The Modified Computer Self-Efficacy Scale (mCSES) and the Osteoarthritis Knowledge Scale (OAKS) were used to assess technology self-efficacy and osteoarthritis knowledge, respectively, at baseline and 6 weeks through surveys. The mCSES asks respondents to rate their confidence using a new technology on a scale from 1 to 10, where 1 represents "not confident at all" and 10 "totally confident" [28]. The OAKS is an 11-item scale assessing important knee osteoarthritis knowledge, with scores ranging from 11 to 55, with higher scores indicating greater knowledge about osteoarthritis [29].

Secondary outcomes collected through the app included changes in knee pain (NRS), BMI, mood, sleep quality and disturbances, physical activity (average step count over the last 7 days), and time asleep (average sleep duration over the last 7 days). The DASS-21 was used to measure the emotional states of depression, anxiety, and stress. The questionnaire consists of 21 statements, with 7 statements pertaining to each subscale. Participants were asked to rate their agreement with each statement from 0 to 3 (where 0 indicates "Never," and 3 indicates "Almost always") [30]. Scores for each subscale were summed and multiplied by 2 for interpretation. The PSQI is a 19-item self-reported questionnaire assessing various aspects of sleep quality (eg, duration, latency, disturbances) over the past month. Scores for each question range from 0 to 3, with higher scores indicating more acute sleep disturbances [31].

Knee pain (NRS) and body weight (kg) were self-reported by participants. Physical activity and time asleep were automatically collected from participants' Fitbit devices, which synced to the mobile app.

Qualitative Feedback

Participants were also asked to provide any feedback regarding the app through open text fields with the option of including their contact details should they wish to discuss the feedback in person with a study team member.

The outcome measures collected in this study were exploratory in nature and were not used for progression, modification, or stopping decisions within the study protocol.

Sample Size

As this study was a feasibility study, no formal sample size calculations were conducted. We aimed to recruit a total of 30 participants for this study, which is an acceptable size for a feasibility study [32].

Statistical Analysis

Participant baseline demographics and clinical characteristics were expressed using means and SDs or medians and IQRs if not normally distributed. The primary outcome (MAUQ) was summarized descriptively. The secondary outcome measures at baseline and 6 weeks were summarized using median and IQR. The change scores (baseline minus 6 weeks) were summarized using median and IQR. Analyses were conducted using STATA (version 18.0). Qualitative data from participant feedback were collated into an Excel spreadsheet, and each comment was mapped to a general category (eg, App download, Fitbit integration, goals, instructions, learning materials, notifications, design, or other) by 1 researcher (NB). These were reviewed by a second researcher (VD) and suggestions on how to improve the app were discussed and documented. The suggestions were then reviewed within the wider study team, including the app developer. Changes that the researchers or developer deemed reasonable and appropriate informed the next iteration of the OA Coach mobile app. Changes that required additional resources and funding were temporarily put on hold.

Results

Participant Demographics

A total of 30 participants were recruited between March 2023 and April 2023. There was an even split of female and male participants (n=15 per sex), and participants had an average age of 66.9 (SD 9.1) years and a median pain level of 6.0 (IQR 5.0-6.8) on an 11-point NRS. The participant baseline demographics are summarized in Table 1. Due to technical issues, there were some participants who did not have complete step, and sleep data at baseline and demographics in Table 1 are based on a complete case analysis.

Primary Outcome

Overall, participants found the app usable, with the majority of scores greater than 5 out of 7 on the MAUQ. Most participants found the app easy to use (mean 5.8, SD 1.5), easy to learn how to use (mean 6.1, SD 1.2), and were satisfied with the amount of time involved in using the app (mean 6.0, SD 0.9). The lowest scoring statements were regarding improving access to health care services (mean 3.6, SD 1.8) and the app functionalities and capabilities (mean 4.1, SD 1.9), which are in alignment with the qualitative data collected. The results of the MAUQ statements are summarized in Table 2.

XSL•FO

Table . Results of the mHealth App Usability Questionnaire (MAUQ).

Statement[a]	Mean (SD)[b]	Min-max
The app was easy to use.	5.8 (1.5)	2-7
It was easy for me to learn to use the app.	6.1 (1.2)	2-7
The navigation was consistent when moving between screens.	5.5 (1.5)	1-7
The interface of the app allowed me to use all the functions (such as entering information, responding to reminders, viewing information) offered by the app.	5.1 (1.9)	2-7
Whenever I made a mistake using the app, I could recover easily and quickly.	5.2 (1.7)	0-7
I like the interface of the app.	5.1 (1.7)	2-7
The information in the app was well organized, so I could easily find the information I needed.	5.2 (1.7)	2-7
The app adequately acknowledged and provided information to let me know the progress of my action.	5.3 (1.6)	2-7
I feel comfortable using this app in social settings.	5.8 (1.6)	1-7
The amount of time involved in using this app has been fitting for me.	6.0 (0.9)	4-7
I would use this app again.	5.2 (1.7)	2-7
Overall, I am satisfied with this app.	4.7 (2.0)	0-7
The app would be useful for my health and well-being.	5.4 (1.8)	0-7
The app improved my access to health care services.	3.6 (1.8)	0-7
The app helped me manage my health effectively.	5.1 (1.2)	2-7
This app has all the functions and capabilities I expected it to have.	4.1 (1.9)	1-7
I could use the app even when the internet connection was poor or not available.	4.3 (1.9)	0-7
This mHealth[c] app provides an acceptable way to receive health care services, such as accessing educational materials, tracking my own activities, and performing self-assessment.	5.3 (1.2)	3-7

[a]n=29; 1 participant had missing data.

[b]Scores range from 1 to 7, where 1 indicates strongly disagree, 2 indicates disagree, 3 indicates somewhat disagree, 4 indicates neither agree nor disagree, 5 indicates somewhat agree, 6 indicates agree, and 7 indicates strongly agree.

[c]mHealth: mobile health.

Secondary Outcomes

The NRS median pain reduced from a median of 5.0 (IQR 4.0 - 6.0) at baseline to 4.0 (IQR 2.0 - 5.0) at 6 weeks, giving a within-patient median reduction of 1 point (IQR 0.0 - 3.0). The modified Computer Self-Efficacy Scale (mCSES) moved in the opposite direction: the median score declined from 89 (IQR 74 - 100) to 81 (IQR 67 - 93), reflecting a median change (reduction) score of 2.5 points (IQR –1.0 to 7.0). The OAKS score did not indicate a substantial change in knowledge (median change of 0.0 points, IQR –2.0 to 3.0).

The magnitude of change in BMI was very small—change from a median 26.7 (IQR 24.4 - 31.2) to 26.6 (IQR 24.5 - 29.1)—corresponding to a median within-patient change of 0.02 (IQR –0.15 to 0.05). There was a small improvement in the psychological distress measure. The median depression scores falling from 6.0 (IQR 2.0 - 8.0) to 4.0 (IQR 2.0 - 8.0), anxiety from 4.0 (IQR 0.0 - 6.0) to 2.0 (IQR 2.0 - 6.0), and stress from 10.0 (IQR 4.0 - 16.0) to 6.0 (IQR 2.0 - 12.0). Sleep quality improved slightly, with the median PSQI score decreasing from 6.5 (IQR 5.0 - 10.5) to 6.0 (IQR 4.0 - 9.0).

The median 7-day step count increased from 8073 (IQR 5392 - 10,726) to 8616 (IQR 6028 - 10,057), a median gain of

XSL•FO
RenderX

446 steps (IQR –1433 to 2,322), while the average nightly sleep duration remained almost equal at median 7.02 (IQR 5.56 - 7.68) hours and 6.90 (IQR 5.40 - 7.65) hours. These changes are minimal and may be partially explained by the cohort that was recruited. Most participants were either previous participants of our clinical trials or had been receiving care from an osteoarthritis management team and therefore were more likely to be knowledgeable about their condition, already be engaged in some form of physical activity and have sufficient sleep hygiene. Secondary outcomes are summarized in Table 3.

Table . Secondary outcomes.

Measure	Baseline, median (IQR)	Six weeks, median (IQR)	Change (baseline to 6 weeks), median (IQR)
NRS[a] pain	5.0 (4.0 to 6.0)	4.0 (2.0 to 5.0)	1 (0.0 to 3.0)
Technology self-efficacy (mCSES)[b]	89.0 (74.0 to 100.0)	81.0 (67.0 to 93.0)	2.5 (–1.0 to 7.0)
Osteoarthritis knowledge (OAKS)[c]	41.0 (38.0 to 49.0)	42 (35 to 48.0)	0.0 (–2.0 to 3.0)
BMI (kg/m^2)	26.7 (24.4 to 31.2)	26.6 (24.5 to 29.1)	–0.02 (–0.15 to 0.05)
Depression (DASS-21)[d]	6.0 (2.0 to 8.0)	4.0 (2.0 to 8.0)	0.0 (0.0 to 6.0)
Anxiety (DASS-21)	4.0 (0.0 to 6.0)	2.0 (2.0 to 6.0)	0.0 (–2.0 to 2.0)
Stress (DASS-21)	10.0 (4.0 to 14.0)	6.0 (2.0 to 12.0)	2.0 (–6.0 to 6.0)
Sleep quality and disturbances (PSQI)[e]	6.5 (5.0 to 10.5)	6.0 (4.0 to 9.0)	1.0 (0.0 to 2.0)
Physical activity[f]	8073 (5392 to 10726)	8616 (6028 to 10057)	446 (–1433 to 2322)
Time asleep[g]	7.02 (5.56 to 7.68)	6.9 (5.4 to 7.65)	0.15 (–0.58 to 0.57)

[e]PSQI: Pittsburgh Sleep Quality Index.

[f]Average step count over the last 7 days

[g]Average sleep duration in hours over the last 7 days

Overall, when comparing outcomes at 6 weeks to baseline, there was a small reduction in pain and psychological distress; slight improvements in sleep quality and physical activity; and stability in knowledge, BMI, and sleep duration. These outcomes were expected in a small, uncontrolled feasibility study that was not designed to detect statistically significant changes within the group.

Qualitative Feedback

The qualitative feedback largely focused on usability and suggestions for improving the app, such as better integration of the exercise programs and improved personalization of goals and activity tracking. Additionally, participants highlighted the need for improved onboarding support. Participants also noted confusion over the labeling of certain features. The main areas for improvement and updates made to the next iteration of the OA Coach app are outlined in Table 4.

XSL•FO
RenderX

Table . Summary of qualitative feedback from participants at 6 weeks.

Page	Areas lacking and suggestions for improvement	Updates made to OA Coach app
Goals	• Not possible to set a one-off goal in the app, only recurring goals • Tying goals to specific time was not appropriate • Unable to find DASS-21[a] and PSQI[b] questionnaires	• A new "Activities" section was created to log one-off activities. The goals section will remain for recurring goals. • Clarified that the time next to the goal was for the time for the reminder to be sent. The time has been removed from under the goal so as not to cause confusion but can be edited by selecting the icon next to the goal. • DASS-21 and PSQI questionnaires were renamed to "Sleep" and "Mood" questionnaires to avoid confusion. Clarified instructions on how to complete the questionnaires and goals to fill questionnaires will repeat daily until they have been completed.
Instructions	• Setting up Fitbit goals and duration of exercise activities were confusing	• Clearer instructions and explanatory text were provided. An introductory video was created to explain all features of the app.
Learning	• Some links in the article did not work • Could not find the knee strengthening exercises	• Links in articles were checked and updated. • An introductory video was created to explain how to use the app and features.
Messages	• Feedback notifications were too generic	• Notifications were modified, and changes were made underpinned by behavior change theory. New notifications and messages underwent comprehensive co-design and survey study.

[a]DASS-21: 21-item Depression, Anxiety, and Stress Scale.

[b]PSQI: Pittsburgh Sleep Quality Index.

Discussion

The OA Coach mobile app is designed to provide education to people with osteoarthritis to help them self-manage their condition. The app aims to address the current gaps in mobile apps for the management of osteoarthritis, focuses on all aspects of osteoarthritis management (eg, pain flares, weight management, mood, sleep, physical activity, and exercise), and has been co-designed with end user input. Overall, the usability of the OA Coach mobile app prototype was deemed acceptable by participants when assessed using the MAUQ. The lowest scoring item on the MAUQ was access to health care services, and although the app provides recommendations for how to access services in the learning modules, including the types of support available with relevant links, improvements to the app could be made to make this more explicit, for example, including a directory of health care professionals or service providers who manage different aspects of osteoarthritis and their contact details. The secondary outcomes demonstrated small reductions in pain and psychological distress and slight improvements in sleep quality and physical activity (step count). Interestingly, technology self-efficacy worsened. However, as this was a feasibility study only, the sample size was not powered to reliably detect a true effect. The 6-week duration of the study was also likely too short to detect a change in outcomes.

From the qualitative feedback, study participants recommended improving the clarity and personalization aspects of the OA Coach mobile app. As a result, the app was updated to include more instructions and clarification text within different features of the app. Updates to the app were made, including the addition of an introductory instructional video and an improved interface for the exercise programs and "Inbox." A total of 80 notifications sent through the app also underwent an extensive co-design process and were refined. An additional 12 educational messages were also co-designed for the new "Inbox" feature of the app [33].

A major strength of the study is that the OA Coach mobile app was co-designed and tested with people with lived experience of osteoarthritis. There was also input from researchers and health professionals with various backgrounds and expertise. The developer, Vulsen, is familiar with the requirements for data privacy in Australia, and their mobile apps have been approved for use in collecting patient data within local health districts within Sydney, Australia. Another major strength of the study is that we used objectively measured physical activity and sleep to provide tailored recommendations in the app. We also used validated questionnaires for mood and sleep, allowing the app to tailor learning modules on these topics to participants. The balanced distribution of female to male participants was also a strength of our study, as there is usually a greater proportion of female participants in osteoarthritis clinical trials [34].

Limitations of our study include selection bias—we were only able to include participants in the study who owned a

XSL•FO
RenderX

smartphone and therefore may be more familiar with the use of mobile apps. The usability scores of the app may be biased upward due to the self-selection of participants who were more technology-literate. The participants in our trial were generally older as well and living in metropolitan Sydney, which limits the generalizability of the results. Participants were also recruited from our database of previous clinical trial participants or from the Osteoarthritis Chronic Care Program. As a result, they were more likely to have prior knowledge about their condition and to already be engaging in some form of physical activity or exercise. At baseline, participants were already achieving an adequate level of physical activity as measured by step count and were sleeping the recommended number of hours. This high starting point limits the potential for further improvement, which may partially explain why changes in secondary outcomes were minimal. The study had a short follow-up duration of only 6 weeks, and a longer period of follow-up (eg, 12 wk) would have been ideal to evaluate long-term outcomes and behavior change. For the purposes of this study, we did not analyze the app meta-data, such as time spent interacting with the app and completing learning modules; however, these data may be used to refine future versions of the app. Finally, the educational content featured in our app is mainly limited to knee osteoarthritis; future versions of the app may also target other commonly affected joints, such as the base of the thumb or the hip joint.

The OA Coach mobile app was theory-driven and informed by behavior change theory and best-evidenced osteoarthritis care. The components of the app extend beyond aggregating features and are intended to enhance users' capability, motivation, and self-efficacy. The OA Coach app combines the core aspects of osteoarthritis management, alongside objective monitoring of activity, symptoms, and behaviors. To our knowledge, this is the first mobile app developed for knee osteoarthritis management in the Australian market, which has the ability to measure physical activity objectively using a fitness tracker. Our methodology was consistent with a systematic review published in 2019 by Choi et al [35] that provided a framework for developing mobile apps for osteoarthritis management, particularly apps that have the ability to track pain and symptoms, provide instructional audio/video of exercise regimes, and set goals to maximize adherence. A more recent review by Hensley et al [20] in 2023 also found a lack of quality information, structured exercise programs, and health information protection in the mobile apps evaluated (n=14). OA Coach addresses many of the features missing in previous mobile apps developed for osteoarthritis management. The app will also undergo effectiveness testing in a 3-armed randomized controlled trial before being launched in public app stores [36]. This will also include in-depth interviews with participants to discuss barriers and facilitators to using the app. This will ensure that the final version of the app is effective at managing osteoarthritis-related symptoms. Future updates to the OA Coach mobile app functionality will be informed by consumer feedback as well as data analytics to ensure that the app continues to meet the evolving needs, preferences, and expectations of people living with osteoarthritis.

The results from this feasibility study provide evidence to support the use of the OA Coach mobile app by encouraging patients to self-manage their condition by providing educational resources; addressing comorbidities, such as sleep and mood changes that commonly coexist with osteoarthritis; and encouraging them to be more physically active. The feedback from the feasibility study has been used to refine the current version of the OA Coach app, and it is currently being tested in a randomized controlled trial assessing 3 different models of care. Further development of the app may involve the use of generative artificial intelligence to further tailor notifications to provide personalized recommendations, and the ability to sync with Apple Health or Google Health to track activity levels without the use of an activity tracker.

Acknowledgments

We would like to thank the participants of the study.

No generative artificial intelligence tools were used at any stage in preparation of this manuscript.

Funding

Lenity Australia provided funding for the prototype of the OA Coach mobile app.

Authors' Contributions

VD and DJH conceived the study and all authors contributed to the protocol. RH developed the app with input from VD, NB and DJH. VD and NB conducted the study, with recruitment assistance from LD, AF, CP, CS, SY and DJH. VD and VV conducted the statistical analyses. VD drafted the manuscript, and all authors provided input to the manuscript preparation and approved the final version of the manuscript.

Conflicts of Interest

VD is supported by a Lenity Foundation Fellowship. JE is supported by a National Health and Medical Research Council Investigator Grant (2025504). DJH is the editor of the osteoarthritis section for UpToDate and co-Editor in Chief of Osteoarthritis and Cartilage. DJH provides consulting advice on scientific advisory boards for Haleon, Naia Health, Novartis, Tissuegene, Lilly, Doron, Sanofi, Formation Bio. All other authors declare that there are no conflicts of interest in relation to this work.

Abstract

Background: Recruiting patients in primary care research remains challenging due to clinical workload, staffing constraints, and the need to limit disruption to routine care. Traditional recruitment methods often place a substantial burden on clinics, prompting research teams to adopt low-burden and scalable approaches such as email-based recruitment. Despite its growing use, limited empirical evidence describes how email recruitment campaigns are designed and how they perform when targeting primary care patients in real-world settings.

Objective: This study aims to descriptively examine engagement metrics from an email recruitment campaign targeting primary care patients.

Methods: We conducted a formative, descriptive secondary analysis of engagement metrics generated during a large-scale email recruitment campaign conducted as part of the Quebec component of the Patient-Reported Indicator Survey-Organisation for Economic Co-operation and Development survey. Between June 2023 and January 2024, a total of 12 primary care clinics invited eligible adult patients (aged ≥45 years) to complete an online survey using a standardized email template distributed via an email marketing platform. Collected engagement metrics included delivery rates, open rates, click-through rates, conversion rates, and device type. Analyses were descriptive and conducted at the clinic level.

Results: For 15,277 patients, invitations were successfully delivered to 14,758 (96.6%). The mean open rate for the initial invitation was 73.4% (10,828/14,757; range 57% - 88%), decreasing with reminders. Most emails were opened on computers (25,868/30,279, 85.4%). Out of a total of 445 emails, 42 (9.4%) were undelivered due to technical issues, and 403 (90.6%) were undelivered due to incorrect email addresses. The overall conversion rate was 9.7% (1430/14,758). Click-through rates varied by content, with the highest engagement observed for the survey link and lower engagement for supplementary video materials. Reminder emails substantially increased survey participation across clinics (759/1138, 66.7%). Participants who completed the questionnaire were predominantly aged 60 to 69 years, identified as female, and had completed postsecondary education.

Conclusions: This formative analysis suggests that email-based recruitment is a feasible and low-burden approach for engaging primary care patients in research. Engagement metrics offer valuable insights at the implementation level to inform the design, adaptation, and monitoring of digital recruitment strategies in real-world primary care settings. These findings provide practical, implementation-oriented insights to inform the design, refinement, and evaluation of email recruitment campaigns in primary care research.

KEYWORDS

web-based survey; primary care; email-based recruitment; patient recruitment; engagement metrics

Introduction

The increasing administrative burden and the insufficient workforce place significant pressure on Canadian primary care clinics [1,2]. The schedules of family physicians in primary care are overloaded, and their participation in research initiatives can be hindered by numerous factors, including mismatches between their needs and the research objectives, staff shortages,

XSL•FO
RenderX

administrative burdens, disruptions to clinical routines, and additional documentation requirements [3]. Consequently, their participation in research initiatives must be made as easy and straightforward as possible. Recruiting patients for research participation in clinics is highly challenging [4]. If clinic staff are required to dedicate time to explaining the initiative and responding to patients' questions, this fragments their clinical practice and disrupts the routine workflow. While this added burden is unavoidable, it necessitates the use of low-burden recruitment methods, moving away from traditional on-site or mail-based approaches. Despite many clinics showing interest in participating in research, engaging them remains challenging due to complex procedures, extensive paperwork, staffing shortages, and insufficient office space for recruitment and consent [3,5,6]. Ethical issues concerning the initial contact with patients are also at stake because it "should be made by someone that individuals would expect to have relevant information about them, or in other ways that do not inappropriately intrude on their life or privacy" [7].

Nearly 29 million Canadians use email, with approximately 20% opening marketing emails [8]. As a result, email has become a convenient and efficient method for recruiting research participants across various fields [4,9]. Recruitment emails typically outline the research purpose, potential benefits for participants, and any compensation or incentives that will be offered. Combined with a web-based survey, email recruitment enables primary care researchers to quickly reach a broad audience and track responses, while being less resource intensive than in-clinic or phone recruitment.

Beyond initial recruitment, sustaining participant engagement amidst the myriad of digital stimuli remains challenging. Capturing and maintaining the interest and commitment of potential participants requires deploying specific strategies. Innovative approaches grounded in empirical research are crucial for achieving optimal participant recruitment and engagement outcomes in navigating this complex landscape. Numerous factors have been shown to influence response rates, including shorter survey length, providing incentives, high relevance of the content and survey topic, and attractive visual display [10]. However, there is a lack of information on how patients in primary care engage when invited to participate in research via email. Most existing studies focus on email recruitment of health care professionals [11-13], and those describing email content in sufficient detail or using marketing platforms to monitor engagement metrics are rare.

In recent years, research teams have increasingly relied on email as a recruitment strategy, underscoring the need to better document how such campaigns are designed and how they perform in real-world settings. Accordingly, this study aims to describe the implementation and performance of an email-based recruitment campaign targeting primary care patients using engagement metrics collected from a large-scale survey. The findings are intended to provide practical, implementation-oriented insights to inform the design, adaptation, and monitoring of future email recruitment strategies in primary care.

Methods

Overview

This secondary analysis followed a prespecified descriptive analytic plan focused on characterizing engagement patterns at the clinic level. Primary outcomes included email delivery, open rates, click-through rates, device type, and conversion rates. No hypothesis testing was conducted, as the study objective was exploratory and formative. This paper presents data from reports and indicators gathered during the Patient-Reported Indicator Survey (PaRIS) national survey in Quebec, Canada. The PaRIS is an international survey led by the Organisation for Economic Co-operation and Development (OECD) to develop, standardize, and implement a new generation of indicators that measure the outcomes (patient-reported outcome measures [PROMs]) and experience of health care (patient-reported experience measure [PREMs]) most relevant to primary care patients worldwide. The PaRIS initiative has been described in detail elsewhere [14,15]. The OECD provided guidance on patient recruitment across participating countries, enabling each country to tailor its recruitment methods to its chosen approach, whether by phone, mail, email, or in-person at clinics. Quebec opted to recruit patients through a large-scale email campaign. The sample consisted of patients attending primary care clinics participating in the Canadian PaRIS-OECD national survey in the province of Quebec. The inclusion criteria for patients were as follows: (1) being 45 years or older, (2) having consulted their primary care clinician within the last 6 months, and (3) providing an email address. In accordance with the OECD's guidelines for the PaRIS study, the targeted sample size was established at 75 patients per clinic, although clinics could recruit more if feasible [15].

Our team, comprising a registered nurse and researcher, a research coordinator, a patient partner, and a scientific graphic designer, cocreated an invitation template for patient recruitment. STW and MEP are coleads for PaRIS-OECD in Canada. First, we identified the essential items to include in the email invitation. We then drafted the initial content, refining it before the scientific graphic designer further refined it to enhance its visual clarity and usability. As Canada has 2 official languages, French and English, we created bilingual email recruitment materials.

Building on the Canadian Institutes for Health Research's strategy for patient-oriented research [16] and our previous findings, which demonstrated that recruitment facilitated by a patient partner results in a higher participation rate, we incorporated a patient partner video clip in the email invitation. This 1-minute 50-second French video, featuring English subtitles, showcased a patient partner explaining the project's objectives and emphasizing the importance of participation. The scientific graphic was produced using Adobe Premiere Pro (version 25.4). The email template (Multimedia Appendix 1) was designed using the online marketing platform CyberImpact 2025, which provides delivery and engagement metrics and contains the following 5 sections:

1. Title of the study and catchy wording

XSL•FO
RenderX

2. Greetings and invitation purpose, including an introduction to the patient partner video and a link to it (research team's YouTube channel)
3. Links to French and English PaRIS study questionnaires and contact information to obtain support from the research team
4. Aim of the study, participants' contribution, and what is in it for participants
5. Two links leading to a video about PREMs and PROMs (research team's YouTube channel), previously produced by the research team, and greetings

We also created a reminder template with adjusted wording to include the reminder element and remove links to video clips discussing PREMs and PROMs, thereby streamlining the invitation template. Finally, we created support materials for participating clinics, including a PDF illustrating the steps for importing emails into the marketing platform and how to schedule email campaigns and several examples of email subjects such as "PaRIS Study-Survey on your care experience at [name of the clinic]," "[name of the clinic]: PaRIS research project," and "We need your opinion, please help us!" Each clinic was instructed to program 1 initial invitation and 3 reminders, all scheduled to be sent at 6 AM.

Participating primary care clinics obtained data from the statistics provided by CyberImpact and shared anonymized reports with the research team, as approved by the ethics committee. The following categories of data were used: mailing performance, opening statistics, and statistics on embedded links. Briefly, email open and click rates were measured using hidden tracking pixels. Specifically, the pixel was activated only when the images embedded in the email were downloaded, which helped reduce false openings generated by automated systems that scanned messages. A certain margin of error remained, for example, due to image blocking or user privacy settings. However, CyberImpact considers the reliability of these measures to be very high, estimating data accuracy at approximately 95%. We used the analytic data from YouTube to track metrics (number of views, average view duration, and average percentage of video viewed) for the patient partner introduction video.

The open rate was calculated as the percentage of patients who opened the email out of the total number of patients who received the email. The click-through rate refers to the percentage of people who click a link in an email out of those who open it. The conversion rate is the number of recipients who take the desired action compared with the number of recipients who received the email. The unsubscribe rate refers to the number of patients who unsubscribe out of the number of patients who received the email [17]. Quantitative data were analyzed using descriptive statistics, including measures of central tendency (mean) and variability (SD) using a 95% CI, as well as the minimum and maximum values of the variables' means across clinics, using SPSS (IBM Corp) software. We did not use a reporting guideline. Instead, we emphasized transparency in describing the data sources, metrics examined, unit of analysis, and descriptive analytic approach, consistent with the exploratory objectives of the study and the reporting standards commonly used for formative and implementation-focused research.

Ethical Considerations

This study was in accordance with the ethical standards of the responsible committee on human experimentation and with the World Medical Association Declaration of Helsinki. Ethics approval was obtained from the research ethics board of the Ministry of Health and Social Services of the province of Quebec (CCER-22-23). Patients gave their consent to participate in the PaRIS-OECD national study, and this consent covered secondary analysis. Patients participating in the PaRIS study in Quebec were eligible for a draw to win one of three US $25 grocery gift cards among respondents from their clinic. Demographic characteristics are presented in aggregate, and no identifiable participant information is included in this study.

Results

Between June 2023 and January 2024, a total of 12 primary care clinics participated in the PaRIS-OECD national survey in the province of Quebec. The research coordinator met with a staff member from each participating clinic to assist in programming and sending email invitations and reminders to patients. The clinic staff member then chose their preferred formulation for the email subject, either by creating their own subject line or using 1 of the provided examples. The clinic staff sent a first invitation to patients the day after the meeting. Email distribution was scheduled to accommodate each clinic's operational context, including avoidance of public holidays and alignment with concurrent recruitment activities. All clinics expressed that 3 reminders were excessive and that they did not want to oversolicit their patients. Accordingly, only 2 reminders were sent to comply with this request. All invitations and reminders were sent on weekdays at 6 AM, except for 1 clinic that preferred to send them at 8 AM to coincide with its opening hours.

Twelve primary care clinics sent the initial email invitation to 15,277 patients. Across clinics, 14,758 (96.6%) patients received the email invitation in their inbox, while 14,662 (96%) patients received the first reminder email, and 14,640 (95.8%) patients received the second reminder email. The number of invited patients per practice varied from 47 to 4366 (median 416.5, IQR 143.5-945). Combining the initial invitation and the 2 reminders, a total of 44,771 emails were sent, and 98.4% (n=44,060) were delivered. Patients who had already initiated or completed the questionnaire still received the reminder emails. A total of 629 emails were undelivered due to technical issues (n=119, 18.9%) or an incorrect email address (n=510, 81.1%). A total of 176 patients unsubscribed from the email invitation, corresponding to an unsubscribe rate of 1.2% (176/14,758). Patients provided some reasons explaining their unsubscription; 48 (27.3%) patients unsubscribed because they never subscribed to the emailing list, 34 (19.3%) patients unsubscribed because they no longer wished to receive the communications, and 13 (7.4%) patients unsubscribed because they received too many emails. A total of 7 (4%) patients reported that they did not like the content. Of the 176 patients, 76 (43.2%) patients who unsubscribed did not provide a reason.

XSL•FO
RenderX

A total of 0.3% (39/15,277) of patients contacted the research team by phone or email to obtain more information, validate their eligibility, or seek support with the web-based survey. Among them, 12 (30.7%) asked for a paper copy of the questionnaire.

For the initial invitation, the open rate was 73.4% (10,828/14,758), with a range of 57% to 88% (SD 6.57) across clinics. For the first reminder, the open rate dropped to 68% (9968/14,662; range 52%-86 %; SD 8.51), and for the last reminder, the open rate was 64.8% (9483/14,640), with a range of 47% to 84% (SD 10.09). Of the 30,279 opened emails, most invitation and reminder emails (n=25,868, 85.4%) were opened on a computer, 3803 (12.6%) invitation and reminder emails were opened on a mobile phone, and 643 (2.1%) invitation and reminder emails were opened on a tablet. The information was missing for 19 (0.1%) emails.

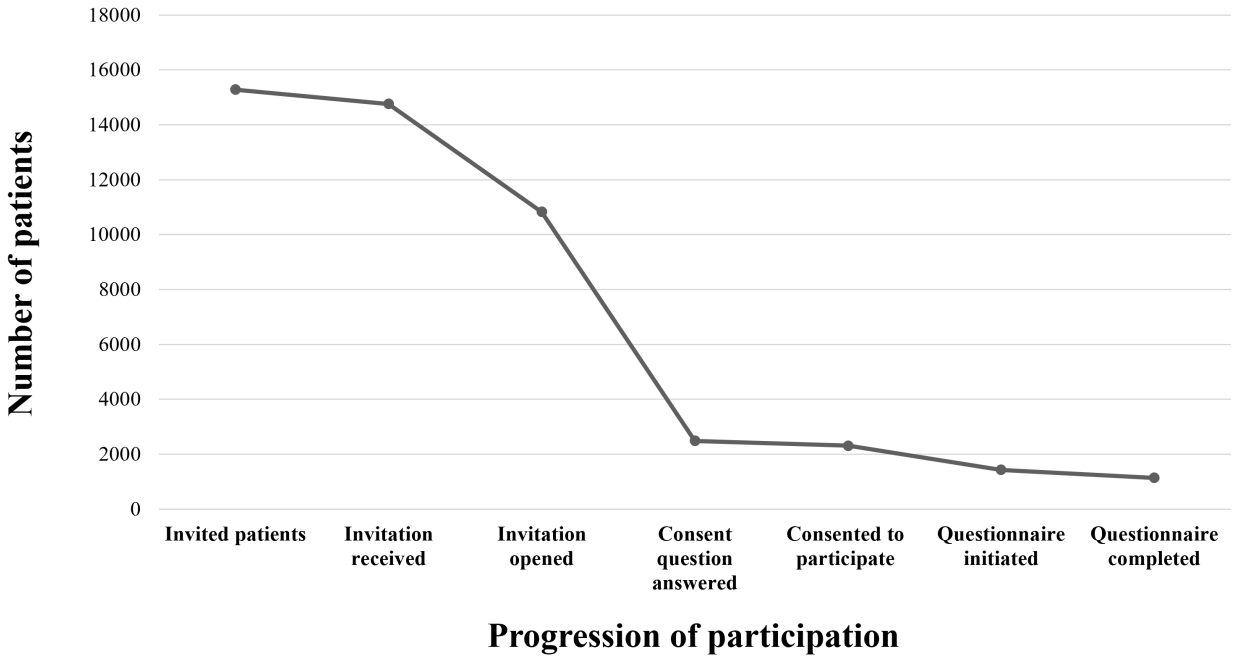
The highest click-through rate was 16% (range 7% - 27%), observed with the first reminder and linked to the French questionnaire. The video clip featuring the patient partner obtained the highest click-through rate in the first email invitation (8%; range 1-19) and was viewed 1700 times (direct URL source). The average view duration was 1 minute and 20 seconds, and the average percentage of the video viewed was 73%. The initial invitation and reminders were viewed 863 times in a web browser. Table 1 lists the click-through rates for each link included in the invitations.

Table . Click-through rate for invitation sections.

Link to	Click rate[a] (range)[b] for the first email (n=10,828)	Click rate (range) for the first reminder (n=9968)	Click rate (range) for the second reminder (n=9483)
Patient partner video clip	8.1% (1.2%-18.9%)	5.3% (0.8%-11.7%)	4.0% (0.0%-7.8%)
French Patient-Reported Indicator Survey questionnaires	15.2% (5.3%-25.7%)	16.6% (6.8%-27.5%)	13.9% (3.8%-20.0%)
English Patient-Reported Indicator Survey questionnaires	2.1% (0.0%-14.9%)	0.6% (0.0%-2.9%)	0.4% (0.0%-2.2%)
View invitation in a web browser	4.8% (0.8%-7.1%)	2.8% (0.0%-9.5%)	4.0% (0-8.6%)
Video clip about patient-reported experience measures	1.3% (0.0%-2.7%)	N/A[c]	N/A
Video clip about patient-reported outcomes measures	0.6% (0.0%-2.7%)	N/A	N/A

[a]Number of patients who clicked on the link/number of patients who opened the invitation.

[b]Minimum and maximum click rate across clinics.



[c]N/A: not applicable. The link to the video clip was not included in the reminders.

In this study, the conversion rate was 9.7% (1430/14,758), defined as the proportion of patients who initiated the questionnaire (n=1430) among those who received the initial email invitation (n=14,758).

Figure 1 illustrates the flow of recruited patients from the initial email invitation to the completion of the web-based survey. Across the initial invitation and the 2 reminders, the emails were opened 30,279 times; however, it was not possible to determine whether these were unique individuals, as the same person could have opened both the initial invitation and 1 or more reminder emails. A total of 2486 patients opened the Research Electronic Data Capture (REDCap; Vanderbilt University) survey and answered the consent question. Among them, 2307 (92.8%) patients provided their consent to participate in the study, and 1430 (62%) initiated the questionnaire. From them, 1138 (79.6%) patients completed all the included items.

XSL•FO
RenderX

Figure 1. Recruitment and retention across study phases.

Across clinics, the first reminder was sent on average on day 10 (range across clinics: 7 - 16 days from initial invitation), and the second reminder was sent on average on day 22 (range across clinics: 3-22 days after the first reminder). Across clinics, questionnaire completion rates increased with the use of reminder emails, with 379 (2.6%) out of 14,758 questionnaires completed after the initial invitation, 437 (3%) out of 14,662 after the first reminder, and 322 (2.2%) out of 14,640 after the second reminder (Table 2). Completion rates varied substantially between clinics, and the inclusion of reminder emails resulted in an approximate 200% (759/379) increase in the cumulative number of completed questionnaires.

Table . Questionnaire completion per clinic after initial invitation and reminders.

Clinic number	Patients who completed the questionnaire after receiving the initial invitation, % (n/N)	Patients who completed the questionnaire after receiving the first reminder, % (n/N)	Patients who completed the questionnaire after receiving the second reminder, % (n/N)
2401	1.7 (16/966)	2.3 (22/955)	4 (34/949)
2402	3.4 (47/1364)	4.6 (63/1361)	2.5 (34/1356)
2403	3.9 (7/178)	2.2 (4/178)	1.1 (2/177)
2405	5 (42/849)	4.8 (41/850)	3.1 (26/850)
2407	3.6 (30/838)	5.0 (42/833)	4.3 (36/832)
2408	5.2 (25/481)	4.6 (22/476)	4.8 (23/476)
2409	3.8 (87/2272)	4.5 (103/2271)	3.4 (78/2264)
2410	3.6 (46/1273)	4 (50/1267)	2.4 (31/1265)
2414	0 (0/83)	7.2 (6/83)	7.2 (6/83)
2418	2.4 (45/1908)	2.8 (53/1903)	1.4 (27/1900)
2419	0.7 (29/4366)	0.6 (24/4348)	0.4 (19/4310)
2420	2.8 (5/179)	5.1 (7/137)	3.4 (6/178)
Total	2.6 (379/14,758)	3 (437/14,662)	2.2 (322/14,640)

We examined the characteristics of patients who completed the sociodemographic section of the questionnaire (Table 3). Respondents were mainly aged between 60 and 69 years, identified as female, had a college or university diploma, and were of White ethnicity.

XSL•FO

[a]One clinic made a mistake when extracting patients' email addresses. Patients aged younger than 45 years received the invitation, and some patients responded to the questionnaire, despite being ineligible for the study.

[b]Ethnicity categories were determined by the Organisation for Economic Co-operation and Development and reported as found in the questionnaire.

Discussion

Principal Findings

Overall, this formative secondary analysis provides practical insights into how primary care patients engage with email-based research invitations in real-world clinical contexts. Our findings suggest that email invitations are an efficient and effective method for reaching a large number of primary care patients. High delivery and open rates suggest that emails sent on behalf of trusted primary care clinics are effective at reaching patients. Moreover, conversion rates indicate that a meaningful proportion of recipients proceeded to survey participation. These findings support the feasibility of email recruitment as a low-burden approach for clinics and research teams. These results lead us to the following observations: (1) email is a highly feasible recruitment method in primary care settings; (2) email makes it possible to reach older patients, but equity issues persist; and (3) commitment varies greatly depending on the clinic, which indicates that the organizational and relational context matters.

