subgroups and combined strata.

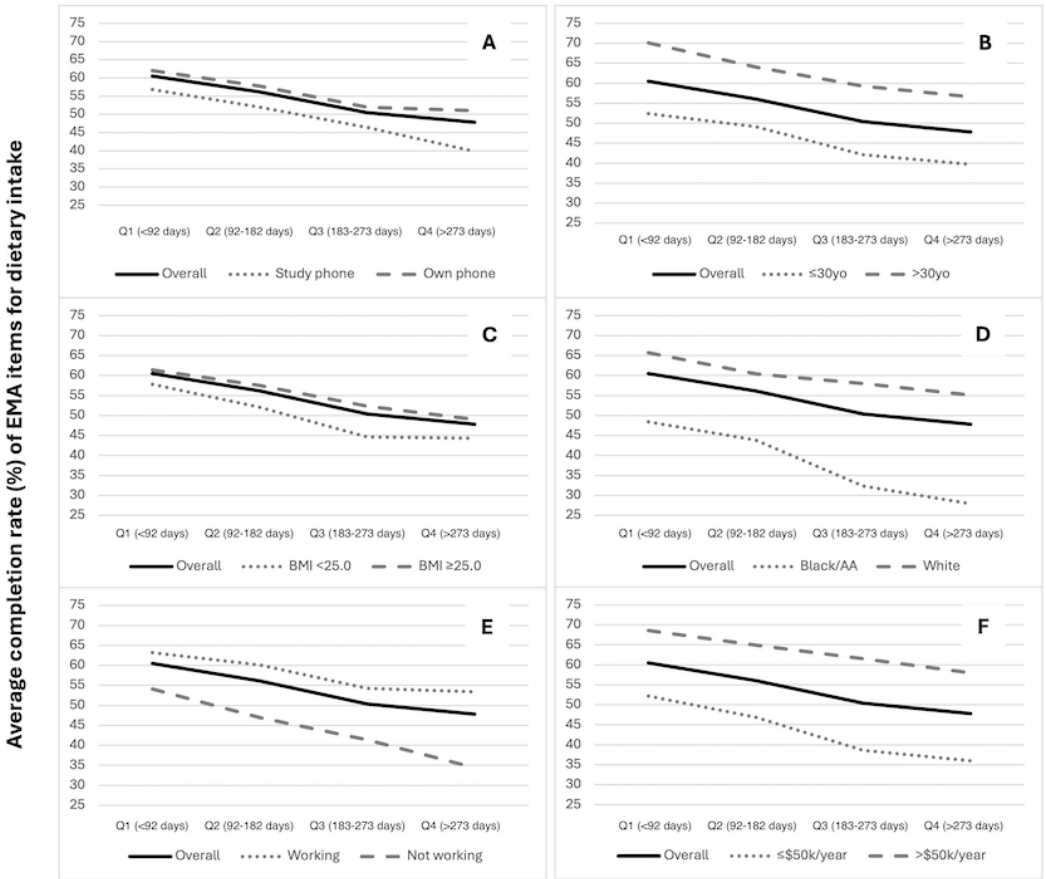
XSL•FO
RenderX



Overall, participants had higher average completion rates for dietary intake items during the postpartum period (59.1%, SD 22.0%) compared to the pregnancy period (52.4%, SD 27.8%). Looking at subgroup strata, participants using a study phone had lower completion rates on average (46.7%, SD 29.2%) compared to those using their own phone (54.7%, SD 26.9%) during pregnancy, but this difference was nearly eliminated after giving birth (59.2%, SD 20.7% vs 59.0%, SD 22.5%, respectively). Across both pregnancy and postpartum periods, participants who had an overweight BMI before pregnancy (>24.9), were older (>30 years), self-identified as White, were working, or earned a higher income (>US $50,000 annually) had higher average completion rates of dietary intake items.

We also examined completion rates within combined strata, which consisted of race (Black or White) and another variable (eg, phone use), to have a better understanding of variation in responding to EMA surveys within racial groups (Table 2). We observed increased average completion rates from pregnancy to post partum across all strata of Black participants, with the largest increases found for those not working at the time of study enrollment (61%), those with a healthy prepregnancy BMI (48%), and those 30 years old or younger (47%). Black participants using the study phone had considerably higher completion rates on average compared to those using their own phone in both the pregnancy and postpartum periods. During pregnancy, Black participants who were not working at the time of study enrollment (eg, unemployed, on disability) had lower average completion rates (35.2%) compared to those who were working (39.3%), but this was reversed in the postpartum period (56.8% vs 46.9%, respectively).

Similarly, we observed increased average completion rates from pregnancy to post partum across all strata of White participants, although with considerably less variation between time periods. The largest increases were found for White participants earning more than US $50,000 annually (31%) and those who were not working at the time of study enrollment (20%).

Lastly, given the length of the postpartum period (12 mo), we reported completion rates for each postpartum quarter (approximately 3 mo or 91 d) in the overall sample and across subgroup strata (Figure 1). With very few exceptions, completion rates generally decreased over time during the postpartum period, with the lowest rates for all subgroups in the fourth quarter (>273 d after giving birth). We saw similar declining trends in average completion rates for the same combined strata across postpartum quarters (Table S1, Multimedia Appendix 1).

Figure 1. Line graphs depicting average completion rates (%) of EMA items for dietary intake across four postpartum quarters (~91 d) for overall sample, compared against individual characteristics: study phone usage (A); age at study enrollment (B); prepregnancy BMI (C); self-reported race (D); employment status at study enrollment (E); and annual household income (F). AA: African American; EMA: ecological momentary assessment.

Discussion

Principal Findings

Our secondary study is innovative in its examination of overall completion rates for EMA surveys of dietary behavior in a longitudinal, childbearing cohort (~15 mo, from late pregnancy to 1 y post partum), as well as across individual characteristics. Overall, the analytic sample (N=310) had average completion rates of 52.4% during pregnancy (approximately 3 mo) and 59.1% during the first postpartum year (12 mo). This relationship generally held true across subgroups, with average completion rates increasing during the postpartum period, compared to the pregnancy period.

The average completion rates examined here are lower than ideal for EMA research, where at least 80% is often cited as the minimum threshold for "adequate" levels of compliance [40]. Most dietary behavior studies using EMA report adherence rates close to this level or higher [19]. Even so, very few of these studies employed EMA for more than a month, with many of them having study durations of just 1 week [19,41,42]. In our secondary analysis, we observed average completion rates over periods of about 3 months, potentially obscuring higher adherence during shorter intervals. Furthermore, the compensation structure for PMOMS participants was based on monthly rates of EMA adherence, rather than individual survey completion, which may have influenced participant responses.

Our findings partially contradict previous research that demonstrates reduced adherence to EMA protocols over time [19,20,43]. We observed an increase in average completion rates from pregnancy to post partum for all strata examined, potentially attributable to added availability for responding to EMA prompts (ie, maternity leave), reduced stress related to pregnancy symptoms, or increased interest in the study's objectives regarding postpartum health.

Even so, during the postpartum period, we observed a gradual decline in survey completion across the cohort (Table S1, Multimedia Appendix 1), in agreement with previous literature. We interpret these reductions to survey burden, as well as changing parental obligations, which may impact some populations more than others. In the last postpartum quarter (>273 d after giving birth), our overall cohort had an average completion rate of 47.8%. It is also important to highlight previous evidence demonstrating increased EMA adherence in the morning [20,43,44], whereas the dietary intake items being examined here appeared on the EOD survey.