We found that a large-scale email campaign using a marketing platform effectively reached a significant number of primary care patients. The high delivery rate of 96.6% (14,758/15,277) is consistent with previous studies [9,18]. Only a few email addresses were incorrect, indicating that patients generally provided valid addresses to their clinic. As expected, reminders were effective for primary care patients recruited by their clinic [10]. Unlike paper questionnaires sent by traditional mail, which remain physically present and serve as a constant reminder, digital questionnaires do not provide a lasting prompt [19]. A high proportion of primary care patients (10,828/14,758, 73.4%) opened the invitation, which is high compared to 35% to 51% rates reported in other studies [20,21]. The average open rate in email marketing campaigns related to health care services sent by the industry is 23% [22]. Within the email marketing industry, open rates above 50% are considered outstanding, typically reflecting the presence of a highly loyal or well-targeted niche audience [23]. This may be attributed to the sender's email address being from a reputable authority (ie, a primary care practice), which could lead patients to perceive it as more relevant [24] and reduce the likelihood of them mistaking our invitation for spam or a fraudulent solicitation. Indeed, participants may hesitate to open emails from unknown or suspicious addresses [9,25]. Additionally, the clinic used a catchy email subject to capture patients' attention, which may have contributed to the high open rate [8]. Targeted email campaigns can also enhance recruitment effectiveness, as all invited patients were directly concerned with the study topic

XSL•FO
RenderX

[26]. This confirms the organizational feasibility of large-scale recruitment campaigns while imposing minimal burden on clinics.

Our email invitations achieved high engagement indicators, successfully engaging more than 1000 primary care patients. The conversion rate of our email recruitment strategy was 9.7% (1430/14,758), which is higher than the rates typically reported in similar studies (2.9%-4%) [9,24,25,27-29]. General email marketing campaigns in Canada average a conversion rate of less than 3% [8]. This may also be attributed to the clear division of materials into sections, allowing patients to quickly assess the relevance and interest of the information provided [18]. Including multimedia elements, such as illustrations and video clips, likely contributed to higher performance [18]. A total of 1512 clicks were recorded on the patient partner video link, which suggests that this content seems to be of interest to patients. Moreover, simply knowing a patient partner was involved in the study and made a video may have reassured some patients and added external validity [30]. However, the study design does not allow conclusions regarding its causal impact on participation. These findings suggest that while cocreation may enhance acceptability and trust, its contribution should be understood as contextual and supportive rather than as a measurable driver of engagement. This strategy, along with the contribution of patient partners in research and recruitment, is highly recommended as best practice guidelines for patient-oriented research [16,31].

The age range of patients who responded to the survey was broad. Notably, patients aged 70 years or older also answered the questionnaire, suggesting that email can be an effective method for recruiting older patients. This observation aligns with the increasing internet use among older adults in Canada over recent years, as the proportion of those aged 75 years or older using the internet rose from 62% in 2020 to 72% in 2022 [32]. The online survey received a higher response rate from women, which is consistent with comparable studies [33-37]. Additionally, because patients were invited if they had an encounter with their health care professional within the previous 6 months, and women tend to consult primary care more frequently than men, this may have led to a higher proportion of women being invited to participate in the survey [28,38]. For ethical and privacy reasons, our team did not have access to the identity of admissible invited patients and, consequently, to their sociodemographic characteristics. We also observed a low number of responses among people of non-White ethnic origin. Due to the unavailability of data on the ethnic origins of the invited patients, it is not feasible to calculate or compare specific response rates by ethnicity. However, the literature suggests that ethnicity may be a source of nonresponse bias [39,40]. Heerman et al [28] observed similar results, finding that technology-enabled recruitment approaches are not the most efficient for enrolling non-White patients. Therefore, it is essential to consider strategies to enhance the participation of these underrepresented groups in health surveys, primarily because it is known that ethnic groups other than White have a less positive primary care experience [41].

Engagement metrics varied substantially across participating primary care clinics, including differences in open rates, click-through rates, and conversion rates. These variations suggest that a strictly standardized recruitment protocol may not be optimal in all primary care contexts. Although a common email template and overall recruitment strategy were used, clinics adapted key implementation elements—such as timing of invitations, number of reminders, and communication practices—to better align with their organizational context and patient population. This adaptability appears necessary to maintain acceptability and feasibility, highlighting that digital recruitment strategies in primary care may benefit from a balance between standardization (to ensure efficiency and comparability) and local tailoring (to reflect clinic-specific realities and patient expectations). These findings emphasize the importance of context-sensitive implementation when deploying digital recruitment approaches in real-world primary care settings.

This study should be interpreted as a formative, implementation-oriented analysis rather than a test of behavioral theory or recruitment effectiveness. The use of descriptive engagement metrics offers actionable information for research teams seeking to monitor, refine, and adapt digital recruitment strategies over time. Future studies could build on this work by incorporating comparative designs, experimental testing of message components, or qualitative inquiry to elucidate mechanisms of engagement further.

Limitations

This study had a few limitations that must be underscored. Ideally, participation invitations would have been sent to all patients across clinics simultaneously, and the time between reminders would have been consistent across clinics, allowing for a deeper exploration of factors influencing response rates across clinics. Ideally, to assess the effect of the various strategies embedded in the email, different versions of the message should have been sent to separate groups of patients (for instance, a plain or less visually appealing email or the same message without the patient partner video). However, within the PaRIS study context, it was not feasible to send potentially less-engaging messages to patients, as the primary goal was to maximize participant recruitment. Due to the PaRIS study's design, objectives, and ethical constraints, we could access only the sociodemographic characteristics of patients who responded to the questionnaire, not those who received the email invitation. Sample representativeness is a major concern, given that only 9.7% (1430/14,758) of the invited patients partially or fully completed the questionnaire. Additionally, staff from some clinics discussed the study with some patients, which may have contributed to a higher conversion rate. However, this intervention was not measured, and its effect cannot be assessed. Our study also revealed variation in indicators across clinics, demonstrating that patients do not all respond similarly to email invitations. These differences may be attributed to the type of clinic (private, public, or university-affiliated) and the characteristics of the patients enrolled in the study. However, our study lacks sufficient power to determine these characteristics.

Conclusions

This formative, descriptive secondary analysis documents the functioning of email-based recruitment in real-world primary care research settings. Using routinely collected engagement metrics, we show that emails sent on behalf of trusted primary care clinics are a feasible and low-burden approach for reaching patients and supporting participation in web-based surveys. These findings offer practical, implementation-oriented insights for research teams seeking scalable recruitment approaches. They can inform the design, refinement, and ongoing monitoring of digital recruitment strategies in future primary care studies.

Acknowledgments

The authors would like to acknowledge Catherine Deschenes for her support in extracting data from the emailing platform reports.

Funding

The Academic Research Chair on Optimal Professional Pratices in Primary Care (grant 2020-2025 to MEP) funded this study, and Health Canada funded the Patient-Reported Indicator Survey (PaRIS)-Canada initiative. The PaRIS-Quebec component was funded by the Réseau en recherche en sciences infirmières, the Réseau-1 Québec, and the Centre intégré universitaire en santé et services sociaux du Saguenay-Lac-Saint-Jean. The funders had no role in the conceptualization, design, data collection, analysis, or other aspects of the study.

Data Availability

The datasets used or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

VTV had the original idea for this manuscript and wrote it. She coordinates the Patient-Reported Indicator Survey (PaRIS) study and is responsible for data collection and analysis in the province of Quebec. MDP is a patient partner and shares responsibility for the study in Quebec. She was involved in designing the invitation template and revising the manuscript. MEP is the study's principal investigator and revised and improved the manuscript. AF is a scientific graphic designer and designed the invitation template and the patient partner video. STW is the principal investigator of the national PaRIS survey in Canada and reviewed the manuscript. All authors approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: mHealth (mobile health) interventions that integrate psychoeducation with structured problem-solving training (PST) hold strong potential for improving self-management of chronic conditions. Evaluating the usability of these interventions requires assessing technological, pedagogical, and sociocultural fit. However, most usability evaluations remain narrowly technocentric, focusing on interface-level metrics while neglecting pedagogical coherence, cultural responsiveness, and patient learning needs.

Objective: This exploratory study aimed to characterize usability challenges and facilitators across 3 psychoeducational mHealth PST interventions and to identify technological, pedagogical, and sociocultural design features that can improve engagement, accessibility, and implementation for diverse users.

Methods: This study used an exploratory, multimethod, collective case study design. Three independent mHealth PST usability studies used structured think-aloud protocols, with sessions conducted remotely via Zoom (Zoom Communications, Inc), except for 1 in-person session for Epilepsy Journey 2.0. A total of 14 participants were enrolled across 3 independent cases via purposive sampling from their respective target populations. Case 1 – Epilepsy Journey 2.0 (n=6; 4 male, 2 female; ages 12 - 18 y; adolescents with epilepsy), case 2 – Survivor's Journey (n=3; 1 male, 2 female; ages 18 - 30 y; adolescent and young adult survivors of brain tumor), and case 3 – electronic problem-solving training (n=5; 2 male, 3 female; ages 30 - 65 y; adults with a history of severe traumatic brain injury). Participants completed a presession technology comfort survey and the Comprehensive Assessment of Usability for Learning Technologies postsession. All sessions were recorded, transcribed, and analyzed thematically. Comprehensive Assessment of Usability for Learning Technologies data were analyzed using descriptive quantitative methods.

Results: Electronic problem-solving training demonstrated the highest usability (mean 87.96, SD 13.73), followed by Survivor's Journey (mean 83.00, SD 7.70), and then Epilepsy Journey 2.0 (mean 79.00, SD 12.75). Findings revealed that usability in health care learning design is shaped by how effectively the technology, learning content, and contextual factors align with patients' needs. Recurring challenges across interventions included unclear navigation, poor mobile responsiveness, instructional ambiguity, insufficient feedback, potential for greater inclusivity, and limited error recovery. Twelve cross-case design principles were derived, emphasizing mobile-first accessibility, cognitive load reduction, context-sensitive feedback, and empathetic, inclusive design.

Conclusions: Usability challenges in mHealth PST interventions arise not only from interface-level issues but also from how effectively the intervention supports users' understanding, decision-making, and real-world application demands. This extends prior mHealth usability research by demonstrating that user difficulties often reflect misalignments between technological features, instructional structure, and the everyday contexts in which individuals engage with PST. The resulting design principles highlight specific, actionable priorities for developers, including mobile-first optimization, clearer task scaffolding, and better feedback

RenderX

and error recovery. Future work should evaluate these principles in larger samples and clinical settings to determine their impact on engagement, adherence, and downstream health outcomes.

Introduction

Background

Digital health interventions have become foundational to modern health care, offering accessible, scalable, and patient-centered models of care [1,2]. Among the most promising are mHealth (mobile health) interventions that integrate psychoeducation with structured problem-solving training (PST). Grounded in social-cognitive and self-regulation frameworks, these interventions equip patients not only with disease-specific knowledge but also with step-by-step strategies for identifying barriers, generating solutions, and applying them to real-world health challenges [3-6]. Across diverse populations, PST-based mHealth interventions have demonstrated consistent benefits, including reductions in depressive and anxiety symptoms, improvements in medication adherence, and increases in caregiver self-efficacy [6-8].

Usability Is Central to the Success of mHealth Interventions

While rigorous, evidence-based design constitutes the methodological bedrock of digital therapeutics, usability, a central dimension of patient experience, is pivotal for uptake and sustained engagement, which in turn mediate clinical effectiveness [9-11]. Usability refers to how effectively, efficiently, and satisfactorily patients can interact with technology to achieve their desired goals [12]. The ISO defines usability as the extent to which a system, product, or service can be used by specified users to achieve a specified goal, encompassing five attributes: effectiveness, efficiency, satisfaction, freedom from risk, and context coverage [13]. Well-designed mHealth interventions that prioritize usability and patients' experiences are more likely to be adopted, maintained, and found beneficial by patients over time [14]. Conversely, poor usability can lead to frustration, disengagement, and abandonment, directly undermining any clinical benefit the intervention might offer [15]. For example, high-school testers in the LIFE4YOUth study reported that poor functionality and difficult navigation made them cease using the app altogether [16], while a systematic review of 60 studies on electronic personal health records and digital mental health tools consistently identifies poor usability as a primary driver of low adoption and high dropout [17,18]. As PST mHealth interventions are complex, serve diverse patient populations, and play a central role in self-management, comprehensive usability evaluations are increasingly regarded as indispensable for designing effective digital tools that support behavior change, chronic disease management, and mental health outcomes [19,20].

General Usability Measures Are Limited for Evaluating mHealth Psychoeducation

Despite growing recognition of usability's importance, most digital health studies rely on general human-computer interaction instruments for usability evaluation [21,22]. The most widely used is the System Usability Scale (SUS) [23], a 10-item questionnaire yielding a composite score from 0 to 100 that captures users' overall perceptions of ease of use and learnability; scores around 50 are generally considered marginal, scores around 70 are considered good, and scores above 85 are considered excellent [24]. Other common instruments include the Computer System Usability Questionnaire [25] and the Software Usability Measurement Inventory [26]. While these tools can efficiently capture surface-level interface mechanics such as ease of use, interface flaws, and navigation flow, they were not designed to evaluate pedagogical alignment, social dynamics, or cultural responsiveness [22,27]. These dimensions are especially important for psychoeducational mHealth interventions, which share structural features with learning technologies (eg, modularized content, formative assessments and feedback, and self-directed practice) and require more than interface usability to support meaningful health behavior change.

Narrowly focused mHealth psychoeducation usability evaluation presents a significant limitation in light of the layered interactions between content, patient needs, and learning objectives in these interventions. Indeed, evidence shows that strong perceived technological usability does not guarantee meaningful impact. In a diabetes self-management study, participants rated the app high on the SUS (mean 80.5, 95% CI 72.3 to 88.7), yet struggled with key tasks, recording the most errors and lowest success rates on activities essential for effective self-management [28]. A pilot randomized trial of an osteoarthritis physical-activity app likewise found acceptable usability ratings (mean 71.3), but found no significant improvement over usual care for most outcomes [29]. Similarly, a usability study of home blood-pressure and pulse-oximeter devices reported satisfactory SUS scores for both a blood pressure monitor (mean 72.4, 95% CI 68.8 to 76.0) and a pulse oximeter (mean 71.52, 95% CI 68.7 to 74.3), despite users making frequent handling errors and some abandoning the devices altogether [30]. These findings illustrate that high usability ratings can coexist with limited learning, behavior change, or health benefits, suggesting a need for more holistic approaches to usability capable of not only evaluating technological aspects, but also aspects such as patient relevance, learning effectiveness, and social acceptability.

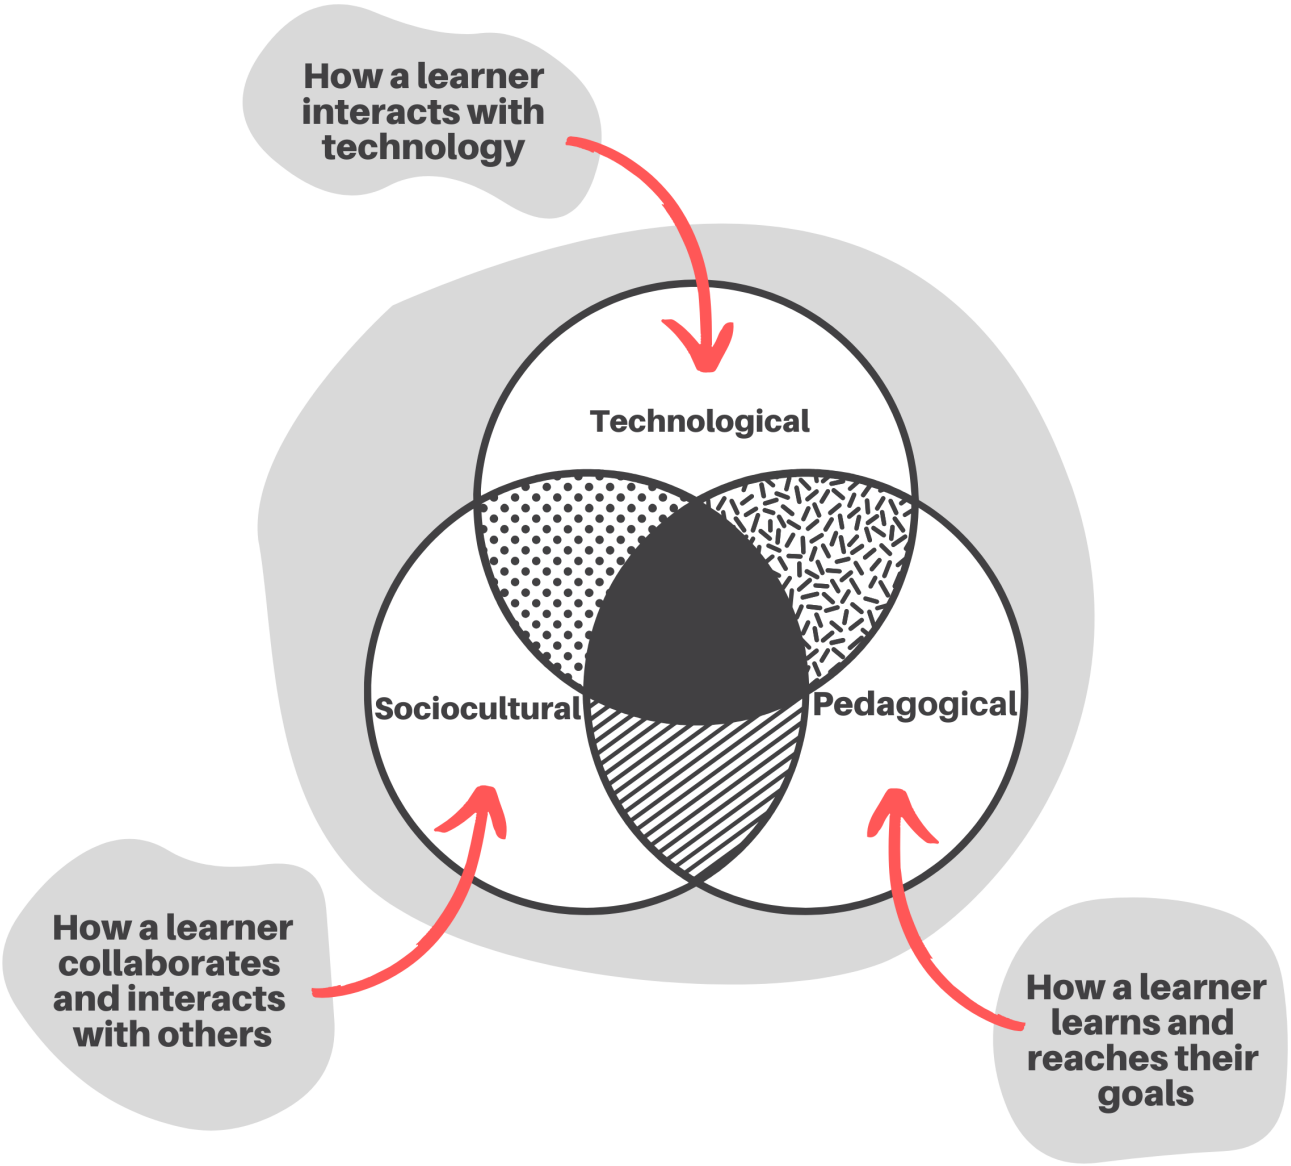
Addressing Usability Gaps in Health Care Learning Design Through Multidimensional Evaluation



Although more comprehensive evaluation frameworks exist, most usability studies in health care learning remain narrowly focused on interface-level metrics. A growing body of research documents this gap and its consequences. A scoping review of 124 digital health tools for individuals with multiple sclerosis found that only 26% conducted usability testing, and among those, the majority used limited metrics [31]. A review of sensor-based health technologies found that while 83% - 91% assessed usability through satisfaction measures, fewer than 7% evaluated efficiency, and only 9% addressed users' ability to interpret clinical data [32]. A broader analysis of 610 digital health usability studies found that nearly half relied solely on the SUS, with little to no attention to accessibility, instructional utility, or cultural fit [33]. Minimal consideration of contextual or educational dimensions has similarly been noted in health IT evaluations [34] and in health care education specifically, where most mobile app usability studies relied on checklists and surveys, rarely assessing whether tools effectively supported learning or improved patient understanding [35]. The consistent absence of pedagogical and contextual considerations in usability evaluations may explain the high abandonment rates observed for health-related digital tools [36-39], and highlights the necessity of frameworks capable of capturing the complex and multifaceted nature of health care learning environments.

Addressing Usability Gaps in Health Care Learning Design Through Multidimensional Evaluation

The sociotechnical-pedagogical framework addresses this gap by conceptualizing usability as a multimodal, emergent property of 3 interdependent dimensions: technological (eg, interface design and navigation), pedagogical (eg, learning activities, instructional clarity, and task relevance), and sociocultural (eg, cultural values, emotional responsiveness, and social norms), rather than as a property of the interface alone. These dimensions interact to shape users' overall experience of a learning system (Figure 1). Importantly, the sociocultural dimension specifically recognizes that emotional responses, cultural backgrounds, and social contexts profoundly influence how individuals engage with and accept health learning technologies [40]. This integrated view is particularly relevant for PST mHealth interventions designed for populations with neurological or neurodevelopmental conditions, where sociocultural context and learning demands are inseparable from technological use.

XSL•FO
RenderX

Figure 1. Sociotechnical-pedagogical usability framework reprinted with permission from Schmidt et al [40].

To translate the sociotechnical-pedagogical framework into actionable usability assessment, Lu et al [41] developed the Comprehensive Assessment of Usability for Learning Technologies (CAUSLT), a validated instrument specifically designed to assess usability across all three sociotechnical-pedagogical dimensions. The CAUSLT was developed and empirically validated through multiple studies in learning contexts, demonstrating strong psychometric properties: exploratory factor analysis confirmed a coherent 3-factor structure aligned with the sociotechnical-pedagogical model (Kaiser-Meyer-Olkin=0.95; Bartlett test P<.001), with excellent overall internal consistency (Cronbach α=.95) and strong subscale reliability (technological α=.92; pedagogical α=.95; sociocultural α=.82) [41].

Study Rationale and Aims

Despite increasing adoption of psychoeducational mHealth interventions, current usability evaluation practices remain technocentric, focused on interface functionality and user satisfaction, while largely neglecting pedagogical coherence and sociocultural responsiveness [31,33-35]. This limitation is particularly problematic for PST interventions, where learning is not incidental but essential to sustained self-management. The purpose of this collective case study, therefore, is to examine how usability is experienced and manifested across technological, pedagogical, and sociocultural dimensions within 3 psychoeducational PST mHealth interventions. Anchored in the sociotechnical-pedagogical framework [21] and its sociocultural extension [40], and operationalized using the CAUSLT evaluation instrument [41], this study identifies core design principles and recurring usability challenges, with the goal of informing more holistic, patient-centered approaches to digital health design.

Research Questions

The following were the research questions (RQs):

1. How do participants perceive usability across technological, pedagogical, and sociocultural dimensions within mHealth PST interventions?
2. What recurring technological, pedagogical, and sociocultural usability challenges emerge across the three mHealth PST case studies?

XSL•FO
RenderX

3. What design principles can be derived from cross-case patterns in participants' usability experiences?

Methods

Research Design Overview

This study used an exploratory, multimethod, collective case study design [42] in which 3 independently developed psychoeducational mHealth PST interventions were evaluated through structured think-aloud usability sessions. Each of the 3 cases (Epilepsy Journey 2.0, Survivor's Journey, and electronic problem-solving training [ePST]) constituted an independent usability study with its own participant cohort, recruitment context, and data collection procedures. Findings from individual cases were subsequently examined together to identify recurring usability challenges and cross-case design principles. The multimethod approach integrated qualitative think-aloud usability data as the primary analytic source, and quantitative descriptive data from the CAUSLT instrument provided complementary, descriptive usability metrics for triangulation. Consistent with the exploratory and descriptive nature of this study, no inferential statistical tests were conducted across cases, and findings should be understood as preliminary.

Intervention Descriptions

Overview

Three mHealth PST interventions evaluated in this study were independently developed for distinct clinical populations and are described below. While each intervention was developed separately, they share several core foundational features related to the structure and delivery of PST [4]. Each intervention implements the core ABCDE (Assess, Brainstorm, Consider and Choose, Develop, and Evaluate) problem-solving sequence, with ePST adding the F (Flex; ABCDEF [Assess, Brainstorm, Consider and Choose, Develop and Do, Evaluate, and Flex]) step. In addition, all interventions incorporate guided coaching components in certain conditions. Table 1 illustrates design overlaps across interventions.

Table . Common features across interventions.

Feature	Epilepsy Journey 2.0	Survivor's Journey	ePST[a]
Clinical population	Adolescents with epilepsy	Adolescent and young adult survivors of brain tumors	Adults with a history of TBI[b]
PST[c] Framework	ABCDE[d]	ABCDE	ABCDEF[e] (additional Flex step)
Delivery Format	Mobile and web-based modules	Web-based modules	Mobile and web-based modules
Coaching Support	Therapist session	Therapist session	Coach session
Session Structure	10 themed virtual lands, each representing an instructional module	8 learning modules, with supplemental modules	5 learning modules, short lessons with problem-solving prompts
Learning Focus	Executive functioning support	Coping and daily functioning	Independent problem-solving and self-efficacy

[a]ePST: electronic problem-solving training.

[b]TBI: traumatic brain injury.

[c]PST: problem-solving training.

[d]ABCDE: Assess, Brainstorm, Consider and Choose, Develop, and Evaluate.

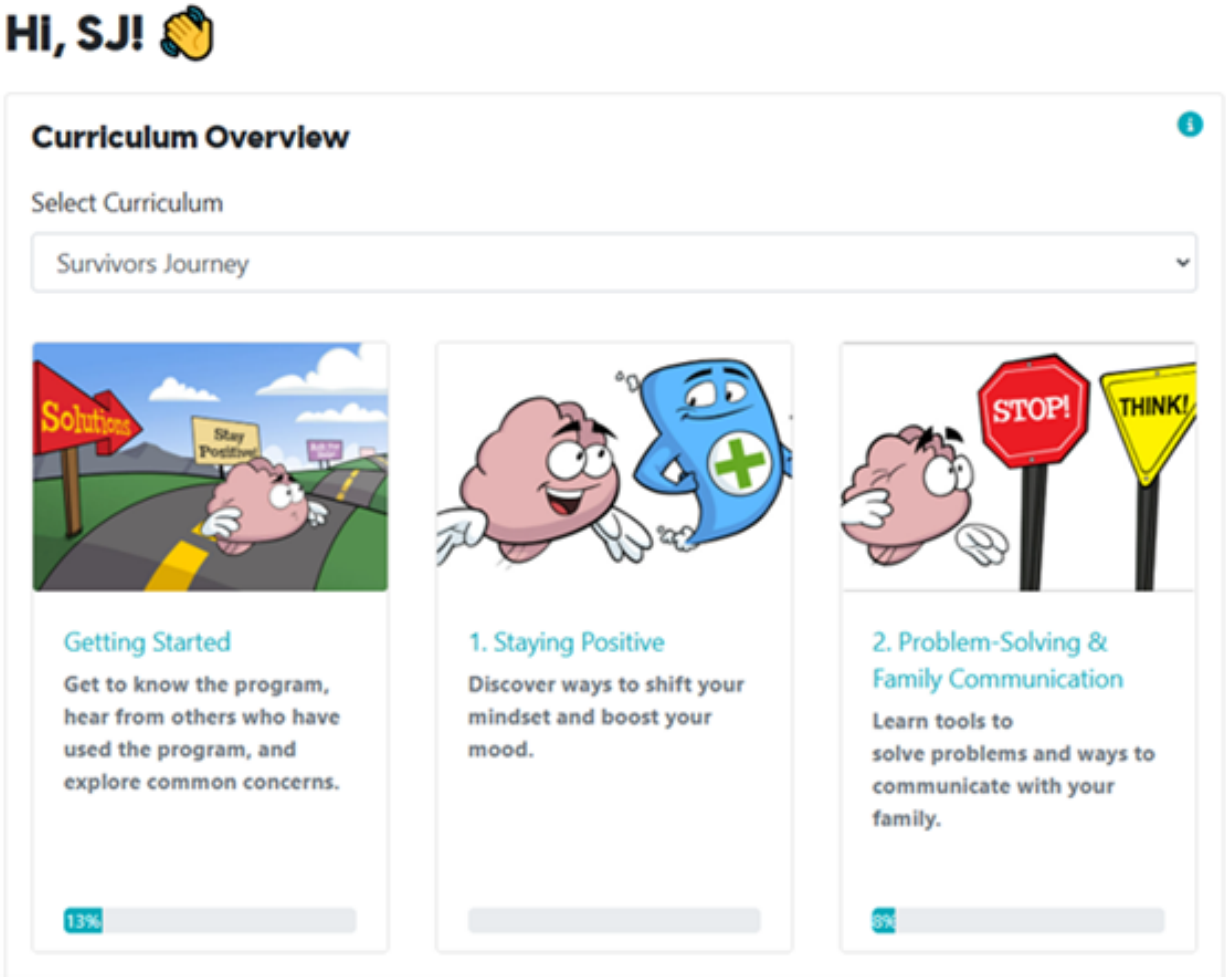
[e]ABCDEF: Assess, Brainstorm, Consider and Choose, Develop and Do, Evaluate, and Flex.

Case 1: Epilepsy Journey 2.0

Epilepsy Journey 2.0 is a web-based, mHealth PST intervention designed to support adolescents with epilepsy who experience executive functioning difficulties (Figure 2). The intervention includes multimedia instruction, short interactive tasks, and scaffolded guidance to support self-regulation, planning, and problem-solving skills. Instruction includes a 5-step problem-solving sequence using the "ABCDE" mnemonic. Content is organized using a "journey" metaphor, in which users progress through 10 themed virtual lands, each representing an instructional module related to executive functioning [43,44].

XSL•FO
RenderX

Figure 2. Epilepsy Journey 2.0 interface.

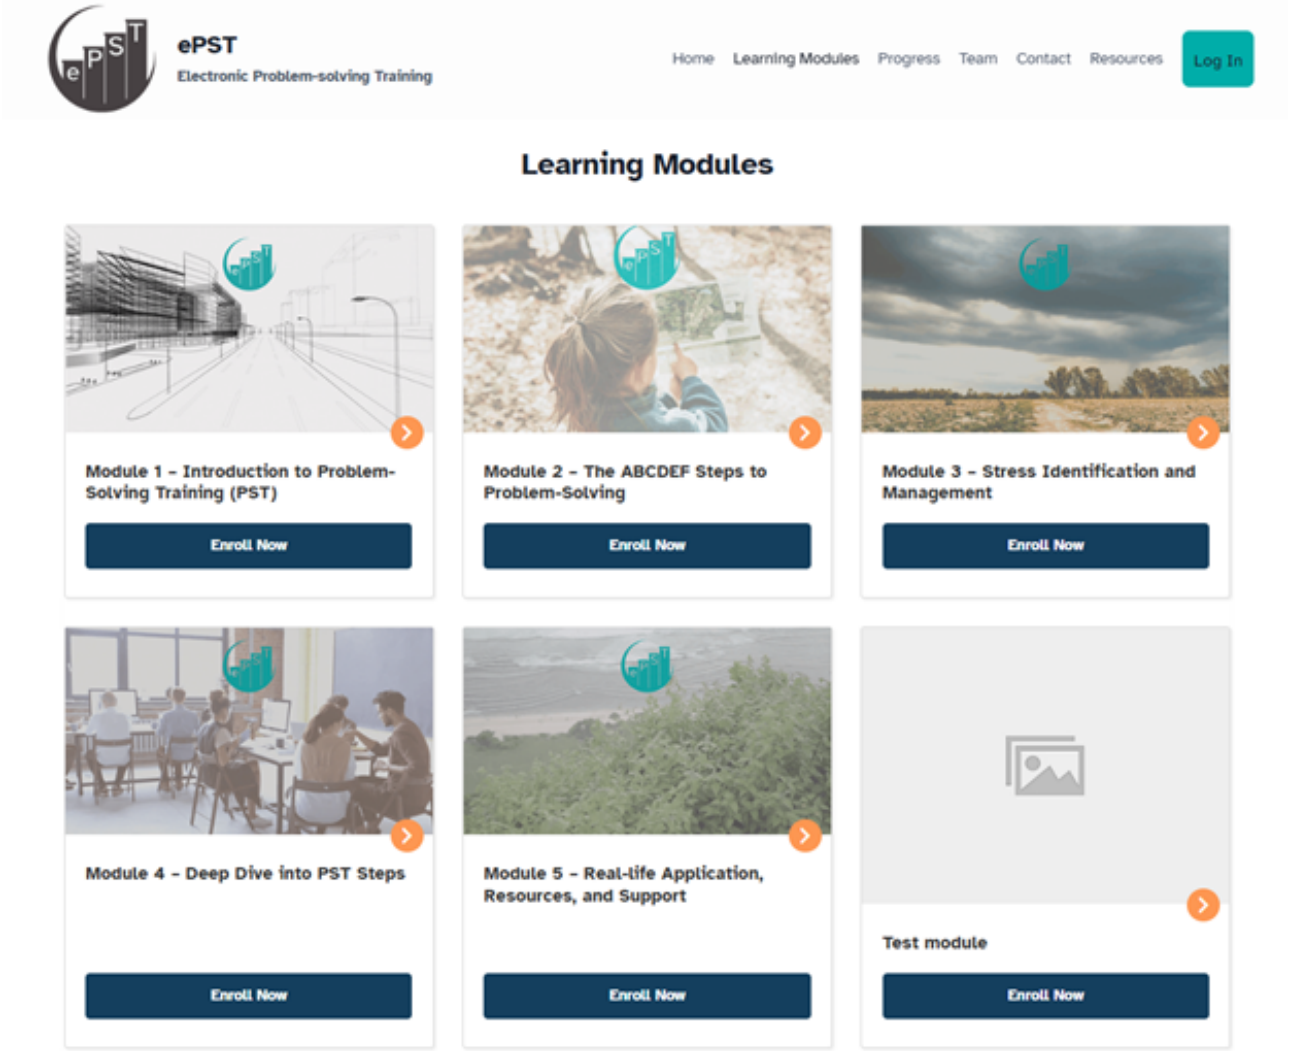


Case 2: Survivor's Journey

Survivor's Journey is a web-based psychosocial intervention designed to provide problem-solving therapy and coping skills training for adolescent and young adult survivors of brain tumors (Figure 3). It delivers PST-based coping and adjustment strategies through interactive multimedia lessons, therapist-supported sessions, and tailored problem-solving activities. The problem-solving sequence also adopts the "ABCDE" mnemonic. Modules focus on managing late effects, emotional regulation, fatigue, and everyday functional challenges among adolescent and young adult survivors of pediatric brain tumors. Instruction is structured through a stepwise problem-solving framework and emphasizes real-world applicability using developmentally appropriate scenarios. The platform has undergone feasibility and preliminary efficacy testing [45].

XSL•FO
RenderX

Figure 3. Survivor's Journey interface.



Case 3: ePST

ePST is a self-guided mHealth PST intervention for adults with a history of traumatic brain injury (TBI) with sustained loss of consciousness (characterized as "severe"; Figure 4). ePST builds on a traditional problem-solving framework by adapting it into an interactive, digital format to enhance accessibility and autonomy for users. The program teaches a 6-step problem-solving sequence using the "ABCDEF" mnemonic. Content is delivered through short lessons, interactive decision points, personal examples, and initial guidance from a coach to support users in applying PST strategies independently and at their own pace. Recent development work has described its person-centered adaptation process and community-based participatory design components [46,47].

Participant Characteristics

A total of 14 participants were enrolled across the 3 usability studies. Table 2 presents participant characteristics by case, while Figure 5 presents the participant flowchart.

XSL•FO
RenderX

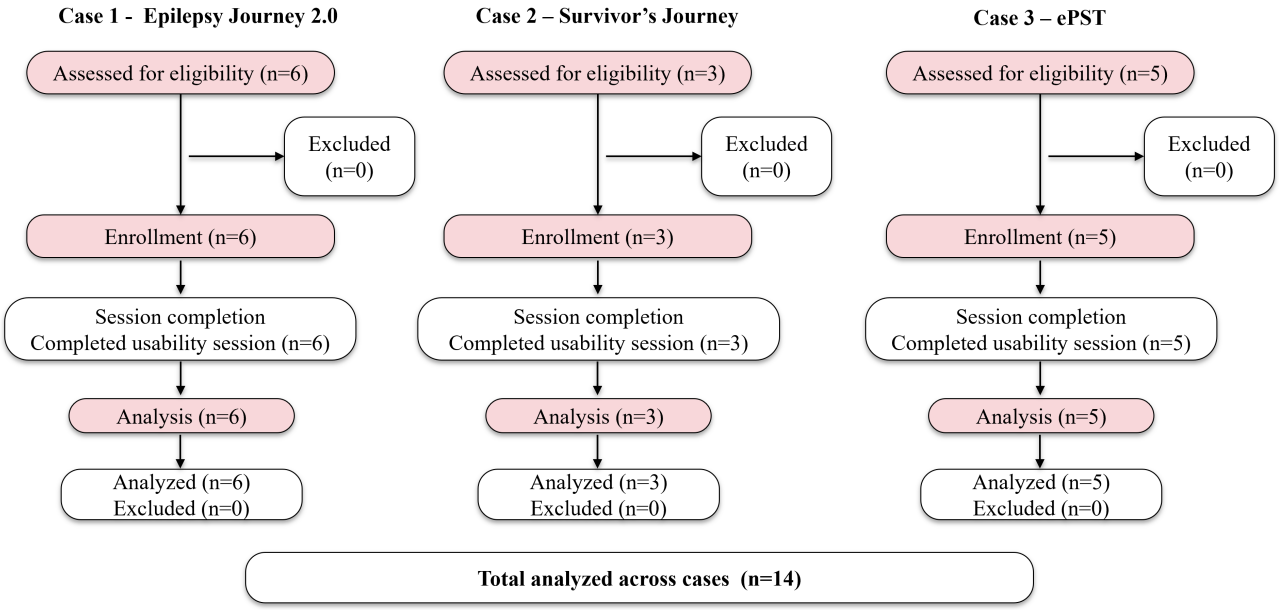

Table . Participants' characteristics and recruitment parameters.

Case	mHealth intervention	Participants, n	Recruitment parameters
1	Epilepsy Journey 2.0	6 (*M*=4, *F*=2)	Adolescents living with epilepsy who were able to navigate a digital platform and provide verbal feedback.
2	Survivor's Journey	3 (*M*=1, *F*=2)	Young adult survivors of brain tumors who were able to participate in remote usability testing and provide feedback on usability, navigation, and support for learning and coping goals.
3	ePST[a]	5 (*M*=2, *F*=3)	Adults who had sustained a severe TBI[b] 11 to 20 years prior and who were able to participate in a virtual session independently

[a]ePST: electronic problem-solving training.

[b]TBI: traumatic brain injury.

Figure 5. Participants flowchart. ePST: electronic problem-solving training.

Inclusion and Exclusion Criteria

Participants were recruited from the intended user populations for each respective intervention. Inclusion and exclusion criteria were defined at the case level. For case 1 (Epilepsy Journey 2.0), eligibility included adolescents with a confirmed clinical diagnosis of epilepsy who were able to access and navigate a web-based digital platform and provide verbal feedback during a usability session. For case 2 (Survivor's Journey), eligibility included young adults aged between 18 and 30 years with a documented history of pediatric brain tumor survivorship who were able to participate independently in a remote usability session and provide verbal feedback on platform navigation, learning content, and problem-solving supports. For case 3 (ePST), eligibility included adults with a documented history of severe TBI occurring 11 to 20 years before participation who were able to engage independently in a virtual session and had access to a personal smartphone or computer with internet connectivity.

Across the 3 cases, participants were excluded if they were unable to complete at least one assigned module during the usability session, could not provide verbal feedback, or lacked the technical access required to participate. No additional clinical exclusion criteria were applied beyond the diagnostic and functional requirements specified for each case in the preceding paragraph.

Sampling Procedures and Participant Recruitment

Purposive sampling was used across all 3 case studies, with participants selected for their direct experiential relevance to the intended user populations of each mHealth PST intervention. This approach was appropriate given the exploratory nature of the study and the goal of obtaining usability feedback from individuals with lived experience relevant to the interventions being evaluated [48].

XSL•FO
RenderX

Case 1 participants (n=6) were recruited through an existing advisory board established as part of the Epilepsy Journey 2.0 development process at Cincinnati Children's Hospital Medical Center (CCHMC). The advisory board comprised adolescents and young adults with epilepsy, their caregivers, health care providers, and educators. Usability participants were drawn from the adolescent member subset of this board. Case 2 participants (n=3) were recruited through clinical and research networks at CCHMC, including the pediatric neuro-oncology program. Eligible young adult survivors of brain tumor were identified by the clinical research team and invited to participate via direct outreach. Case 3 participants (n=5) were recruited through clinical and research settings affiliated with UT (University of Texas) Health Houston and TIRR (The Institute for Rehabilitation and Research) Memorial Hermann. Recruitment materials were shared within these medical center settings, and individuals who expressed interest were screened for eligibility based on TBI history and functional capacity to participate independently.

The sample sizes were determined by the independent protocols, recruitment timelines, and feasibility constraints of each respective usability study. In formative usability research, relatively small samples are commonly used for problem discovery, with foundational studies showing that the first 4 to 5 participants often identify a substantial proportion of major usability problems [49-51]. At the same time, later work has cautioned that 5 users should not be treated as a universal rule, because larger samples improve stability and increase the proportion of problems detected, particularly when systems or user groups are more heterogeneous [52]. Consistent with this broader literature, recommendations for usability studies in health-related digital systems commonly place formative samples in the range of approximately 5 to 10 participants, with larger samples warranted when interface complexity or user diversity is greater. On this basis, the sample sizes for case 1 (n=6) and case 3 (n=5) were considered appropriate for identifying prominent usability issues within their respective intervention contexts, whereas the smaller sample in case 2 (n=3) is interpreted more cautiously and its findings are presented as preliminary.

Measures and Instruments

Quantitative data were collected from two sources: (1) a brief preassessment questionnaire evaluating participants' general technology comfort and familiarity with digital learning platforms, and (2) the CAUSLT scale. For the technology comfort assessment, participants responded to a five-item Likert-type technology comfort survey. It comprised five items which assessed: (1) frequency of eHealth app use; (2) general comfort with digital technology; (3) comfort using digital health or educational tools specifically; (4) confidence navigating new mHealth platforms; and (5) prior experience with interventions similar to the one being tested. Each item was rated on a 5-point scale (1=not at all comfortable/experienced to 5=extremely comfortable/experienced). Responses were summarized using descriptive statistics across all participants. For CAUSLT, the instrument comprises 20 items rated on a 5-point Likert scale (1=strongly disagree to 5=strongly agree), organized into 3 subscales aligned with the sociotechnical-pedagogical framework [41]. Item scores were averaged within each subscale and converted to a 0 - 100 standardized scale to facilitate interpretation and cross-subscale comparison.

Ethical Considerations

The 3 studies reported in this paper were reviewed and approved by the appropriate institutional review boards (IRBs). The Epilepsy Journey 2.0 and Survivor's Journey studies were approved by the CCHMC IRB (Federalwide Assurance #00002988). Epilepsy Journey 2.0 recruited an advisory board of adolescents/adults, caregivers, health care providers, and teachers. For the purpose of this study, only adolescents who completed usability testing were included. Due to the advisory board nature, only an agreement form was signed, and participation implied consent, as they were considered consultants, not participants. Survivor's Journey followed the same institutional review requirements and received CCHMC IRB approval under protocol 2024 - 0546. The ePST usability study was reviewed by the University of Georgia Human Research Protection Program (IRB #00009943) and was deemed exempt under federal guidelines.

All participants provided written informed consent before data collection. For remote sessions, consent was obtained electronically using Qualtrics; for in-person sessions, consent was documented via approved parental permission, assent, or adult consent forms, as required. Consent documents described study procedures, audio or video recording, risks and benefits, voluntary participation, HIPAA (Health Insurance Portability and Accountability Act) authorization where applicable, and data handling. All data were deidentified before analysis and stored on encrypted institutional servers with access restricted to authorized research personnel. Raw recordings and master linking files will be destroyed at the conclusion of each study. Participants in the ePST study received US $25 per session. Advisory board members in Epilepsy Journey 2.0 were compensated US $50 per advisory board meeting they participated in (up to 3 meetings). Participants in the Survivor's Journey usability study received US $50. No identifying information is presented in this paper or supplementary materials.

Data Collection Procedures

Overview

Usability testing was conducted across the 3 mHealth PST interventions between June 2024 and July 2025. Across all studies, participants completed a structured think-aloud session in which they interacted with selected modules of their assigned intervention, followed by a postsession CAUSLT survey and a presession technology comfort survey. Sessions were conducted remotely via Zoom, except for 1 in-person session for Epilepsy Journey 2.0. A standardized "think-aloud" protocol was used, including facilitator-led introductions, verbal consent, verbal reflection prompts, and observational note-taking. All sessions were audio- and video-recorded and transcribed for analysis.

Case Study 1: Epilepsy Journey 2.0

Conducted in June and August 2024 (n=6; 5 remotely and 1 in person), this study evaluated ease of use, interface design,

XSL•FO
RenderX

content delivery, and interactive features. Participants explored the platform, completed 1 assigned module focused on memory or problem-solving, and provided feedback through verbal protocols.

Case Study 2: Survivor's Journey

Conducted remotely in June and July 2025 (n=3), this study assessed navigation, functionality, and problem-solving support features. Participants explored the platform by completing account sign-up and landing-page tasks, followed by working through a learning module and using the problem-solving tools.

Case Study 3: ePST

Conducted remotely in July 2024 (n=5), this study evaluated the introductory and advanced modules focused on the problem-solving strategies. Each participant completed 2 assigned lessons addressing the full "ABCDEF" problem-solving strategy. Participants accessed the platform via personal smartphones (1 participant used a personal computer) and were prompted to reflect on both ease of use and learning support.

Data Analysis

Quantitative Data Analysis

Quantitative data were analyzed using descriptive statistics appropriate to the exploratory and small-sample nature of each case study. No inferential statistical tests were conducted, and no α level was set. CAUSLT item scores (rated 1 - 5) were converted to a standardized 0 - 100 scale by averaging item responses within each subscale and rescaling proportionally ((mean−1)/4×100). Case-level subscale means and overall usability means were calculated by averaging participant-level standardized scores within each intervention. Technology comfort survey data were analyzed using descriptive statistics (frequencies and percentages) and reported at the case level to contextualize participants' baseline familiarity with digital tools. Regarding missing data, complete CAUSLT and technology comfort survey data were obtained from all 14 enrolled participants. No item-level missing data were identified in any case.

Qualitative Data Analysis

The qualitative component of the study followed established usability testing procedures rather than thematic coding approaches. Session recordings, think-aloud verbalizations, and observer field notes served as the primary qualitative data sources. A semistructured, task-based usability protocol guided each session, during which participants completed a series of predefined tasks while thinking aloud and sharing their screens. Tasks targeted both technological usability (eg, navigation and multimedia interaction) and pedagogical usability (eg, clarity of content and instructional structure).

Transcripts generated from Zoom's automated transcription tool were reviewed for accuracy and used alongside field notes to identify instances where participants encountered navigation difficulties, misunderstandings, or breakdowns in task flow. Two trained members of the research team independently reviewed and discussed each usability session to document observed usability barriers and to verify that identified issues were grounded in direct participant behavior rather than interpretive coding. The team collaboratively reviewed usability issues and assigned severity ratings using the Nielsen 5-point severity framework [53], which categorizes usability problems as: 0=not a usability problem; 1=cosmetic problem only (need not be fixed unless time allows); 2=minor usability problem (low priority to fix); 3=major usability problem (important to fix, high priority); and 4=usability catastrophe (imperative to fix before product release). Disparities in ratings were discussed until consensus was reached. In the case that consensus could not be reached within the research team, the faculty advisor was consulted. This only occurred once, with an issue related to the loading time of 1 video. Representative usability issues and corresponding severity ratings are provided in Multimedia Appendix 1. All team members who participated in usability data analysis received training in applying the Nielsen severity scale as part of the research group's standard usability research training procedures, including review of criteria definitions, worked examples, and calibration exercises before the study. Efficiency-related data, such as time on task and error rates, were extracted from session recordings and incorporated into the analysis. Findings were summarized in structured usability reports for each intervention.

Results

Overview

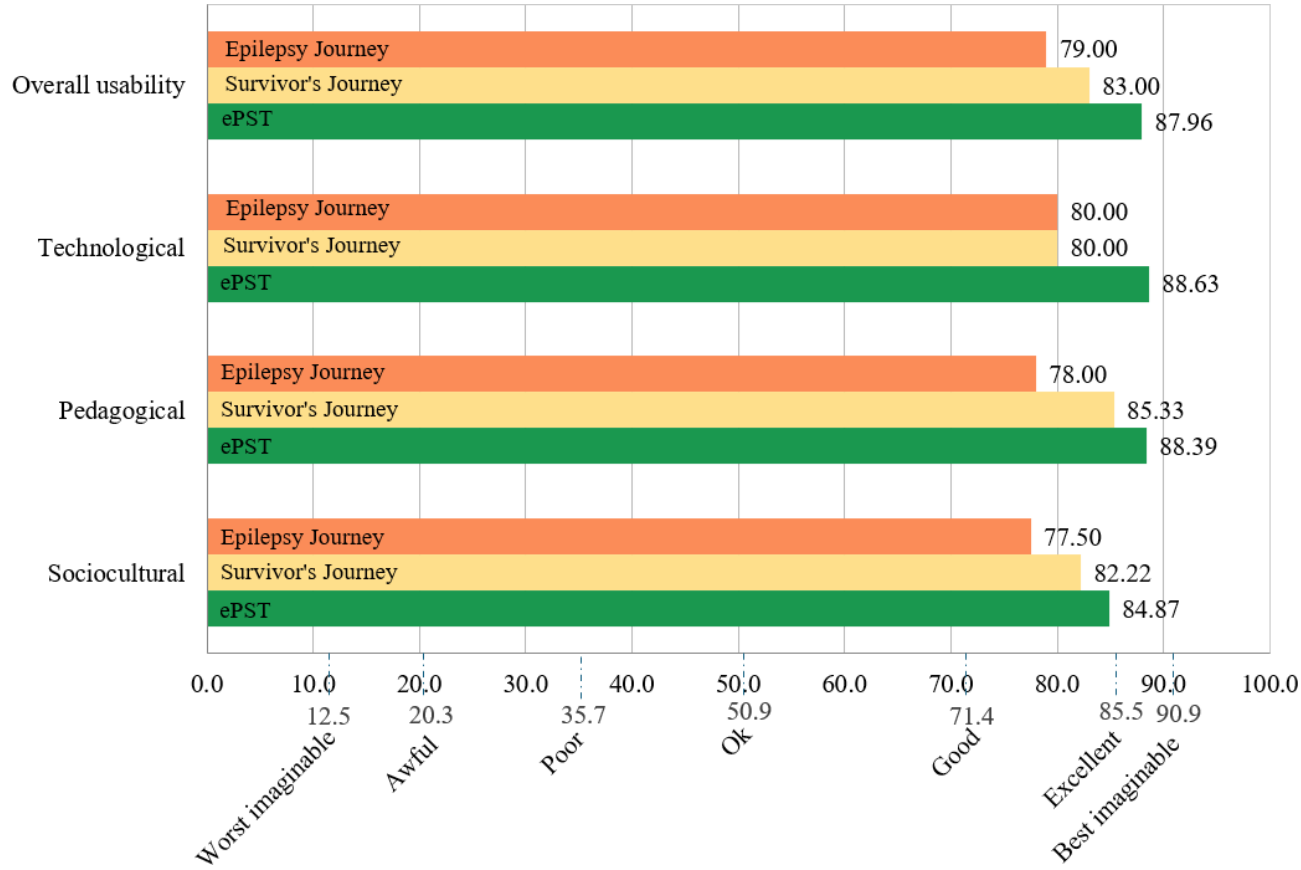
This section presents findings from the exploratory usability evaluation across the 3 case studies. No cross-case statistical comparisons were made. Quantitative findings are reported descriptively and interpreted within the context of each case. First, participants' technology comfort levels are summarized to contextualize subsequent usability findings. Next, CAUSLT results are reported for overall usability and for the technological, pedagogical, and sociocultural dimensions aligned with the sociotechnical-pedagogical framework. Finally, we highlight recurring usability challenges and corresponding design principles that emerged in relation to these dimensions.

RQ1: How Do Participants Perceive Usability Across Technological, Pedagogical, and Sociocultural Dimensions Within mHealth PST Interventions?

Participants' Technology Comfort Levels

Participants reported varied levels of technology comfort across the 3 interventions. In Epilepsy Journey 2.0, half of the participants (3/6, 50%) identified as experienced technology users; in ePST, 3 of 5 (60%) participants did so; and in Survivor's Journey, two-thirds (2/3, 66.7%) of participants also identified as experienced users. Most participants reported feeling comfortable using technology both in general and for health or educational purposes, including 83.3% (5/6) of participants in Epilepsy Journey 2.0, 100% (3/3) of participants in Survivor's Journey, and 60% (3/5) of participants in ePST. Prior experience with eHealth or digital health tools varied, with the majority in each intervention indicating occasional use. Confidence using technology independently ranged from slightly confident to very confident across all interventions. Detailed

XSL•FO
RenderX



case level technology comfort responses are provided in Multimedia Appendix 2.

CAUSLT Results

Overall Usability

Figure 6 displays average CAUSLT scores across the 3 mHealth PST interventions. Scores are reported on a standardized 0 to 100 scale. All 3 interventions received overall mean scores in the upper range of the scale, indicating generally high participant agreement that the interventions exhibited usability characteristics across the measured dimensions. ePST received the highest overall mean score (87.96, SD 13.73), reflecting consistently high participant agreement across technological, pedagogical, and sociocultural dimensions. Survivor's Journey and Epilepsy Journey 2.0 received an overall mean score of 83.00 (SD 7.70) and 79.00 (SD 12.75), respectively, reflecting similarly strong overall agreement.

Figure 6. Average Comprehensive Assessment of Usability for Learning Technologies scores across the 3 mHealth (mobile health) interventions based on sociotechnical-pedagogical dimensions. ePST: electronic problem-solving training.

Technological Usability

Technological usability was assessed using the 7 technological CAUSLT items (Figure 7). ePST received the highest technological mean scores, reflecting strong participant agreement across items related to ease of navigation and functional clarity. Additionally, Epilepsy Journey 2.0 and Survivor's Journey both received technological mean scores in the upper portion of the scale, with somewhat lower agreement on items related to navigation clarity and user control. These items reflected areas in which participants indicated difficulty understanding interface structure or completing tasks without assistance, suggesting room for technological improvement in both cases.

Pedagogical Usability

Pedagogical usability results are shown in Figure 8. ePST received high mean scores across items reflecting instructional support, content clarity, and learning goal alignment. Epilepsy Journey 2.0 received high mean scores, particularly for items related to engagement and satisfaction, with slightly lower agreement on items concerning instructional clarity and guidance. Survivor's Journey showed consistently strong pedagogical usability, with high mean scores for learning goals, engagement, and pacing, and slightly lower ratings on items related to instructional support and content quality.

Figure 7. Technology usability of 3 interventions. ePST: electronic problem-solving training.

XSL•FO
RenderX

Figure 8. Pedagogical usability of three interventions. ePST: electronic problem-solving training.

XSL•FO
RenderX

Sociocultural Usability

Sociocultural usability was assessed using 3 CAUSLT items focused on inclusivity, lack of prejudice, and opportunities for social interaction (Figure 9). ePST received high mean sociocultural scores, with slightly lower agreement on whether the intervention could be used by a wide range of learners. Survivor's Journey also demonstrated predominantly excellent sociocultural usability, particularly for perceptions of safety and opportunities for social interaction, with somewhat lower mean scores on items related to accommodating diverse users. Epilepsy Journey 2.0 received somewhat lower mean sociocultural scores relative to the other 2 cases, with greater variability across items and more neutral responses regarding social interaction and inclusivity. These scores indicate that participants experienced fewer supports for resolving errors or receiving corrective guidance in this intervention.

RQ2: What Recurring Technological, Pedagogical, and Sociocultural Usability Challenges Emerge Across the 3 mHealth PST Case Studies?

Overview

The think-aloud sessions and field notes across all 3 case studies yielded a set of preliminary usability challenges that appeared with some consistency across interventions, participants, and sociotechnical-pedagogical dimensions. Representative usability challenges and their associated Nielsen severity ratings are summarized in Multimedia Appendix 1. These challenges are organized below by dimension.

Technological Usability Challenges

Overview

Participants across all 3 interventions identified recurring technological difficulties, including unclear navigation structures, technical performance issues, limited mobile compatibility and readability, confusing progress indicators, and problematic visual design and layout.

Inconsistent and Confusing Navigation Structures

Participants frequently reported uncertainty about how to proceed within modules. In Epilepsy Journey 2.0, a participant stated, “I found it unclear how to start and navigate through the modules and was confused about what button to select at the end of a module.” In ePST, a participant (Pe3) described unexpected behavior when using arrow-based navigation. Similarly, all participants in Survivor’s Journey reported navigation confusion due to misleading labels and screen indicators that did not accurately match where they were in the modules. For example, 1 participant (Ps2) noted that “the system sometimes displays ‘Session Content’ even when I am still on the Start page, and I’m not sure whether clicking Save or Next will complete a task or simply store my progress.”

Poor Mobile Responsiveness and Technical Glitches

Participants noted difficulties when accessing the interventions on smartphones, including slow loading and multimedia glitches. In ePST, a participant (Pe5) remarked, “The video didn’t load properly, and it caused confusion for me.” In Survivor’s Journey, participants encountered system glitches that disrupted smooth task completion. These included the “site tour” repeatedly appearing even after completion and certain features such as the AI-supported Refine button being positioned in ways that made them effectively hidden or difficult to locate.

Lack of Clear Progress Tracking

Participants in Epilepsy Journey 2.0 and Survivor’s Journey reported uncertainty about task completion status, stating that it was not always clear whether activities were finished or how far along they were within a module.

Pedagogical Usability Challenges

Overview

Participants reported several pedagogical issues related to how the interventions supported learning, cognitive engagement, and instructional flow. Key issues included instructional ambiguity, sequencing gaps, information overload, and limited feedback.

Instructional Ambiguity and Sequencing Gaps

Participants across interventions described uncertainty about intended next steps. In Epilepsy Journey 2.0, a participant (Pj5) stated, “I wasn’t sure whether I was supposed to read or click.” ePST participants reported difficulty recalling and following multistep instructions after completing videos. Survivor’s Journey users described similar uncertainty regarding task order and inconsistent message design.

Dense Content Affecting Working Memory

Participants in Epilepsy Journey 2.0 and Survivor’s Journey noted that some pages contained dense text or tightly condensed content that was challenging to process. A participant in Survivor’s Journey (Ps1) explicitly struggled with poor message design regarding text hierarchy and reported confusion caused by redundant and repetitive messages, while Epilepsy Journey 2.0 participants commented on sections being “too wordy.”

Limited Feedback and Progress Cues

Across interventions, several participants expressed uncertainty about whether their actions had been recorded or whether they had completed tasks. Epilepsy Journey 2.0 users noted difficulty determining module completion status, and ePST participants occasionally interpreted badges as indicators of progress. Survivor’s Journey participants also reported uncertainty about overall progress, as they could not distinguish between the progress bar and actual lesson completion.

Sociocultural Usability Challenges

Overview

Participants identified sociocultural concerns related to emotional sensitivity, inclusivity, representational authenticity, and error recovery.

Content Sensitivity and Emotional Impact

In Epilepsy Journey 2.0, a participant (Pj4) expressed concern about a flashing background and questioned, “if it was intended to cause seizures.” In ePST, a participant reported that the orange color scheme was intimidating, and a motivational quote felt misaligned with their expectations as a user with a brain injury. In Survivor’s Journey, 1 participant (Ps1) expressed that the website’s name did not clearly communicate that the intervention was designed for survivors of pediatric brain tumors, which lessened her confidence in its relevance and purpose.

Accessibility and Inclusivity Beyond Technical Features

Participants noted that mobile display challenges affected readability and ease of use for individuals relying exclusively on smartphones. These concerns extended beyond technological accessibility, reflecting broader needs for inclusive visual, cognitive, and layout design.

Relevance and Relatability of Content and Narratives

In ePST, a participant (Pe5) commented that “someone in the lesson does not appear to be brain injured,” raising questions

XSL•FO
RenderX

about the perceived visual authenticity of character portrayals. In contrast, participants in Epilepsy Journey 2.0 noted that characters and testimonials felt relatable.

Lack of Support for Error Recovery and Comprehension Feedback

Participants across cases expressed interest in clearer explanations when answers were incorrect or when navigation errors occurred. For example, a participant in Epilepsy Journey 2.0 (Pj4) stated that understanding "why an answer was wrong would be helpful for learning and retention."

RQ3: What Design Principles Can Be Derived From Cross-Case Patterns in Participants' Usability Experiences?

Cross-case analysis of participants' usability experiences resulted in a set of preliminary design considerations that appeared with directional consistency across the 3 mHealth PST interventions. These considerations were organized into technological, pedagogical, and sociocultural categories to align with the multidimensional structure of the CAUSLT and the broader sociotechnical-pedagogical framework. Table 3 presents the resulting design principles, each linked to observed usability challenges and participant-reported needs.

Table . Usability-driven design principles that emerged across 3 mHealth[a] PST[b] interventions.

Dimension and design principle	Description
Technological	
Intuitive, consistent navigation	Use clear labeling, standardize button behavior, and ensure directional cues are predictable to reduce confusion and improve wayfinding.
Mobile-first design	Optimize layout, font size, multimedia compatibility, and interaction design specifically for smartphone use, particularly for users with no access to a desktop.
Transparent progress tracking	Provide clear, visual indicators of task and module completion to help users track their learning and reduce frustration.
In-platform troubleshooting support	Include tooltips, guided walkthroughs, or pop-ups to help users recover from errors and reduce reliance on external help.
Pedagogical	
Clear instructional guidance	Use explicit instructions, consistent "next step" cues, and scaffolded transitions to guide learners through the intervention without ambiguity.
Reduce cognitive overload	Break up long text blocks, use visual hierarchy, and incorporate multimedia to improve comprehension and decrease fatigue.
Context-sensitive feedback and completion cues	Provide immediate, relevant feedback and clear visual indicators of progress or task completion to reinforce engagement and comprehension.
Use narrative and interactive learning strategies	Incorporate relatable characters, scenarios, or gamified interactions to enhance learner connection and motivation.
Sociocultural	
Safety-conscious and empathetic design	Avoid triggering visuals (eg, flashing), intimidating color schemes, or emotionally insensitive language; test content with end users.
Universal accessibility and flexibility	Design with inclusive features such as adjustable font size, high contrast, and alternative inputs to accommodate diverse users and contexts.
Authentic, relatable content	Include stories, testimonials, and characters that reflect the lived experiences, language, and identities of the target user population.
Provide feedback for error recovery and reflection	Offer explanatory feedback on incorrect answers and missed actions to foster user confidence, learning, and self-efficacy.

[a]mHealth: mobile health.

[b]PST: problem-solving training.

Discussion

Principal Findings

This exploratory study aimed to examine how usability manifests across technological, pedagogical, and sociocultural dimensions within 3 mHealth PST interventions and to identify recurring issues within and across cases that influence patient learning and engagement. Using the sociotechnical-pedagogical framework as an analytic lens, the findings reveal how these dimensions interact to shape user experience and highlight observations regarding challenges within each case. Within and across cases, quantitative CAUSLT findings indicated generally high perceived usability, alongside meaningful variability across dimensions and interventions that highlighted specific areas for improvement. Complementing these findings, qualitative think-aloud data and observational field notes revealed a recurring set of usability challenges spanning navigation

XSL•FO
RenderX

ambiguity, limitations in mobile responsiveness, instructional uncertainty, cognitive overload, insufficient feedback, and condition-specific sociocultural concerns. Despite differences in clinical populations and intervention design, these challenges exhibited notable directional consistency across cases. Synthesis of observations within each case further yielded 12 preliminary design principles organized along sociotechnical-pedagogical dimensions and grounded in observed user behaviors. In the following sections, we discuss key insights associated with each RQ. We conclude by reviewing the study's limitations and outlining implications for future mHealth learning design and evaluation.

RQ1: Participants' Perceptions of Usability Across Technological, Pedagogical, and Sociocultural Dimensions

Across all 3 interventions, participants' perceptions suggested that technological, pedagogical, and sociocultural usability operate as mutually reinforcing dimensions rather than isolated components. Interventions with strong interface clarity, such as ePST and Epilepsy Journey 2.0, appeared to provide a smoother entry point into the learning experience, but participants' comments showed that interface success alone did not determine overall usability. Even when navigation was described as intuitive, uncertainties about task flow, expectations, and progress frequently shaped how users interpreted the system's coherence. This pattern suggests that technological usability is necessary, but not sufficient, in mHealth PST contexts, where learning (not just interaction) drives engagement.

Conversely, the Survivor's Journey case study offered a particularly illustrative, though preliminary, window into the consequences of pedagogical and sociocultural misalignment. Despite receiving relatively strong technological scores, participants in that intervention encountered what Nielsen [53] would classify as "usability catastrophes" in the pedagogical domain, where the pedagogical structure failed to communicate progress accurately, leaving participants unsure whether they had completed learning objectives or inadvertently skipped content. These challenges illustrate that users evaluate usability not solely by whether the system works, but also by whether it supports comprehension, reduces cognitive load, and acknowledges their context of use, in alignment with research suggesting that patients interpret usability through the lens of learning demands, emotional states, and everyday constraints (not just interface performance) [21,54,55].

Taken together, these preliminary observations support the view that usability in learning-oriented mHealth interventions is most productively understood as a relational property, one that materializes at the intersection of how the technology performs, how the instruction guides, and how the content speaks to participants' experiential realities [21,40]. This integrated perspective is consistent with broader arguments in health informatics that narrowly technocentric usability evaluation fails to capture the dimensions of the user experience most consequential for clinical engagement and behavior change [31-34].

RQ2: Recurring Usability Challenges Across Technological, Pedagogical, and Sociocultural Dimensions

Within each intervention case, usability challenges reflected potential misalignments across technological, pedagogical, and sociocultural dimensions. Rather than isolated interface flaws, participants' experiences within each case suggested deeper tensions relative to how users attempted to navigate, learn from, and make sense of the interventions. Within individual cases, when 1 dimension falters, it appeared to trigger or amplify challenges in the others, suggesting an entangled nature of usability in mHealth PST contexts [40]. For example, in Survivor's Journey, participants' difficulties distinguishing between progress storage and task completion (a technological navigation issue) undermined their ability to determine whether learning objectives had been met, resulting in pedagogical uncertainty and disrupted task flow. Similarly, in Epilepsy Journey 2.0, the absence of clear module completion indicators and ambiguous navigation cues left participants uncertain not only about their location within the intervention but also about whether they had fully engaged with core PST components, reflecting cascading pedagogical consequences of technological signaling gaps.

Technological challenges, such as inconsistent navigation pathways, limited mobile responsiveness, and unstable multimedia performance, frequently disrupted participants' ability to orient themselves within the interventions. Even when individual screens appeared well designed, unclear directional cues or difficulty returning to previous sections undermined participants' sense of control and progress. These issues point to a need to consider technological usability not as surface-level interface performance but as a foundational condition that can enable or constrain participants' learning. Indeed, when navigation or responsiveness became unpredictable, participants struggled to maintain focus on problem-solving tasks, indicating that technological clarity is a prerequisite for cognitive engagement. In this case sample, the participants with brain tumors (n=3) indicated a preference for tablets or desktops over smartphones. While this preliminary observation in a limited sample suggests that mobile-only design may introduce accessibility burdens for certain users with specific neurological conditions, validation in larger samples is needed before drawing broader conclusions about device preferences.

Pedagogical challenges emerged when instructional sequences, task expectations, or content density failed to align with participants' cognitive needs. Ambiguity about what to do next, difficulty following multistep processes, and the burden of overly dense or text-heavy material created avoidable cognitive load. These challenges were not simply presentation issues. Instead, they reflect gaps in how systems guide users through the problem-solving process. Even when the interface itself was functional, pedagogical misalignment disrupted participants' ability to interpret, retain, and apply the PST framework. Further, sociocultural challenges shaped participants' experiences by influencing how understood and represented they felt while using a given intervention. Elements that might seem minor from a design perspective, such as color schemes,

XSL•FO
RenderX

character portrayals, or emotionally neutral phrasing, sometimes carried unintended emotional weight for participants with neurological conditions. For example, when examples felt inauthentic or insensitive, participants questioned the intervention's relevance and legitimacy. Participants' judgments about usability were shaped as much by cultural resonance, emotional tone, and instructional clarity as by the mechanics of the interface itself.

Collectively, these recurring challenges demonstrate that usability breakdowns are rarely confined to a single point of failure. Difficulties with navigation, comprehension, or emotional resonance often co-occurred and reinforced one another, illustrating the interdependence of sociotechnical-pedagogical dimensions and underscoring the utility of the sociotechnical-pedagogical framework for identifying these interactions. The systemic perspective offered by the sociotechnical-pedagogical framework underscores why mHealth PST interventions require integrated, context-sensitive design approaches able to anticipate the cognitive and emotional realities of diverse patient populations.

RQ3: Design Principles Derived From Cross-Case Usability Patterns

Building on the recurring usability challenges identified across the 3 interventions, the third RQ focused on how these patterns translate into actionable design principles for mHealth PST environments. Findings from this exploratory study revealed that effective usability is not the outcome of isolated interface improvements, but the result of design decisions that simultaneously support technological clarity, pedagogical coherence, and sociocultural resonance. The preliminary design principles derived illustrate how these dimensions interact to shape patient experience and highlight that usability emerges from the alignment of these layers rather than from any single dimension in isolation.

Across cases, technological design principles emphasize the need for intuitive navigation pathways, mobile-first responsiveness, transparent progress indicators, and embedded troubleshooting support. These principles suggest that ease of use in mHealth PST interventions involves more than functional stability. It requires interfaces that anticipate learners' cognitive flow, device constraints, and need to recover quickly from errors. Participant experiences showed that technical clarity enables deeper engagement with problem-solving content, whereas even small inconsistencies in navigation or responsiveness disrupt orientation and confidence. Thus, technological usability functions as the infrastructural layer that supports, rather than competes with, the learning process.

Pedagogical design principles emphasized instructional clarity, reduced cognitive load, context-sensitive feedback, and the use of narrative or interactive elements to support comprehension. Interventions in which instructions were explicit, sequences were well-paced, and content was visually organized allowed participants to focus on the "ABCDE" or "ABCDEF" steps of PST rather than the mechanics of navigating the system. Conversely, ambiguous instructions or dense content increased cognitive effort and weakened participants' ability to internalize core problem-solving strategies. Such patterns demonstrate the centrality of pedagogical usability to learning-oriented mHealth design, in which the quality of instructional scaffolding can directly shape users' performance and perceptions of system usability.

Finally, sociocultural design principles extended usability beyond technological and pedagogical domains and into the areas of sociocultural authenticity and inclusive representation. Participant perceptions demonstrated that issues such as color choice, narrative tone, and representational accuracy can meaningfully shape trust, comfort, and identification with the content. When these elements aligned with participants' lived experiences, responses suggested that participants perceived the intervention as supportive and credible, whereas when they did not, participants perceived the system as less usable, even if the technology and underlying pedagogy were otherwise sound. This suggests that sociocultural usability mediates how technological and pedagogical decisions are interpreted and underscores the need for co-design practices that meaningfully involve target populations through design and development phases [56].

As a whole, the design principles derived from RQ3 reveal that usability is best understood as a relational construct that materializes when technological, pedagogical, and sociocultural dimensions are coherently integrated. The sociotechnical-pedagogical framework proved particularly effective for identifying where misalignments occurred and how they could be addressed through design. This integrated view offers a path forward for developing digital health PST interventions that are not only functional but also instructionally sound and culturally responsive.

Limitations

Several important limitations should be considered when interpreting these findings. First, and most critical, the sample sizes across all 3 cases were small, and the sample for case 2 (Survivor's Journey; n=3) falls below the commonly cited 5-participant threshold for formative usability testing [50]. The small sample hence limits transferability and precludes inferential cross-case conclusions. Second, demographic data, including race, ethnicity, gender, age, and educational background, were not systematically collected as part of these usability evaluations. This limits the ability to examine how these dimensions interact with condition-specific sociocultural usability experiences. While the sociotechnical-pedagogical framework's sociocultural dimension in this study was operationalized through participants' condition-specific lived experience (as described in the Methods section), it is recognized that demographic factors may intersect with and amplify condition-specific experiences in ways that this study could not detect. Future studies should systematically collect and report demographic data to enable a more complete examination of sociocultural usability. Third, usability testing was predominantly conducted in controlled, virtual environments, potentially affecting participants' natural interactions with the platforms. Real-world usage scenarios might reveal additional usability issues not captured in this structured testing context. Fourth, participant familiarity with technology varied significantly across interventions, which may have influenced

XSL•FO
RenderX

usability perceptions independently of the interventions' inherent design. However, it is notable that the intervention with the highest overall usability also included participants with the lowest average confidence using technology; it may be that those with more technology familiarity also have higher expectations and are more critical than those with less familiarity (rather than those with less familiarity simply struggling more). Finally, this study's primary reliance on observational data without longitudinal follow-up restricts the ability to assess sustained usability perceptions and real-world intervention effectiveness.

Comparison With Prior Work

The preliminary findings of this exploratory study align with and extend prior research that argues for multidimensional approaches to usability in digital health. Consistent with earlier work, technological elements such as navigation clarity, visual readability, and mobile responsiveness remain foundational determinants of user satisfaction and engagement [40,55,56]. However, this study demonstrates that technological usability alone cannot fully account for how individuals evaluate or experience digital health PST interventions. Instead, technological features become meaningful only when aligned with the pedagogical and sociocultural demands of learning and self-management. This perspective aligns with emerging critiques in the mHealth literature that evaluations focusing only on technological factors tend to overlook the bigger picture of how users interpret and make sense of an intervention as a learning environment [57,58].

Pedagogically, this study supports previous arguments by Jahnke et al [21] and others advocating for the incorporation of instructional clarity, cognitive load management, and meaningful feedback into usability design. However, the present findings extend this literature by showing empirically how instructional misalignment often underlies perceived usability failures, emphasizing that interface efficiency must be evaluated alongside how effectively a system teaches, guides, and motivates its patients [21,41]. Socioculturally, the results resonate with scholars [40,59] who emphasize emotional safety, cultural sensitivity, and inclusivity as vital to mHealth engagement. Yet, this study advances prior work by demonstrating that sociocultural usability functions as a mediating layer, shaping how technological and pedagogical design decisions are perceived, trusted, and adopted by diverse users. Empathetic design and authentic representation thus emerge as central to achieving sustained participation and emotional connection [47,56].

More broadly, these findings contribute to a growing body of literature calling for multidimensional usability evaluation in digital health. Reviews of current practice have consistently identified a reliance on single-dimensional instruments, most commonly the SUS, across the field, with little attention to pedagogical or sociocultural dimensions [31-35]. The present study provides a concrete, case-level demonstration of what such evaluations miss: in 2 of the 3 cases, CAUSLT subscale scores revealed variation across sociotechnical-pedagogical dimensions that would not have been visible with a single overall usability score, and think-aloud data revealed condition-specific sociocultural concerns absent from the technological usability narrative. The CAUSLT, as operationalized in this study, proved useful for surfacing these multidimensional patterns, though, as noted in the Methods section, no validated benchmark classifications for the CAUSLT exist yet, and the instrument's psychometric performance in clinical populations beyond those represented here remains to be established [41]. Future research should adopt longitudinal designs, include more diverse populations, and be conducted in real-world clinical settings to examine how technological, pedagogical, and sociocultural factors dynamically interact to shape usability in psychoeducational mHealth interventions. Such work is needed to clarify how multidimensional usability influences engagement, learning processes, and behavioral health outcomes over time.

Implications and Future Directions

The preliminary findings of this exploratory study present several implications for mHealth PST design, evaluation practice, and future research, implications that extend beyond the specific interventions examined here. At the most fundamental level, these findings provide initial evidence that the prevailing practice of evaluating psychoeducational mHealth tools primarily on the basis of interface-level usability metrics is likely to produce an incomplete and potentially misleading picture of whether an intervention is ready for clinical deployment. An mHealth PST tool that scores well on the SUS or similar instruments, but whose instructional scaffolding generates cognitive overload, whose feedback mechanisms fail to support error recovery, or whose characters and scenarios feel inauthentic to the target population, may be perceived as technically usable while failing to deliver meaningful psychoeducational benefit. The CAUSLT, operationalized within the sociotechnical-pedagogical framework, offers a more complete evaluation approach precisely because it surfaces these multidimensional gaps. Broader adoption of multidimensional evaluation tools in the formative development of digital health interventions could improve the alignment between usability, learning, and clinical effectiveness, contributing to stronger engagement, adherence, and ultimately better health outcomes for patients using PST mHealth tools.

For intervention developers and health care teams, the 12 preliminary design principles derived from this study offer a starting framework for building multidimensional usability into the design process from the outset, rather than addressing usability deficits reactively after development. Mobile-first design, explicit instructional scaffolding, context-sensitive feedback, and co-design with condition-specific communities are not complex or expensive design choices; they are design commitments that reflect a genuine prioritization of the user's learning experience. The growing literature on community-based participatory approaches in digital health design [56] suggests that these commitments are most effectively implemented when the target population is involved as a genuine partner in the design process rather than as a late-stage test user.

For researchers, these findings suggest several high-priority directions for future work. First, the 12 design principles identified here require prospective empirical testing to determine

XSL•FO
RenderX

whether implementing them improves usability, learning, engagement, and clinical outcomes in PST mHealth contexts. Second, the CAUSLT requires further psychometric validation within clinical populations with neurological and neurodevelopmental conditions, including the development of population-specific descriptive norms that would enable more meaningful score interpretation than is currently possible. Third, longitudinal usability research is needed to understand how usability experiences at first interaction predict sustained engagement, treatment completion, and behavioral health outcomes over time, a critical but currently understudied link in the mHealth effectiveness chain. Fourth, future studies should use larger, more diverse samples within each condition-specific population and should systematically collect demographic data to enable examination of intersecting sociocultural dimensions of usability experience.

In sum, this exploratory study provides preliminary evidence that usability in psychoeducational mHealth PST interventions is a multidimensional construct shaped by the coherent integration of technological, pedagogical, and sociocultural design decisions. When these dimensions are aligned, the intervention creates conditions for meaningful engagement with PST content; when they diverge, the result is not merely user inconvenience but a potential disruption of the very learning process that the intervention is designed to support. Advancing the field requires evaluation practices and design approaches that take this multidimensionality seriously, and this study offers an initial empirical foundation from which that advancement can proceed.

Abstract

Background: Lung-protective ventilation (LPV) reduces complications of mechanical ventilation, yet adherence in intensive care units (ICUs) remains inconsistent. Digital dashboards may support LPV by improving situational awareness and supporting protocol adherence. However, adoption of such tools in high-acuity clinical environments depends on a range of cognitive, professional, and contextual determinants. The Measurement Instrument for Determinants of Innovations (MIDI) provides a validated framework to systematically assess these factors.