We observed considerable disparities between subgroups in average completion rates, some of which provide insights into how racial and socioeconomic privilege may impact participation in research applying EMA. Participants who were >30 years old, self-identified as White, and earned >US $50,000 annually had higher completion rates than their counterparts across both prenatal and postpartum periods. Although research examining demographic differences in EMA adherence is limited, a 9-week smoking cessation study found greater declines in adherence for participants who were younger, working full-time, and not White [44]. These differences in EMA completion rates may be attributable to the socioeconomic advantages associated with privileged groups, such as increased access to resources (eg, employment, childcare) and reduced exposure to stressors (eg, food insecurity, housing instability). Chronic exposure to stressors, particularly related to caregiving, may exacerbate EMA burden for participants, even from one day to the next [42].

During the first postpartum year, average completion rates increased by 38%, 35%, 32%, and 24% for participants who self-identified as Black, reported not working (upon study enrollment), had lower income (≤US $50,000 annually), and were 30 years old or younger, respectively. These increases were more considerable than those observed among the privileged subgroups, which ranged from 0.5% to 7%. Beyond the experience of survey burden for participants, these findings suggest that the prenatal period carries additional burdens for childbearing people from racially and socioeconomically oppressed groups, potentially inhibiting their participation in research.

Examining combined strata here provided additional insights that would not have been afforded to us if we had ceased the analysis at single-identity categories. Black participants using the study phone had average completion rates approximately 20% higher than those using their own phone, across the study period, contrasting with results from both the overall study cohort and strata of White participants. We consider this a novel finding in EMA research, where study designs typically leverage the use of the participant's current mobile device, potentially excluding those who lack compatible devices or access to quality phone or internet service [41].

Strengths and Limitations

While this study offers novel, scientific insights into demographic and socioeconomic factors associated with completion of EMA surveys regarding food intake in a longitudinal, childbearing cohort, it is not without its limitations. First, PMOMS is an ancillary study to a randomized clinical trial, which had specific exclusionary criteria (eg, history of diabetes diagnosis) that may have ultimately biased EMA survey responses within the cohort. Second, examining combined strata (eg, race and income) resulted in some small samples, making our study underpowered to conduct comparative analyses or report statistical significance. For this reason, we decided to provide descriptive results only. Future investigations of variation in EMA participation across sociodemographic factors would benefit from a larger, representative sample to apply comparative methods (ie, linear regression). Next, we conducted our assessment of employment status upon study enrollment (during late pregnancy). We asked about employment status in an exit survey within an administrative supplement of the study, meaning only a subset of the population had employment information at the conclusion of the study. Lastly, we would also like to qualify that our study findings do not include information about any technical issues (eg, device malfunction, survey delivery failure), which would likely impact participants' EMA completion. Although the PMOMS team documented these issues throughout the study period to assist participants

XSL•FO
RenderX

and troubleshoot, these data were not prepared to be included in these analyses.

Public Health Implications

The findings presented here are novel and valuable to perinatal health research, particularly that which applies EMA or telehealth technologies to collect data in diverse, representative cohorts for longer periods (eg, several weeks, months). Although PMOMS is considerably longer than most EMA studies, here we demonstrated relatively stable engagement (average completion rate of 59%) in a childbearing population over the course of 15 months. Given evidence linking contextual factors (eg, stress) to parental behavior, including dietary behaviors [41], EMA may serve as a better methodological tool in maternal health research compared to more burdensome dietary recalls.

Our descriptive analysis of EMA completion rates in a childbearing cohort has important implications for future research and intervention designs. PMOMS remains unique in its application of EMA over more than 12 months, though there is room for improving completion rates in longer EMA studies. Immediately actionable strategies include reducing the number of EMA surveys per day or week and increasing opportunities for compensation among participants. Another approach would be increasing participant engagement through an online dashboard where they can see their own response data, as well as aggregate data for the entire cohort.

We recommend that investigators consider the intersections between race and other factors (eg, employment) in relation to study participation and develop strategies to improve EMA completion (eg, study-provided smartphone) among participants who are likely to face more socioeconomic burdens.

Acknowledgments

The authors thank the study participants who generously gave their time and effort. The authors would also like to thank Terri Washington, study coordinator; Maura Dugan, Marquita Smalls, and Gabriella Mendez for study recruitment and follow-up; Er Wang, Pedram Gharani, Meirman Syzdykbayev, and Bradley Wheeler, and Dr Hassan Karimi for technology and app development and support; and John Gianakas for database development and management. Finally, the authors thank all the staff and investigators of the Comparison of Two Screening Strategies for Gestational Diabetes trial.

Abstract

Background: Patients with inflammatory rheumatic diseases often experience drug-related problems (DRPs). As these can result in negative health consequences, DRPs should be identified and addressed in a timely manner. Text messaging between patients and pharmacists at the initiative of the patient has the potential to deliver support with DRPs more continuously, increase accessibility and efficiency, and enhance patient involvement in the process of identifying and solving DRPs.

Objective: This study aimed to assess the feasibility of text messaging from both the patients' and health care practitioners' perspectives before a large-scale implementation.

Methods: Adult patients using a disease-modifying antirheumatic drug were given access to text messaging with pharmacists to discuss DRPs for a period of 8 weeks. Patients received a response from a pharmacist within 4 working hours. Feasibility was evaluated based on five domains of Bowen's framework for designing feasibility studies: (1) demand: actual use, expressed interest (user version of the Mobile Application Rating Scale – section E), and factors impacting future use; (2) limited efficacy: number of DRPs solved, DRPs resulting in follow-up, and DRPs warranting involvement of health care provider; (3) implementation: degree of execution (number of conversations answered within service level) and resources needed (pharmacists' time investment per conversation); (4) acceptability: satisfaction and appropriateness (theoretical framework of acceptability); and (5) practicality: ability to carry out intervention activities (System Usability Scale). Data were collected by means of usage data and a questionnaire.

Results: In total, 45 patients (median age 57, IQR 52-65 y; n=31, 69% female) and 5 pharmacists (median age 41, IQR 26-47 y; n=1, 20% female) actively participated in this study. In the demand domain, 158 unique DRPs were raised in 133 conversations, with a median of 3 (IQR 2-4) unique DRPs per patient. Expressed interest was rated high by patients (median 4, IQR 4-5), and 90% (37/41) of patients would recommend text messaging to others. In the limited-efficacy domain, all DRPs were solved, and 77% (122/158) of DRPs warranted involvement of a health care provider. In the implementation domain, 87% (116/133) of conversations were answered within the promised timeframe with a median time investment of 4:15 (IQR 2:21-7:27) minutes per conversation. Acceptability was rated high by patients (median 4, IQR 4-5) and pharmacists (median 5, IQR 4-5). Finally, in the practicality domain, System Usability Scale was scored above average for patients (mean 72, SD 18) and pharmacists (mean 81, SD 16).

Conclusion: Text messaging with pharmacists at the initiative of patients with rheumatic diseases seems feasible for discussing DRPs in terms of limited efficacy, implementation, acceptability, demand, and practicality for patients and pharmacists.

Introduction

Pharmacotherapy is the cornerstone of the treatment of many inflammatory rheumatic diseases, which involves patients often using multiple drugs chronically. Disease-modifying antirheumatic drugs (DMARDs) are effective in decreasing disease activity and disability in patients with inflammatory rheumatic diseases and can even decrease or prevent joint damage [1]. For optimal treatment outcomes and patient safety, it is essential that DMARDs are used as agreed upon between a patient and health care provider, also called adherence [2]. However, nonadherence is common in this population [3], which is partly caused by drug-related problems (DRPs) experienced by patients with rheumatic diseases [4]. These DRPs encompass side effects, difficulties with medication management (eg, problems regarding opening medication packaging, administering and storing medication, or traveling with medication), a lack of knowledge, or concerns about lack of effect and unwanted effects of long-term medication use, among others. DRPs can potentially lead to negative health consequences, such as increased morbidity, which in turn can result in increased health care costs and decreased quality of life [5,6]. Thus, DRPs should be identified and resolved as soon as possible (ie, at the earliest stage of DRP development possible) to be able to prevent or minimize these negative consequences. However, during regular health care provider consultations, patients either do not always report all DRPs or health care providers do not act upon DRPs reported by patients [7]. In addition, patient-provider consultations occur only a few times a year, while DRPs can occur continuously, often in between these contact moments. Ideally, for adequate management of DRPs, patients should be able to contact their health care provider as soon as a DRP occurs, and health care providers should be able to react in a timely manner. To this end, one could argue that more continuous accessible contact between patients and health care providers is needed.

eHealth, which entails information and communication technology in health care that can benefit both patients and health care providers, could facilitate such contact by, for example, making health care more efficient and more easily accessible because of its time- and place-independent possibilities [8,9]. In addition, eHealth can increase patient involvement in the process of identifying and solving DRPs, for example, by lowering the threshold for patients to contact health care providers. Previous research has shown that patient involvement is important in identifying and solving clinically relevant DRPs [10,11], underlining the key role of patients in this process.

One such eHealth instrument is text messaging with a pharmacist regarding DRPs. Text messaging has the potential to enable patients to discuss DRPs in a timely manner with a health care provider, as it can provide faster contact between patients and health care providers without waiting or travel time. In addition, text messaging can be an addition to the already available communication channels, such as contact via telephone. Research demonstrated that offering multiple communication channels is important in providing patients with a suitable channel for discussing individual DRPs [12]. Finally, text messaging seems more efficient compared with phone calls, as shown by diabetes self-management support via text messaging requiring less staff time than via phone [13]. Furthermore, text messaging has been shown to be effective and feasible as an intervention to manage, for instance, blood pressure [14], adherence in type 2 diabetes [15], and postoperative pain [16]. However, these studies evaluated text messaging only as a channel for communication at the initiative of the health care provider to instruct patients (eg, by sending reminders regarding adherence) and provide health-related information to patients, and in most cases, only encompassed one-way texting from health care provider to patient (ie, patients could not respond to text messages).

As patients fulfill a key role in timely identifying potentially clinically relevant DRPs, this study opts for text messaging at the initiative of the patient, in which patients can contact their pharmacist when DRPs arise to facilitate timely resolution. This potentially provides a personalized and quick channel to raise, discuss, and resolve DRPs effectively. As patient-initiated text messaging with a pharmacist to address and resolve DRPs has not been evaluated, it is important to first study the feasibility of this functionality from the perspectives of both patients and pharmacists before its effect on reducing DRPs can be studied and large-scale implementation can be considered. Therefore, this study aims to assess the feasibility of text messaging between patients with inflammatory rheumatic diseases and pharmacists at the initiative of the patient when experiencing DRPs.

Methods

Study Design

A prospective feasibility study was conducted at the outpatient pharmacy of the Sint Maartenskliniek in the Netherlands between August 2023 and February 2024.

Ethical Considerations

The Medical Research Ethics Committee of Arnhem-Nijmegen, the Netherlands, reviewed this study and waived official ethical approval (case 2023 - 16580) as this study was deemed not subject to the Medical Research Involving Human Subjects Act. All participants gave informed consent digitally before commencement of the study (Multimedia Appendix 1). All participant data were anonymized to protect participant privacy and were stored on a secure environment only accessible to the researchers. Participants did not receive compensation for participation.

Participants

Adult patients (≥18 y) with an inflammatory rheumatic disease receiving at least 1 DMARD from the outpatient pharmacy were eligible for inclusion. In addition, pharmacists covering pharmacy day shifts during the study period were eligible for participation. Pharmacists conducted study activities as part of their daily routine and gave consent verbally.

As the number and types of DRPs are likely dependent on the type of DMARDs patients use, as well as on the duration of their treatment [17], purposive sampling was performed using

XSL•FO
RenderX

the following criteria: (1) biological disease-modifying antirheumatic drugs (bDMARDs), conventional synthetic DMARDS or targeted synthetic DMARDS; (2) patients initiating a new DMARD (new users) or patients using a specific DMARD for at least 6 months before inclusion (existing users). Although previous studies regarding sample sizes in feasibility studies advise sample sizes ranging from 12 to 35 participants per group [18,19], we aimed to include 60 participants (30 new and 30 existing users) distributed evenly among the 3 groups of DMARDs.

New users were selected from the pharmacy information system and were defined as patients who got their DMARD dispensed for the first time in the 2 weeks before inclusion. For bDMARDs, only bDMARD-naïve patients (ie, patients starting their first bDMARD ever) were eligible for participation, as switching between bDMARDs is common and DRPs reported by patients usually differ minimally between bDMARDs.

Existing users were selected from all patients who received a DMARD from the outpatient pharmacy in the last 3 months before the study started and those who had been using that specific DMARD for at least 6 months before the study started. A random sample was then taken from which patients were purposively approached for inclusion.

Inclusion was performed by telephone. During this phone call, patients received a verbal explanation of the study content. Patients willing to participate received written study information and a digital informed consent form. Participation started after informed consent was given.

Intervention

The intervention used in this study was text messaging with a pharmacist at the initiative of the patient. This enables patients to report DRPs directly to a pharmacist. Participants were able to access the text messaging functionality by securely logging in to the hospital's patient portal either via the hospital's website or a smartphone app before each use. Participants were asked to discuss questions or problems regarding their antirheumatic drugs with a pharmacist using text messaging for a period of 8 weeks and received reminders at the start of the study and every 2 weeks thereafter, to ensure exposure to the intervention. There was no restriction on the number of conversations participants were allowed to initiate. The service level (ie, the aimed maximum time between patients reporting a DRP and pharmacists responding) was set at 4 hours from the moment the question was asked, within working hours and days (Monday to Friday between 9 AM and 5 PM).

Feasibility Evaluation: Outcome Measures

Overview

Feasibility was assessed using the framework for designing feasibility studies by Bowen et al [20]. This widely applied model describes feasibility in 8 areas of focus. For this study, five of these eight domains were assessed: (1) demand, (2) limited-efficacy testing, (3) implementation, (4) acceptability, and (5) practicality. Furthermore, 3 domains (adaptation, integration, and expansion) were not included in this study as these focus on implementation and scale-up of the intervention, which was not yet relevant for the intervention under investigation. The domains of the framework by Bowen et al [20] were assessed using the outcomes of interest and outcome measures that are presented in Table 1.

Q: Positive and negative properties regarding ease of use of text messaging	Pt and Ph

[a]Outcome measures part of the questionnaire were answered by patients, pharmacists, or both.

[b]Outcome measures with prefix 'D' were collected by means of usage data.

XSL•FO
RenderX

[c]Not applicable.

[d]DRP: drug-related problem.

[e]Outcome measures with prefix 'Q' were collected by means of questionnaire data.

[f]Pt: patients.

[g]Ph: pharmacists.

[h]HCP: health care provider.

Demand

To measure demand for the intervention, the actual use of the intervention in terms of conversations and DRPs was assessed. In addition, the extent to which the intervention was likely to be used was assessed by determining participants' expressed interest in using the intervention, as well as factors impacting future use.

Limited-Efficacy Testing

To measure the efficacy of the intervention, the effect of the intervention on relevant key variables was measured. This was by measuring the extent to which discussed DRPs could be solved, the number of DRPs that needed follow-up from a health care provider other than a pharmacist, and the number of DRPs warranting health care provider involvement (ie, did an individual DRP need to be discussed with a pharmacist, or could this be solved by, for example, a frequently asked questions [FAQ] page).

Implementation

To measure implementation, the degree of execution was assessed by determining protocol fidelity, defined as the extent to which pharmacists responded to conversations within the service level. In addition, the resources needed to execute the intervention were assessed by calculating pharmacists' time investment per conversation.

Acceptability

To measure the acceptability of the intervention, satisfaction and appropriateness of text messaging with a pharmacist were assessed as part of the questionnaire sent to participants. In addition, participants' intention to (continue) using the intervention, satisfaction, preferred service level, preferred way patients wish to be addressed, preferred alternative if text messaging was not available, and added value of the text messaging to current care were assessed.