Objective: This study aims to identify determinants influencing the adoption of a newly piloted mechanical ventilation dashboard in the ICU using the MIDI framework.

Methods: We conducted a single-center, cross-sectional evaluation among ICU health care professionals during a dedicated survey period within a pilot introduction of a mechanical ventilation dashboard at Amsterdam University Medical Center. Participants completed a structured questionnaire consisting of 24 MIDI items adapted to the ICU context rated on a 5-point Likert scale (“completely disagree” to “completely agree”), supplemented by open-ended questions on perceived barriers and facilitators to its use. Determinants were classified as facilitators when ≥80% of respondents selected “agree” or “completely agree” and as barriers when ≥20% selected “disagree” or “completely disagree.” Open-ended responses were analyzed using a general inductive thematic approach.

Results: A total of 71 completed questionnaires were analyzed, including responses from nurses, physicians, intensivists, ventilation specialists, and researchers in mechanical ventilation. Six determinants met the criteria for facilitators: outcome expectations, self-efficacy, procedural clarity, low complexity, correctness, and observability. Two determinants met the criteria for barriers: relevance for client and professional obligation. Analysis of open-ended responses highlighted perceived barriers such as additional workload, the need for an extra device, overlap with existing systems, and limited role-specific relevance. Facilitators included improved situational overview, educational value, easier trend monitoring, and increased efficiency.

Conclusions: This evaluation identified key determinants influencing the adoption of a mechanical ventilation dashboard in the ICU. While the dashboard was generally perceived as useful and easy to understand, adoption was shaped by determinants related to workflow integration, role-specific relevance, and professional responsibility. These findings suggest that successful introduction of digital clinical support tools in intensive care requires attention not only to technical design, but also to how such tools align with users’ roles, daily work processes, and shared clinical responsibilities. Systematic assessment of determinants provides actionable insights into the adoption of digital decision-support tools in high-acuity care settings.

Introduction

Mechanical ventilation is a critical and often lifesaving intervention for patients admitted to intensive care units (ICUs). However, mechanical ventilation can also contribute to lung injury and complications, including acute respiratory distress syndrome and ventilator-induced lung injury, which increase morbidity and mortality [1,2]. To reduce these risks, clinicians use lung-protective ventilation (LPV) strategies, including low tidal volume (4‐8 milliliters/kilogram ideal body weight [V_T/IBW]), limited plateau pressures (<30 cm H_2O), and limited driving pressures (<15 cm H_2O) [2-6].

Despite strong evidence, adherence to LPV in daily ICU practice remains inconsistent [7,8]. Both patient factors, such as body size and disease severity, and organizational factors such as protocols, staffing and unit routines, contribute to variation in LPV delivery [8-10]. In addition, high cognitive workload, competing clinical demands, and limited protocol visibility can hinder consistent application of evidence-based ventilation practices [11,12].

Clinical dashboards may support LPV by integrating relevant data into a single view, improving situational awareness, and reducing cognitive effort during decision-making [13,14]. In the context of LPV, a ventilator management dashboard with tidal volume alerts was associated with improved hospital-wide adherence and facilitated timely correction of suboptimal ventilator settings [15,16]. Beyond adherence, dashboards may also increase efficiency in prerounding data gathering and, when displayed on shared screens, enhance communication accuracy, information exchange, and clinical satisfaction during multidisciplinary discussions [17]. More broadly, prior studies have shown that clinical dashboards can support care delivery by integrating relevant data, reducing cognitive burden, and providing real-time feedback, which may contribute to improved guideline adherence and fewer errors in complex clinical settings [13,14,18].

Adoption of change in the ICU is shaped by perceived role relevance and feasibility within existing workflows, and influenced by a complex and multifaceted set of facilitators and barriers at the personal, organizational, and health system levels, including engagement, available resources, and local organizational context [19-23]. To systematically assess these factors, the Measurement Instrument for Determinants of Innovations (MIDI) has been widely applied in health care settings [24,25]. The MIDI extends beyond technical considerations by capturing determinants such as procedural clarity, compatibility with daily practice, and relevance for professionals and patients. Previous research has demonstrated its utility in identifying barriers and facilitators that influence the adoption of new technologies and interventions in clinical practice [26-30].

The aim of this study was to use the MIDI questionnaire to identify barriers and facilitators influencing the adoption of a newly piloted mechanical ventilation dashboard designed to enhance LPV in the ICU.

Methods

Design, Setting, and Participants

We conducted a single-center, cross-sectional questionnaire study among ICU health care professionals in a Dutch tertiary academic referral center, where a mechanical ventilation dashboard was introduced as part of a pilot implementation. The study had a descriptive and exploratory aim: to identify determinants influencing adoption of the dashboard in the ICU context. The study took place at Amsterdam University Medical Center (Amsterdam UMC).

The study population consisted of ICU health care professionals involved in mechanical ventilation, including intensivists, ICU nurses, physicians, ventilation practitioners (ICU nurses with additional training as ventilation practitioners), and researchers in the field of mechanical ventilation.

Ethical Considerations

The Medical Ethics Review Committee of Amsterdam UMC reviewed the study protocol and confirmed that the Dutch Medical Research Involving Human Subjects Act (WMO) did not apply to this study, and gave approval for this study (reference: 2025.0194). Participation was voluntary and informed consent was implied by completion of the questionnaire. Questionnaire responses were pseudonymized, stored securely, and handled confidentially. No financial or other incentives were provided for participation.

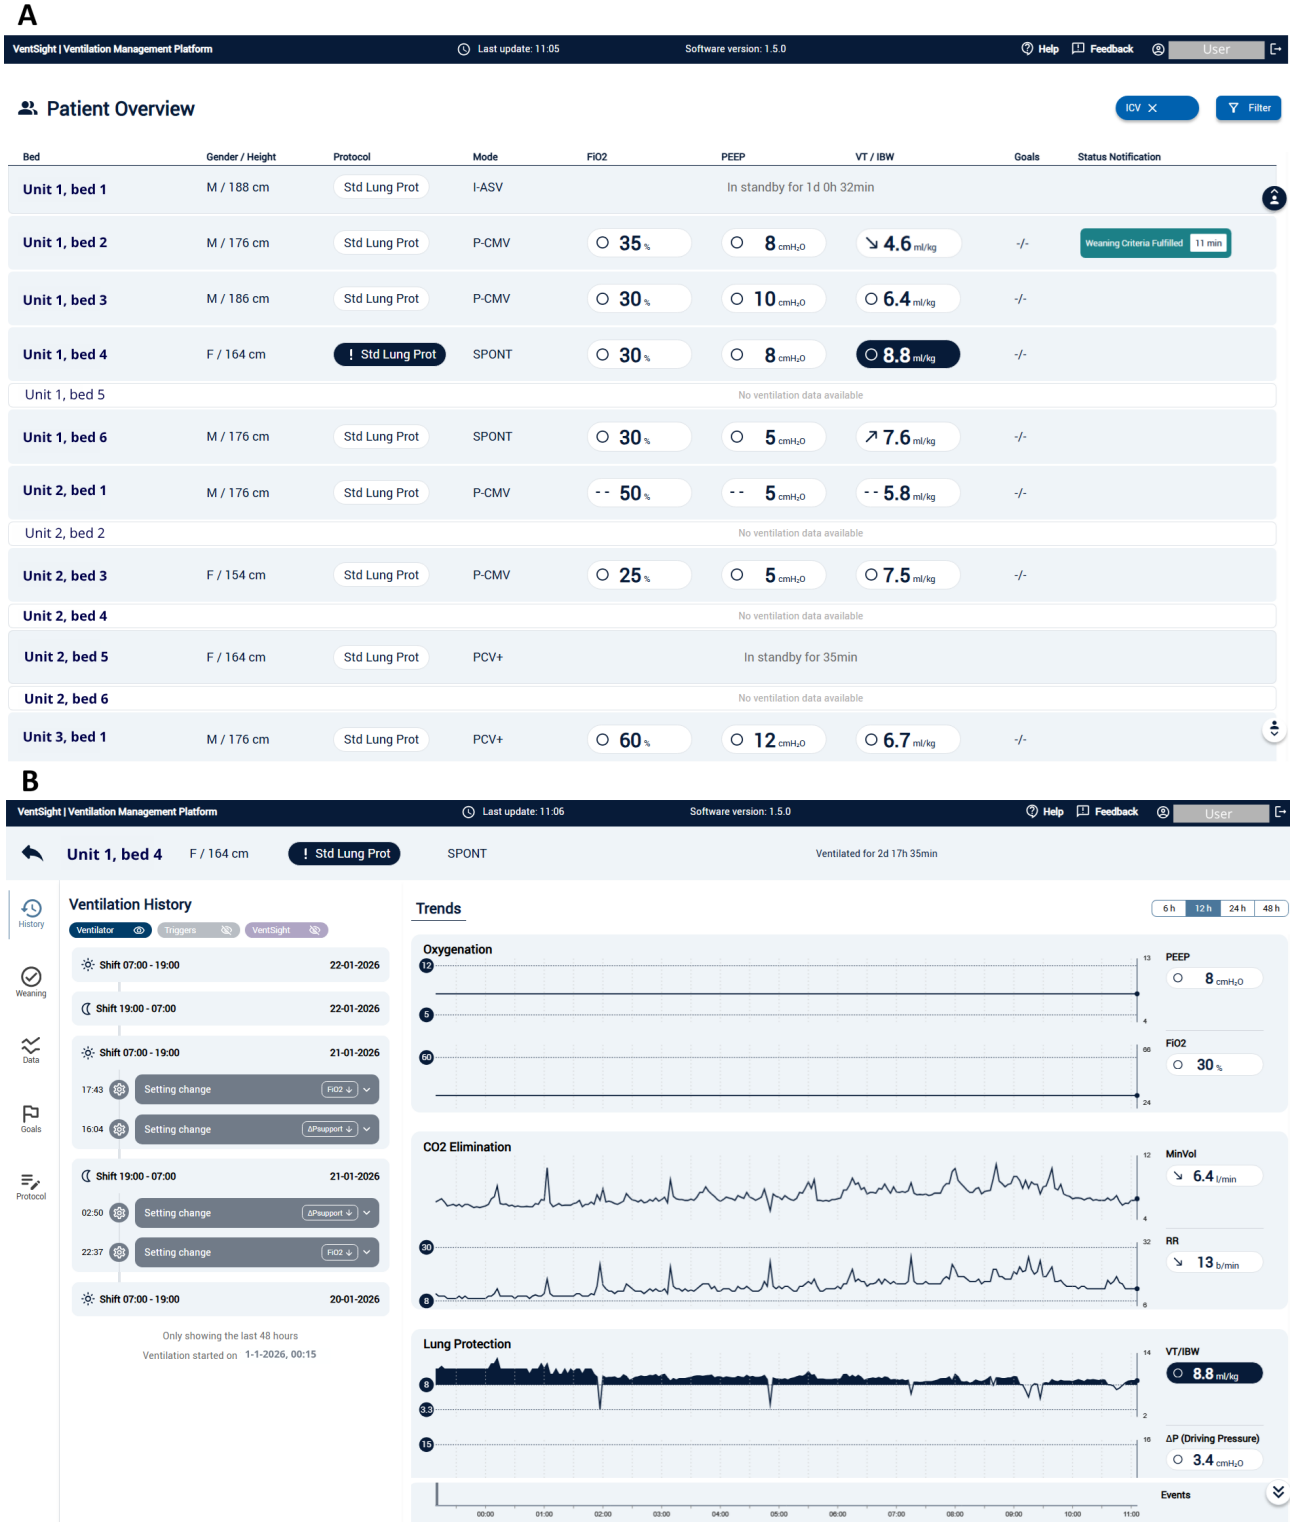
Innovation: VentSight Ventilation Dashboard

The innovation under study was the VentSight ventilation dashboard, a web-based application developed by Hamilton Medical. The dashboard was installed in the ICU of Amsterdam UMC during the first months of 2025 and made available to authorized staff and researchers as part of routine pilot use. The present study evaluated user perceptions collected during a dedicated MIDI survey period conducted within this pilot.

The dashboard was designed to support evaluation of and adherence to LPV by providing continuously updated visualizations of key ventilation parameters. Deviations from predefined target ranges, derived from the hospital's local ventilation protocol, were highlighted to facilitate timely recognition and response. Target ranges varied according to the selected clinical protocol (acute respiratory distress syndrome, obstructive lung disease, normal LPV, or venovenous extracorporeal membrane oxygenation). Protocol selection was performed manually to align with the patient's clinical context. Access to the dashboard for authorized users was provided through a secure environment within the hospital's information technology domain.

For patients receiving invasive or noninvasive ventilation, the dashboard presented 2 levels of information: a unit-wide overview display and individual ventilator detail pages. The overview displayed all active ventilators on a single screen, including positive end-expiratory pressure (PEEP), fraction of inspired oxygen (FiO_2), V_T/IBW, ventilation mode, and basic patient characteristics (sex and height). Parameters were updated every minute, and values outside target ranges were highlighted,

XSL•FO
RenderX



accompanied by trend arrows indicating changes over the preceding hours.

Selecting an individual ventilator opened detailed modules showing graphical trends such as FiO_2 , PEEP, V_T/IBW, respiratory rate and driving pressure, a weaning module aligned with local protocols, continuously refreshed pressure and flow waveforms, and additional ventilator readouts such as cumulative ventilation duration. An example of the dashboard interface is presented in Figure 1. The dashboard and implementation process are further described using the TIDieR (Template for Intervention Description and Replication) guidelines (Checklist 1).

The dashboard's design supported use across professional roles. For nurses, reviewing individual ventilator parameters for assigned patients aligned with their day-to-day bedside responsibilities. For physicians and ventilation practitioners, the unit-wide overview aligned with their roles in monitoring ventilation practices across the whole unit and identifying ventilators requiring additional attention. During the pilot period, the dashboard was not integrated into standard clinical care. Access to and use of the dashboard were limited to study participants during the study procedures and were voluntary. Dashboard use took place under the supervision of the leading researcher (SFCM) to prevent unintended clinical use.

XSL•FO
RenderX

Figure 1. Example of the ventilation dashboard's interface. The dashboard consists of 2 main layers: (A) the intensive care unit (ICU)–wide overview page, displaying all ventilators, and (B) the individual ventilator page, showing trends, waveforms, and protocol-relevant ventilator parameters.

MIDI-Based Determinants Assessment

The study intervention consisted of administering the MIDI questionnaire to identify determinants influencing the adoption of the ventilation dashboard in daily ICU practice [25].

Questionnaire Development

Determinants were assessed using the MIDI framework. The MIDI is intended to be tailored to the specific innovation and implementation context under study. Therefore, in this study, the MIDI was used as intended and tailored to the VentSight dashboard context without redeveloping the questionnaire or changing the underlying MIDI determinant structure. From the original 28 MIDI determinants, 17 were considered relevant to the ICU context and operationalized into 24 questionnaire items rated on a 5-point Likert scale ("completely disagree" to "completely agree"). Items were framed around the use of the

XSL•FO
RenderX

dashboard to support LPV, including timely recognition of deviations and adherence to local ventilation protocols.

Several MIDI determinants, such as personal benefits and outcome expectations, were operationalized using multiple items, which are reported separately in the "Results" section. Additional questions captured professional role, intention to use the dashboard (yes, no, or maybe), and open-ended reflections on perceived barriers and facilitators. A complete overview of items is provided in Multimedia Appendix 1.

The questionnaire was developed by a multidisciplinary team, including an implementation specialist, intensivist, ICU nurse, and physician, and was tailored into 2 role-specific versions. ICU nurses received a version aligned with individual ventilator assessment (individual assessment setup), whereas physicians, ventilation practitioners, and researchers received a version emphasizing the unit-wide overview (ICU overview setup). Both versions contained the same 24 MIDI items; only wording and examples were adapted to reflect role-specific use. The questionnaire was built and administered using Castor EDC.

Pilot Testing

Three ICU ventilation practitioners piloted the questionnaire to evaluate face validity, clarity, and feasibility of completing the questionnaire within the intended time frame (20 min). Feedback indicated that all items were understandable and could be completed within 15 minutes. Minor revisions were made to improve phrasing and logical flow. Pilot testing, therefore, focused on usability and contextual clarity rather than psychometric revalidation of the MIDI instrument itself.

Questionnaire Administration and Recruitment

Information about the study and the dashboard was disseminated 1 week before and during the questionnaire administration period via posters and the digital ICU newsletter. The MIDI questionnaire was administered between July 28, 2025, and August 4, 2025. The target sample size and distribution across professional groups were determined pragmatically, in line with the descriptive and exploratory purpose of this single-center implementation study. As the study aimed to identify determinants of dashboard adoption in the local ICU context rather than to test a predefined hypothesis or estimate an intervention effect, no formal power-based sample size calculation was performed.

Participants were recruited using a stratified convenience sampling approach. Professional groups involved in mechanical ventilation and dashboard use were considered relevant strata, and recruitment was targeted to ensure participation from each of these groups. Within these strata, participants were recruited based on availability and willingness to participate, rather than through random sampling. We aimed for approximately 75 respondents to obtain a broad representation of intended end users. This included approximately 40 ICU nurses, representing about 20% of the approximately 200 ICU nurses working in the ICU, and approximately half of the available physicians and intensivists involved in ICU ventilation care. The higher target number for ICU nurses reflected their larger share of the ICU workforce and their role as key end users of the individual ventilator assessment view. This approach was considered appropriate for the exploratory implementation-focused aim of the study and feasible within the local pilot implementation period.

All participants received a standardized 5- to 10-minute face-to-face onboarding session led by 1 researcher (SM), ensuring consistent exposure to the dashboard's key function. Participants then briefly explored the dashboard using short exploratory questions (Multimedia Appendix 2), followed by completion of the pseudonymized questionnaire via a QR code linking to the secure Castor EDC platform. Therefore, responses reflected initial perceptions after short-term, voluntary exposure, rather than experience with sustained use in routine clinical practice. All sessions were facilitated by the same researcher to ensure consistency of exposure. No modifications were made to the dashboard or study procedures during the questionnaire administration period.

Statistical Analysis

All analyses were descriptive, consistent with the exploratory aim of this single-center implementation study. Questionnaires with less than 70% completion were excluded from analysis to ensure adequate data completeness. For each MIDI item, we calculated the median and IQR, as well as the proportion of respondents selecting "agree" or "strongly agree" (scores 4 or 5) and "disagree" or "strongly disagree" (scores 1 or 2).

In accordance with the MIDI developer recommendations, determinants were classified as facilitators when ≥80% of respondents scored 4 or 5 and as barriers when ≥20% scored 1 or 2 [30]. Determinants were ranked descriptively by these proportions in the combined sample and examined separately by dashboard setup (individual assessment vs ICU overview) to account for differences in use context. Responses to open-ended questions were analyzed using a general inductive approach; responses were read iteratively and grouped into recurring thematic categories to summarize reported determinants. All analyses were performed using R statistical software (version 4.3.3; RStudio).

Results

Participant Characteristics

A total of 78 questionnaires were started. After exclusion of questionnaires with less than 70% item completion, 71 questionnaires were included in the analysis: 36 from the individual assessment setup and 35 from the ICU overview setup. Respondents represented a wide range of ICU professional roles, with ICU nurses forming the majority (39/71, 54.9%), followed by physicians (16/71, 22.5%) and intensivists or intensivist in training (11/71, 15.5%). Five respondents were specialized in mechanical ventilation, either as ventilation practitioners or members of their ICU's ventilation work group. Respondent characteristics are shown in Table 1.

Overall, 51 out of 71 (71.8%) respondents indicated that they intended to use the dashboard, while 20 out of 71 (28.2%) respondents answered "maybe." No respondents indicated that they did not intend to use the dashboard. In the individual assessment setup, 28 out of 36 (77.8%) respondents indicated

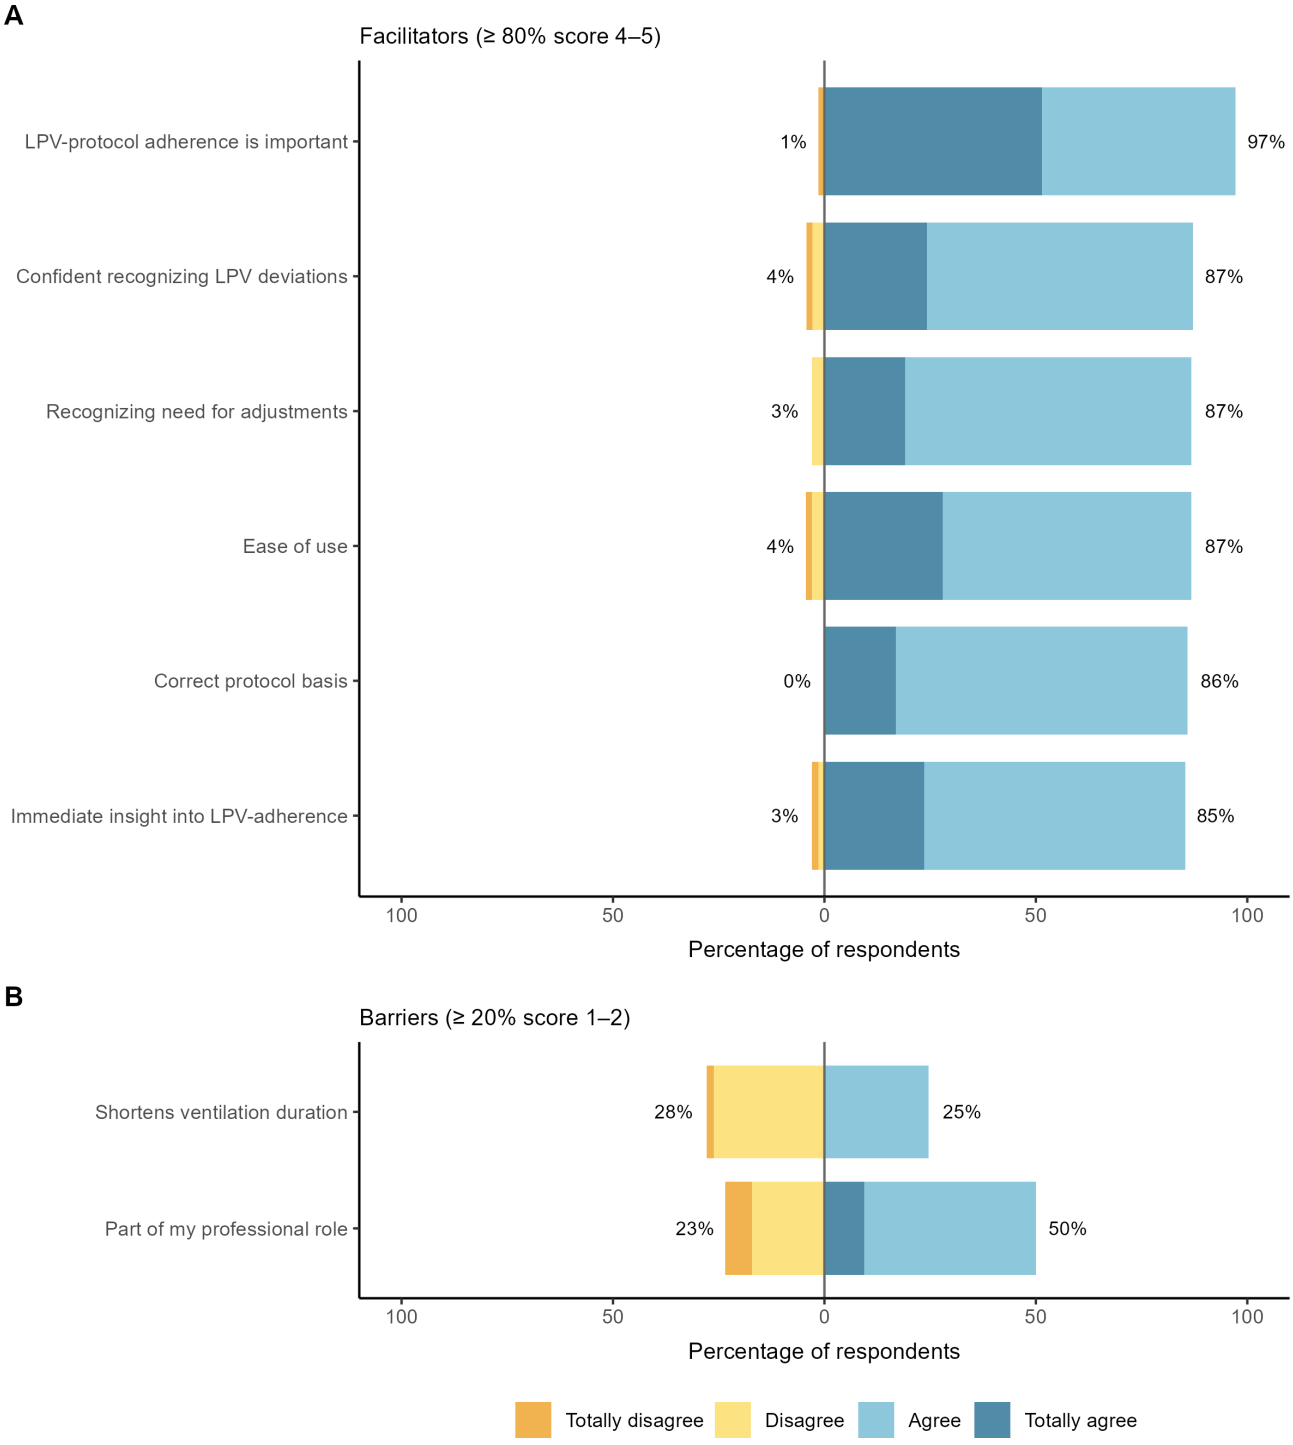
XSL•FO
RenderX

an intention to use, compared with 23 out of 35 (65.7%) respondents in the ICU overview setup.

Table . Respondent characteristics (N=71).

Characteristics	Value
Professional role, n (%)	
ICU[a] nurse	39 (54.9)
ICU nurse in training	7 (17.9)
ICU nurse (<5 years of experience)	16 (41)
ICU nurse (>5 years of experience)	16 (41)
Physician	16 (22.5)
Intensivist	10 (14.1)
Intensivist in training	1 (1.4)
Researcher in the field of mechanical ventilation	5 (7.0)
Specialized in mechanical ventilation[b]	5 (7.0)
Comfortable with applying mechanical ventilation on a 9-point Likert-scale, median (IQR)	8 (6-8)

[a]ICU: Intensive care unit.



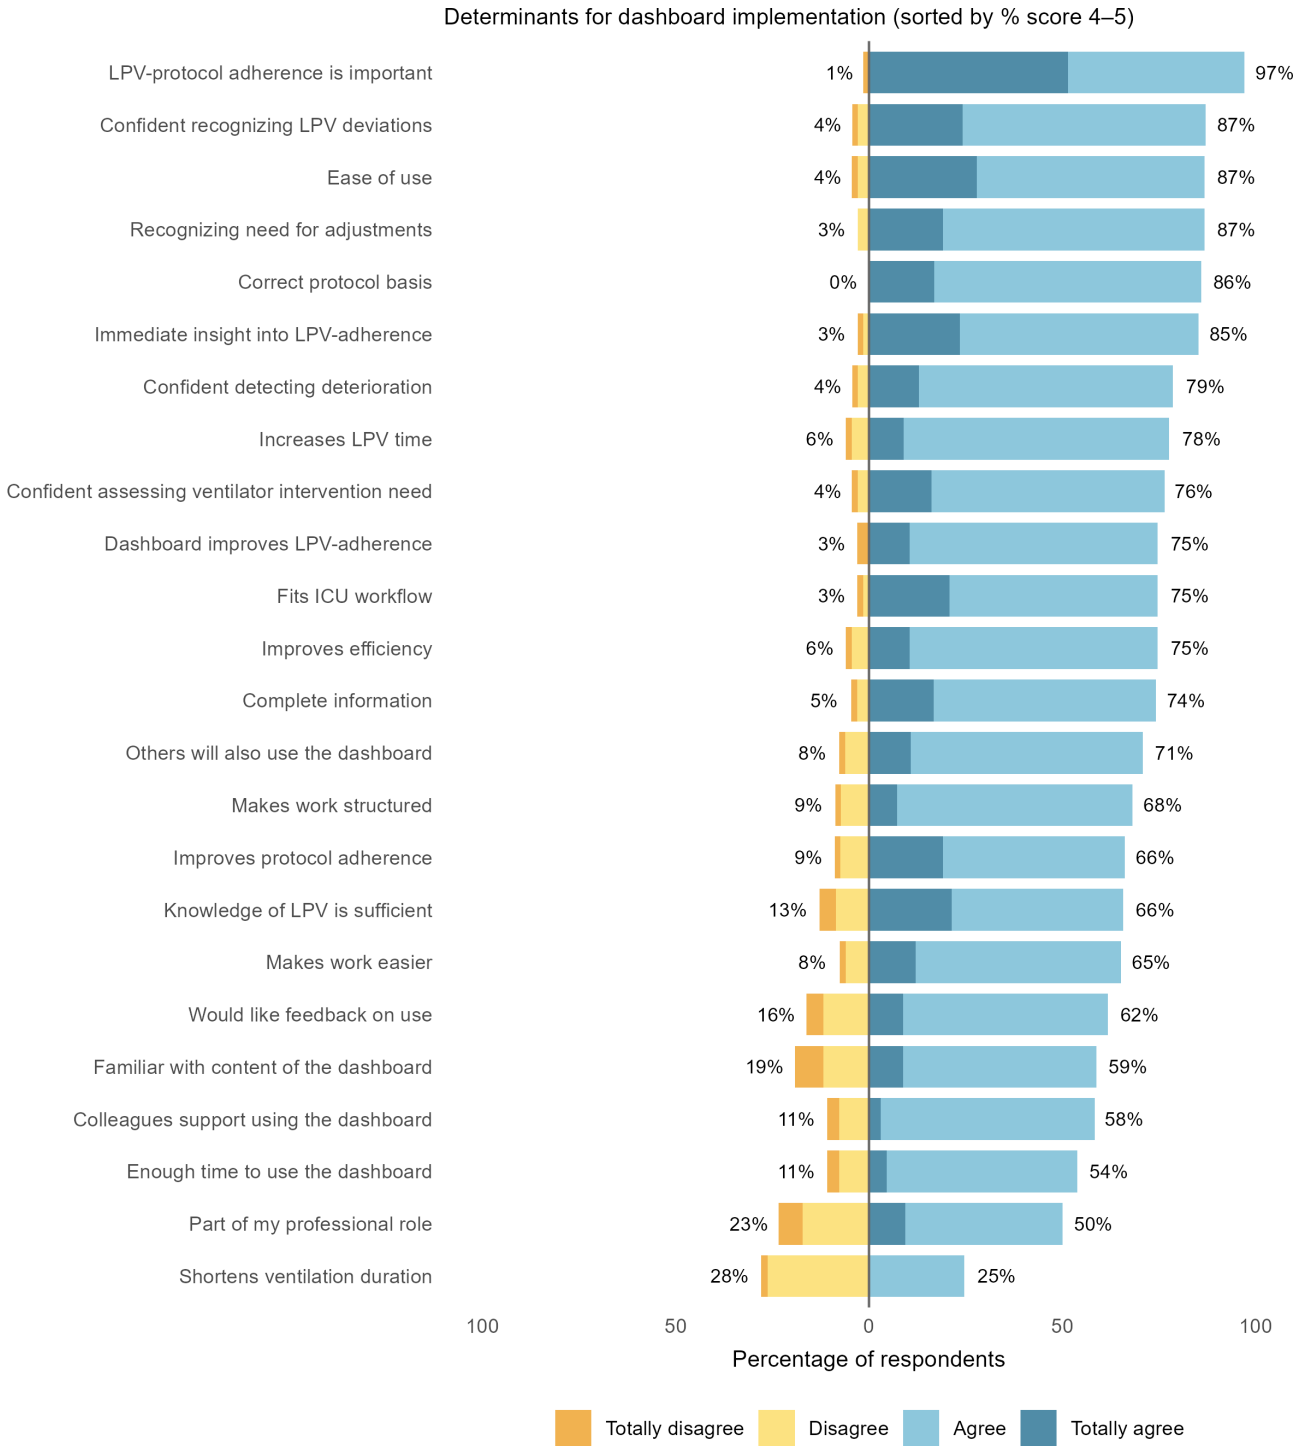
[b]Besides other professional role; for example, a nurse who is also a ventilation practitioner or intensivist who is a member of a ventilation working group.

Facilitators for Implementation

Six determinants met the predefined criteria for classification as facilitator (Figure 2). These included outcome expectations (MIDI item 9a, reflecting the importance of maintaining patients within protocol-defined ventilation targets), self-efficacy (MIDI item 16a, related to recognizing deviations from the ventilation protocol using the dashboard), procedural clarity, low perceived complexity, correctness of the dashboard, and observability. Outcome expectations and self-efficacy received the highest levels of agreement, with 97% (68/70) and 87% (61/70) of respondents, respectively, scoring “agree” or “strongly agree.” Of the 6 determinants classified as facilitators, 2 were related to the end user (outcome expectations and self-efficacy), whereas the remaining 4 facilitators were related to the innovation (procedural clarity, low perceived complexity, correctness, and observability).

XSL•FO
RenderX

Figure 2. Facilitators and barriers based on Measurement Instrument for Determinants of Innovations (MIDI) cutoffs. (A) Facilitators and (B) barriers identified among all participants based on the predefined MIDI thresholds. Facilitators were defined as MIDI items for which ≥80% of respondents scored 4–5, whereas barriers were defined as MIDI items for which ≥20% of respondents scored 1-2. LPV: lung-protective ventilation.



Barriers for Implementation

Two determinants met the predefined criteria for classification as barriers (Figure 2). These were relevance for client (MIDI item 7b, reflecting uncertainty about whether dashboard use would shorten mechanical ventilation); and professional obligation. Disagreement was reported by 28% (17/61) of respondents for relevance for client and by 23% (15/64) for professional obligation. Relevance for client is associated with the innovation, whereas professional obligation is associated with the adopting user. An overview of all determinants is presented in Figure 3.

XSL•FO
RenderX

Figure 3. Likert responses for all Measurement Instrument for Determinants of Innovations (MIDI) items sorted by agreement. Likert-scale responses (1-5) for all MIDI items, ordered by the proportion of respondents scoring 4-5 among all participants. ICU: intensive care unit; LPV: lung-protective ventilation.

Determinants Across Dashboard Setups

Facilitators differed by dashboard use context. Six facilitators were identified in the individual assessment setup, including outcome expectations (MIDI item 9a, importance of maintaining patients within protocol-defined ventilation targets), correctness, observability, self-efficacy related to recognizing protocol deviations and deteriorating ventilator settings, and low perceived complexity. Nine facilitators were identified in the ICU overview setup, including procedural clarity, outcome expectations, multiple self-efficacy items related to protocol monitoring, low perceived complexity, observability, perceived personal benefits related to efficiency, correctness, and compatibility with workflow (Multimedia Appendix 3).

Across both setups, relevance for the client (MIDI item 7b, reflecting uncertainty about whether dashboard use would shorten mechanical ventilation), and professional obligation were consistently identified as barriers. Feedback on performance was an additional barrier in the individual assessment setup, while limited awareness of the innovation's

XSL•FO
RenderX

content emerged as a barrier in the ICU overview setup. Detailed item-level results are provided in Multimedia Appendix 4.

Perceived Barriers and Facilitators

Responses to open-ended questions revealed that perceived barriers included the dashboard being considered extra work and time-consuming, requiring an additional device, presenting information already available in existing systems, and being perceived as not relevant to certain users' roles (particularly nurses).

Facilitators included providing the unit with a broader overview of all patients, supporting education, and enabling easier trend monitoring. Reported benefits were improved efficiency and time savings, enhanced situational overview, and the ability to monitor multiple patients simultaneously. Reported disadvantages were the need for an additional screen and the potential for increased screen-focused work, which could reduce direct patient contact. All open-ended responses are presented in Multimedia Appendix 5.

Discussion

Main Findings

Using the MIDI, we found that adoption of the dashboard aimed at supporting LPV was mainly facilitated by high perceived outcome expectations, self-efficacy, and procedural clarity, while relevance for the client and professional obligation emerged as barriers to implementation. Facilitators and barriers differed slightly by dashboard use context. Most respondents intended to use the dashboard in clinical practice.

Strengths

This study has several strengths. The questionnaire was developed using the validated MIDI framework [24,25], ensuring systematic assessment of a wide range of determinants for implementation. The questionnaire was tailored to 2 user contexts (individual assessment- and ICU overview setup) and piloted for clarity and feasibility. Recruitment during active demonstration of the dashboard ensured that respondents were familiar with the tool before providing feedback. The combination of quantitative Likert-scale items with open-ended questions provided both structured and nuanced insights into perceived facilitators and barriers. The MIDI provided a structured approach to assess determinants of dashboard adoption in the ICU context. Combining structured ratings with open-ended responses allowed us to identify facilitators and barriers and to descriptively compare findings across dashboard use contexts.

Limitations

Some limitations must be considered. First, the study was conducted in a single tertiary ICU in the Netherlands, which may limit generalizability to other settings with different workflows, staffing models, or digital infrastructure. Although the specific determinants identified are context- and innovation-dependent, several reflect broader features of ICU practice and may therefore be relevant beyond this single dashboard. Moreover, this study illustrates how a framework-based approach, such as the MIDI, can be used to systematically identify context-specific barriers and facilitators for digital tool adoption across ICU settings. Second, this was a descriptive and exploratory implementation study with a pragmatically determined sample size. The study was not designed or powered to test predefined hypotheses, estimate intervention effects, or perform formal subgroup comparisons. The findings should therefore be interpreted as context-specific insights into determinants of dashboard adoption, rather than as precise estimates generalizable to all ICU health care professionals. In addition, the professional distribution of respondents was pragmatically determined and was not based on formal stratified random sampling, which may limit interpretation of differences between professional groups. Third, participation was voluntary, which may have introduced selection bias; those more interested in innovation or ventilation practices may have been more likely to respond. Social desirability bias may also have influenced responses, despite pseudonymization, as the dashboard was a local initiative. Fourth, respondents were introduced to the dashboard through a brief standardized onboarding session rather than through prolonged real-world use, and dashboard use was voluntary and limited to study participants. The timing and voluntary context should be considered when interpreting perceived ease of use and intention to use [31]. Initial perceptions shortly after introduction may differ from perceptions after sustained routine use, particularly once users have more opportunity to evaluate workflow integration, peer use, and the dashboard's practical contribution to ventilation care. To partially mitigate limited exposure, participants were given time to explore the dashboard themselves by completing several short explanatory tasks, allowing hands-on interaction that approximated early real-world exposure. Finally, as this was a perception-based questionnaire, findings do not directly measure actual changes in LPV adherence or patient outcomes.

Relation With Prior Work

Our findings align with previous studies showing that adoption of change and implementation of digital tools in ICU settings are shaped by a complex and interconnected set of facilitators and barriers operating across individual, organizational, and health system levels, rather than by technological usability alone [20-23]. Consistent with earlier studies, determinants identified in our study emphasize the importance of staff engagement, professional beliefs, and perceived relevance of the innovation, alongside feasibility within existing workflows and workload constraints [20,23]. Both the MIDI-based assessment and the open-ended responses suggest that barriers to adoption predominantly arise from challenges related to integration into daily practice, competing clinical demands, and unclear professional responsibility, reinforcing the notion that successful uptake of digital tools in critical care depends on alignment with human and organizational factors within the ICU context [13-15,19].