Practicality

To measure practicality, participants' ability to carry out intervention activities (ie, using the intervention) was assessed. For patients, this meant using text messaging to initiate conversations with pharmacists, and for pharmacists, this meant answering conversations initiated by patients.

Measurement Instruments

Study Sample

The patient characteristics that were retrieved from the electronic health record were age, sex, diagnosis, disease duration, number of drugs prescribed by a rheumatologist, and type of DMARDs at the start of the study.

Demand

Actual use was measured from usage data by counting the number of interactions initiated by the participants, the number of DRPs raised (as multiple DRPs can be raised in a single conversation), and the types of DRPs. To this end, individual DRPs were categorized according to the DRP classification as used by Haegens et al [4]. One researcher categorized DRPs (LH), which were reviewed by a second researcher (VH), after which discrepancies were discussed until consensus was reached. In case patients had not responded to the question of whether a DRP had been answered satisfactorily, one researcher (LH) determined if the DRP was resolved, after which a second researcher (VH) reviewed these cases, and discrepancies were discussed until consensus was reached. Expressed interest was assessed by incorporating the questions of the validated User version of the Mobile App Rating Scale [21] (uMARS) section E regarding subjective app quality into the questionnaire sent to the participants, consisting of 4 questions answered on 5-point Likert scales (Multimedia Appendix 2), which are reported individually. Other sections of the uMARS were not incorporated in this questionnaire, as they aim to assess factors other than demand for the intervention or other domains that are not of interest in this study. In addition, participants were asked about factors that positively or negatively impacted their future use of text messaging and how future use of text messaging can be ensured.

Limited-Efficacy Testing

DRPs were regarded as solved either when participants answered a confirmatory question at the end of every conversation positively or, in the case participants did not answer this question. In total, 2 researchers (LLH and VJBH) determined if DRPs were solved separately, after which discrepancies were discussed until consensus was reached. The number of DRPs that involved follow-up with a health care provider other than the pharmacist, or contained advice to do so, was counted from usage data. For each DRP, it was determined if raised DRPs warranted health care provider involvement by 2 researchers (LLH and VJBH), determining if individual DRPs needed to be discussed with a pharmacist or could be solved by, for example, an FAQ page independently, after which discrepancies were discussed until consensus was reached.

Implementation

Degree of execution was assessed by determining if pharmacists responded to individual conversations within the predefined service level of 4 hours, as well as pharmacists' average response time. To measure this, only working hours (ie, time between 9 AM and 5 PM on Monday to Friday) were counted, and hours outside working hours were not. Pharmacists' time investment per conversation (ie, including time for researching answers and contacting other health care providers) was

XSL•FO
RenderX

registered by the pharmacist responding to conversations using a stopwatch.

Acceptability

Acceptability was measured using the questionnaire from the theoretical framework of acceptability [22], which consists of questions targeting 8 acceptability constructs answered on 5-point Likert scales (Multimedia Appendix 2) and are reported individually. In addition, open-ended questions regarding the intention to (continue) using the intervention, participants' satisfaction, the preferred service level (ie, within what timeframe do patients expect to receive an answer from a pharmacist), patients' preferred form of address, what alternatives patients would use instead of text messaging, and the added value of the text messaging to current care were constructed based on the framework by Bowen et al [20] and its description of the acceptability domain. All questions regarding acceptability were constructed by one researcher (LH) and discussed among coauthors (LH, BB, and VH) until consensus was reached.

Practicality

Participants' ability to carry out intervention activities was assessed by using the validated Dutch translation of the System Usability Scale (SUS) [23], which is a 10-item questionnaire scored on a 5-point Likert scale from "strongly disagree" to "strongly agree" (Multimedia Appendix 2) that results in a score between 0 and 100. These questions were supplemented with open-ended questions regarding the main benefits and disadvantages of text messaging with a pharmacist, the main positive and negative properties regarding the ease of use of text messaging, and the fit of text messaging with current care.

Data Collection

Data on the feasibility of the intervention were collected either via a web-based questionnaire sent to all participants (both patients and pharmacists) or from usage data from the text messaging app. Furthermore, 2 separate questionnaires were constructed for participating patients and pharmacists. These questionnaires consisted of the same domains and predominantly differed in wording (eg, asking questions vs answering questions). Some questions, however, were not included in the questionnaire for pharmacists due to nonrelevance (Multimedia Appendix 2). Participants received a notification from an electronic data capture system via email with the invitation to complete the questionnaire and were reminded after 1 week if needed. Usage data were collected from the system that the text messaging is part of, by extracting relevant data regarding individual conversations into a separate database.

Data Analysis

Participating patients were regarded as "active participants" if at least 1 conversation was initiated via text messaging and were otherwise regarded as "nonactive participants" and thus excluded from the analyses. Usage data and data from questionnaires were descriptively analyzed using STATA 17 (StataCorp LLC) [24]. Proportions were presented as percentages. Parametric data were presented as means with SDs; nonparametric data were presented as medians with IQRs. Questionnaires with standardized analysis were scored and reported accordingly.

Results

Population Characteristics

Of the 108 patients that approached for participation, 56% (n=60) of patients were included and signed informed consent with a median age of 58 (IQR 53-65) years, and 70% (n=42) were female (Table 2). The most frequent reasons reported by patients for not participating were not interested (n=13) or too busy (n=8). Of the 60 included patients, 75% (n=45) of patients (median age 57, IQR 52-65 y; and n=31, 69% female) raised at least 1 DRP via text messaging (hereinafter referred to as active participants) and received the questionnaire. Reasons for not actively participating were that participants forgot to ask questions or were unable to ask questions due to personal reasons. Of the active participants, 87% (n=39) completed the questionnaire fully (hereinafter referred to as responders), 4% (n=2) of active participants completed the questionnaire partly, of whom only the fully completed domains are reported. Furthermore, 5 pharmacists (median age 41, IQR 26-47 y; and n=1, 20% female) participated in this study by responding to the text messages.

XSL•FO
RenderX

Table . Population characteristics.

Characteristic	Active participants[a] (n=45)	Nonactive participants[b] (n=15)
Sex, n (%)		
Female	31 (70)	10 (64)
Age (y), median (IQR)	57 (52 - 65)	61 (54 - 65)
Diagnosis, n (%)		
Rheumatoid arthritis	24 (53)	11 (73)
Psoriatic arthritis	10 (22)	1 (7)
Axial spondyloarthritis	6 (13)	1 (7)
Other	5 (11)	1 (7)
Disease duration (y), median (IQR)	6 (2-10)	9 (2-15)
Drugs prescribed by rheumatologist, median (IQR)	3 (4-5)	3 (5-6)
DMARD[c] group of inclusion, n (%)

New user	23 (51)	7 (47)
Experienced user	22 (49)	8 (53)

[a]Active participants are defined as included patients that discussed at least one drug-related problem during the study using text messaging.

[b]Nonactive participants are defined as included patients that did not raise a drug-related problem during the study.

[c]DMARD: disease-modifying antirheumatic drug.

[d]csDMARD: conventional synthetic disease-modifying antirheumatic drug.

[e]tsDMARD: targeted synthetic disease-modifying antirheumatic drug.

[f]bDMARD: biological disease-modifying antirheumatic drug.

Demand

During the study, 45 participants initiated 133 conversations via text messaging containing 158 unique DRPs (ie, DRPs that had not been raised before by individual participants), with a median of 3 (IQR 2-4) unique DRPs per participant. DRPs reported concerned information needs (n=42, 27%), (suspected) side effects (n=36, 23%), problems regarding medication management (n=34, 22%), logistics (n=14, 9%), medication concerns (n=13, 8%), medication effectiveness (n=9, 6%), contraindications (n=5, 3%), and others (n=5, 3%).