Interpretation of Findings

The high intention-to-use rate suggests initial acceptability of the dashboard among a wide range of ICU professionals, although this should be interpreted in the context of voluntary participation and short-term exposure during a study-specific

XSL•FO
RenderX

onboarding session. This finding can be interpreted in light of technology acceptance models such as the technology acceptance model (TAM) and TAM2, in which perceived usefulness and perceived ease of use are important predictors of usage intention and actual system use [31,32]. Although these constructs were not directly measured by the MIDI, several identified facilitators may reflect conditions that support them. High scores for procedural clarity, low perceived complexity, correctness, and observability suggest that the dashboard was experienced as clear, reliable, and straightforward to interpret, supporting perceived ease of use in a complex clinical environment. High outcome expectations and self-efficacy may similarly reflect perceived usefulness and confidence in using the dashboard for protocol monitoring. Together, these findings may help explain the high initial intention to use the dashboard.

However, our findings indicate that successful implementation is unlikely to be achieved by introducing the technology alone; it requires clear integration strategies into daily workflows. This is particularly relevant in light of TAM2, which emphasizes job relevance as an important determinant of perceived usefulness and user acceptance. In our study, low scores for relevance for client, reflecting uncertainty about patient-related benefit, and professional obligation emerged as barriers [31]. This suggests that the dashboard's relevance for patient care and its place within shared professional responsibilities were not yet fully established across professional groups. The lack of perceived personal benefit, particularly among respondents in the individual assessment setup, may further reduce the likelihood of sustained use. Addressing these barriers should therefore be a key focus of future implementation strategies, including targeted education on the downstream clinical impact of consistent LPV and explicit clarification of how dashboard use contributes to team-based ventilation care.

Because the dashboard was not yet integrated into standard clinical care, respondents' perceptions may differ from perceptions after sustained routine use. In particular, perceived usefulness may increase once users have more opportunity to experience how the dashboard fits into daily workflow, supports shared situational awareness, and contributes to ventilation monitoring over time. Although continuous display of the dashboard at the nursing station was not formally evaluated in this pilot, our findings suggest that such continuous visibility may further reinforce situational awareness and promote routine use, particularly among bedside nurses. In addition, introducing a structured "ventilation review moment" on each ICU, using the dashboard as a central reference tool, could support its use in daily practice, promote protocol adherence, enhance shared situational awareness, align perspectives on ventilation status across professionals, and reinforce shared responsibility for LPV.

Several determinants, including time available, social support, and awareness of the innovation's content, did not meet formal barrier thresholds but showed comparatively low scores. These factors may reflect practical constraints and limited peer reinforcement rather than definitive barriers, yet they represent areas of vulnerability that could hinder adoption if left unaddressed. Embedding dashboard use within a dedicated, team-based ventilation review moment may help mitigate these constraints by normalizing use, strengthening shared responsibility, and increasing familiarity with the dashboard's functionality.

Although the specific configuration and relative importance of determinants identified in this study are shaped by the local ICU context and the characteristics of this dashboard, the findings may point to more general challenges inherent to implementing digital support tools in critical care settings. Determinants such as limited time availability, uncertainty about perceived patient-related benefits, and unclear professional responsibility may reflect underlying features of ICU work, including high workload, task fragmentation, and shared responsibility across professional roles. Rather than implying that these determinants apply uniformly across settings, our findings illustrate how implementation challenges in critical care often arise from the interaction between human, organizational, and contextual factors, extending beyond technical usability alone.

These findings indicate that implementation strategies for nurses should focus on building buy-in and peer support for dashboard use, allocating protected time, and reinforcing the relevance and positive effects of LPV. For physicians, role-specific strategies should emphasize education highlighting the patient benefits of LPV and emphasizing that delivering LPV as a team aligns with professional responsibilities. Practical next steps include tailoring role-specific dashboard views, integrating the dashboard directly into existing systems, and introducing structured moments to jointly assess and evaluate ventilation practices. Finally, clearly communicating the rationale and benefits of LPV, while fostering a culture in which feedback on ventilation practices is normalized and acted upon, may substantially enhance adoption and quality of patient care.

Conclusions

Using the MIDI questionnaire to evaluate adoption of a ventilation dashboard, we found that ICU professionals generally perceived the dashboard as feasible and useful and reported a high intention to use it, while also identifying adoption barriers. Our findings highlight that successful adoption of digital dashboards in critical care depends on human, organizational, and contextual factors at the workplace. Recognizing and addressing these factors is essential for implementing digital tools that aim to improve quality of care in the ICU.

Acknowledgments

The authors would like to thank the 3 intensive care unit (ICU) ventilation practitioners who piloted the questionnaire for their valuable feedback on clarity and feasibility. The authors also gratefully acknowledge the colleagues from the departments of Clinical Engineering Department (Ruud Voorn and Gertjan van der Veldt), ICT (Sanne Terpstra), and the EHR Innovation and

XSL•FO
RenderX

Implementation Center (Jasper van Dijk) at Amsterdam UMC for their essential support in making the practical implementation of the VentSight dashboard possible. Finally, the authors would like to thank the ICU nursing staff, physicians, and ventilation practitioners at Amsterdam UMC for their participation in this study. Generative AI was used solely to check spelling and improve the English writing of the manuscript. ChatGPT (OpenAI) was not used to generate scientific content, perform analyses, or interpret the results.

Funding

This study was partly funded by Hamilton Medical, which covered project costs for piloting and evaluating the VentSight ventilation dashboard. The funder had no role in study design, data collection, analysis, interpretation of data, or writing of the manuscript.

Data Availability

The datasets generated and/or analyzed during the current study are available from the corresponding author upon request.

Authors' Contributions

SFCM, DAD, and FP designed the study. SFCM led the project preparation, coordinated the study project, conducted the pilot, collected the data, performed the analysis, and drafted the manuscript. TDVL contributed extensively to project preparation by piloting the questionnaire and pilot preparation. MCR contributed to the preparation and installation of the piloted dashboard. AV contributed to questionnaire development and study design. DAD and FP supervised the project and contributed to study conception and interpretation of findings. All authors have read and approved the final version of the manuscript and agree to be accountable for all aspects of the work.

Conflicts of Interest

None declared.

Abstract

Background: Posttraumatic stress, along with comorbid mental health challenges and hazardous alcohol use, disproportionately affects people living with HIV. The drivers of these stressors are both intraindividual, rooted in early life adversity and firsthand violence exposures, and contextual, often place-based. Imparting effective coping skills and distinguishing between changeable and unchangeable stressors can improve stress management in the short term, with cascading effects on key HIV continuum of care end points, such as antiretroviral therapy adherence. However, problem- and emotion-based coping skills, delivered via traditional linear in-person group modalities, may falter in the moment. To address this, we adapted the evidence-based Living in the Face of Trauma intervention into an iOS- and Android-native app, featuring daily diary–triggered coping skills recommendations, self-guided Living in the Face of Trauma psychoeducational sessions, and a customizable geofencing function.

Objective: This mixed methods study aimed to examine the acceptability, feasibility, and user experiences of NOLA (New Orleans, Louisiana) Gem, focusing on user interaction costs relative to geographic ecological momentary assessment (GEMA) alone and refining future optimization options.

Methods: People living with HIV (N=32) were recruited across New Orleans and initially randomized 1:1 to treatment (NOLA Gem + GEMA) versus control (GEMA) for 21 days. Feasibility was assessed via enrollment and attrition rates. At the immediate postassessment, participants completed acceptability and usability measures and a brief structured usability interview. Analyses included descriptive statistics, bivariate logit modeling, and synergistic human–large language model deductive coding.

Results: In total, 30 participants (n=22 in the GEMA + NOLA Gem treatment arm) completed the pilot, representing 94% (n=29) of baseline enrollees. Acceptability was very high across the board: 100% (n=30) of users considered NOLA Gem “very” or “somewhat” successful in addressing their daily lives, with 91% (n=28) endorsing increased calm and emotional well-being. In addition, 50% (n=11) of NOLA Gem users were “extremely likely” (Net Promoter Score=10/10) to recommend the app to friends. Eight (27%) GEMA and GEMA + NOLA Gem users reported privacy concerns. Eleven (50%) NOLA Gem users received geofencing alerts; perceptions of this feature’s helpfulness were mixed. No statistically significant sociodemographic or clinical predictors of disparate acceptability or increased privacy concerns were found. No additional frictions were evidenced by GEMA + NOLA Gem versus GEMA users. Qualitatively, NOLA Gem users praised the just-in-time mindfulness, breathing, problem-solving skills delivery, and broader stress control and self-insight benefits. A subset of users pointed out the burdensome length and sometimes inconvenient timing of the daily diaries. Recommendations for next-generation personalization included user-specific dynamic daily diary and geofencing prompt tailoring.

Conclusions: Our small pilot study demonstrated high NOLA Gem acceptability and feasibility, as well as a rich and beneficial user experience among people living with HIV, with clear and actionable opportunities for improvement.

Introduction

Background

Posttraumatic stress is endured by an estimated 28% of people with HIV, globally [1]. Nearly two-thirds (64%) report symptoms consistent with diagnosable posttraumatic stress disorder (PTSD) [2]. The trauma burden can reach as high as 97.1%, with an average of 4.2 out of 10 recognized adverse childhood experiences (ACEs) on the ACEs Questionnaire, among women with HIV in clinical samples. Lifetime trauma has been linked, in a dose-response manner, to greater likelihoods of self-reported depressive and anxiety symptoms, as well as alcohol and illicit drug use [3]. Indeed, the origins of traumatic stress among many people with HIV in the United States are often attributable to multiple sources, including compounded early life adversities, economic hardship, and, in particular, firsthand violence exposures [4-6]. Brown et al [5], in South Carolina, reported 3 overarching components of traumatic life experiences among people with HIV: firsthand extreme violence and secondhand homicide and suicide exposures, physical and sexual assault, and accidents and natural disasters. Among people with HIV, these experiences can encompass childhood sexual abuse [4], racial trauma, incarceration [5], homelessness, rape, intimate partner and intrafamilial violence, and comorbid life-threatening illness [6].

Brezig et al [7], pointing to the disproportionate prevalence of violent (vs nonviolent) trauma among people with HIV, developed a syndemic theory of trauma alongside the acquisition, forward transmission, and later-life outcomes associated with HIV survivorship. Trauma, per the American Psychological Association, can manifest in heightened fear, vulnerability, rumination, disorientation, and dissociative tendencies [2]. Among some people with HIV, these symptoms are linked to anger, isolation, distrust [6,7], comorbid anxiety, depression, suicidal ideation [8,9], and hazardous drug and alcohol use [2,7].

Through a behavioral medicine lens, posttraumatic stress represents a crucial, robustly demonstrated, within-person determinant of antiretroviral therapy (ART) adherence [2-4]. Among women with HIV, acute trauma is linked to 4 times the odds of lapsed ART [7]. Within the Brown et al [5] sample, people with HIV who experienced past extreme violence–related or death-related trauma were 63% less likely (adjusted odds ratio 0.37, 95% CI 0.15-0.95) to demonstrate adherence than non–trauma-exposed participants; people with HIV exposed to any trauma were 58% less likely (adjusted odds ratio 0.42, 95% CI 0.21-0.86). Among Black gay and bisexual men in Baltimore, Maryland, and Jackson, Mississippi, 24% reported past-year physical, sexual, or psychological violence exposure, and recent and lifetime violence exposure was linked to ART nonadherence (adjusted prevalence risk ratio 1.59, 95% CI 1.25-2.01) [10]. Qualitatively similar effects, entangling lifetime trauma, mental health challenges, and substance use or misuse as drivers of poor ART adherence are consistently demonstrated across independent samples of people with HIV and US geographies [11-13], including New Orleans [14].

Narrowly individualistic perspectives on trauma among people with HIV may overlook important neighborhood-based sources of stress [15,16] and stressors that can change across time and space even within a single day [17,18]. In New Orleans, neighborhood-level alcohol outlet density has been linked to alcohol misuse among men with HIV and an increased likelihood of endorsing depressive symptoms among women with HIV [19]. GPS and daily diary data (from a very small feasibility sample; n=11) demonstrate that people with HIV spend an average of just 19% of their awake time within their own residential Census tracts, exposed to neighborhood crime rates ranging from 1 to 28 per 1000 population and alcohol outlet density rates of 0 to 22 per 1000 as they traversed, on average, 23 Census tracts [20]. Emerging evidence, typically captured via geographic ecological momentary assessment, shows that these dynamic place-based factors can affect mood and rumination among people with HIV in New Orleans [9,21].

Effective coping can interrupt traumatic stress and ART adherence lapses [22-25]. Specifically, *adaptive* coping, grounded in the coping framework of Lazarus and Folkman [26], distinguishes between “changeable” and “unchangeable” stressors. The former are approached via problem-focused strategies, such as structured problem-solving and effective communication skills, along with additional cognitive behavioral therapy–oriented strategies, while the latter are addressed via emotion-focused strategies, including cognitive restructuring, mindfulness meditation, and confronting irrational beliefs such as “all-or-nothing” thinking [23]. The Living in the Face of Trauma (LIFT) intervention by Sikkema et al [25], a Centers for Disease Control and Prevention “best evidence” intervention for improving coping with early life trauma stressors and HIV, as well as reducing trauma symptom burden, exemplifies this approach. Across a series of pilot studies [25] and fully powered randomized controlled trials [27], as well as an adaptation for women with HIV in Cape Town, South Africa [28], LIFT has demonstrated efficacy in reducing intrusive symptom burden, forward transmission risk behaviors, and avoidance and arousal PTSD symptoms, while improving ART adherence.

A 15-session, linear, in-person group intervention, LIFT, by definition, does not respond to momentary ecological stressors that people with HIV may encounter throughout the day. Just-in-time adaptive interventions (JITAIs), delivered via smartphone, and often reliant on ecological momentary assessment (EMA) inputs [29,30], can prompt users with brief psychoeducational and coping skills refreshers whenever necessary [24,31]. Similarly, geofencing interventions deliver intervention content triggered by spatial inputs, wherever necessary [32]. JITAIs have demonstrated preliminary efficacy

XSL•FO
RenderX

in reducing ruminative episodes via cognitive behavioral therapy skills prompts and alcohol misuse among homeless adults in pilot studies [33,34], as well as robust efficacy profiles among adults transitioning from inpatient alcohol use disorder treatment [35], alongside a wide array of mental health endpoints [36,37]. Reported acceptability, feasibility, and engagement, including among sexually minoritized men living with HIV [38], are generally high [34,39-41], with many opportunities for incorporating prospective end user insights [42].

Study Objectives

To our knowledge, no prior studies have examined the acceptability, feasibility, and broader user experience of a geographic ecological momentary assessment (GEMA)–leveraging JITAI that incorporates trauma-informed principles and personalizable geofencing to meet the needs of people with HIV. We report the findings of the pilot of NOLA (New Orleans, Louisiana) Gem, a JITAI adaptation of LIFT, trialed among a sample of people with HIV enrolled across Greater New Orleans. The NOLA Gem app was adapted from the *Living in the Face of Trauma: An Intervention for Coping with HIV and Trauma* manual, in consultation with Sikkema [27,28]. The NOLA Gem study covered Aims I to III. The findings of Aim I are reported in detail in Gasik et al [21]. The results of Aim II, the NOLA Gem design synthesizing the insights of Aims I and II (including a detailed user flow diagram and user story maps), and the pilot trial protocol are described in Kabir et al. Here, we report the results of Aim III.

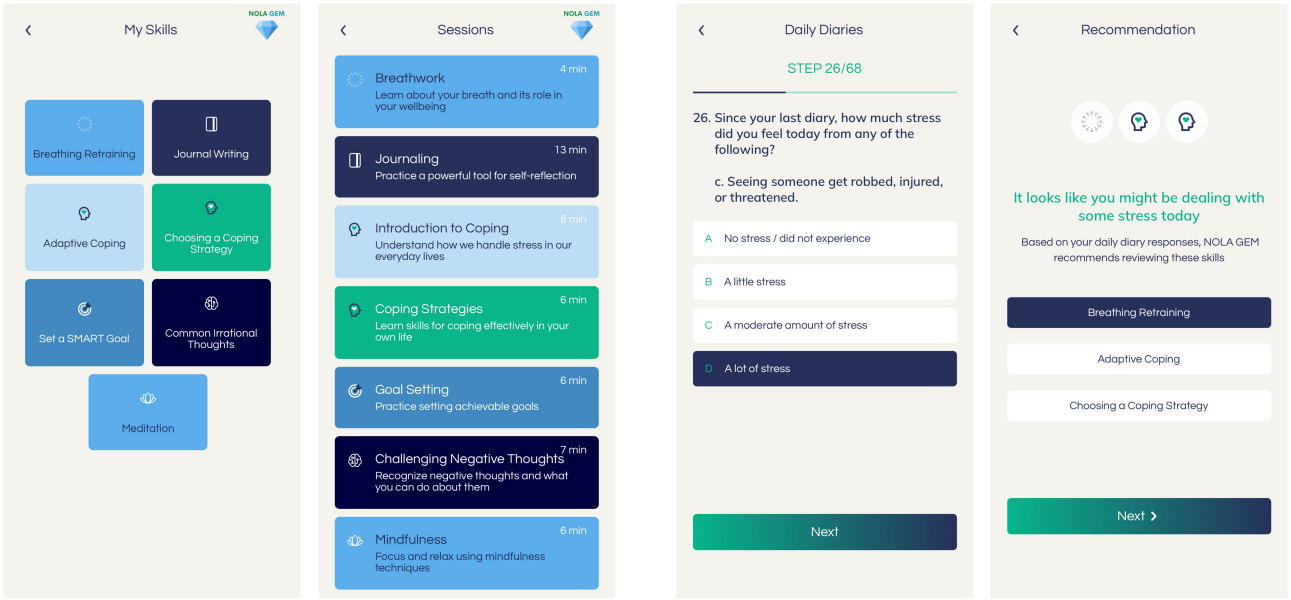
Methods

The NOLA Gem Aim III study was a randomized controlled trial enrolling adults with HIV across Greater New Orleans, spanning from 2023 to 2024.

GEMA: Control Arm

The NOLA Gem app was designed with a control and a treatment version, which were masked to the user. The assignment was dependent on how the user was created in the admin panel by research staff. Both versions had GPS tracking; latitudinal and longitudinal data points were recorded at 1-minute intervals if the device moved more than 20 m for the duration of the 21-day pilot trial [43]. GEMA alone, combining GPS tracking and daily diary delivery via text message at 9:00 AM (due by 12:00 PM) and 6:30 PM (due by 9:30 PM) intervals, but lacking any interventional component, constituted the control condition.

NOLA Gem + GEMA: Treatment Arm



The treatment arm of the NOLA Gem app leveraged the GEMA inputs as tailoring variables, calling on fixed decision rules determined in Aim II, to recommend from among 7 "just-in-time" adaptive coping skills ("Set a SMART Goal," "Common Irrational Thoughts," etc) mapped to predetermined proximal outcomes [39,44]. Each skill was adapted from a LIFT worksheet, culturally tailored to invoke drivers of resilience identified by New Orleanian people with HIV in Aim II. Endorsing more than "a little stress" on daily diary 37f ("Since your last diary, how much stress did you feel today from any of the following? *Had an argument with friend, family member, or romantic partner*") elicited deep-linked recommendations for the "Adaptive Coping" and "Common Irrational Thoughts" in-app brief skills modules, to give just one example. In addition, NOLA Gem users were provided 7 self-directed sessions (estimated 4‐13 minutes in duration), grounded in the traditional, linear delivery of LIFT. These sessions offered psychoeducation on maladaptive or adaptive coping strategies, goal setting, and mindfulness meditation, among other topics. As no generalizable across-case geospatial stressors were evident in Aim I [21], the NOLA Gem treatment arm included a user-determined, essentially personalizable, geofencing feature. Users were asked at baseline to identify 3 locations that they found to be particularly stressful in their lives. Latitude and longitudinal coordinates for these locations were entered into the admin panel with a 150-m geofence; when users entered this geofence, they received a text message asking if they would like to practice their skills, with a link to the skills section of the app. The NOLA Gem JITAI features, built atop and including all aspects of GEMA, constituted the treatment condition for the duration of the 21-day trial period.

Illustrative screenshots of NOLA Gem are shown in Figure 1.

In both arms, the study app was Health Insurance Portability and Accountability Act–compliant and transmitted all data to a Health Insurance Portability and Accountability Act–compliant, Crowdbotics-hosted administrator dashboard.

Study Participants and Procedures

Participants for Aims I and II were convenience-sampled from the longitudinal New Orleans Alcohol Use in HIV cohort, which, since 2017, has followed 365 people with HIV and hazardous alcohol use histories in outpatient care across Greater New Orleans [45]. For Aim III, this study enrolled participants from this cohort while diversifying recruitment to include a range (n=12) of local HIV outpatient clinics and community organizations serving people with HIV, which were provided with study recruitment flyers.

Participants were eligible if they (1) were 18 years or older; (2) maintained a current ART prescription, verified in person or via a photograph uploaded to a secure Qualtrics link; (3) owned a smartphone; and (4) indicated experiencing at least 1 incident of violence on the screener.

Study enrollment spanned from October 2023 to August 2024. Initially, eligible, consented participants were randomly assigned 1:1 to treatment (NOLA Gem + GEMA) or control (GEMA) arms. Once total enrollment reached 16, the remaining participants were assigned to the treatment arm. This step was taken to address compounding enrollment challenges posed by the ongoing COVID-19 pandemic, specifically the Delta and Omicron variants (during the former wave, Louisiana recorded the highest number of new cases relative to the total population in the United States [46]), and Hurricane Ida, which caused widespread evacuations and a prolonged power outage across Orleans Parish [47]. By favoring treatment-arm enrollment, we aimed to achieve a sufficiently sized pilot sample to gather preliminary mixed methods evidence of NOLA Gem's acceptability, feasibility, and usability, despite these unforeseen obstacles, while maximizing the potential human benefits of research involvement for people with HIV in New Orleans.

The study arm was randomly assigned following eligibility verification, prior to the baseline appointment, to streamline onboarding. At the baseline appointment, participants were read an informed consent form aloud, and verbal consent was recorded in Research Electronic Data Capture (REDCap). The NOLA Gem app was then downloaded from the App Store (iOS) or Google Play (Android) onto participants' phones using the institutional Wi-Fi. The research assistant enabled notifications and location tracking on participants' devices, as well as location services for the NOLA Gem app. Onboarding to both control and treatment conditions was supported by illustrated guides. The baseline assessment was research assistant–administered, and responses were recorded in REDCap.

Measures

Baseline Assessment

Demographics were collected at baseline: name; date of birth (to verify self-reported age); address, including ZIP code; assigned sex; gender (male, female, nonbinary, and a "prefer to self-describe" open-ended response option); race, using US Census categories along with a self-describe option; Latine heritage, using a single-item indicator; and sexual orientation (heterosexual or straight, gay or lesbian, bisexual, or self-describe). Relationship status, educational attainment, employment, and housing details were collected using measures carried over from the NOAH parent study [48]. Participants were administered a 4-item Digital Confidence Score measure (eg, "I use a digital device frequently") adapted from Benson [49].

At baseline, a range of clinical variables were captured. Measures used in these analyses, which exploratorily probed potential drivers of, or disparities in, NOLA Gem acceptability, included the 3-item Alcohol Use Disorder Identification Test–Consumption, administered to detect potentially hazardous alcohol use patterns [50]; the Addiction Severity Index "Alcohol/Drugs" section, which collected past 30-day frequency

XSL•FO
RenderX

of alcohol, cannabis, cocaine or crack, opioid, other, and combined substance use or misuse [48]. The PTSD Checklist for *DSM-5* assessed subthreshold and PTSD symptoms that may benefit from treatment [51]. The Posttraumatic Growth Inventory evaluated positive within-person aftereffects of traumatic stress, such as deepened spirituality and enhanced appreciation of life [52]. The "lost friends due to serostatus," "disclosure risk," "interpersonal discomfort," and "hurtful attitudes toward PWH" items of the HIV Stigma Scale assessed those domains of internalized HIV stigma [53]. The 10-item Kaiser Permanente ACEs Questionnaire collected instances of early-life adversity, neglect, and abuse [54].

Quantitative Postintervention Assessment

At offboarding, both GEMA and GEMA + NOLA Gem users were administered a range of acceptability and usability measures. These end points (preregistered in Skeen et al,[55] crucial for the future trialability and scalability of NOLA Gem, are the focus of this study.

Acceptability was assessed using a series of study-specific items designed to evaluate ease of use, perceived success in enhancing well-being, and privacy concerns. For example, the first item asked, "How often were you able to open and use the NOLA GEM app without confusion, frustration, or asking for help? [Very often, somewhat often, not very often]." Ten items, using a 4-point Likert scale, assessed the NOLA Gem app's multifactorial appeal (eg, likeability, visual appeal), and its perceived helpfulness in attaining proximal outcomes; for example: "I found NOLA Gem to be helpful in changing habits [Agree, somewhat agree, somewhat disagree, disagree]." In addition, to test whether participants were willing to expend their own social capital on behalf of NOLA Gem, an adapted Net Promoter Score (NPS) asked participants about their likelihood of recommending NOLA Gem to a friend (1=not at all likely, 10=extremely likely) [56].

Feasibility was measured via attrition rates postenrollment, daily diary completion rates, and paradata descriptives.

Usability was assessed with the 8-item User Experience Questionnaire (UEQ)–*Short*, an abbreviated version of the UEQ that encompasses both *pragmatic* (determinative of user goals) and *hedonic* (determinative of user pleasure) usability domains. The UEQ uses a 7-point scale with item-specific anchors to deter central tendency biases [57]. For accessibility's sake, we simplified these anchors wherever possible. For example, we replaced "obstructive" with "unhelpful" in item 1: "Rate the app from unhelpful to supportive."

Qualitative Postintervention Assessment

Finally, participants were asked a series of open-ended, atheoretical questions: "What did you not like about the app?" "What were your favorite parts of the app?" "What aspects of the app do you think should be changed?" and "What aspects of the app do you think should be kept?" Responses were digitally recorded and transcribed verbatim into dedicated REDCap fields.

Ethical Considerations

All procedures were reviewed and approved by the Socio-Behavioral Institutional Review Board of the Biomedical and Social Behavioral Institutional Review Boards at Tulane University (reference number 2022‐1861). All participants provided verbal informed consent. All recorded data were private, confidential, and anonymous. Participants were compensated with a US $30 Amazon gift card for completing their baseline appointment, US $20 via ClinCard for their immediate postassessment and 30-day follow-up visit (each), US $2 via ClinCard for each daily diary completed, and a US $10 Walmart gift card for the 90-day follow-up. Starting in March 2024, after switching to treatment-arm only enrollment, participants were also compensated with US $5 via ClinCard per session completed, with a US $15 bonus if all 7 were completed.

Analytic Approach

Overview

Background demographic and quantitative acceptability, feasibility, and usability outcomes are reported descriptively. Although the UEQ "Data Analysis Tool" provides a benchmark usability dataset, these values are not validated for the 8-item UEQ short form [58]. Disparate acceptability was assessed, preliminarily, by recoding dichotomous gender (1=male), race (1=Black), Latine identity (yes=1), Test–Consumption and Addiction Severity Index item-wise (1=any lifetime alcohol or past 30-day cannabis use, cocaine or crack, or opioid use), dichotomizing the PTSD Checklist for *DSM-5* at the recommended >33 cutoff, and median-splitting the Post-Traumatic Growth Inventory and *Digital Confidence Score* sum, for entry into bivariate logit regressions as factor variables [59]. Wherever sufficient variation permitted, acceptability outcomes were dichotomized as well (eg, 1 = "Agree" or "Somewhat agree" to "I found NOLA Gem to be useful"). These transformations were undertaken to account for low variability and a very small sample size.

Particular attention was paid to possible differential drivers of GEMA privacy concerns (recoded such that 1="somewhat" and "very concerned" [60]). Potential privacy concern predictors included sexual orientation (1=sexual minority), and median-split HIV Stigma Scale and *ACEs* scores.

The NPS was computed in the industry-standard manner: scores ≥9 were categorized as *promoters*, scores 7 to 8 as *passives*, and scores ≤6 as *detractors*. The NPS metric was obtained by subtracting the percentage of detractors from the percentage of promoters [56].

While direct control-treatment differentials in acceptability (etc) were not preregistered, we tested for potential GEMA (control) versus NOLA Gem + GEMA (treatment) additive interaction costs exploratorily, via 2-tailed independent-samples *t* test and visual inspection, where warranted [61]. Quantitative analyses were run in Stata/SE 18.0 [62]. Data visualizations were created using Naqvi spider package for Stata [63] and Matplotlib in Python 3.13 [64].

XSL•FO
RenderX

Qualitative responses were analyzed using a rapid, atheoretical, human–large language model (LLM) synergistic approach. First, the lead author (SJS), after conducting immersive close readings of the treatment group responses, developed categories inductively, and formalized them within a codebook. The qualitative data frame was transformed by inserting category-specific columns to (1) dummy code each response for every respective category, as warranted, and (2) extract the most salient segment of text: the "rationale" for the coding application [65]. Next, informed by the work of Dunivin et al [66] and the CHALET framework of Meng et al [67], the "Collaborative Human-LLM Analysis for Empowering Conceptualization in Qualitative Research" technique was used. Category-by-category deductive coding prompts were formulated. The prompts were "few-shot," providing human-synthesized examples, and leveraged contemporary LLMs' chain-of-thought capabilities by requiring a 2-sentence justification for each coding decision [66,67]. To maintain data privacy, the Ollama framework was used to run a local on-device 12 billion–parameter (12B) Gemma 3, a lightweight open-source extension of Google's proprietary Gemini foundation model [68,69]. Matching the initial human approach, the 12B Gemma 3 was tasked with (3) dummy coding expressions of each category and (4) providing coding decision justifications (inclusive of the LLM's own "rationales") in dedicated columns. Initial human-LLM intercoder reliability was computed using Cohen κ. For any category that demonstrated $\kappa < 0.70$, a second human consensus coder (ST) resolved coding application discrepancies. All qualitative analyses were conducted in Python 3.13.

Open Code

Stata .do and Python .ipynb replication scripts, including deductive coding prompts, are hosted in a dedicated GitHub repository [70].

Results

Overview

The overall pilot sample was generally in their mid- to late-50s, with slight over-representation by men (n=17, >55%), a plurality identifying as minoritized sexualities (n=10, <45.45% heterosexual/straight), and roughly 3 quarters Black (n=22, 73.33%). A very large majority (n=30, 93.33%) reported <US $50,000 past-year household income. Digital confidence scores were high, in the "strongly agree"–"agree" range on average.

The pilot sample's demographic details, overall and by study arm, are shown in Table 1.

Acceptability

Acceptability, similarly, was generally very high across measures in the NOLA Gem + GEMA (treatment) group (n=22). Overwhelmingly, 16 (72.73%) participants reported the easy use of the app, with perceived helpfulness more equivocal, but a very small minority (n=2, 0% - 9.09%) perceiving the app as totally ineffectual. Bivariate logit regressions were null (male, *P*=.40; Black, *P*=.75; Latine, *P*=.26; lifetime alcohol use, *P*=.70; past 30-day drug use, *P*=.29; positive PTSD screen, *P*=.07; >median posttraumatic growth, *P*=.15; >median digital confidence, *P*=.22), suggesting no detectable social patterning to NOLA Gem acceptability among the pilot sample.

Nearly a third (n=7, 31.82%) reported GPS-related privacy concerns, though no statistically significant associations with privacy-related concerns were evidenced (male, *P*=.23; minoritized sexuality, *P*=.70; >median HIV stigma, *P*=.70; >median adverse childhood experiences, *P*=.30; as GEMA was universal, these models used the complete sample, ie, n=30). Consistent with the qualitative findings, nearly a quarter (n=7, 23.33%) found the daily diaries difficult to incorporate into their daily lives. Within the treatment group, 11 activated a custom geofence; though enthusiasm for this feature was mixed, no participants found it "not at all" helpful.

The app usage and satisfaction measures are summarized in Table 2.

Additional measures of multifactorial appeal are plotted in Figure 2.

Measures of NOLA Gem's perceived helpfulness are plotted in Figures 3 and 4.

RenderX

Table . App usage and satisfaction: geographic ecological momentary assessment (GEMA) + NOLA[a] Gem (treatment group, n=22).

Measure	Response options, n (%)[b]	Mean (SD; range)
How often were you able to open and use the NOLA Gem app without confusion, frustration, or asking for help?	• Very often: 16 (72.73) • Somewhat often: 3 (13.64) • Not very often: 3 (13.64)	2.59 (0.73; 1 - 3)
How successful was the app in addressing your daily life?	• Very successful: 11 (50) • Somewhat successful: 11 (50) • Not very successful: 0 (0)	2.50 (0.51; 1 - 3)
How much has the app increased well-being, sense of calm, or positive feelings?	• A lot: 11 (50) • A little: 9 (40.91) • Not at all: 2 (9.09)	2.41 (0.67; 1 - 3)
Did you feel concerned about your privacy while participating in the GPS tracking part of this study?[c]	• Not concerned: 15 (68.18) • Somewhat concerned: 5 (22.73) • Very concerned: 2 (9.09)	2.67 (0.61; 1 - 3)
Did you receive text messages encouraging or suggesting skills or sessions to try in the NOLA Gem app?	• Yes: 21 (70)	—[d]
If “yes” (n=21): How relevant were these to your daily life or stress?	• Very: 2 (9.52) • Somewhat: 10 (47.62) • A little: 2 (9.52) • Not at all: 1 (4.76) • Did not use: 6 (28.57)	3.48 (1.17; 1 - 4)
Did you receive suggested skills at the end of your daily diaries to try in the NOLA Gem app?	• Yes: 21 (70)	—
If “yes” (n=21): How relevant were these to your daily life or stress?	• Very: 7 (33.33) • Somewhat: 10 (47.62) • A little: 4 (19.05) • Not at all: 0 (0) • Did not use: 0 (0)	3.14 (0.73; 1 - 4)
Geofencing alerts were text messages that appear when you neared areas you identified as stressful at the start of the study. Did you receive any geofencing alert text messages during the study period?	• Yes: 11 (50)	—
If “yes” (n=11): How helpful were these recommendations in the moment?	• Very: 5 (45.45) • Somewhat: 3 (27.27) • A little: 2 (18.18) • Not at all: 0 (0) • Did not use: 1 (9.09)	3.45 (0.93; 1 - 4)
Was the timing of the daily diaries easy for you to incorporate into your daily life?	• No: 7 (23.33)	—
(If “no”) Which timeframe was difficult for you to answer within?	• 9:00 AM-12:00 PM: 4 (57.14) • 6:00 PM-9:00 PM: 0 (0) • Both timeframes: 3 (42.86)	—

Because the control-treatment comparison was essentially additive, building features atop the already-demanding GEMA deployment, we tested for between-group differences in acceptability measures. Although, descriptively, GEMA measures tended to be higher (eg, treatment: mean 2.59, SD 0.73 vs control: mean 2.75, SD 0.46 for "able to open the app without confusion"), between-group *t* tests were uniformly null (*P*=.13 - .87).

NPS scores averaged (mean 7.70, SD 3.04). *Promoters* comprised 63.64% (n=14), and *detractors* comprised 22.73% (n=5) of the GEMA + NOLA Gem treatment sample, yielding an NPS metric of 40.91, approaching the generally accepted ≥50 "excellent" score [56].

Feasibility

At baseline, 32 participants were enrolled, with 30 (93.75%; this study's analytic sample) completing the 21-day trial period and completing ≥1 daily diary. Sociodemographic attributes of noncompleters are withheld to maintain participant confidentiality.

NOLA Gem paradata, collected from the treatment arm, showed that in a majority of the 607 completed daily diaries, across all participants (n=22), no skill was recommended: 463 (76.28%). Only 3 (13.64%) of the users completed 0 skills, and in 1 instance, technical errors may have prevented data recording.

These usage distributions are shown in Table 3.

Table . Living in the Face of Trauma (LIFT) skills: recommendations, time spent, completions: geographic ecological momentary assessment (GEMA) + New Orleans, Louisiana (NOLA) Gem (treatment group, n=22).

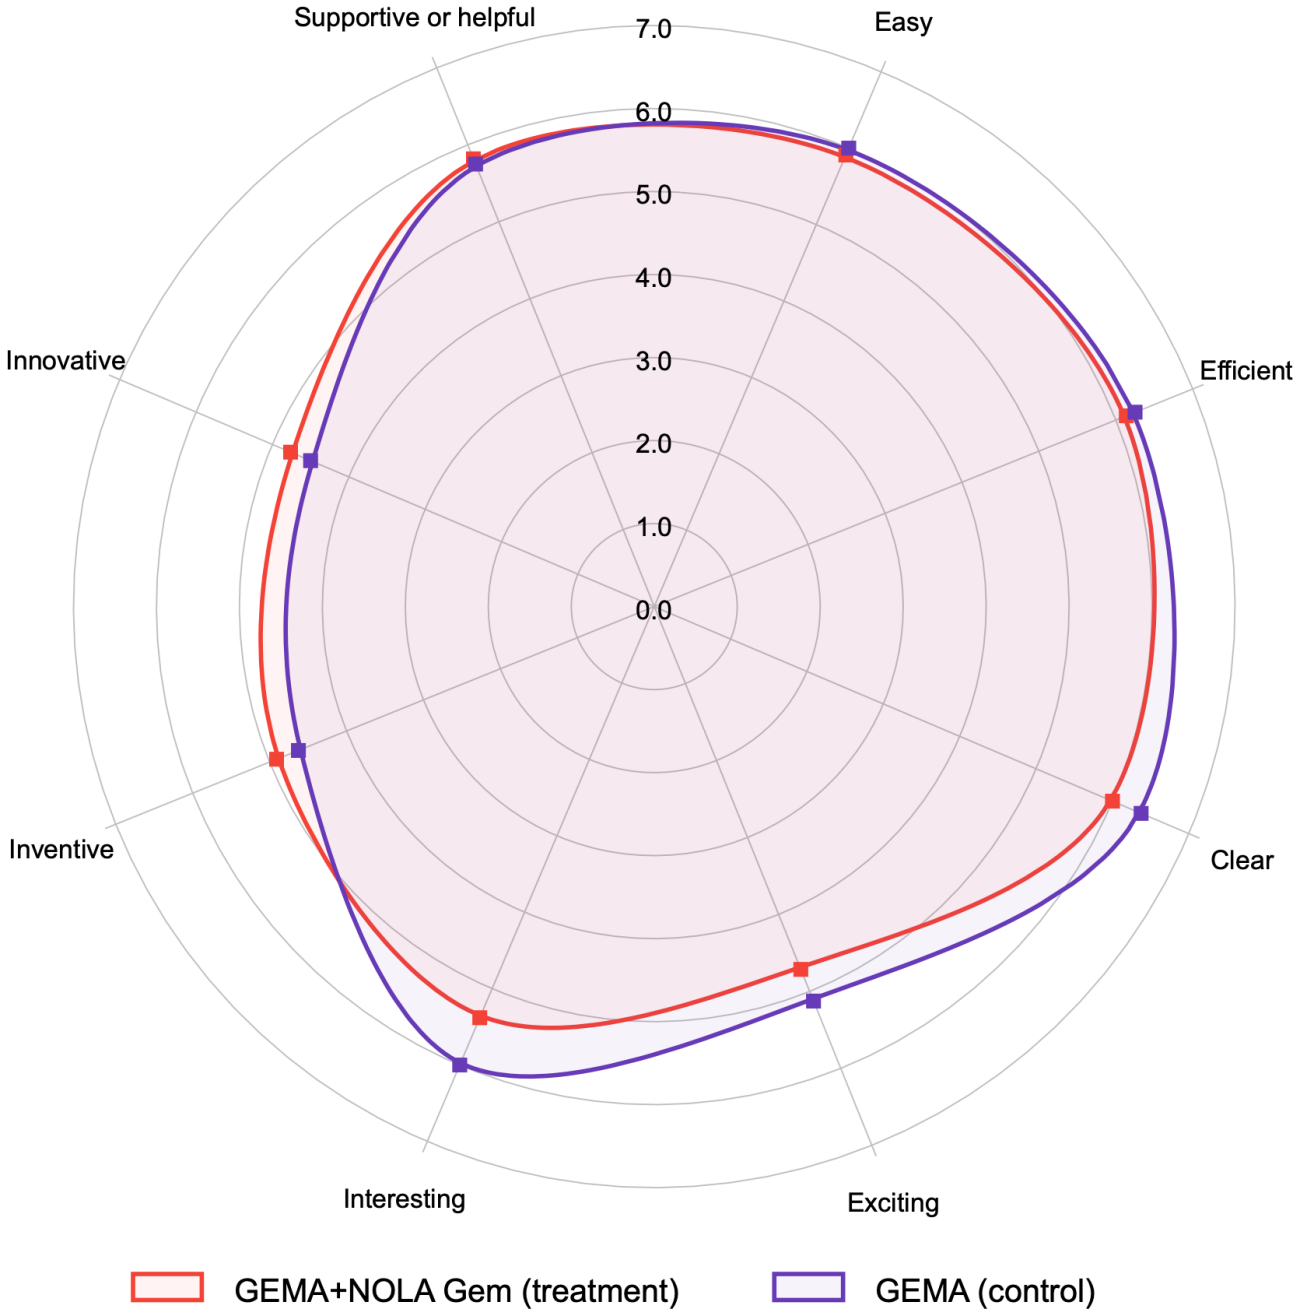
Skill	Recommendation frequency, n (%)[a]	Minutes spent		Completion frequency, n (%)[b]
		Count of 0-minute users, n_0	Median$_{>0}$ (range$_{>0}$)	
Adaptive coping	14 (9.72)	14	10.0 (1 - 409)	26 (12.68)
Breathing retraining	46 (31.94)	12	6.0 (1 - 13)	46 (22.44)
Choosing a coping strategy	15 (10.41)	17	3.5 (1 - 15)	30 (14.63)
Common irrational thoughts	14 (9.72)	16	3.0 (1 - 31)	27 (13.17)
Journal writing	14 (9.72)	17	36.0 (7 - 137)	16 (7.80)
Meditation	31 (21.53)	12	7.0 (2 - 59)	41 (20)
SMART[c] goal-setting	10 (6.94)	15	8.0 (1 - 74)	19 (9.27)

[a]Calculated as *n* skill-specific recommendations/144 total skills recommendations.