In total, 41 patients (91%) and 5 pharmacists (100%) completed the questions regarding demand. Demand was measured as the expressed interest or intention to use text messaging (uMARS section E). Both patients and pharmacists scored text messaging overall with a median of 4 (IQR 4-5) out of 5 stars. Out of 41 patients, 37 (90%) patients would recommend text messaging to others who could benefit from this service, and all 5 pharmacists would recommend text messaging to others. Furthermore, 63% (26/41) of patients would use text messaging at least once a year, and 32% (13/41) would consider paying for text messaging.

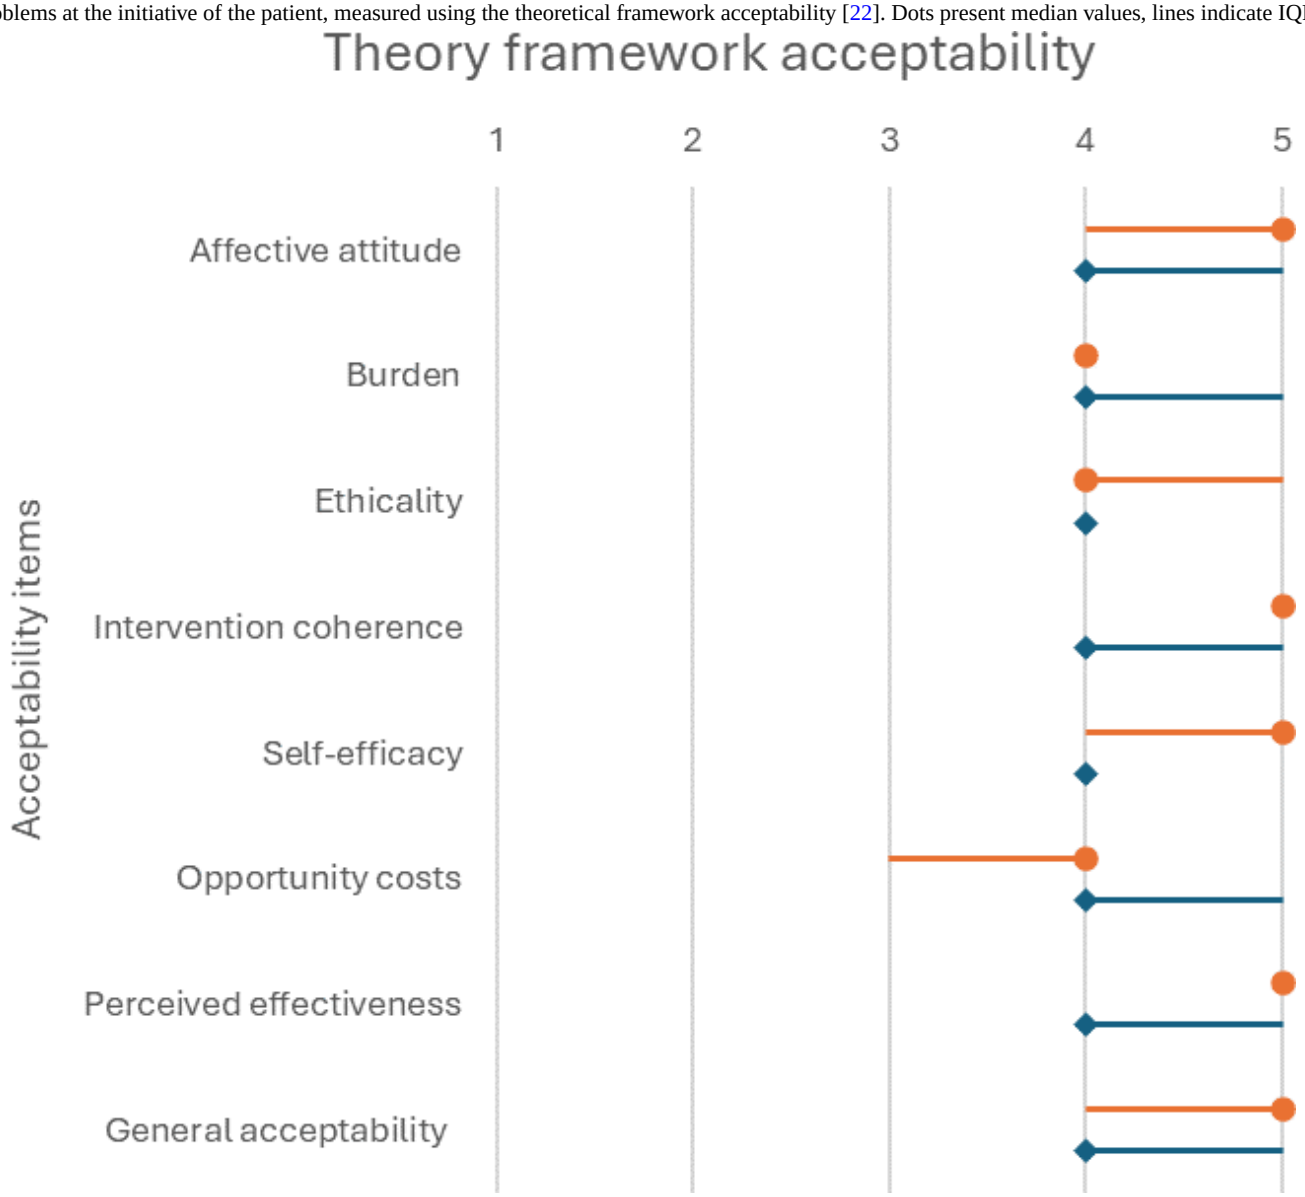
To ensure future use, 39% (16/41) of patients mentioned promotion of text messaging as a means to discuss DRPs, 20% (8/41) providing good instructions regarding and support with text messaging, and 17% (7/41) reducing the number of steps to navigate to the text messaging within the online patient portal as improvements. Furthermore, 34% (14/41) of patients mentioned quick answers, 27% (11/41) mentioned text messaging being easy to use, and 15% (6/41) receiving clear answers to questions as factors that would positively impact future use. Factors negatively impacting future use included text messaging being impractical (2/41, 5%) and impersonal (2/41, 5%).

Limited-Efficacy Testing

Of the 158 unique DRPs raised by patients, 58% (n=92) were solved according to patient confirmation, and the remaining 42% were solved according to pharmacist determination. In total, 5 reported DRPs were followed up in consultation with other health care providers: 3 with a rheumatologist, 1 with a specialized rheumatology nurse, and 1 with a pharmacy technician. In addition, 17 DRPs resulted in pharmacists advising follow-ups, mainly with the patient's rheumatologist (n=12). It was determined that 77% (122/158) of DRPs required a health care provider, and 23% (36/158) could have been solved

XSL•FO
RenderX

without health care provider involvement. Within DRPs that required health care provider involvement, the most common types of DRPs were suspected side effects (32/122, 26%), medication management (30/122, 25%), and information needs (16/122, 13%). DRPs that did not require health care provider involvement consisted of information needs (26/36, 72%), suspected side effects (4/36, 11%), and medication management (4/36, 11%). All types of DRPs were determined to require health care provider involvement for the majority of DRPs within their type (ranging from 30/34, 88% to N=13, 100%), except for DRPs regarding information needs, for which 2 out of 3 DRPs did not require health care provider involvement.



Implementation

Of the 133 conversations initiated by patients, 116 (87%) conversations were answered within the predefined service level of 4 hours. The median time until response was 80 (IQR 34-153) minutes with a total range of 0 minutes to 39.2 hours within opening hours of the pharmacy. The pharmacists' median time investment per conversation was 4:21 (IQR 2:15-7:41) minutes for DRPs that required health care provider involvement and 3:32 (IQR 2:39-6:41) minutes for DRPs that did not require health care provider involvement, which did not differ significantly (P=.10).

Acceptability

From the 45 active participants, 39 patients (87%) and all 5 pharmacists completed the questions regarding acceptability. Patients scored acceptability of the intervention with a median score of 4 (IQR 4-5) out of 5, and pharmacists with a median of 5 (IQR 4-5) (Figure 1).

Figure 1. Patients' (orange) and pharmacists' (blue) acceptability scores for text messaging between patients and pharmacists to discuss drug-related problems at the initiative of the patient, measured using the theoretical framework acceptability [22]. Dots present median values, lines indicate IQRs.

The top 3 most-mentioned advantages and disadvantages regarding the acceptability of text messaging mentioned by participating patients and pharmacists, as well as types of DRPs that are acceptable and not acceptable to discuss via text messaging, are presented in Table 3.

XSL•FO

Table . Top 3 (where available) most-mentioned responses regarding advantages and disadvantages of text messaging, as well as types of DRPs acceptable and not acceptable for discussing via text messaging.

Questionnaire item, respondent, and response	Value, n (%)
Advantages regarding acceptability of text messaging	
Patients (n=39)	
Quick answers	21 (54)
Clear answers	9 (17)
No waiting times	7 (13)
Pharmacists (n=5)	
Accessibility of contact between patient and pharmacist	4 (80)
Sufficient time to formulate answer	3 (60)
Disadvantages regarding acceptability of text messaging	
Patients (n=39)	
Difficulties with logging in	4 (10)
Too many steps to reach text messaging	2 (5)
Less personal than contact via telephone	1 (3)
Pharmacists (n=5)	
Answering messages not yet embedded in daily routine	2 (40)
Contact becoming too accessible might lead to unnecessary contact	1 (20)
Questions need to be carefully answered, as these are in writing	1 (20)
Types of DRPs acceptable for discussing via text messaging	
Patients (n=39)	
Side effects	9 (23)
Everything regarding medication	4 (10)
Medication intake	3 (8)
Pharmacists (n=5)	
Factual questions regarding information	3 (60)
(Mild) side effects	2 (40)
Practical problems such as medication intake	2 (40)
Types of DRPs not acceptable for discussing via text messaging	
Patients (n=39)	
Questions for treating physician	1 (3)
Questions in need of in-person answer	1 (3)
Pharmacists (n=5)	
Insufficient medication effect	1 (20)
Allergies	1 (20)
Acute side effects	1 (20)
Emotionally-loaded questions	1 (20)

In total, 37 out of 45 patients (82%) and all pharmacists (N=5, 100%) completed the additional service-related questions. Regarding the preferred service level (ie, within what timeframe do patients prefer to receive a response to their text message), the majority of patients preferred a response within 4 (17/37, 46%) or 24 hours (12/37, 32%), with 2 patients (5%) indicating that the service level is dependent on individual DRPs. Pharmacists preferred a service level of 24 hours (2/5, 40%), 8 hours (1/5, 20%), or 4 hours (1/5, 20%), with 2 pharmacists (40%) suggesting letting the patient indicate the service level per DRP. Patients preferred to be addressed informally (15/37, 41%), formally (6/37, 16%), or did not have a preference (14/37, 38%). The majority of patients (24/37, 65%) would have called the pharmacy if text messaging were not available, and 11%

XSL•FO
RenderX

(4/37) indicated having contacted their health care provider but did not specify in which way. Another 11% (4/37) of patients indicated they would wait until the next consultation to discuss their DRP, and another 5% (2/37) would not discuss their DRP at all. Patients scored the extent to which text messaging fits into current care with a median of 4 (IQR 4-5), whereas pharmacists scored fit with a median of 4 (IQR 3-4). Pharmacists mentioned the inability to redirect questions to other health care providers and the fact that text messaging is not well-integrated into the existing information technology systems currently in use as disadvantages. In general, the added value of text messaging according to patients included quick answer to questions (7/37, 19%), having an additional way to ask questions (3/37, 8%), easy accessibility of contacting a pharmacist (2/37, 5%), and having an additional option for support when starting with new medication (2/37, 5%).

Practicality

Out of 45 patients, 39 (87%) and all 5 pharmacists (100%) completed the questions regarding practicality. The mean SUS score was 72 (SD 18) among patients, with 22 participants (57%) rating usability as good, excellent, or best imaginable. Mean SUS score was 81 (SD 16) among pharmacists, with 4 pharmacists (80%) rating usability as good, excellent, or best imaginable. The most-mentioned responses to the additional open-ended questions regarding practicality can be found in Table 4.

Table . Most-mentioned responses to additional open-ended questions regarding practicality.

Questionnaire item, respondent, and response	Value, n (%)
Properties positively influencing ease of use of text messaging	
Patients (n=39)	
Quick answer	14 (36)
Time- and place-independent	7 (18)
Easy to use	5 (13)
No waiting time	5 (13)

Image size too small on mobile	3 (8)
Pharmacists (n=5)	
Absence of notifications of new messages	2 (40)
Less personal contact	1 (20)
Uncertainty as to whether DRP has been solved	1 (20)

Discussion

Principal Findings

In this study, the feasibility of text messaging at the initiative of the patient to discuss DRPs directly with pharmacists was examined. Text messaging between patient and pharmacist resulted in 158 unique DRPs in 133 conversations over an 8-week period. Pharmacists responded to all messages with advice to solve the problem or an answer to the question. All DRPs were solved, and most (116/133, 87%) were within the promised service level, and 14% (22/158) of DRPs resulted in follow-up or advised follow-up by health care providers other than pharmacists.

Both patients and pharmacists mentioned good accessibility of information and contact between patient and pharmacist as important factors for the acceptability of text messaging, which is also confirmed by other studies where accessibility was regarded as an important factor in communication between patient and pharmacist [25,26] as well as a driver for patients, preferring more accessible channels [12,27]. However, 1 pharmacist in our study noted that too easily accessible contact between patient and health care provider could lead to unnecessary contact (ie, contact regarding DRPs that do not warrant health care provider involvement) and thus an increased workload, which is a concern found in several other studies regarding the growing application of eHealth and its relation to health care providers' workload [28,29]. However, data on the

XSL•FO
RenderX

actual magnitude of this effect is lacking [30] and should thus be further researched.

In a study by Turcotte et al [25], patients mentioned the feeling of pharmacists being able to devote more time to answering their questions, which is in line with the pharmacists in our study mentioning having sufficient time to answer individual questions from patients when compared with current care. In a study by Zafar et al [26], patients were unsure about what type of questions were appropriate to ask via text messaging. Although patients in our study named several types of DRPs they find suitable to discuss, some differences exist between what patients and pharmacists view as appropriate DRPs to discuss via text messaging, with pharmacists making a distinction between the severity of side effects that patients do not make, which is important to align in managing patients' and pharmacists' expectations.

Although comparable studies did not employ the SUS, usability was rated "good" or "best imaginable" by the majority of patients and pharmacists, and both scored above the average SUS value of 68 [31]. Regarding the ease of using text messaging, which was in general mentioned as a positive factor driving acceptability, patients mentioned time- and place-independence and shorter waiting times of text messaging as positive properties. The SUS scores possibly find their origin in the comparability between the text messaging applied in this study with online and app-based consumer text messaging services. As some downsides regarding the practicality of the text messaging app used in this study were mentioned, it might be beneficial to organize and offer text messaging in a comparable manner to consumer apps to increase ease of use and thus acceptability, for example, by easing or removing the login procedure.