[b]Calculated as *n* skill-specific completions/205 skills completions; completions>recommendations due to user-determined "pull" (nonprompted) skills practice.

[c]SMART: specific, measurable, achievable, realistic, and able to be achieved in time.

User Experience



Overview

The short-form UEQ yielded generally good scores for NOLA Gem across the board, particularly on the "Supportive/helpful" (mean 5.82, SD 1.47), "Easy" (mean 5.91, SD 1.93), and "Efficient" (mean 6.14, SD 1.36) criteria. UEQ scores were qualitatively similar across conditions, suggesting negligible additional burden associated with the NOLA Gem components relative to GEMA alone.

The distribution of these scores by study arm is visualized in Figure 5.

XSL•FO
RenderX

Figure 5. Short-form User Experience Questionnaire (UEQ) mean scores spider plot [63]: geographic ecological momentary assessment (GEMA) (control) versus New Orleans, Louisiana (NOLA) Gem + GEMA (treatment).

Qualitative Description

When prompted, many participants were able to specify their favorite NOLA Gem features. These favorites did not, however, exhibit any across-case consistencies: "I like how it was designed, the colors were very calming … It was simple and it was easy to navigate" (participant C); "The meditation, the extra sessions, the definitions. I read everything and it was very reassuring and inventive" (participant K). Some participants intuited the "just-in-time" EMA-triggered mechanisms of action, as captured by a "You seem a little stressed … it will tell you what you can do" in vivo code: "[I liked the app] asking about your health and your condition … When it's checking up on your skills based on how you feel at one point in time in your daily diary of what you're doing, depending on what space you're in at the time" (participant I); "[I liked] the way when it asks you a question you seem a little stressed today it will tell you what you can do to relieve stress. I liked that" (participant R). Participant L described benefiting from a broad range of intervention components:

> *I had a better [understanding] of myself, meditation and breath control, I really enjoyed all parts of the app and most of the time I got satisfactory. Men don't talk and think about their feelings and I really liked how it brought my feelings to the surface. When I do meditation, thanks to your app I learned that I don't have to be professional, I can just do it how it works for me. It also played a role in increasing my self-esteem. I never practiced breathing but thanks to your app I learned how to do it through the stomach.*

XSL•FO
RenderX

These benefits sometimes came with inherent tradeoffs, as pointed out by participant C:

> *My favorite part is the different type of coping mechanisms that are offered. It will be great for those who need them, if they can get past the survey.*

Six persistently evident across-case topics were detected amid the qualitative responses, 4 subordinate to an overarching "Frictions and frustration" category. Cohen κ scores, by code, ranged from 0.49 to 1.00. As such, human-LLM coding applications of "EMA questionnaire length [κ=0.64]," "EMA prompt timing [κ=0.63]," "EMA item attunement [κ=0.68]," and "You seem a little stressed … it will tell you what you can do [in vivo; κ=0.49]" underwent additional human triangulation and review to achieve consensus.

The length and timing of the daily diary surveys were consistently mentioned as frustrations among NOLA Gem participants: "The number of questions. Unable to complete the questions in three hours. Inconvenience part of the three-hour time limit" (participant E); "Survey is too long and redundant. No reason to ask the same questions in a different way" (participant F). Participant E pointed to the daily conflicts potentially raised by study participation (and, by extension, intervention fidelity): "Being that I work on a boat that starts at 6 and doesn't dock until 10, I do not have time to complete the entries"; "The times for diaries were inconvenient due to my work schedule," participant P concurred. The daily diary's *attunement* to the lives of enrolled people with HIV, as well as each question's cultural congruence and ecological validity in tapping routine stressors, was questioned sporadically as well: "the questions were all basically the same, in some cases it did not include emotions that I thought should be included … it asked about seeing trash in the neighborhood and I don't really understand how is that relevant for daily life" (participant J); "I do not drink and I could not answer the questions. Did not feel the questions applied to everyday life experiences for PWH" (participant H). In addition, occasional malfunctions were experienced by certain users: "I don't like that it glitches, last time I used it, it wasn't glitching, this time you could not log in man I didn't like that" (participant G).

Although some participants described the app's "perfection" ("Nothing is going to be perfect, but this app is perfect. All the tools. Keep it authentic, just the way you designed it," participant L), various recommendations for updates were elicited. These included multimedia options: "… incorporating audio to where it's like soothing or calming white noise, ocean, waterfalls, stuff like that" (participant C). Participant J felt that opportunities remain to activate the *adaptive* aspect of JITAI design: "I think that it should be a little more interactive, more interactive and it should adjust to what questions are being asked … doesn't seem to be lifelike; say after it asked about being depressed, it would just move on to the next question rather than going deeper into it." Similarly, participant P saw opportunities for enhanced personalization of the geofencing feature: "Just ask if a person is okay with being reminded that they're in a stressful area before they get alerted about it being stressful if you didn't ask beforehand."

Discussion

Principal Findings

We trialed NOLA Gem, a trauma-informed JITAI leveraging GEMA inputs to provide people with HIV in New Orleans adaptive coping skills refreshers, against a GEMA-exclusive control, over a 21-day pilot period. In general, GEMA + NOLA Gem users (n=22) endorsed high acceptability, particularly in domains of perceived helpfulness, ease of comprehension, and ease of use. Of the 32 participants enrolled, 30 (93.75%) completed at least 1 daily diary, highlighting the app's feasibility. Among GEMA + NOLA Gem (treatment-arm) participants, for every skill, completions exceeded recommendations, indicating a nontrivial rate of "pull," or user-determined, app interactions, and suggesting valuable "Big E" (behavioral) engagement among a subset of dedicated users [39,44]. Most skills saw zero inflation among their "minutes spent" distributions, which were heavily skewed; this pattern might indicate user self-selection into accessible LIFT skills. Conversely, these users might miss out on new and potentially more beneficial coping skillsets. Qualitative user experience concerns converged on the frictions and interaction costs associated with the twice-daily EMA inputs: their sometimes-inconvenient timing and often-burdensome duration. While the relatively low skills recommendation rate *among* daily diary completers suggests those items may not be parsimoniously tapping frequently encountered stressors, the lower recommendation rates also prevent habituation—users "tuning out" a JITAI due to excess "push" notifications of no clear benefit [44]. Nevertheless, many participants declined to offer recommendations for next-generation changes, describing the app as "perfect" and acknowledging the value of the "just-in-time" adaptive coping skills delivery intuitively.

The *protocolization*, or defining the ruleset that determines how intraindividual dynamic inputs trigger just-in-time interventions [44], for each stressor-triggered adaptive coping skills prompt was formally mapped by the study team via feature hypothesis charting in 2022. Work on within-person JITAI optimization has advanced substantially since then, incorporating methods as diverse as reinforcement learning [71], *N*-of-1 model-predictive controller personalization algorithms [72], LLM-enabled free-text user preference updates in real time [73], and, most commonly, microrandomized controlled trials to isolate the most promising, in Nahum-Shani terms, "states of vulnerability/opportunity" and "states of receptivity" for momentary intervention delivery [74]. NOLA Gem, in contrast, was protocolized based on the findings of Aims I and II [21] and HIV biobehavioral domain expertise. These rulesets were static [55], even as they responded daily to EMA inputs. It is evident, based on our qualitative findings, that the sprawling battery of inflexibly scheduled daily diaries [55] was the primary driver of user burden and, as such, the foremost threat to acceptability. Despite some participants' insistence that "nothing" in NOLA Gem should change, a clear opportunity exists to optimize the JITAI mechanisms of action, *re*-protocolizing and pruning surplus daily diary measures in an evidence-based manner.

XSL•FO
RenderX

Though, by most standards, our findings support the advancement to a fully powered randomized controlled trial, in light of the abovementioned emergent methods for JITAI optimization, an additional microrandomized controlled trial cycle using contemporary techniques may further enhance acceptability. Launching intraindividual microrandomized trials, the most robust *stressor → state of receptivity → coping skill → proximal outcome → distal outcome* dynamics can be modeled and protocolized, at a within-person and within-user base (eg, across an outpatient HIV clinic network) level [75]. Indeed, the required in-app feature set already exists, in the form of single-item "SkillCheck" quizzes tap each delivered skill's success in improving a hypothesized JITAI-consistent proximal outcome.

Such improvements would benefit the prospective user base of people with HIV. However, the efficiencies built in by such a "pruning" cycle would benefit future clinical workflow integration—a potential prerequisite to a successful Phase III trial—and, ultimately, scalability and sustainment. The nonadoption, abandonment, scale-up, spread, and sustainability of technological innovation framework recognizes 7 domains. These include the condition, or health issue itself; the technology under consideration; its inherent value proposition, supply- or demand-side; adopters, including staff, patients, caregivers, and providers; organizational climate; political and regulatory considerations; and temporal aspects of implementation and organizational resilience (or lack thereof) [76]. Interventions that incorporate rampant complexity across the sum of these domains are shown, across empirical case studies and hermeneutic literature reviews [77], to rarely, if ever, achieve scale and sustainability. HIV prevention and treatment, despite past policy successes, remain subject to a volatile political climate [78]. People with HIV engaged in outpatient care endure poverty, violence, and medical and psychiatric comorbidities disproportionately [1,7,11,79]. Complexity, across the HIV continuum of care, is all but assured. Even at the pilot stage, it is incumbent upon technologists and HIV digital therapeutics investigators to prioritize simplicity, wherever possible, in intervention design and delivery. The NOLA Gem pilot study, and, in particular, the valuable insights contributed by NOLA Gem pilot users, lay the groundwork for concurrent optimization via simplification to advance next-generation HIV mobile health.

This study is subject to limitations as well. First, the pilot sample was not powered to detect between-group differences, either in GEMA versus GEMA + NOLA Gem acceptability (a proxy for differential interaction costs [61]), or predictors of disparate acceptability across subsets of outpatients with HIV. Null findings on these questions should be understood as highly preliminary. In particular, we are unable to extend the important work of Hubach et al [60], revealing EMA-related confidentiality concerns among a sample of rural men who have sex with men. A confluence of external factors—namely the COVID-19 variants still endemic in Louisiana, and Hurricane Ida [46,47]—delayed the trial launch substantially, hampering our ability to obtain our preregistered enrollment target of 60 participants, and to achieve balanced 1:1 random assignment. Though oversampling treatment-arm participants was ultimately to the benefit of these analyses, focused on the experiences of those NOLA Gem–assigned participants, our capacity to demonstrate equivocal acceptability across GEMA and JITAI paradigms is, similarly, undermined. We are also unable to gauge meaningful engagement metrics via paradata due to the small sample size, beyond a dichotomized "high" versus "low" engager subsetting [80]. Although these findings suggest future directions for NOLA Gem optimization, and support the need for a fully powered randomized controlled trial, attention toward protocolizing user-centered in-app adaptiveness to spur engagement is needed [45,75].

Conclusions

Trauma, particularly trauma rooted in firsthand violence exposures, disproportionately affects the health and wellbeing of people with HIV [1]. Interventions tailored to the needs of people with HIV must not only address environmental stressors across spatial and temporal dimensions [17-20], but they must also embrace principles of trauma-informed care [2,7]. To this end, we developed NOLA Gem, a smartphone-delivered JITAI adaptation of the effective LIFT group intervention [39]. This pilot study demonstrated the acceptability, feasibility, and usability of NOLA Gem, supporting future optimization, and a fully statistically powered evaluation of the app's efficacy among outpatients with HIV.

Acknowledgments

The authors extend their gratitude to Kathleen J. Sikkema, Meghna Daga, and Anudnya Durgule of Crowdbotics; the nursing and research staff at the Louisiana State University Clinical and Translational Research Center; their Tulane-affiliated study staff (Lauren Baker, Claire English, Leah Kimbrough, and Chelsea Solano) and the participants of the New Orleans, Louisiana Gem pilot trial.

Funding

New Orleans, Louisiana Gem is funded by National Institute on Alcohol Abuse and Alcoholism R34AA028961 and P60AA009803. Additional support was provided by National Institute of General Medical Sciences U54GM104940, which funds the Louisiana State University Clinical and Translational Science Center. SJS was supported by a Garvin Shands Saunders Foundation scholarship for the duration of this work.

Abstract

Background: While behavioral interventions remain an evidence-based treatment for obesity, they often require long durations and frequent sessions. To address this, we hypothesized that interventions delivered in daily life via a smartphone app combined with personalized optimization using reinforcement learning may effectively support behavior changes.

Objective: This study aimed to develop and evaluate the feasibility of such an app for individuals with obesity.

Methods: We developed a smartphone app to assist in setting and reviewing daily behaviors related to weight loss. On the screen on which daily behaviors were shown, the order of presentation was optimized using Thompson sampling, a multiarmed bandit algorithm. Twenty individuals with obesity used the app for 4 weeks, and the daily app use rates were quantified. Body weight and mood status were measured daily during the study, and a brief-type self-administered diet history questionnaire and the International Physical Activity Questionnaire were administered at the beginning and end of the study. Changes in these measures were evaluated using the Wilcoxon signed rank test. Furthermore, the longitudinal data collected during this study were analyzed using a linear mixed-effects model to examine factors related to the number of behaviors performed daily.

Results: All 20 recruited individuals with obesity completed the 4-week study schedule. The median app use rate was 98.3% (range 76.9% - 100%). Significant improvements were observed in BMI (median at start 34.9 kg/m^2, range 27.4-52.9; median at end 34.1 kg/m^2, range 26.7 - 51.0; P=.01), as well as daily energy intake and weekend sitting time. The linear mixed-effects model showed a significant association between higher preceding depressive mood levels and fewer behaviors (P<.001).

Conclusions: The feasibility of the smartphone app using reinforcement learning for obesity was sufficient, and the potential effectiveness of the treatment was suggested. Preceding depressive mood may influence daily behaviors related to weight loss.

KEYWORDS

cognitive behavioral therapy; ecological momentary intervention; machine learning; multiarmed bandit; obesity; reinforcement learning; smartphone app

Introduction

Obesity leads to diseases such as type 2 diabetes and hypertension, which further increase the risk of serious complications, including cardiovascular diseases and certain types of cancer [1]. Obesity often coexists with psychiatric disorders and has a bidirectional relationship with them [2]. Obesity reduces well-being, resulting in a vicious cycle that leads to further weight gain [3]. The prevalence of obesity is increasing worldwide, including in Japan [4], underscoring the need for effective treatment.

Current obesity treatments include glucagon-like peptide-1 receptor agonists and bariatric surgery, which cause adverse gastrointestinal effects and postoperative psychiatric comorbidities, respectively [5-7]. Behavioral interventions remain important as a low-risk and low-cost treatment [5,8], and successful long-term weight maintenance often relies on behavioral strategies [5]. Although structured cognitive behavioral therapy for obesity has been developed [9,10], the frequent and long duration of sessions burdens both participants and therapists. Furthermore, behavioral science findings indicate that reinforcers should be provided immediately after performing behaviors [11], which is challenging in outpatient settings. To

XSL•FO
RenderX

address these issues, we hypothesized that ecological momentary intervention (EMI) through smartphone apps in daily life would be helpful [12,13].

In the context of EMI for obesity, tailored presentation of behavioral content may play an important role in promoting effective behavior change. In face-to-face cognitive behavioral therapy, behavior changes for diet and physical activity are tailored to individuals' daily lifestyles and preferences [9,10]. From a technical perspective, machine learning and reinforcement learning have been widely deployed for content optimization in modern web applications and smartphone apps [14]. One study used a multiarmed bandit algorithm, an optimization technique using reinforcement learning, to suggest health behaviors [15]. The algorithm explores items with limited prior information to reduce uncertainty and simultaneously exploits items with higher estimated rewards based on accumulated data. Such optimization by multiarmed bandit algorithms is applicable for recommending daily behaviors to individuals with obesity through smartphone apps.

Numerous studies on smartphone apps and web-based interventions for obesity have been conducted, and an umbrella review suggests that they can achieve greater weight loss when combined with usual treatments [16]. Relevant studies have involved sending text messages related to physical activity or dietary intake [17-20]. However, to the best of our knowledge, no study has used an app specifically designed for setting daily behaviors with personalization using machine learning or reinforcement learning. Accordingly, such an app would be novel and could lead to more effective treatments.

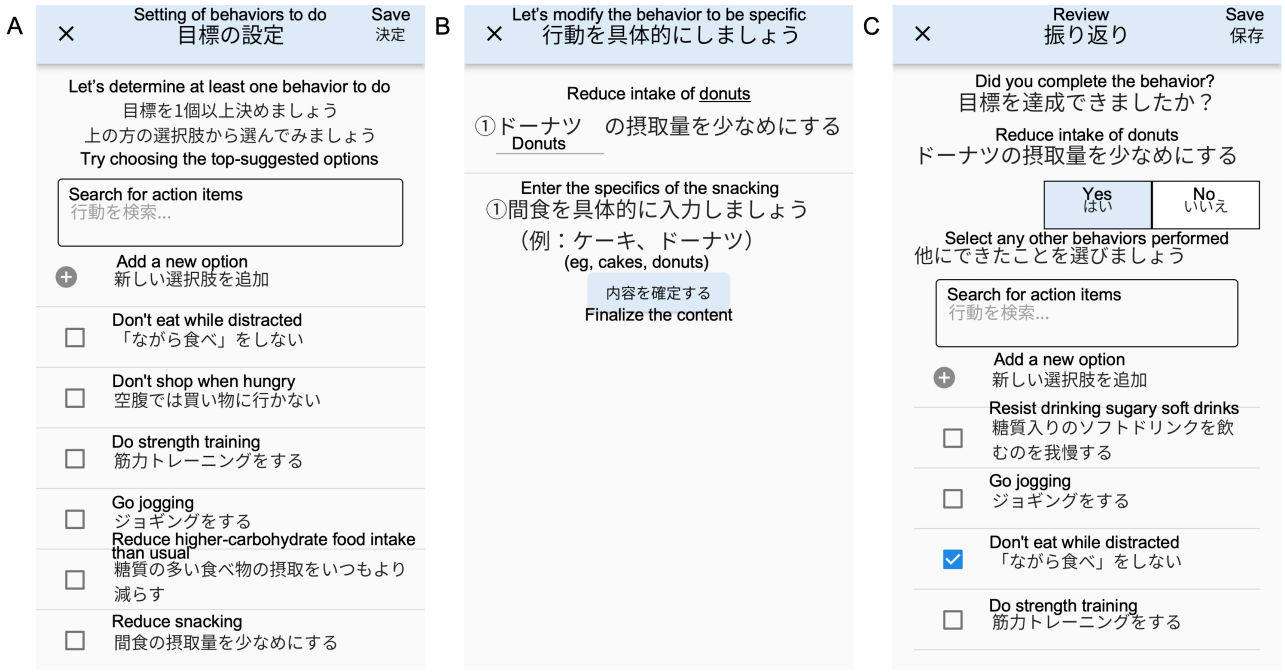
Additionally, the completion of behaviors related to weight loss suggested through smartphone apps may be influenced by daily psychosocial factors. Many psychosocial factors reportedly influence the maintenance and progression of obesity [2,3,5]. Studies using ecological momentary assessments, which analyze data collected in daily life, have suggested that preceding mood status and other factors influence daily calorie intake and physical activity in individuals with obesity [21-24]. Examining the relationship between daily behaviors and preceding mood collected through a smartphone app may help improve the app.

In summary, we hypothesized that interventions in daily life delivered via smartphone apps could effectively address current challenges in behavioral interventions and that personalization through multiarmed bandit algorithms could further enhance their effectiveness. Therefore, this study aimed to develop a smartphone app with a multiarmed bandit algorithm for individuals with obesity and evaluate its feasibility. In addition, as psychosocial factors may influence the effectiveness of this intervention, the secondary aim was to examine factors influencing daily behaviors related to weight loss.

Methods

Ethical Considerations

This study was approved by the Institutional Review Board of the University of Tokyo (2022061NI). The research protocol was registered with the University Hospital Medical Information Network Clinical Trials Registry (UMIN000048667). All the participants provided written informed consent. All data were anonymized, and access was limited to authorized research team members only. Participants received up to JP¥ 20,000 (approximately US $150 based on the exchange rate at the time of study start) via QUO Card.



Smartphone App

Figure 1 shows screenshots of the smartphone app we developed for obesity management. Users launch the app upon receiving a notification at the end of the day, typically in the evening at an individually preset time, and select behaviors to perform the following day (Figure 1A). The selected behaviors can be further modified for specificity (Figure 1B). The user receives reminder notifications several times the following day regarding the behaviors they have set. Upon receiving a notification at the end of the following day, users launch the app to record whether they performed the selected behaviors and log any additional behaviors (Figure 1C). Users then select the behaviors to perform the following day. The researchers prepared a behavioral list based on the cognitive behavioral therapy manual [9] and the Japanese guidelines for obesity management [4]. Each participant can also create original items individually. The app displays a complimentary message and a graphical presentation of the number of behaviors performed immediately after recording them.

The presentation order was optimized to display easily achievable, low-effort items earlier on the screen (Figure 1A). This optimization was based on the theory of cognitive behavioral therapy [9,10] and the Fogg behavior model [25], similar to a study on a smartphone app using reinforcement learning to promote health-related activities [15]. A multiarmed bandit algorithm was used, which simultaneously performs exploration (collecting data to determine which items are achievable) and exploitation (presenting achievable items based on the collected data). This has the advantage that it can be applied to even a small number of users while ensuring a diversity of suggestions [14].

XSL•FO
RenderX

Figure 1. Screenshots of the app (translated from Japanese into English): (A) at the end of the day, users select behaviors to perform the following day, with on-screen guidance encouraging them to choose top-listed items suggested by a reinforcement learning algorithm; (B) selected behaviors can be specified further (eg, “Reduce snacking” to “Reduce intake of donuts”); and (C) a notification is sent at the end of the following day to record whether the selected behaviors were performed. Users can also log additional behaviors performed.

We used Thompson sampling, a multiarmed bandit algorithm that does not require prior hyperparameter adjustments [14]. In this study, each behavior was treated as an independent arm and scored by a randomly sampled value of θ from the following beta distribution, where *N* is the number of times the user selects the item and *a* is the number of executions:

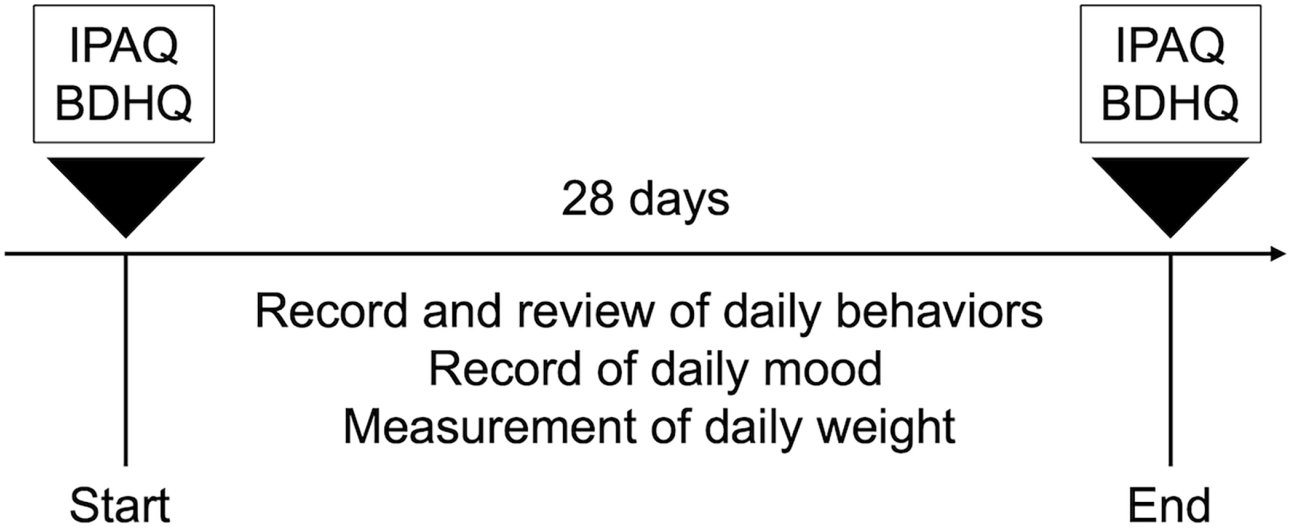
$$p\theta a,N=\theta a(1-\theta)N-a\int 01\theta a(1-\theta)N-ad\theta$$

When *N* is small, samples of θ from the beta distribution exhibit a large variance, and the model assigns random scores to behaviors with few selections, which promotes exploration. As *N* increases, the samples converge toward the actual achievable rate of each behavior, which promotes exploitation by assigning higher scores to behaviors with higher completion rates than to those with lower completion rates. In this study, each participant had an independent model trained using only their own behavior data. Each behavior was initialized with a uniform prior over the interval (0, 1).

The app was developed using Flutter (Google) and Firebase (Google). Reinforcement learning was implemented using Python (version 3.9; Python Software Foundation) on the Google Cloud Platform. The app was distributed exclusively to participants’ smartphones (iPhone or Android) through DeployGate (DeployGate, Inc) [26] rather than being publicly released on the Apple App Store or Google Play Store.

Study Participants

This study included individuals diagnosed with “obesity disease” according to criteria established by the Japan Society for the Study of Obesity. This disease is defined as a BMI of ≥25 kg/m^2 with one or more obesity-related disorders such as type 2 diabetes or visceral fat accumulation that likely causes health problems [4,27]. Individuals aged ≥18 years attending the University of Tokyo Hospital were eligible for this study. Exclusion criteria were (1) extremely severe physical or psychiatric diseases, (2) conditions for which the burden of the study would be harmful, and (3) lack of decision-making ability.



A previous study examining the feasibility of an app using a multiarmed bandit algorithm included approximately 20 participants over 3 weeks [15]. Following this, we set the study period to 4 weeks (28 days) and the sample size to 20. Eligible individuals were recruited continuously until the target sample size was achieved.

Study Procedure

Figure 2 provides the study schedule. At the beginning of the study, the Japanese version of the International Physical Activity Questionnaire (IPAQ) long form, last–7-day version, was used to assess physical activity [28]. The brief-type self-administered diet history questionnaire (BDHQ) was used to assess nutritional intake [29]. The BDHQ consists of questions assessing the consumption frequency of 58 food and beverage items over the preceding month and estimates average daily energy intake and various nutrient intakes.

XSL•FO
RenderX

Figure 2. Study schedule. The study period lasted 28 days, with the International Physical Activity Questionnaire (IPAQ) and brief-type self-administered diet history questionnaire (BDHQ) measured at the start and end of the study. Daily behaviors related to weight loss, mood, and weight were recorded during the study period.

During the study, daily behaviors were recorded using the app. Participants received a notification daily at a random time within a prearranged 1-hour interval and recorded their mood status (Figure 3). Nine items from the Depression and Anxiety Mood Scale were used to calculate scores for anxiety, positive affect, and depression [30]. This was recorded on a 101-point (0 - 100) visual analog scale. Additionally, we provided the participants with a body scale (HN300T2; OMRON) connected via Bluetooth to a smartphone (iPhone or Android) to record weight automatically [31]. Their weight was recorded daily upon waking.

XSL•FO
RenderX

Figure 3. Screenshot of records of daily momentary mood status (translated from Japanese into English).

At the end of the 4-week study, the IPAQ and the BDHQ were administered, as at the start of the study. The top 5 behaviors displayed on the app screen were evaluated on paper using a visual analog scale regarding their subjective likelihood of achievement. In addition, qualitative interviews were conducted to identify potential improvements to the app.

Statistical Analyses

Feasibility was assessed via app use rate, defined as the percentage of days on which the behavior was recorded during the study period. Relevant EMI studies using smartphone apps for obesity or type 2 diabetes have reported recording rates of approximately 80% to 95% [20,32,33], which we set as the benchmark for feasibility.

BMI, physical activity measured using the IPAQ, and calorie and salt intake measured using the BDHQ were compared between the start and end of the study using the Wilcoxon signed rank test, with statistical significance set at .05.

These analyses were performed using R (version 4.3.1; R Foundation for Statistical Computing).

Analysis of Predictors of Daily Behaviors for Weight Loss

In this post hoc analysis, we combined data on daily behaviors with mood status recorded within the preceding 24 hours. Only behavioral records reviewed more than 12 hours and less than 36 hours after setting were included. A linear mixed-effects model was developed using this nested longitudinal dataset, with the daily number of behaviors performed as the outcome. The outcome was defined as the sum of the preselected behaviors that were actually performed and any additional behaviors.

XSL•FO
RenderX

Level 1 variables included (1) preceding mood status (anxiety, positive affect, and depression) measured using the Depression and Anxiety Mood Scale, which was scaled from 0 to 1; (2) the difference between the weight recorded immediately before the behavior review and the weight at the start of the study; (3) the difference between the weight recorded immediately before the behavior review and the weight recorded at one earlier time point; and (4) the number of weeks, ranging from 1 to 4. Level 2 variables included (1) sex; (2) BMI at the start, centered by subtracting 35; and (3) the presence of comorbid psychiatric disorders. The inclusion of these variables and random effects was determined based on the Akaike information criterion.

R (version 4.3.1) and the package *lmerTest* (version 3.1-3) were used for this analysis.

Results

Feasibility Evaluation

Participants were recruited from August 2022 to July 2023, and all 20 individuals with obesity completed the 4-week study. Table 1 provides the descriptive statistics. The median app use rate, defined as the percentage of days on which behaviors were recorded, was 98.3% (range 76.9% - 100%), with a mean of 94.8% (SD 7.1%).

Table . Characteristics of the participants (N=20).

Treatment Effectiveness

Table 2 shows treatment-related results. BMI decreased significantly (median at start 34.9 kg/m^2, range 27.4 - 52.9; median at end 34.1 kg/m^2, range 26.7 - 51.0; *P*=.01). In total, 15% (3/20) of the participants gained weight during the study period, 2 of whom had undergone bariatric surgery. Significant changes were also observed in calorie intake and weekend sitting time.

[b]IPAQ: International Physical Activity Questionnaire.

[c]MET: metabolic equivalent of task.

Usability Survey

The median number of behaviors performed over the 4 weeks, including individually created behaviors, was 11 (range 6 - 27). The subjective evaluation of the achievability of the items presented at the top of the app screen, which ranged from 0 to 100, had a median score of 85 (range 58 - 100).

In the qualitative interviews, the most frequently raised concern was the following (8/20, 40%):

> *Toward the latter part of the study period, I tended to choose only a few types of items displayed at the top and felt a sense of monotony.*

This implies that the algorithm converged on a small subset of items with higher completion rates toward the end of the study, resulting in these items being repeatedly displayed at the top and predominantly selected by users.

The next most frequently raised concern was the following (6/20, 30%):

> *I was unable to modify some items to be more specific.*

This means that, although each behavior could be further specified, as exemplified in Figure 1B, users had difficulty doing so for several items.

Predictors of Daily Behaviors for Weight Loss

A total of 432 records collected during the study were included in the analysis. The final model developed based on the Akaike information criterion is presented below, where subscript *i* denotes each participant and subscript *j* denotes the time point. Yi,j is the daily number of behaviors performed, Depressioni,j is the preceding depressive mood, and Psychiatryi indicates the presence of psychiatric comorbidities. Fixed and random effects are represented by γ and ζ, respectively.

Level 1:

$$Y_{i,j}=\Pi_{0,i}+\Pi_{1,i}\text{Depression}_{i,j}+\varepsilon_{i,j}$$

Level 2:

$$\Pi_{0,i}=\gamma_{0,0}+\zeta_{0,i}$$

$$\Pi_{1,i}=\gamma_{1,0}+\gamma_{1,1}\text{Psychiatry}_i+\zeta_{1,i}$$

The coefficients of each variable are listed in Table 3. The following can be interpreted from each coefficient: (1) a higher preceding depressive mood was associated with fewer behaviors, and (2) individuals with comorbid psychiatric disorders had smaller coefficients for preceding depressive mood.

Table . Coefficients of the linear mixed-effects model for the daily number of performed behaviors.

	Fixed effects coefficient (95% CI)	*P* value
Intercept ($\gamma_{0,0}$)	4.45 (3.47 to 5.43)	<.001
Depression ($\gamma_{1,0}$)	−1.88 (−2.87 to −0.88)	<.001
Depression × psychiatric comorbidity ($\gamma_{1,1}$)	1.59 (0.34 to 2.85)	.01

Discussion

Principal Results

The smartphone app developed in this study for individuals with obesity was used by 20 recruited participants over 4 weeks, with a median use rate of 98.3%. Participants' BMI decreased significantly during the study period. Furthermore, a linear mixed-effects model based on data obtained through the app showed that a higher preceding depressive mood was associated with a reduced number of completed behaviors related to weight loss.

XSL•FO
RenderX

The median use rate was 98.3%, which exceeded the adherence rates of approximately 80% to 95% reported in relevant studies [20,32,33], indicating sufficient feasibility. Future studies should address the concerns identified in the qualitative interviews. To prevent the selection of behaviors from being monotonous, items that are consistently completed may be retired from the list. In addition, improving the clarity of item explanations may effectively address the challenges in specifying item content.

The median decrease in BMI was 2.3% over 4 weeks. The Japanese clinical guidelines recommend a 3% weight loss for individuals with a BMI of <35 kg/m^2 and a 5% to 10% weight loss for those with a BMI of ≥35 kg/m^2 over 3 to 6 months [4]. Accordingly, the weight loss achieved in this study appeared sufficient. Calorie intake and weekend sitting time improved, and these behavior changes may have contributed to weight loss. Thus, the developed app may be effective for weight loss.

The effect size should be interpreted with caution due to several features of this study design. Daily weight measurements were conducted throughout the study, which may have influenced weight loss [34]. In total, 15% (3/20) of the participants gained weight during the study, 2 of whom had undergone bariatric surgery, a population known to frequently experience weight regain [35]. A previous umbrella review of smartphone app and web application interventions for obesity showed a mean difference of −0.12 kg compared with face-to-face treatment and −4.32 kg compared with no treatment [16]. However, our study was a single-arm trial with a follow-up duration different from those of previous studies, making direct comparisons difficult. Therefore, further studies are warranted to more accurately determine the effect size of the app developed in this study.

Given the high ratings for the subjective likelihood of achievement of the top-suggested items, with a median of 85 on a scale from 0 to 100, the multiarmed bandit algorithm seemingly approached convergence. Qualitative interviews revealed that the participants tended to choose only a few types of items presented at the top and reported a sense of monotony, further suggesting algorithm convergence. Future studies with more accumulated data should evaluate the convergence of the algorithm and may consider applying other optimization approaches such as collaborative filtering [14]. On the basis of the Fogg behavior model [25], this study prioritized behaviors based solely on completion rates; however, future studies should also consider the behaviors' contributions to clinical outcomes such as weight loss, along with the effort and duration required for achievement.

In the post hoc analysis, the linear mixed-effects model showed that preceding depressive mood was related to weight loss behaviors. This aligns with a previous study showing that baseline depression is associated with emotional eating and binge eating [22]. One study showed that delay discounting mediates the association between depressive symptoms and the onset of diabetes [36], which may help explain these findings. Another study suggested that individuals with higher levels of depression exhibited unhealthy behaviors such as physical inactivity [37]. On the basis of these findings, future studies may benefit from providing suggestions on the number of behaviors to select on the app and prioritizing lower-effort behaviors according to daily depression levels. The interaction coefficient of depressive mood and psychiatric comorbidity was positive, indicating that, when adjusted for depressive mood as a covariate, the number of behaviors performed was large for individuals with psychiatric diseases. This may suggest that treating psychiatric disorders positively influences weight loss behaviors; however, further studies are needed to interpret these findings.

Limitations and Future Directions

This study has several limitations. First, the study period was short, and long-term use of the app remains unexplored. Second, the dietary and physical activity questionnaires were administered only at baseline and after the intervention, which limited assessment of temporal changes and intervention feasibility. Third, energy intake estimated using the BDHQ appeared low. Alternative assessment tools such as the Automated Self-Administered 24-hour dietary recall [38] may be preferable in future studies. Fourth, this study used weight alone without distinguishing between fat and muscle mass; this is particularly relevant for participants receiving glucagon-like peptide-1 receptor agonists or who underwent bariatric surgery. Future studies should assess body composition using tools such as bioelectrical impedance analysis. Fifth, in the optimization algorithm, the behaviors were evaluated only with regard to achievability. Their contributions to weight loss may vary and should ideally be incorporated into the algorithm. Sixth, the impact of the multiarmed bandit algorithm on optimization remains unevaluated. Seventh, the effect size for weight loss was inconclusive in this single-arm study. Finally, the analysis of the relationship between preceding depressive mood and daily behaviors used only the subjective input of behavioral execution.

Future research should improve the app based on the findings of this study and assess the treatment efficacy through a randomized controlled trial with a longer follow-up period. Additionally, future studies should assess the contribution of optimization to weight loss using a randomized design that compares optimized and nonoptimized interventions. Furthermore, although this study used an item-fixed measurement based on classic test theory, future research could use computer-adaptive tests [39,40] to measure mood status more efficiently.