The top 3 most common types of patient-reported DRPs were information needs (42/158, 27%), (suspected) side effects (36/158, 23%), and medication management (34/158, 22%). These numbers are comparable with previous research regarding types of DRPs discussed with patients with inflammatory rheumatic diseases via 4 biweekly phone calls, in which (suspected) side effects accounted for 28% (85/308) and medication management for 26% (80/308) [4]. In our study, 27% (42/158) of DRPs were related to information needs, which is considerably higher than the 4% (13/308) of DRPs in the aforementioned study, which could be explained by the fact that DRPs in this study were patient-initiated, while the referred study assessed DRPs in health care provider–initiated conversations. In addition, the conceivability that patients regard information-related DRPs as more suitable to discuss via text messaging than via telephone might also have contributed to this. Although one might conclude that DRPs related to information needs could be solved by channels without health care provider involvement as this mainly pertains to information provision, 77% (122/158) of all DRPs were determined to warrant health care provider involvement, including 38% (16/42) of all DRPs related to information needs which mostly concerned needs for information regarding individual patient's treatment (eg, questions regarding safety of alternative medicine in combination with current therapy).

In practice, questions and DRPs can be answered and solved through various communication channels, such as during consultations, telephone calls, or with an FAQ page, for example. In this context, text messaging is a valuable addition to currently available channels, offering patients with a wide array of channels to discuss and resolve DRPs with high quality and efficiency, corresponding with patients' individual needs [12].

Implications

Patients in this study were generally positive regarding the feasibility of text messaging with pharmacists to discuss DRPs. The fact that 65% (24/37) of patients indicated that they would have raised their DRPs via telephone if text messaging had not been available implies that patients view text messaging as a suitable channel for raising DRPs in which health care provider involvement is warranted from the patient's perspective. In addition, 16% (6/37) of patients indicated that they would wait for the next consultation to raise a DRP if text messaging were not available, indicating DRPs possibly remain unraised and thus unsolved for a longer period of time. Although presumably part of these DRPs can wait until the next consultation, another part can lead to negative health consequences if not solved in a timely manner. Offering text messaging in addition to the currently available channels could lead to more DRPs raised, as well as in an earlier stage, which might therefore prevent negative health consequences associated with DRPs, as well as save time during consultations normally dedicated to such problems. Although all DRPs raised by patients were solved, either by patient confirmation or expert determination, the effect of this on patients' health outcomes was not assessed. Therefore, future research should aim to quantitatively assess the impact of the intervention on patients' clinical outcomes, such as medication adherence or improvement of health, as pharmacist interventions aimed at lowering DRPs seem to be able to improve clinical outcomes in other settings [32].

For health care providers, implementing text messaging can have several implications. First, the actual demand of text messaging in a large population will have an impact on its feasibility, as pharmacists must be able to incorporate the workload associated with text messaging into their daily routine. To this end, real-life demand needs to be further researched. As demand for text messaging is also related to the demand for other available channels, this should be researched in the context of all available channels rather than for text messaging alone. Second, although patients mentioned some advantages of text messaging over contacting a pharmacist via telephone, the extent to which text messaging can reduce the number of contacts via telephone or other channels and save time and resources is still unknown and should be researched in a trial with sufficient follow-up and a subsequent cost-benefit analysis. Third, although text messaging might initially increase pharmacists' workload, the potential of text messaging to save time and resources further down the chain (eg, by saving time during consultations) should be researched to determine the net decrease (or increase) in workload. Fourth, to avoid offering text messaging from leading to an additional workload, it is important to prevent (intentional or unintentional) inappropriate use of text messaging (ie, raising DRPs that could be solved

XSL•FO
RenderX

without health care provider involvement, for example, using an FAQ), which could be applicable for approximately 1 in 4 DRPs raised in this study that did not warrant health care provider involvement. Therefore, it is important to communicate to patients what DRPs are suitable to discuss via text messaging and what DRPs better suit different channels, or direct patients to the most suitable channel based on the subject of their DRP, for which DRPs warranting health care provider involvement in this study could be a first indication.

In terms of technological feasibility, several implications need to be considered to improve implementability and future uptake. Patients indicated that ease of use should be optimal for them to use text messaging most optimally. To this end, minor improvements should be made (eg, to the logging in procedure and the number of steps patients need to take) to be able to raise a DRP within the online patient portal. However, overall feasibility was scored as high, and 90% (37/41) of participants would recommend text messaging to others. Importantly, although pharmacists scored system usability above average and higher than patients, the fit with current care was scored lower than patients. Therefore, it is essential to look further into seamless integration of text messaging into the existing pharmacy systems and workflow, as well as ensuring seamless communication with other health care providers, to maximize its potential and ensure future use.

Limitations

Some limitations should be acknowledged. First, patients were reminded to ask a question at least once every 2 weeks to ensure user experience before completing the questionnaire. This could have led to DRPs being made up for study purposes, and thus we cannot conclude on the real-life demand that exists for text messaging from the patients' side in the researched population and setting. Second, 2 out of 5 pharmacists who answered patient messages were also involved in the conception of this study and as coauthors of this paper. This could have led to bias regarding outcome measures that included pharmacists' involvement, such as answering DRPs within the promised service level. However, as feasibility was researched in the context of current practice, the involvement of participating pharmacists in the conception of outcome measures was an added value, as they were able to include metrics that are needed for assessing feasibility and deciding future research and implementation. Third, selection bias might have been present in the study sample; for example, more digitally inclined or eHealth-literate patients could have agreed to participate than digitally-averse or eHealth-illiterate patients. This possibly led to an overestimation of the feasibility of text messaging from the patient's perspective, as these patients might have a more positive attitude toward digital tools and eHealth in general. Although 1 in 4 patients did not actively participate, these patients did not significantly differ from active participants in terms of sex, age, diagnosis, disease years, or prescribed DMARD group. Fourth, the response rate to the question of whether a DRP was answered sufficiently was low, with a nonresponse rate of 42%, resulting in a large number of DRPs determined to be answered sufficiently by the pharmacist's determination. Despite meticulous determination by 2 researchers (LLH and VJBH), this determination might not be as precise as patient confirmation. The relatively low response rate might be caused by the fact that the need to indicate if a question was answered satisfactorily after the conversation is concluded might not be intuitive and is normally not present in face-to-face conversations. Finally, the generalizability of the study is limited. As this study was performed in a specialized center rather than a general hospital and on a limited number of chronic conditions, standards of current (digital) care might differ from those in general hospitals and other chronic conditions. This can result in a different point of reference and thus make this study's findings not fully generalizable to other settings.

Conclusion

To conclude, 2-way text messaging between patients and pharmacists for discussing DRPs seems feasible from the patients' and pharmacists' perspectives. Furthermore, participants used text messaging primarily for raising DRPs, warranting health care provider involvement, which shows the potential of text messaging as an efficient addition to currently available information and communication channels if correctly integrated and intuitively usable. However, the impact of actual demand in a larger population on the feasibility for health care providers, as well as the impact on prevention of possible negative health consequences of DRPs, should be researched before full-scale implementation.

Abstract

Background: Burn automated diagnosis may be instrumental for accurate and timely decision-making at point-of-care, helping to ensure that the right patients are triaged to burns centers. This is particularly important in resource-poor settings.

Objective: We studied the intention of nonspecialized clinicians to engage in automated diagnosis in burn care as well as their perceptions toward clinical risks.

Methods: A self-administered survey was used among a purposive sample of first contact clinicians (n=56) and burns specialists (n=35). The survey had 2 main parts: 1 measuring the intention to use automated diagnosis as per 7 constructs of the Automation Acceptance Model (yielding 8 hypotheses) and 1 on clinical risk perceptions (likelihood and severity of 7 risks). Structural Equation Modelling was used to test the hypotheses among first contact clinicians, and the Mann-Whitney U test was used to measure differences in risk perceptions between the two clinical groups.