Conclusions

The smartphone app for obesity developed in this study demonstrated sufficient feasibility, and its potential effectiveness for weight loss was suggested. Data obtained through this app indicate that a preceding depressive mood may influence daily behaviors related to weight loss.

Abstract

Background: Postural education is crucial during childhood and adolescence, yet traditional approaches often lack engaging tools that promote awareness and behavioral change. Wearable technologies and real-time biofeedback systems offer new opportunities to support postural learning through immediate, embodied feedback. However, most existing systems focus on clinical rehabilitation, with few designed specifically for educational use.

Objective: This study aimed to design, develop, and evaluate the usability and technical performance of EduBack, a mobile app that delivers real-time lumbar posture biofeedback through inertial sensors, with a specific focus on educational settings such as schools and physical education environments.

Methods: EduBack was developed using Kotlin (JetBrains) for Android OS (Google; version 8.0 and above) and integrates with 2 inertial measurement units via Bluetooth (2.4 GHz). The app provides visual biofeedback through a dynamic interface showing a virtual spine, corrective messages, and a color-coded alignment bar. The usability evaluation involved 24 undergraduate students (mean age 21.4, SD 1.8 y) who used the app in a controlled session. Participants completed the system usability scale and open-ended qualitative feedback questions. Technical performance data were collected from system logs, latency measurements, and received signal strength indicator values to assess connection stability and sensor-to-app communication.

Results: The average system usability scale score was 83.5 (SD 8.7), indicating excellent usability. Participants reported the interface to be intuitive, the biofeedback visualization clear, and the posture information easy to interpret. Qualitative responses highlighted the app's potential to support postural awareness and motor learning, especially in school-aged populations. From a technical perspective, the system demonstrated robust performance: mean data transfer latency was approximately 120 milliseconds, with less than 1% packet loss across sessions. Received signal strength indicator values consistently remained within the optimal signal range, confirming stable Bluetooth connectivity. All session data were successfully stored and exported without errors. The real-time posture tracking displayed on the app closely matched raw sensor data, ensuring fidelity in feedback.

Conclusions: EduBack is a usable and technically stable mobile app designed to support postural education through wearable sensors and real-time biofeedback. Its user-friendly interface and reliable data transmission make it well-suited for use in schools and educational programs targeting postural health. The app fills a gap in the mobile health field by offering a preventive, educational tool rather than a clinical one. Future research should explore its application in younger populations, integration into physical education curricula, and long-term effects on postural behavior and motor skill acquisition.

Introduction

Musculoskeletal disorders represent one of the most prevalent health problems across different age groups and populations and are currently recognized as a major global public health concern [1,2]. Among these, low back pain (LBP) is particularly significant, as it is one of the most widespread conditions [3,4], surpassing complaints in other spinal regions such as the cervical or thoracic spine [4,5]. Its global incidence has increased by approximately 55% over the last 3 decades, making it the leading cause of work-related disability today [3-9]. Current estimates suggest that by 2050, nearly 850 million people worldwide will

XSL•FO
RenderX

suffer from LBP, representing a 36% increase from 2020 levels [4].

Unfortunately, children and adolescents are not exempt from this musculoskeletal condition [10,11]. The lifetime prevalence of LBP by ages 10 - 12 years is approximately 20%, increasing significantly during adolescence and reaching rates comparable to adults—up to 70% by late adolescence [12,13]. Several studies have highlighted the upward trend in LBP prevalence among adolescents over the last 2 decades [1,14,15].

LBP is considered a multifactorial syndrome, influenced by a range of biological, biomechanical, psychological, emotional, behavioral, and environmental factors [16-21]. Among the modifiable risk factors, poor postural hygiene, obesity, improper lifting techniques, prolonged sedentary behavior, and low levels of daily physical activity have been identified [5,7,16,20-23]. Although multidisciplinary approaches are often recommended for LBP prevention and treatment [24], there is broad consensus that physical exercise combined with posture-focused educational programs is one of the most effective strategies for reducing both the incidence and severity of LBP [3,25-27].

Numerous researchers and international organizations have advocated for posture education and its integration into school-based programs as a strategy to prevent both present and future LBP [28-39]. This may be due to the strong potential of educational institutions to equip children and adolescents with the knowledge and skills necessary to preserve and improve their health [39,40]. Indeed, one of the most powerful tools to prevent back pain—or at least reduce its frequency and severity—is the implementation of educational interventions that promote long-term acquisition of postural knowledge and healthy habits [39,41].

Technology plays a pivotal role in modern education and has demonstrated clear benefits in enhancing student learning outcomes [42-44]. In this context, biofeedback has emerged as an efficient and effective tool for enhancing postural awareness and promoting corrective behavior in diverse activities and settings [45-48]. Biofeedback is a technique that monitors and quantifies physiological or biomechanical parameters and converts them into real-time visual, auditory, or tactile signals [49,50]. Technological advances have enabled the integration of biofeedback into wearable systems, which offer advantages such as portability, lightweight, low cost, and energy efficiency [51-53].

Despite these advances, wearable tools specifically designed to provide postural biofeedback in educational settings remain limited [45,54]. This scarcity is largely due to the recent emergence of such technologies, as well as the lack of published studies evaluating their implementation and effectiveness in schools. Although some posture-monitoring and correction devices exist, most are designed for clinical or sports use and are poorly adapted for educational contexts. As a result, further research is needed to explore the role of these technologies in teaching and learning healthy postural habits. In particular, such research is envisioned for children and adolescents in both primary and secondary school settings, where early intervention is most relevant for long-term musculoskeletal health.

Therefore, the objective of this study was to develop and preliminarily evaluate EduBack, a mobile app based on inertial sensors and real-time biofeedback. Specifically, this study aimed to assess the usability and technical performance of the system as a first step toward its long-term educational goal of supporting the learning and internalization of correct lumbar posture in school settings. The study followed a descriptive technological development design with an embedded user evaluation, combining the development of the EduBack system with a preliminary assessment of its usability and technical reliability.

Methods

Study Design

This study followed a cross-sectional descriptive technological development design with an embedded user evaluation (mixed methods approach). Detailed methods are presented in the following subsections.

Participants

Although the long-term target population of EduBack is children and adolescents, university students were intentionally selected for this preliminary evaluation to ensure feasibility and technical stability before adapting the system to younger users. Therefore, a convenience sample of 24 undergraduate students (mean age: 21.4, SD 1.8 y; n=10, 42% female participants) from the Faculty of Education was recruited. Inclusion criteria were: (i) no known musculoskeletal or neurological conditions affecting posture and (ii) basic familiarity with smartphone use.

Ethical Considerations

All participants provided written informed consent after receiving detailed information about the study procedures, potential risks, and their right to withdraw at any time without penalty. This study was approved by the Ethics Committee of the University of Alicante (reference number UA-2023-11-16) and conducted in accordance with institutional guidelines and the principles of the Declaration of Helsinki.

All data were anonymized prior to analysis, and no identifying information was collected or stored. Privacy and confidentiality were ensured throughout the study, with data accessible only to the research team. Participants did not receive financial or material compensation for their involvement. The sample consisted of adult undergraduate students, who are not considered a vulnerable population.

Tools and Instruments

System Conceptualization

Based on a review of the literature on wearable tools for postural education [51-53], design principles for educational systems aimed at postural training [36,40,55], usability evaluations of similar health technologies [56,57] and user reviews of commercially available mobile apps for postural correction (Google Play and Apple App Store), 3 core features were defined to build an effective mobile educational system for postural hygiene and training: (i) real-time biofeedback of lumbar posture using inertial sensors, providing immediate visual feedback to raise awareness and enable posture correction;

XSL•FO
RenderX

(ii) local data recording and storage for long-term postural monitoring; and (iii) personalized recommendations based on the user's postural patterns, including suggestions, adaptations, or corrective cues.

Furthermore, for the system to be suitable for long-term educational use, we established the following usability requirements: (i) the interface must be intuitive and user-friendly, requiring no prior technical knowledge from students and (ii) both data collection and postural feedback must be automated and seamlessly integrated into activities to avoid interfering with the learning process.

App Development

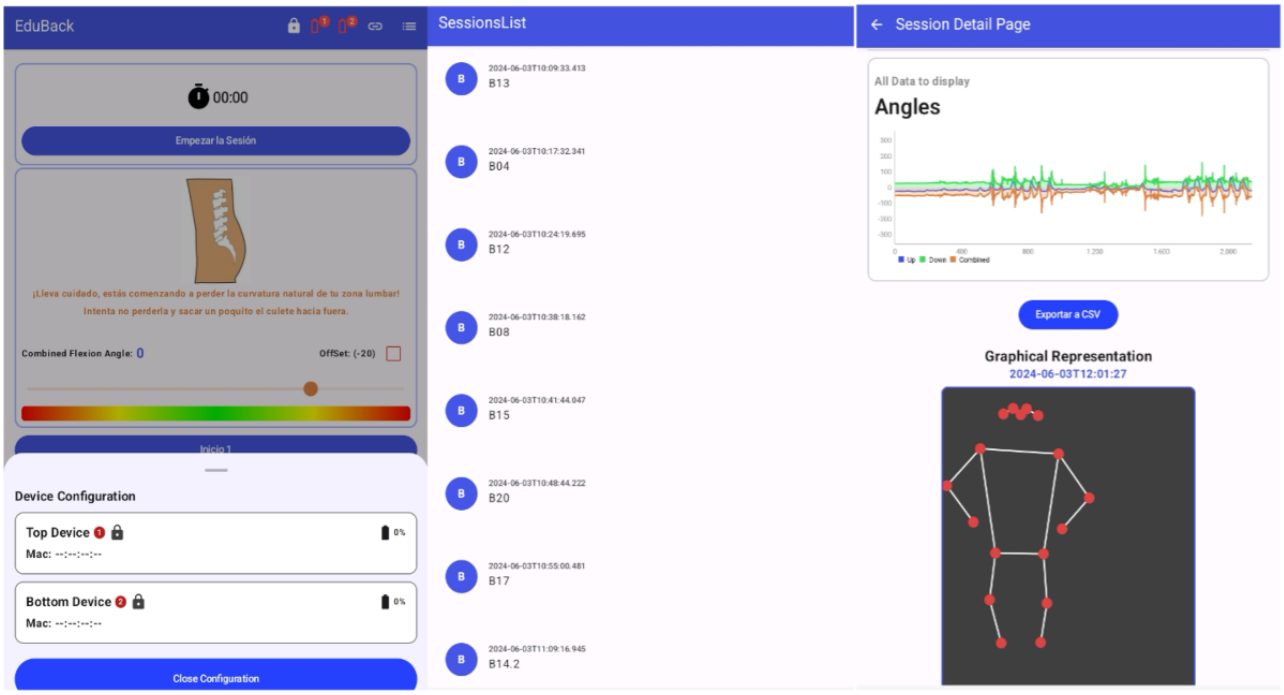
During the initial development phase of the EduBack system, a list of key parameters for real-time postural monitoring and biofeedback was formulated. Due to the lack of existing solutions that met our specifications—particularly apps offering intuitive and real-time visualization of lumbar posture in educational settings—we developed a dedicated mobile app to effectively collect and display this information.

Technically, the EduBack system is composed of two primary components: (i) a mobile app designed for local data collection and real-time visual feedback, enabling students to autonomously and effectively monitor their posture and (ii) an inertial measurement unit (IMU) system, consisting of 2 IMU devices placed on the user's lumbar spine. These devices connect via Bluetooth to a smartphone or tablet running the EduBack app and are responsible for capturing data on spinal alignment and movement.

In addition, the EduBack app integrates a computer vision module (MoveNet) to provide a simplified visual representation of the user's skeleton. This representation is based on 17 anatomical reference points (head, shoulders, elbows, wrists, hips, knees, and ankles), detected in real time through the smartphone or tablet camera and displayed using Canvas. The purpose of this visualization is to complement the inertial sensor data with intuitive feedback, enhancing user awareness of posture during educational tasks. Importantly, this skeletal visualization was intentionally designed as a set of abstract points rather than a full video image, in order to respect user privacy. This approach is particularly relevant for the intended target population of children and adolescents, as it allows external recording of postural tasks by another person without displaying identifiable visual features of the participant.

Overview of the EduBack System

EduBack is a mobile app developed using Kotlin for devices running Android OS 8 and above. It features three main screens: Home, List, and Detail. The Home screen basically displays: (i) the sensor status (connection, inclination, etc); (ii) a real-time visual representation of 17 points, based on Canvas and MoveNet, showing the human skeleton detected by the smartphone or tablet camera; and (iii) the integrated biofeedback that includes a spinal visualization with associated messages, a color bar, and a dynamic dot that moves along the bar according to the user's posture. The List screen provides an overview of recorded sessions. In the Detail screen, users can view ratings and key details for each recorded session. Figure 1 displays the 3 main screens of the app, while Figure 2 illustrates some graphical representations of the EduBack app's functionality and its biofeedback, such as when lifting a heavy object from the ground.



XSL•FO
RenderX

Figure 1. Illustrative examples of the EduBack app functioning and its biofeedback indicators for lumbar posture. Panel A shows the neutral lumbar lordosis, which refers to the natural inward curvature of the lumbar spine in standing posture. Panels B and C represent intermediate deviations from this neutral posture. Panel D illustrates lumbar hyperlordosis, defined as an excessive inward curvature of the lumbar spine. Panel E illustrates lumbar kyphosis, defined as an abnormal outward curvature of the lumbar spine in the lumbar region. Together, these examples demonstrate how the EduBack app provides real-time visual feedback on different postural states.

XSL•FO
RenderX

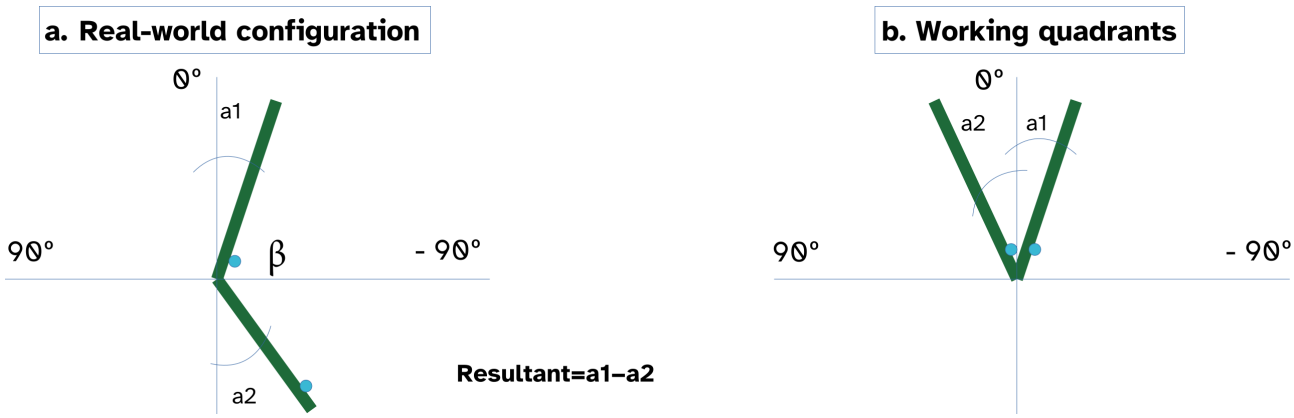


Figure 2. Main screens of the EduBack mobile app. The Home screen (left) displays the sensor status (connection and inclination), a real-time skeleton visualization based on 17 anatomical points detected by the device camera, and integrated biofeedback including a spinal visualization, color bar, and dynamic dot indicating posture. The List screen (center) provides an overview of recorded sessions. The Detail screen (right) shows ratings and key information for each recorded session, allowing users to review their performance and feedback.

The design of the EduBack interface was informed by principles of motor learning, instructional design, and behavior change. Systematic reviews and meta-analyses have consistently shown that color-coded visual cues and dynamic prompts enhance attentional focus, facilitate error correction, and support self-regulated learning in motor tasks [58,59]. Similarly, systematic reviews in instructional design highlight the pedagogical value of visual displays for improving comprehension and engagement [60]. Finally, reviews of digital behavior change interventions confirm that immediate, intuitive feedback is a key driver of adherence and habit formation [61,62]. These findings provide a strong theoretical and empirical foundation for the interface design choices implemented in EduBack.

Figure 3 illustrates how the lumbar angle was estimated from the inclinations of the 2 IMUs placed at L1 and S1. Each sensor provided a flexion angle relative to the vertical axis (A1 and A2). In practice, these angles are calculated in opposite quadrants, with opposite signs. By subtracting them, the resultant angle corresponds to the relative inclination between the 2 sensors, with the sign indicating the orientation direction. The lumbar angle β was then obtained as 180 minus this resultant value. This computational approach has been previously validated in García-Luna et al [63], where IMU-derived pelvic and lumbar tilt angles showed high agreement with a 3D optical motion capture system, considered the gold standard for kinematic assessment.

Figure 3. Representation of the lumbar angle calculation using 2 inertial measurement units. Each sensor (placed at L1 and S1) provides an inclination relative to the vertical axis. By combining these values, the relative lumbar angle (β) is obtained, with the sign indicating orientation. Blue points represent the inertial measurement unit LEDs, showing sensor orientation.

RenderX

Data Processing Software

The mobile app connects to the inertial sensors using Bluetooth Low Energy, a protocol that supports low-latency communication. Once paired, the device transmits data via notifications, which are received by the smartphone. Internally, the data—originally in byte format—is decoded using bitwise operations and mathematical transformations to convert hexadecimal values into decimal format, allowing for accurate on-screen visualization.

While receiving the data, the app stores it in a local database to enable later retrieval and export in CSV format. This export process transforms the locally stored tabular data into rows and columns, a common practice in this type of system. Storage capacity depends on the available device memory; however, modern smartphones typically do not present limitations in this regard. The app uses a secure local database implemented with Room (Android persistence library) to ensure reliable record keeping.

At the beginning of each session, the user must connect the sensors, triggering real-time data transmission and visualization. During the session, data is temporarily stored in cache memory; once the session ends, the data is transferred to the local database. This process ensures data persistence and prevents information loss if the app is restarted.

Inertial Sensors

The inertial sensors used were Ergotex IMUs (JVTech Solutions), designed specifically for spinal posture monitoring. Each device operates at a frequency of 20 Hz and is equipped with a triaxial gyroscope (±1000 deg/s) and triaxial accelerometer (±2 g), enclosed in a compact unit measuring 21×10 mm and weighing only 8 grams. These sensors record acceleration across 3 axes and transmit data in real time via Bluetooth (2.4 GHz) to a mobile device running the EduBack app.

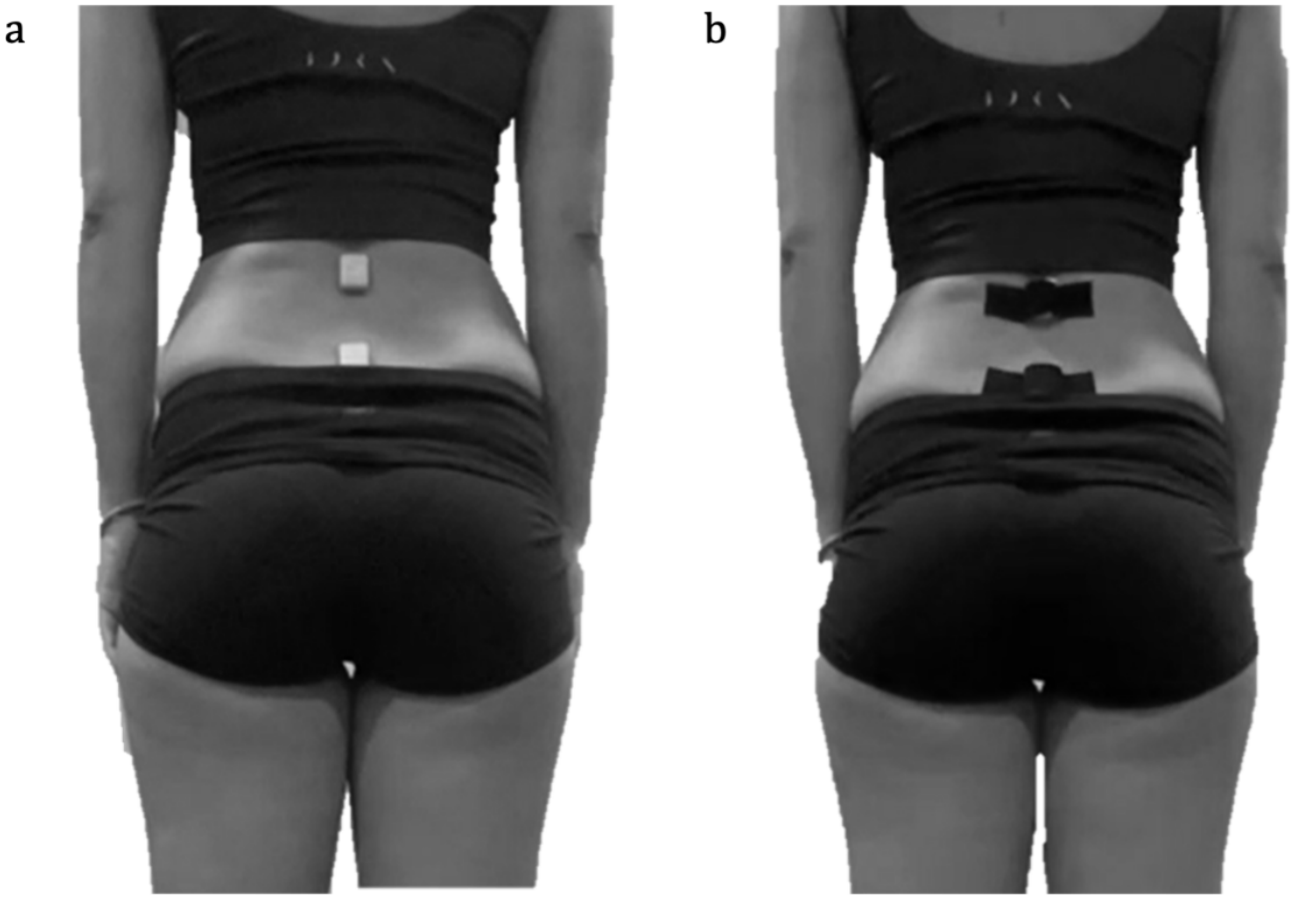
To ensure optimal performance, each Ergotex IMU integrates the ICM-20602 MEMS MotionTracking sensor (TDK Corp), known for its high accuracy and reliability. This sensor offers a gyroscope sensitivity error within ±1% and gyroscope noise levels of ±4 mdeg/s/√Hz, while accelerometer noise is maintained at 100 µg/√Hz. Additionally, its integration with a 1K-byte first-in, first-out buffer reduces serial bus traffic, enhancing measurement stability and energy efficiency.

The system includes a battery connected to a regulated power supply to ensure a stable voltage output. A microprocessor collects the raw data from the accelerometer and gyroscope through the serial peripheral interface bus and sends the processed information to a radio frequency module for wireless transmission. This system allows for efficient data flow and ensures the precision and reliability of postural data collection.

Importantly, the concurrent validity of these inertial sensors for estimating lumbar and pelvic tilt angles has been previously established against a 3D optical motion capture system, considered the gold standard for kinematic assessment. García-Luna et al [63] reported minimal systematic error (0.08° overall) and high agreement between IMU-derived angles and optical measurements, with correlation coefficients exceeding 0.90 and mean absolute errors around 1°. Bland-Altman analyses confirmed that most data points fell within ±2° limits of agreement, supporting the accuracy of the Ergotex IMUs for sagittal pelvic tilt measurement in both static and dynamic positions. These findings validate the suitability of the sensors for postural monitoring in educational contexts and justify their use in the present study.

Usability Assessment Instrument

To assess the perceived usability of the EduBack app, participants completed the Spanish version of the system usability scale (SUS) [64] immediately after the testing session. The SUS is a widely used, validated 10-item questionnaire that provides a global view of subjective usability [65,66]. Each item is scored on a 5-point Likert scale ranging from “strongly disagree” to “strongly agree.” The total score ranges from 0 to 100, with higher scores indicating better usability. The SUS was selected due to its brevity, ease of application, and frequent use in digital health evaluations, making it an appropriate benchmark for assessing mobile health-related apps [67-69].



In addition to SUS, qualitative comments on educational value (biofeedback clarity, motor awareness, and school applicability) were collected post-session to complement usability scores.

Procedure

Participants were individually invited to a simulated laboratory setting replicating a postural education session. Sensor placement over the spinous processes of L1 and S1 (Figure 4) was performed directly by a trained researcher to ensure consistency and reliability of the instrumentation. Likewise, all instructions regarding the use of the EduBack app and the inertial sensors were provided orally by the researcher during the session, with no written guide, to guarantee standardized guidance across participants. Each participant then used the EduBack app on a standardized tablet provided in the laboratory during a guided 30-minute session that included a predefined sequence of postural tasks. The protocol included anterior and posterior pelvic tilts in both standing and seated positions, forward and backward trunk inclinations, picking up an object from the floor, and repeated sit-to-stand transitions from chairs of different heights, in addition to maintaining upright and seated postures. All participants performed the same tasks in the same order under standardized instructions. Sessions were conducted individually, with each participant completing the protocol one by one under controlled laboratory conditions. During the session, real-time feedback was displayed on the app. After completing the session, participants were asked to evaluate the app’s usability using a validated questionnaire. In addition, brief qualitative comments were collected regarding the perceived educational value of the biofeedback (clarity, motor awareness, and applicability in school contexts), complementing the quantitative usability scores.

XSL•FO
RenderX

Figure 4. . Placement of the inertial sensors over the spinous processes of L1 and S1. (A) Sensors were initially attached to the skin using hypoallergenic double-sided tape. (B) Sensors were subsequently secured with kinesio tape to ensure stability during the 30-minute postural task protocol.

Data Analysis

Descriptive statistics were used to analyze the usability data. SUS scores were calculated according to standard methods [65], and summarized using means, SDs, and score ranges. Technical performance data were collected through internal logs generated by the EduBack app, including latency (sensor-to-screen transfer time), Bluetooth connection stability, and data packet loss rate. Signal quality was additionally assessed using the Received Signal Strength Indicator, a standard metric for evaluating the strength of wireless signals. Based on predefined thresholds, signal quality was classified as optimal (−50 to −70 dBm), moderate (−70 to −80 dBm), or poor (below −93 dBm), with all sessions falling within the optimal range. These metrics were used to evaluate the robustness of the hardware-software integration and the reliability of real-time postural monitoring. Analyses were conducted using SPSS Statistics (version 27; IBM Corp). Qualitative feedback was collected in the form of brief participant comments at the end of each session and reviewed descriptively to complement the quantitative usability scores.

Results

System Usability

The usability of the EduBack app was assessed using the SUS (Spanish version), a widely validated instrument for evaluating user satisfaction and perceived system usability. The overall mean SUS score obtained was 83.5 (SD 8.7), which corresponds to an "excellent" rating according to established interpretation thresholds [66]. This result places the system well above the average usability benchmark of 68, indicating a high level of user satisfaction and ease of use.

A closer inspection of individual SUS items revealed that the system was particularly well-received in terms of learnability and confidence. For example: (1) 90% (18/20) of participants "strongly agreed" or "agreed" that they felt confident using the system; (2) 85% (17/20) considered that most people would learn to use the app very quickly; and (3) 90% (18/20) agreed that the app was easy to use and that its functionalities were well integrated.

Items related to system complexity and the need for technical support also received favorable evaluations: 90% (18/20) of users reported that they did not require technical assistance to use the app, and 85% (17/20) strongly disagreed with the statement that the system was unnecessarily complex.

Despite these high scores, certain aspects showed slightly more variability. While still favorable, the lowest-rated item was related to the consistency of the interface, where 70% (14/20) users "strongly agreed" or "agreed" that the various system functions were well integrated, and 20% (4/20) selected a neutral response. This suggests a potential area for further refinement in terms of user interface design consistency and alignment across different screens or tasks. No participants rated the system as cumbersome or difficult to use, and no significant usability issues were reported during the testing sessions.

XSL•FO
RenderX

A detailed breakdown of responses to each SUS item is provided in Table 1, which highlights item-level agreement rates and helps pinpoint specific strengths and areas for improvement.

Table . Participant responses to individual SUS[a] items (N=20).

SUS item	Statement (paraphrased)	Agree/strongly agree, n (%)	Neutral, n (%)	Disagree/strongly disagree, n (%)
1	I would use this system frequently	17 (85)	2 (10)	1 (5)
2	The system is unnecessarily complex	1 (5)	2 (10)	17 (85)
3	The system was easy to use	18 (90)	2 (10)	0 (0)
4	I would need help from a technical person	1 (5)	1 (5)	18 (90)
5	The functions were well integrated	14 (70)	4 (20)	2 (10)
6	The system was inconsistent	2 (10)	3 (15)	15 (75)
7	Most people would learn to use it quickly	17 (85)	2 (10)	1 (5)
8	The system is cumbersome to use	0 (0)	1 (5)	19 (95)
9	I felt confident using the system	18 (90)	2 (10)	0 (0)
10	I needed to learn a lot before using the system	1 (5)	2 (10)	17 (85)

[a]SUS: system usability scale.

Technical Performance

The Bluetooth connectivity between the IMU sensors and the EduBack app remained consistently stable throughout all test sessions. System performance logs indicated an average latency of 120 milliseconds for sensor-to-screen data transfer, ensuring a responsive user experience. The rate of data packet loss was minimal, remaining below 1% across all sessions, and no failures in data storage or export were recorded.

Received signal strength indicator values monitored during the sessions consistently remained within the optimal range, confirming stable wireless communication between the sensors and the mobile device as defined by technical thresholds.

Real-time lumbar posture tracking was accurately displayed within the app's biofeedback interface, as confirmed by synchronized screenshots and analysis of the raw data logs. These results support the technical reliability of the EduBack system for continuous, real-time postural monitoring in educational settings.

Qualitative Feedback

Qualitative feedback collected during the usability evaluation provided additional insights beyond the SUS scores. Participants highlighted that the real-time biofeedback display, with its color-coded indicators and dynamic corrective prompts, enhanced their understanding of lumbar movement and posture control. Several students emphasized that the app facilitated motor awareness and contributed to acquiring correct lumbar mobilization patterns, supporting functional learning and the transfer of healthy postural habits to everyday activities. Importantly, participants suggested that EduBack could be particularly beneficial in school settings, especially for children and adolescents, where early postural education is essential for prevention and long-term musculoskeletal health. These comments illustrate the perceived educational value of the system and its potential applicability in real-world contexts.

Discussion

Principal Findings

This study presents the development process (described in the Methods) and reports the preliminary evaluation of EduBack, an innovative mobile app designed to deliver real-time postural biofeedback through wearable IMU sensors. The primary goal of the present study was to evaluate usability and technical reliability, establishing feasibility for future educational apps. While the long-term aim of EduBack is to facilitate postural education and the internalization of correct lumbar posture, these educational outcomes were not directly assessed here and remain directions for future research.

System Usability

From a usability perspective, the results demonstrated that EduBack achieved high acceptance among participants, with SUS scores indicating strong usability. Feedback from undergraduate students was notably positive. Participants appreciated the intuitive interface, particularly the biofeedback visualization that included dynamic color bars, real-time vertebral tracking, and corrective prompts. These findings suggest that the interface design and feedback mechanisms are transferable to educational contexts, although future studies

XSL•FO
RenderX

should confirm this in younger populations. This type of immediate, embodied feedback appears to support postural self-awareness—a key aspect of motor learning—and may foster metacognitive reflection about posture, which is rarely achieved through traditional instruction alone. Unlike clinical systems where usability is often compromised by multisensor burden or complex interfaces, EduBack's simplicity may represent an advantage for adoption in schools. These outcomes align with prior findings on the effectiveness of biofeedback systems in physical rehabilitation and posture correction [45-48], but extend them by highlighting usability in an explicitly educational context.

Technical Performance

Regarding technical performance, the system proved reliable under real-time conditions. The results confirmed that the system performs with low latency and minimal data loss during sensor-to-screen transmission. Participants experienced stable Bluetooth connectivity and consistent visual feedback, which suggests that the system is well-suited for educational environments that demand real-time interaction and reliability. Additionally, session data were securely stored and successfully exported, which is essential for both instructional follow-up and research use. It should be noted that in this context, "reliability" refers to technical robustness rather than psychometric reliability of the instrument. Psychometric reliability (eg, test-retest or interrater consistency) was not assessed in this preliminary study and remains an important direction for future validation. Prior studies have reported frequent technical challenges in wearable systems (eg, unstable wireless connections and battery limitations), which often hinder long-term use [70,71]. By demonstrating stable connectivity and efficient data handling, EduBack addresses some of these recurring barriers, although further testing in uncontrolled environments (eg, crowded classrooms) and formal reliability analysis are needed to confirm its robustness and measurement consistency.

Qualitative Feedback

Qualitative feedback provided complementary insights into the educational value of EduBack. EduBack is distinguished from other wearable-based systems by its explicit focus on postural education rather than clinical intervention. Most prior research in this field has focused on rehabilitation in patients with chronic back pain, scoliosis, or musculoskeletal disorders [45,53,56]. Clinical and occupational apps of wearable posture systems commonly collect user-level information (eg, perceived usefulness, convenience, comfort, and practicality) alongside objective kinematic outcomes. Reviews consistently highlight real-time corrective feedback as promising, but also report heterogeneous and often limited documentation of user preferences and compliance, as well as recurring usability challenges (multisensor burden, attachment or removal, wearability over time, wireless stability, battery or power management) that impact acceptance and scalability. In contrast, the feedback gathered in the present study was explicitly educational: participants emphasized biofeedback clarity, enhanced motor awareness, and applicability in school settings—underscoring shared mechanisms (feedback-guided posture correction) but different aims (therapeutic adherence and symptom management versus prevention and movement literacy in educational contexts). This preliminary evidence of educational value, although not yet linked to measurable learning outcomes, highlights the potential of EduBack to bridge the gap between technological feasibility and pedagogical impact.

Building on this distinction, EduBack is designed for educational training, where the goal is not treatment but awareness, prevention, and acquisition of correct motor habits. This is particularly relevant in school-based educational contexts, where early intervention in postural habits can play a key role in long-term musculoskeletal health. By offering an engaging and interactive biofeedback experience, EduBack could facilitate motor learning of lumbar mobilization and may encourage the correct execution of daily movements from an early age. While the app may also support training in higher education or preprofessional programs as a secondary use case, its primary value lies in promoting postural awareness and self-regulation among children and adolescents in primary and secondary education settings.

Although EduBack was designed primarily for educational settings, several students highlighted its potential for use in clinical teaching environments, suggesting that the system could also help bridge the gap between academic learning and applied health care practice. The visualization of spinal posture, when combined with immediate feedback, may reinforce theoretical content from lectures and provide a meaningful learning experience. This aligns with pedagogical models that emphasize experiential learning and self-regulation in motor skill acquisition [72-74]. Future iterations of EduBack will incorporate gamification strategies (eg, rewards and interactive challenges) to increase engagement among younger users, particularly in primary and secondary school contexts. Such features are expected to enhance motivation, adherence, and the educational impact of postural training. Thus, qualitative insights not only confirm usability but also point toward the system's potential pedagogical relevance, which should be validated with objective educational outcomes in future trials.

Broader Applicability and Future Directions

Moreover, although this study did not include professional educators or clinicians as participants, the students' perspective already points toward broader applicability. Future studies could involve instructors, physical therapists, or school teachers to explore how the system can be integrated into formal curricula or used in clinical decision-making. There is growing interest in using wearable technology in both school-based [75] and outpatient rehabilitation [76] settings, and EduBack may offer a scalable, cost-effective option that meets usability standards in both domains.

In practical terms, EduBack could be integrated into physical education curricula through teacher-guided sessions, where students receive real-time feedback while performing standardized postural exercises. The system may also be incorporated into modules on ergonomics or injury prevention, allowing teachers to demonstrate correct lifting techniques or seated posture with immediate visual reinforcement. Adolescents could use the app independently under supervision, while

XSL•FO
RenderX

younger children would benefit from structured, teacher-mediated activities. These scenarios illustrate how EduBack can complement existing educational practices, providing an interactive tool that supports awareness, prevention, and the acquisition of healthy motor habits within the classroom environment.

EduBack was designed primarily for educational environments, with physical education teachers expected to guide its application. Adolescents may be able to use the system independently, while younger children would require teacher supervision. Clarifying these user profiles is essential to ensure appropriate implementation and will be a key focus of future research.

Future research should also focus on multisite evaluations involving diverse populations and formal educational settings, possibly incorporating mixed method approaches to assess user engagement, learning outcomes, and behavioral adherence. It would also be beneficial to test EduBack in younger populations (eg, primary or secondary school students) and in clinical training contexts, where postural education is part of professional development.

Limitations

This study has several limitations that should be considered when interpreting the findings. First, the sample size was small and limited to university students, which may affect generalizability and highlights the need to test EduBack in younger and more diverse populations. Second, technical performance was evaluated in controlled academic settings; future studies should assess robustness in less stable environments such as classrooms or homes. Third, while the SUS provided a validated measure of usability, future studies could complement it with domain-specific instruments, such as the mobile health App Usability Questionnaire, to capture nuances related to health behavior change and long-term adherence. Finally, the study focused on short-term interactions; longitudinal research is needed to evaluate sustained use, user satisfaction, and potential impacts on posture-related outcomes.

Conclusions

Beyond the usability and technical outcomes, a key contribution of this study is the creation of EduBack itself, a novel educational tool that integrates wearable sensors and real-time biofeedback for postural training. EduBack demonstrates strong usability and technical reliability as a tool for posture-related education. It fills an important gap in the current landscape of mobile health apps by providing real-time, interactive biofeedback specifically tailored for learning rather than therapy. The system offers a promising foundation for future educational interventions in schools, universities, and clinical environments aimed at promoting postural health, awareness, and motor competence.

Acknowledgments

The authors thank all participants for their involvement in the study.

Funding

This work was primarily supported by a predoctoral fellowship awarded to MAGL by the Ministry of Universities of Spain (reference: FPU20/01843). Additional funding was provided by 2 project grants from the Valencian Innovation Agency of Spain (references: INNVA1/2020/81 and INNVA1/2022/34), which contributed to the development of the EduBack app. The funding bodies had no role in the study design, data collection, analysis, interpretation, or manuscript preparation.

Abstract

Background: Many patients attending hospital emergency services with recent-onset eye symptoms could have been managed in the community. This may reflect a lack of specialist experience or triage capacity among primary care providers. Online triage tools collect patient symptomatology and relevant ophthalmic and medical history virtually, compile a report, and suggest an outcome decision which can support the streaming and direction of patients to a suitable service within an appropriate timeframe.

Objective: Our objectives were to implement and analyze the real-world use of a novel online triage tool in a community optometry setting.

Methods: This was a real-world mixed methods evaluation of a web app "eye+dot" (Cambridge Medical Innovation Ltd), which uses a conditional logic multiple-choice questionnaire to produce a symptom report and automated triage recommendation. A preimplementation survey was used to gather views regarding current triage practices and interest in trialing an online triage tool among community optometrists. The app was then implemented in participating practices, with optometrists receiving the symptom report but not the automated triage disposition. The sensitivity and specificity of optometrists and the app at identifying urgent cases (those requiring specialist examination within 24 h) were compared to a gold standard, generated by retrospective review of the symptom reports by hospital specialists. Metadata including patient age, test duration, and usability feedback from patients and optometry staff were analyzed.