Results: Many first contact clinicians would intend to use automated diagnosis for burns should the technology be made available in their departments (41/56, 73%). The Automation Acceptance Model concepts contributed moderately to explain what the intention to use automated diagnosis rests on (R^2=0.432), with 5 out of 8 hypotheses being supported. The intention to use automated diagnosis was associated with perceived usefulness but not with attitudes toward using it. Of the 7 risks studied, the 1 that was most often considered as high risk of occurring was that of complex burns not being recognized (n=23, 29%). The 2 groups differed significantly in their concern regarding both the likelihood of happening and the severity of 2 risks: the undermanagement of severe burns and the overmanagement of minor burns. Specifically, a larger proportion of first contact clinicians were more concerned than burns specialists (n=13, 27% versus 6% and n=11, 23% versus 6% for undermanagement and overmanagement, respectively).

Conclusions: Almost three-quarters of first contact clinicians were inclined to seek automated advice for burn diagnosis. The proposed model contributes to explaining the intention to use with 5 hypotheses supported. When seeking additional determinants, clinical risk perception is a dimension that should be considered in any artificial intelligence implementation process, to help ensure sustainability.

Introduction

Image-based automated diagnosis is developing rapidly, not least with the access to deep neural networks and even more with recent methods that can improve performance, such as foundation models or vision transformers [1-3]. These algorithms can outperform clinicians in medical specialties such as cancer pathology [4], ophthalmology [5], dermatology [6], and burns [7]. However, implementation of the technology into the clinical setting has been relatively low and is dependent on

XSL•FO
RenderX

the medical specialty. For instance, results in the radiology field emphasized the need for grounded, well-structured, and hospital-wide implementation processes [8]. In surgical pathology, rapid and accurate results provided by automated diagnosis enabled pathologists to focus on more complex consultative tasks [9]. Further, maxillofacial surgeons, ophthalmologists, dermatologists, and radiation oncologists acknowledged the need to be trained before implementation and to have well-defined responsibilities among all users involved in the implementation process, especially if errors were to happen [10,11].

In Sub-Saharan Africa, the potential for artificial intelligence (AI) is big, as it could assist with early detection of infectious diseases [12,13], but also assist with the lack of specialists in underserved areas [14]. As an example, a solution for tuberculosis detection in chest x-rays has been proposed in South Africa [15].

Despite those promises, AI has not unleashed its full potential in the continent, with the uptake of this technology being relatively low at first point of care, perhaps because of limited involvement from health care specialists at the development stage [16,17]. Users' trust and task seamlessness [18] have been well described as uptake barriers since the introduction of telemedicine [19,20] and mHealth [21]. Gaining knowledge on first contact clinicians' intention to adopt automated diagnosis procedures is an essential milestone in their development and implementation process, allowing for user-sensitive transformations of diagnostic decision making in the clinical setting.

The visual nature of burns, the wide uptake of mHealth [22], the progress made in the technology [16], and the scarcity of specialists, not least in low resource settings [23], are important arguments in favor of implementing automated diagnosis in this clinical domain. This current study follows prior work showing that the technology performs well [16] and investigates the factors influencing the willingness of first contact clinicians to use automated diagnostic assistance in burn care. It adds to the body of knowledge generated from implementation science studies, setting the stage for translation from knowledge to practice and informing on end users' perceptions in view of a change in clinical procedures.

Methods

Aim

The primary aim of this study was to determine the factors influencing the intention to use an automated burn diagnosis tool among first contact clinicians. An additional aim was to assess whether the views of those clinicians are like those of burns specialists, in particular, how they perceive the likelihood and severity of certain clinical risks.

Study Design

This was a questionnaire-based cross-sectional study. The CHERRIES checklist for reporting results of e-surveys was used [24], with results presented in Table S1 in Multimedia Appendix 1.

Data Collection

In 2019, two consecutive international congresses took place in South Africa and gathered clinicians involved in burn injury care at different levels, both first-contact care and specialized care delivery. Those were judged good opportunities to reach out to several professionals from different parts of Sub-Saharan Africa and other parts of the world that, otherwise, would have been difficult to reach. The survey took place in the context of the development of an algorithm for image-based automated burn diagnosis [23]. The meetings were the Pan African and South African Burn Congress 2019 and the EMSSA (7th Emergency Medicine Society of South Africa) International Conference. At both events, participants were informed about this study taking place when they registered, and pamphlets containing information about the survey were distributed in sessions. Using a QR code provided, those who wished to participate could go on and fill in the survey on their own device or using one of the tablets provided by the research team.

Questionnaire

A questionnaire developed built on previous publications [20,21,25] was used to assess the intention to use an automated burn diagnosis tool among the participants based on the Automation Acceptance Model (AAM) [25]. For that purpose, the questionnaire was divided into 3 parts. Following some information on the context of automated burn diagnosis tool development, and with a specific description of what such a tool would consist of, the first section included demographic questions about the participant and its practice in burn care. The second part included 23 questions representing the 7 constructs from AAM [25], as well as anxiety [21,26,27] to reflect the intention to use an automated burn diagnosis tool in resource-poor settings in Africa (Table 1). The 7 constructs were behavioral intention (1 measurement item), attitude (3 items), perceived usefulness (8 items), perceived ease of use (2 items), trust (2 items), and compatibility (2 items) all directly inspired from the AAM and adapted to burns diagnosis and anxiety (5 items) which was shown to be predictive in similar populations for the introduction of telehealth. All constructs were measured on a 7-point Likert scale from 1 "strongly disagree" to 7 "strongly agree." The third part of the questionnaire evaluated the participant's perceptions of the risks linked with the use of an automated burn diagnosis tool. Seven risks were specifically evaluated: (1) that severe burns are missed, leading to undermanagement; (2) that minor burns are diagnosed as severe, leading to overmanagement; (3) that clinicians feel less responsible for the care they provide; (4) that the emotional well-being of the patient will be neglected; (5) that the patient confidentiality will be breached; (6) that patients will be less empowered in decisions around their care; (7) that some complex burns may not be recognized by the algorithm. For each risk, the participant had to evaluate the likelihood of happening on a 3-point scale from low or very low to high or very high; and the severity of the risk would it happen on a 4-point scale (insignificant, minor, moderate, or major).

Table . Measurement items used in the questionnaire in relation to the defined construct they measure.

Construct (definition)	Measurement items
Behavioral intention: The motivational factors that determine an individual's readiness to use the technology, which is assumed to be an immediate antecedent of behavior [28]	· I intend to use automated diagnosis for burns as soon as it becomes available in my department
Attitude: An individual's positive or negative feelings about using the technology [28]	· I believe that using automated diagnosis for burns is a good idea · Using automated diagnosis for burns would make work more interesting · I believe that using automated diagnosis for burns is a bad idea
Perceived usefulness: The degree to which an individual believes using the technology will assist in performing a task [29]	· It would make it easier to do my job when managing patients with burns · It could improve the care I give to my patients with burns · It will reduce the probability of medical errors in burn care · Using it will improve the quality of my burn-related work · It will be useful in my burn-related work · It will be useful in improving patient safety · I would use it for burn wounds that I normally would hesitate to consult a specialist about · Using it in my burn-related work would make me feel more independent
Perceived ease of use: The degree to which an individual believes using the technology will be effortless [29]	· Learning to operate a tool like this would be easy for me · It would be easy for me to become skilled at using such a tool
Trust: The generalized expectancy to which an individual can rely on the technology [25,30]	· I believe that the diagnostic ability of automated diagnosis is superior to the clinical experience of human doctors · I would have difficulties trusting an automated diagnosis
Compatibility: The degree to which the technology is believed to be consistent with an individual's existing values, needs, and experiences [25]	· Using a tool like this would fit well with the way I like to work · Using an app like this would be compatible with most aspects of my work
Anxiety: The degree to which emotional reactions are evoked when using the technology [27]	· I feel apprehensive about using such a tool · Using automated diagnosis for burns would make me feel uncomfortable · I am concerned about possible liability issues associated with its use · Working with such a tool would make me feel anxious · Using it would make me feel less anxious about dealing with burns patients

The questionnaire was pilot-tested before the data collection to ensure comprehensibility, content, and length of time.