Results: Seven optometry practices trialed the app over 5 months. Records of 209 patients with a mean age of 53.5 (SD 17.5; range 13 - 90) years were analyzed. Three patients with potentially sight- or life-threatening symptoms (as defined by Royal College of Ophthalmologists guidelines) received appropriate urgent hospital dispositions by both optometrists and eye+dot. The app's automated disposition had similar sensitivity to optometry triage (75.5% vs 77.3% respectively; P=.99) but significantly better specificity (82.7% vs 54.4%; P<.001) for identification of the 53 cases categorized as requiring either hospital or community specialist examination within 24 hours by gold-standard review. A total of 147 patients gave acceptability feedback, with 121 (82%) of them giving a rating in the top 2 points of a 5-point visual Likert scale. Optometrists in 5 of the 7 practices found the app helpful and were interested in continuing its use.

Conclusions: This real-world study demonstrates the triage tool's accuracy for identifying high-risk symptomatology and its acceptability among patients and optometry services. The significantly lower optometric triage specificity may reflect risk-averse decision-making following direct communication with patients and appointment availability in primary care. In addition, the relatively low mean age of patients suggests possible barriers to uptake among older patients. This and other symptom-based triage tools can provide useful support to eye care providers in the community where access to specialist triage may be limited.

Introduction

Background

Patients with new eye or vision symptoms often contact community optometry practices in person or by telephone for advice. Informal triage and advice may be given if there is capacity to do so, but a lack of specific remuneration for triage activities and limited optometrist availability can mean that such patients are redirected to emergency departments (ED) or emergency eye clinics (EECs) with minimal specialist optometrist input. Community optometrist–delivered Minor Eye Condition Services (MECS) and Community Urgent Eyecare Services (CUES) have been commissioned in many areas of the United Kingdom to provide urgent, optometry-led community eye care and reduce pressure on emergency services, and studies indicate that between 37% and 92% of self or general practitioner-referred patients in EECs may be suitable for these services [1-5]. Efficient and early redirection of suitable patients to MECS or CUES could reduce the 870,000 annual ED attendances across the country for eye and vision symptoms and move care into the community, a key goal in the National Health Service (NHS) Long Term Plan [6].

Paper triage support charts are currently used by many optometry practices and EDs. More recently, patient-facing online symptom-based tools with automated triage algorithms have been developed [7-11]. Several have been validated with encouraging results in EDs, but to our knowledge, no digital specialist triage support tool for ophthalmic symptoms has been used to stream and direct patients in the community setting. However, evaluation studies of nonophthalmic digital triage tools in the primary care setting have provided promising results but reveal possible difficulties around triage accuracy, with automated tools often tending to unnecessarily overtriage cases as emergencies, and equity concerns around access and ease of using such online tools for older patients or patients with disabilities [12]. In addition, integration with existing workflows can be challenging, and low patient compliance with suggested triage advice can prevent gains in practice efficiency from being realized [13,14].

Study Aims

The purpose of this study was to evaluate the potential use of an eye and vision symptom-based online triage support tool, examine its real-world implementation, and analyze its accuracy at identifying high-risk ophthalmic symptomatology in the community.

Methods

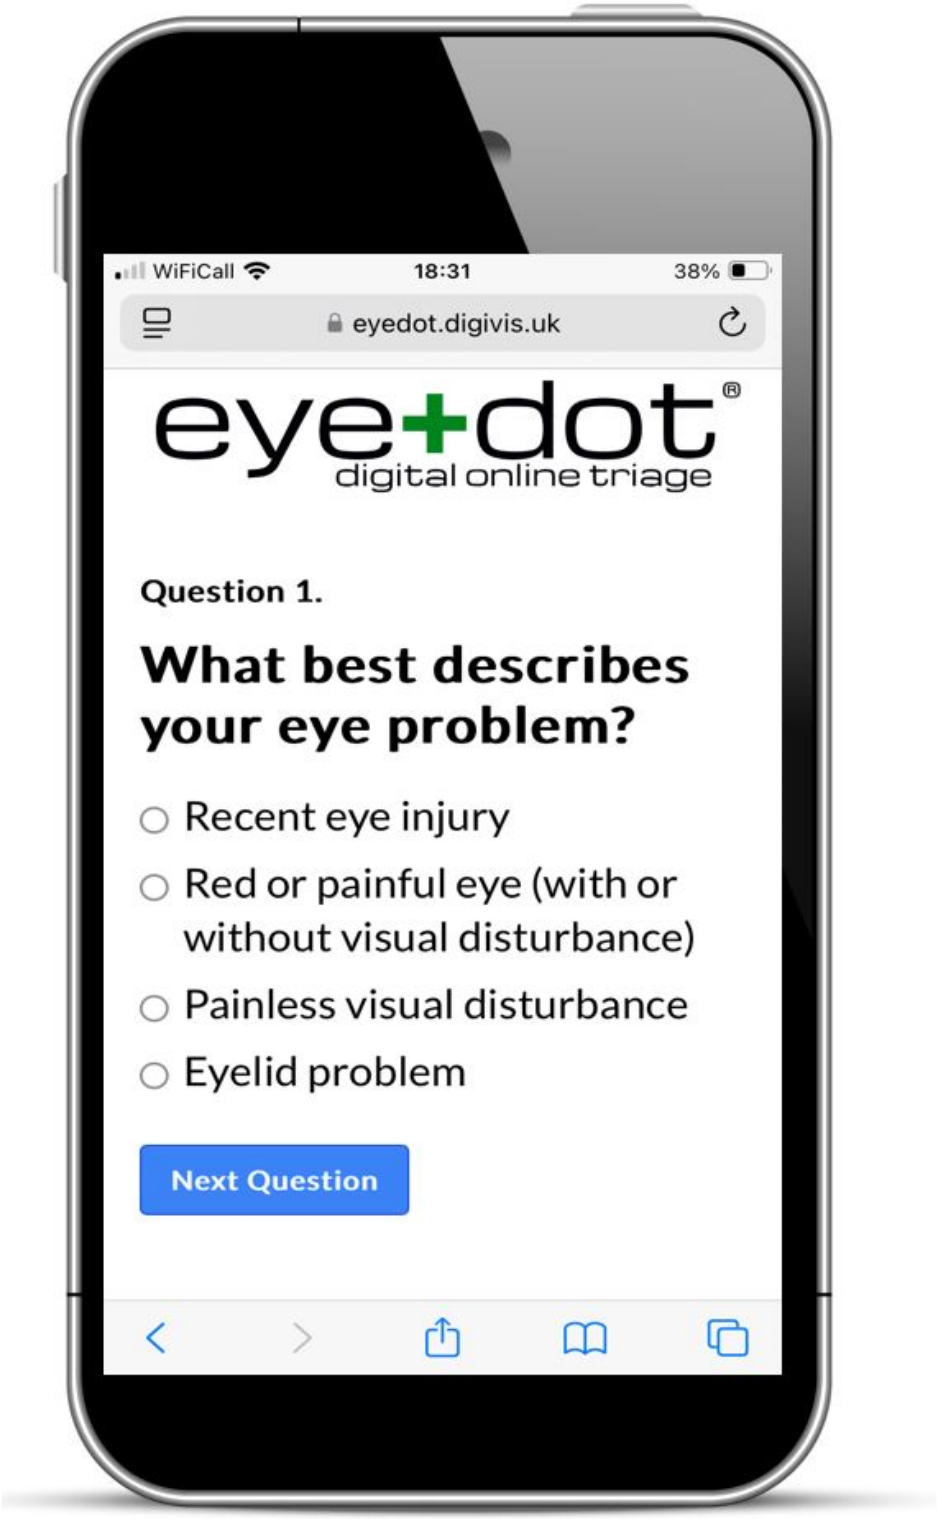
Study Design

This was a prospective, mixed methods real-world study focusing on how the technology works for patients in everyday community optometry practice. Real-world studies enable testing the technology with real patient scenarios and the inclusion of patients and practitioners who might otherwise not take part in research, making the results more useful for the appropriate context but less strictly controlled than formal validation studies.

Ethical Considerations

Approval of the study's methodology was obtained from the quality and safety committee of the Cambridge University Hospitals NHS Foundation Trust and the Cambridgeshire and Peterborough Integrated Care Service (approval reference: PRN10395). As an anonymized service evaluation that did not involve deviation from the current standard of care, this study was exempt from requiring national ethics committee approval [15]. Patients gave verbal agreement to participate and digitally agreed to the General Data Protection Regulation (GDPR) statement prior to undertaking the online eye+dot questionnaire, and the study was undertaken according to the tenets of the Declaration of Helsinki. Patients could choose to opt out without affecting their care.

The Technology



The eye+dot web app (Cambridge Medical Innovation Ltd) is a triage support tool that uses a conditional logic multiple-choice questionnaire of up to 25 questions to collect relevant ophthalmic and clinical history, detect high-risk symptoms, compile a downloadable symptom report, and suggest a triage disposition in terms of appropriate service and urgency. The tool has been developed and iteratively improved over 4 sequential proof-of-concept and validation studies in 3 hospital trusts of the Cambridgeshire and Peterborough Integrated Care Service. The automated triage algorithm used in eye+dot was adapted from the symptom triage guidelines published by the Royal College of Ophthalmologists (RCOphth) [16]. The initial process involved the development of multiple-choice questions and the conditional logic structure. These, and the triage disposition algorithm, were tested and iteratively improved, initially using simulated clinical scenarios, and subsequently evaluation and validation in over 500 real clinical scenarios. Wording, accessibility, and user interface improvements have been made based on patient and clinician feedback. Recent integration with the Electronic Patient Record (Epic) enables clinicians to order and retrieve results directly through the patient record. The app is currently in clinical use in an NHS hospital trust. As the eye+dot app replicates a chart-based symptom scoring chart, it does not meet the criteria for classification as a Medical Device under the UK Medical Devices Regulations based on Medicines and Healthcare Products Regulatory Agency guidance.

The care provider sends the patient a weblink to the online questionnaire by SMS text messaging or email, documenting the unique order number in the patient record. The patient accepts an initial standard disclaimer, GDPR-compliant data usage notice, and inputs their age before starting the questionnaire. The first filter question as seen by the patient is shown in Figure 1. Web browser translation is available but was not used for this study. Symptoms are automatically rated in terms of acuity adapted from previously published triage support tables (Multimedia Appendix 1) [16]. The symptom acuity rating creates an automated disposition, with the suggestion of an appropriate service (ED or EEC, MECS or CUES, and other community optometry services or pharmacist) and urgency (same d, within 24 h, within 48 h, and within a wk or routine). The symptom report and automated disposition are

XSL•FO
RenderX

automatically emailed to the provider's nominated inbox and can also be accessed via the secure online portal (Multimedia Appendix 2). This report can also be used to facilitate effective referrals, which other studies have shown are often affected by incomplete content [17,18]. The report is not routinely made available to the patient unless there is a history of potentially severe chemical, blunt, or high-velocity trauma. In such cases, the patient receives an immediate response with a weblink to the NHS first aid website and advice to attend emergency services urgently.

Figure 1. Initial filter question of the triage tool as it appears on a smartphone.

For the purposes of this study, the ordering provider received the symptom report but was masked to the automated disposition to prevent biasing of their clinical decision.

Preimplementation Survey

Optometrists and managers in the 23 practices registered with the Cambridgeshire Local Optical Committee (a statutory body

XSL•FO
RenderX

representing and supporting optometrists in our region) and accredited in the provision of specialist eyecare with our NHS hospital trust were invited to complete an online survey, designed using Microsoft Forms (Microsoft Corp), regarding current triage practices, and to express interest in participating in a 5-month pilot of a novel online triage tool (Multimedia Appendix 3). These practices serve a population of approximately 920,000. Survey questions were adapted from the validated Normalization Measure Development instrument based on the normalization process theory [19,20] and included questions about patient pathways and volumes, triage tools currently in use, and overall triage outcomes.

Implementation

Practices interested in trialing the triage tool participated in a training webinar (led by LA and SF) to explain the use of the triage tool and the implementation process. Two similar webinars were held at different times of the week to encourage attendance, and a recording was made available online for those practice staff unable to attend. At these webinars, optometrists and administrative staff received instruction in how to order an eye+dot link for patients and complete a study data spreadsheet with the date, name of participating patients, eye+dot reference number, and the outcome of optometry triage. Spreadsheets were pseudonymized prior to being returned to the study team for analysis. Participating practices were asked to use the tool's symptom report in addition to their current triage process for a 5-month period. Patients were directed to services based on their optometry practice's triage decision rather than the eye+dot automated triage disposition.

Criteria for inclusion were that the patient should be aged 13 years or older with normal cognition, a good understanding of English, and recent-onset eye or vision symptoms (within 7 d). Patients may have either walked into the practice or phoned for advice. Patient selection was otherwise highly pragmatic, with practice staff inviting patients to undertake the online questionnaire in addition to the practice's standard triage process. Only patients who agreed to using eye+dot were sent the link to the online tool's questionnaire. Participation was voluntary and patients were informed that the standard of care would not be affected by either agreeing or declining to participate. A further written informed consent process was not necessary for this service evaluation study and was not carried out, although all patients using eye+dot were asked to consent to its GDPR-compliant data use policy before commencing the symptom questionnaire. Patients without digital access were able to undertake the questionnaire over the telephone, with the receptionist documenting the patient's responses on their behalf. The generated symptom report was automatically returned to the nominated practice email inbox to be made available to the triaging optometrist. The unique weblink order number and the optometry triage outcome were recorded by a staff member in a spreadsheet held securely by the practice. To compensate practices for the administration involved, an honorarium of £15 (€17.5 or US $19) was agreed for each completed and deidentified patient record, payable at the end of the study period.

Postimplementation Report Review

Following the 5-month period of implementation, records from optometry practices were deidentified prior to their release to the study team for analysis. Each patient's online symptom report, automated triage disposition, and optometric triage outcome were linked with their unique eye+dot order number. Only patients meeting the eligibility criteria with recorded optometric triage outcome data and a complete online eye+dot report were included for analysis.

Two hospital-based specialists (consultant ophthalmologist LA and hospital optometrist SF), masked to the optometrist and eye+dot triage tool dispositions, reviewed the symptom reports and identified patients with high acuity symptoms who required either urgent hospital care or hospital or community specialist assessment within 24 hours. In cases of disagreement, a third clinician (specialist clinical fellow SN) made the casting decision. This was used as the gold standard triage disposition.

Postimplementation feedback from participating optometrists was communicated by email requesting free-text responses under the following domains: advantages and disadvantages of using eye+dot, barriers and enablers to its uptake, improvements that could be made, and likelihood of adoption in the future.

Statistical Analysis

Preimplementation and postimplementation survey responses were analyzed using descriptive statistics. Differences in sensitivity and specificity of eye+dot automated triage and optometric triage at identifying high-acuity cases as defined above were evaluated using the McNemar test with continuity correction on GraphPad Prism version 10.4.1 (GraphPad Software). In addition, interrater reliability at identifying urgent or nonurgent cases between eye+dot and the other modes of triage, as well as between the 2 main reviewers who determined the gold-standard triage outcome, was evaluated by calculation of Cohen κ. A priori interpretation of κ values was as follows: values ≤0 indicating no agreement, 0.01 to 0.20 (none to slight), 0.21 to 0.40 (fair), 0.41 to 0.60 (moderate), 0.61 to 0.80 (substantial), and 0.81 to 1.00 (as almost perfect agreement). Additionally, adherence to RCOphth guidelines for hospital assessment within 24 hours for presentations suggestive of a sight or life-threatening condition (Multimedia Appendix 4) was assessed. Metadata including duration and completion of the online triage questionnaire, patient age, and feedback on the app using a voluntary visual Likert scale with responses converted to numerical values (Multimedia Appendix 5) were analyzed by descriptive statistics.

Results

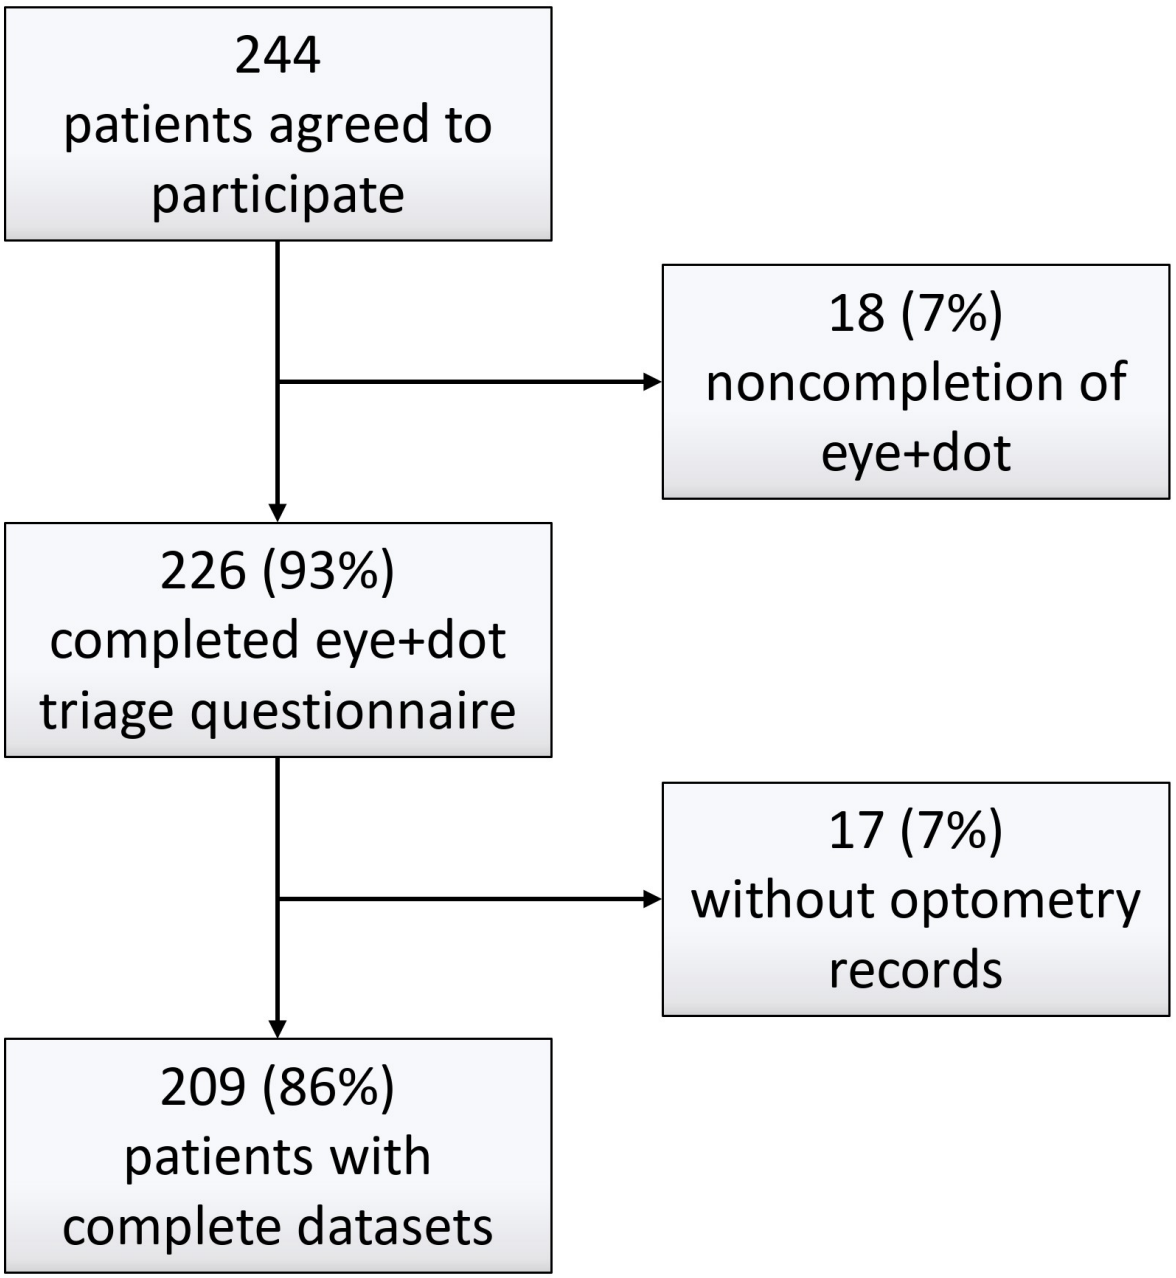
Preimplementation Survey

The preimplementation survey (Multimedia Appendix 3) received 53 responses, 50 (94%) of which were from optometrists, and the remaining 3 from practice managers. From the 53 respondents, 36 (68%) reported that they or their practice currently used a paper-based triage tool, and 45 (85%) reported that they were the first point of contact for most patients with recent onset eye symptoms. The most frequent triage outcome prior to implementation of the online triage tool was reported

XSL•FO
RenderX

as a General Ophthalmic Service or private appointment by 27 (51%) respondents, a MECS or CUES appointment by 23 (43%), and advice with or without purchase of eye drops by 2 (4%). One optometrist reported that the most common outcome was advice to attend ED or EEC.

From the 53 respondents, 45 (85%) agreed or strongly agreed that they would be willing to learn how to use an online triage tool, 39 (74%) agreed or strongly agreed that an online tool could improve patient care and make onward referral easier, and 30 (57%) felt that patients would be willing to undertake an online questionnaire for triage purposes.



Implementation

The online triage tool was implemented in 7 out of 23 invited optometry practices comprising 4 Specsavers branches and 3 independent practices, all of which also provided MECS services. In total, 14 members of staff attended one of the live webinar sessions. Four other practices expressed interest but were unable to participate due to a lack of administrative or time resources.

During the 5-month implementation period, 244 patients agreed to be sent the online triage link by their practice. Of the 244 patients, 18 (7%) started but failed to complete the online questionnaire, and a further 17 (7%) were excluded due to incomplete optometry triage outcome records. The remaining 209 records were analyzed (Figure 2). The mean age of patients was 53.5 (SD 17.5; range 13 - 90) years. Of the 209 records, 136 (65%) included information on the mode of questionnaire completion. For 19 patients, this was undertaken over the phone with the help of a receptionist rather than online. Based on the responses to the first filter question of the online triage questionnaire, the most frequent primary presenting complaint was red or painful eyes, followed by painless visual disturbance, eyelid problems, and eye injuries (Table 1).

XSL•FO
RenderX

Figure 2. Implementation phase flowchart.

XSL•FO
RenderX

Table . Characteristics of patients with complete online and optometry triage records (N=209).

Feature	Patients, n (%)
Age range (y)	
<20	7 (3.3)
20 - 29	22 (10.5)
30 - 39	16 (7.7)
40 - 49	27 (12.9)
50 - 59	51 (24.4)
60 - 69	48 (23)
70 - 79	27 (12.9)
>79	11 (5.3)
Main presenting complaint	
Red and/or painful eye or eyes	95 (45.5)
Painless visual disturbance	82 (39.2)
Eyelid problems	22 (10.5)
Eye injury	12 (5.7)

Triage Outcomes

Optometric triage outcomes (Multimedia Appendix 6): 106 out of 209 patients (51%) were seen within 24 hours. Of these, 4 (2% of 209) were advised to contact or attend ED or EEC and 31 (15% of 209) attended same-day optometry appointments. 89 (43% of 209) patients were offered less urgent optometry appointments, 13 (6% of 209) given advice or dispensed eyedrops without an appointment and 1 (1% of 209) advised to contact their general practitioner.

Eye+dot triage disposition (Multimedia Appendix 6): 67 out of 209 patients (32%) were allocated a disposition of hospital or community specialist assessment within 24 hours, and 9 (4% of 209) of these were recommended same day ED or EEC appointments. A total of 132 (63% of 209) patients received less urgent triage dispositions to hospital or community optometry services, while pharmacist advice was recommended for a further 10 patients.

Accuracy at Identifying High Acuity Cases

From the 209 patients, 53 (25%) were considered to have potentially urgent eye problems requiring hospital or community specialist eye assessment within 24 hours according to the gold-standard triage dispositions established by expert review. This included 3 patients with presentations meeting the RCOphth definition of an emergency eye condition (Multimedia Appendix 4). There was no significant difference in the proportion of patients with gold-standard categorizations requiring specialist assessment within 24 hours presenting to Specsavers branches and independent optometry practices (25% vs 24% respectively; odds ratio 1.07, 95% CI 0.57 - 2.02; *P*=.84).

All 3 patients with presentations meeting the RCOphth definition of an emergency eye condition [16] were correctly identified as requiring urgent hospital attendance by both optometric and automated triage mechanisms.

Of the 53 patients assigned a gold standard recommendation of hospital or community specialist assessment within 24 hours, 40 (76%) were assigned that outcome by eye+dot triage, with the remainder (n=13, 25%) assigned to be seen within 48 hours. Of the same 53 patients, 41 (77%) were assigned a hospital or optometrist assessment within 24 hours by optometry triage, with a further 4 (8%) to be seen within 48 hours, and 8 (15%) cases considered routine (Table 2). The online triage tool had similar sensitivity as optometry triage (75% vs 77%, respectively; *P*=.99) but significantly better specificity (83% vs 54%, *P*<.001) at identifying cases requiring urgent specialist appointments. Eye+dot's automated triage was found to have moderate-substantial agreement with each of the 2 expert reviewers but lower agreement with the optometrist triage (Table 3).

XSL•FO
RenderX

Table . Disposition outcomes for the 53 patients with gold standard high-acuity symptomatology based on their online questionnaire result with sensitivity and specificity for identifying urgent cases (N=53).

Disposition urgency	Optometry triage (N=53)	Online triage (N=53)	*P* value
Within 24 h, n (%)	41 (77)	40 (75)	
Sensitivity, %	77	75	.99
Specificity, %	54	83	<.001
Within 48 h, n (%)	4 (8)	13 (25)	—[a]
Within a wk/routine/advice, n (%)	8 (15)	0 (0)	—

[a]Not applicable.

Table . Interrater reliability for urgent or nonurgent triage dispositions.

Pair	Cohen κ (95% CI)
Optometrist and eye+dot	0.26 (0.15-0.37)
Reviewer 1 and eye+dot	0.75 (0.64-0.86)
Reviewer 2 and eye+dot	0.61 (0.50-0.72)
Reviewer 1 and Reviewer 2	0.40 (0.28-0.52)

Usability

The mean time taken to complete the online questionnaire was 4 minutes 57 seconds (SD 2 minutes 2 seconds; range 1 minute 30 seconds to 16 minutes 15 seconds). Overall, 147 out of 209 (70%) patients provided voluntary feedback about the eye+dot app via a 5-point visual Likert scale. Of these, 121 (82%) patients rated the app 4 or 5 (mean 4.27, SD 0.76) with 5 being the most positive rating. Of patients whose method of undertaking the questionnaire had been recorded, 71 of the 82 (87%) online respondents rated the app 4 or 5 compared to 9 of the 14 (64%) patients undertaking the questionnaire over the phone (mean 0.71, SD 4.39 and mean 4.21, SD 0.94 for online and telephone groups, respectively; *P*=.70 using the Mann-Whitney *U* test).

Postimplementation Feedback

Qualitative postimplementation feedback responses to a semistructured email questionnaire by participating practices are shown in Textbox 1.

XSL•FO
RenderX

Textbox 1. Semistructured postimplementation feedback from the 7 participating practices.

Were there any advantages of using the eye+dot tool?

- The compiled symptom report improved documentation and supported onward referral
- The report provided useful documentation for records
- Helped reduce the need to interrupt optometrists undertaking scheduled work (3 Specsavers practices mentioned this)

Were there any disadvantages of using the eye+dot tool?

- Older patients were more hesitant to accept online triage
- Optometrists found it quite difficult to interpret the symptom report
- Patients often volunteered different symptomatology when telephoned
- Was not found helpful because there was already capacity to triage and book patient appointments without delay (at 2 independent practices)
- Increased triage time (at 2 independent practices)

What were the barriers and enablers to implementing the innovation?

- Uptake was affected by staffing shortages, changes, and the administrative burden of completing the study documentation
- Uptake was improved by the workflow being accepted as normal practice, with all eligible and able patients being routinely requested to complete the online questionnaire

What improvements could be made to the eye+dot tool?

- Recording eye laterality to enable comparison with previous optometric records
- A free text box for patients after the forced choice questions for clarifications, if needed

Would your practice consider using an online triage tool in the future?

- Yes: 5 (4 Specsavers branches, one independent practice)
- No: 2 (independent practices)

Discussion

Utility and Role of the Eye+Dot Triage Tool

Triage systems should ideally have both high sensitivity and high specificity for urgent cases to ensure timely access to care and efficient use of resources. This real-world study suggests that the eye+dot web app has similar sensitivity as community optometrists at identifying high-risk eye or vision symptomatology requiring specialist assessment within 24 hours and possibly superior specificity. The 3 patients whose symptoms were potentially sight- or life-threatening (based on the RCOphth guidelines; Textbox 1) were accurately identified by both optometric and eye+dot triage. Overall, 12 and 11 patients were underrated by optometry triage and eye.dot triage, respectively, compared to the gold-standard hospital clinician disposition based on review of the eye+dot report. In all 11 cases underrated by eye+dot, the disposition was for specialist review within 48 hours. Of the 12 patients who underrated the optometrists, 4 were given appointments within 48 hours and the remainder routine appointments.

There was substantial correlation between the urgency suggested by eye+dot and expert hospital clinician dispositions (κ=0.61 and 0.75). In contrast, there was only a slight correlation between the hospital clinicians and community optometrists (κ=0.26). Interestingly, most automated triage tools are found to have lower specificity than clinician triage for high-risk presentations, which does not align with our findings for the eye+dot triage tool relative to community optometrist triage [8,12,21]. In this study, the higher acuity triage decisions made by community optometrists may have been influenced by other factors, including additional information from the patient such as their level of anxiety and real-time knowledge of appointment availability. This suggests that human contact and decision-making still have an important role, even when an automatic triage tool is used.

Advantages of the real-world nature of our study design include the inclusion of individuals who might not usually contribute to such studies, understanding how technology can be implemented within service workflows, faster timelines, and cost efficiency. This may be particularly helpful for developers of innovative technology to rapidly understand its feasibility and usability in practice, identify improvements, and optimize its implementation model [22]. The qualitative post-implementation feedback has led to the inclusion of a question about symptom laterality and a free-text box for additional information after the forced-choice questions (Multimedia Appendix 2). A randomized controlled trial would have reduced the risk of bias and ensured optimal data quality, but would not have been feasible in busy, commercial optometry practices.

To the extent that these results represent a real improvement in eye+dot's ability to accurately identify low-urgency cases relative to frontline human triage, they suggest that significant improvements in healthcare system efficiency could be achieved

XSL•FO
RenderX

by using eye+dot or a similar tool to reduce overtriage of patients and consequent pressure on acute hospital services. However, the limitations of the pragmatic design of this study and the possible impact of population or region-specific factors mean that more work is required before definite or generalizable conclusions can be drawn from this observation. Of note, only 4% of patients in this study were advised to attend or contact the ED or EEC by the optometrists in this study, all of whom had received enhanced training as MECS providers. The proportion directed to hospital emergency services is likely to be higher among practices without MECS-trained clinicians.

While it is possible for a member of staff to take a patient through the questionnaire over the phone, only a minority of patients—14% of those for whom the delivery method was documented—chose to use this option. This form of delivery may be less feasible, given the time required. Regular smartphone use is less likely among older individuals, and such patients may prefer to have a 2-way conversation with a clinician if they are anxious about new symptoms [23,24]. These barriers to uptake make it important to ensure other means of triage are available.

The voluntary visual Likert score was not completed by 62 out of 209 or 30% of patients, but 82% (121/147) of those who did gave the eye+dot app a rating in the top 2 of 5 options, suggesting a reasonable level of acceptability for patients. The duration of the test was highly variable, with longer tests reflecting the complexity of the individuals' symptoms and history. The use of web browser translation may have improved the triage experience and quality for individuals whose first language was not English, but this was not assessed during this study.

Limitations

The uptake of digital triage technology in this study was influenced by burdensome study administrative requirements and staff turnover in optometry practices. Those recruiting the most patients had embedded the triage tool into their workflow, routinely inviting suitable patients to complete the questionnaire. Despite only having access to the symptom report (and not the automated triage disposition), all Specsavers practices and one independent optometry practice were interested in continuing to use the tool. Reported benefits included ease of documentation, avoiding interruptions to scheduled appointments, and more efficient MECS booking. The tool may be less useful in practices with more generous optometrist scheduling and greater capacity to triage effectively. Conversely, practices where staff adopt a cautious approach to triage due to time or resource constraints are likely to benefit the most from a triage tool with high specificity for urgent cases [5].

It is possible that patient selection was biased towards the inclusion of younger patients (mean age of 53.5, SD 17.5 y), although we do not have data on the average age of all patients presenting to these optometry practices across the relevant time period. Preferential inclusion of younger patients could potentially bias the range of eye symptoms and previous ophthalmic history elicited.

Retrospective review by expert clinicians is a common method used to establish the reference gold standard triage disposition in studies validating both paper and digital triage tools [9,25-27]. However, minor differences in the precise methodology can introduce varying limitations. In this study, the gold standard disposition may not be ideal for evaluation of optometrist triage as it relied purely on specialist review of symptom reports without an option for them to talk directly with the patient and without the eventual clinical diagnosis being known. On the other hand, the lack of clinical outcome data prevented outcome bias which might arise from knowing that a patient with high acuity red-flag symptoms eventually received a relatively benign diagnosis.

Finally, we were not able to estimate theoretical patient compliance with eye+dot's automated triage advice from this study, as all patients were directed to services in line with their optometrist's triage decision. Other studies have noted that patients advised to seek community health care by remote triage often present to the ED regardless [14]. However, since the eye+dot app is designed to support triage decisions made and communicated by clinical teams rather than issuing advice directly to the patient automatically, this risk may be relatively small.

Conclusion

This real-world evaluation demonstrates that use of the eye+dot symptom-based online triage tool is feasible, acceptable to patients and staff, and can provide safe triage support, potentially improving triage efficiency and decreasing unnecessary hospital attendance if implemented in nonspecialist services.

These benefits may be even more pronounced if implemented in primary care settings without specialist triage resources or expertise. We are also currently evaluating the utility of the triage tool in hospital emergency services, both in supporting nurse-led triage for patients contacting the EEC service by phone and as a kiosk-based service for walk-in patients.

Abstract

Background: The rising prevalence of diabetes necessitates continuous monitoring and treatment, especially for type 2 diabetes. Patient education plays a crucial role in enabling self-management, and web-based educational portals can support patients effectively. While the literature highlights various issues impacting self-management system design, few studies explore the usability aspects that either facilitate or hinder such systems for this patient group.

Objective: This study aimed to investigate usability issues related to a web-based educational portal for patients with diabetes in Razavi-Khorasan Province, Iran. Additionally, it sought to develop a framework of design principles to address critical usability concerns for diabetes self-management.

Methods: The literature on diabetes self-management was analyzed. The analysis focused on design and usability issues affecting self-management. A think-aloud study was carried out with 10 patients using a web-based educational portal designed for patients with diabetes. The portal comprises 9 sections, with patients performing tasks related to each one. Participants' task completion times were measured, and severity ratings of usability problems were calculated.

Results: Five design principles were proposed that cover (1) understanding and learning about one's condition, (2) motivation and fostering sustained practices, (3) autonomy and confidence, (4) interaction and collaboration, and (5) privacy and security. The study identified 111 usability problems related to the portal's 9 sections. Feedback from participants was considered to refine the principles, and participants' considerations were recorded for any issues that worked against the principles. A total of 16 suggestions for improvement were extrapolated from the data.

Conclusions: This study highlights critical usability and design aspects to consider when developing web-based educational portals to support self-management in type 2 diabetes.

Introduction

Background

Diabetes is a chronic disease rapidly increasing in incidence; in 1990, the number of people with diabetes was 200 million but rose to 830 million in 2022, and in low- and middle-income countries, the prevalence has been rising more rapidly than in high-income countries [1], with type 2 diabetes (T2D) accounting for 90% of all diabetes [2]. As there is no cure for diabetes, solutions have focused on preventing complications by educating patients, more recently through online interventions. Web-based patient education interventions may help improve T2D self-management [3]. The increased availability of the internet and smartphone apps targeting patients with diabetes can offer opportunities and improvement [4]. Websites and mobile apps are readily available, cost-effective, and easy for patients to use anywhere and at any time [5]. Furthermore, studies have also shown that internet-delivered diabetes education is easier for patients to access than traditional education [6].

Today, there is a growing number of websites and other forms of online patient education, especially for patients with diabetes [7], and digital diabetes self-management education has been shown to improve patients' knowledge and clinical outcomes [8]. Many diabetes apps offer a selection of similar functions necessary for diabetes self-management [9]. With the right technical skills, a patient with T2D can take advantage of online patient education and services.

Computer literacy has been defined as "basic skills in using a computer, for example, to save and open a file, use a word processing program, and send and receive e-mail" [10]. Similarly, eHealth literacy is defined as the "ability to seek, find, understand, and appraise health information from electronic sources and apply the knowledge gained to addressing or solving a health problem" [11]. A study recently conducted in Iran concluded that the level of eHealth literacy regarding health technologies is increasing [12]. In addition, according to statistics presented by the Global Economy, approximately 82% of Iran's 85 million inhabitants were using the internet in 2022 [13], while in 2012, the number was only 53.3% (as identified in the data accessed in 2014 for previous research referenced in a study by Jafari et al [14]). This reveals the rapid increase in the use of the internet in the Iranian population and the need for computer and eHealth literacy for this T2D population to extract the benefits of online patient education and services.

Designing Tools for Self-Management

Self-care focuses on the prevention of a disease and the maintenance of well-being, while self-management focuses on coping with the disease and controlling the clinical parameters [15]. Research shows that the digital health industry has a promising future [16]. Technology can be used to enhance or regulate people's emotions, motivation, and well-being [17]. Proactive communication by health care teams can help patients foster autonomy and encourage them to develop better self-management skills [18]. In addition, technology can support patients with chronic conditions by allowing them to increase their control of the disease [19]. There is a need for a supplementary design in developing supportive health care technology, especially for older people with diabetes [20]. However, it is not obvious how all these issues should be implemented in practice when designing web-based resources for the group of patients with T2D.

When self-managing the disease, patients should take responsibility for interacting with health care providers and have the ability to monitor their own condition [15]. Technology designed for diabetes self-management can be helpful in terms of improving blood sugar control, but it is necessary for designers to know how patients use the technology in their daily routines and over an extended period [19].

Quality of life (QoL) is defined by the World Health Organization as "an individual's perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards, and concerns" [21]. QoL is fundamental for human-centered design. In human-centered design, trade-offs are general and unavoidable [21]. Design trade-offs are crucial in any design process, particularly as the digital age continues to evolve in the context of T2D self-management. A "trade-off" is a condition that involves losing one aspect or quality of something in return for gaining another aspect or quality [21]. Trade-offs are associated with matching problem solving and problem framing [22]. Designers need to explore QoL [21] and act in the best interests of all stakeholders, including patients. To achieve this, it is necessary to understand the strengths and weaknesses of the technology to be designed [23]. Technology has resulted in progress, but technology adaptation has not improved QoL for patients [22]. An analysis of design trade-offs in developing self-management systems for patients with heart failure concluded that design trade-off analyses can improve understanding of health self-management technologies [24], and analogous analyses are needed for T2D.

Designing Web-Based Educational Portals

A web-based educational portal is an online tool that allows patients to interact with health care systems and health care providers and follow treatment recommendations for improving their clinical outcomes, while it can also promote preventative measures [25]. In our previous research, a prototype portal was designed and tested for usability in an Iranian context. The development of the web-based educational portal and its preliminary testing has been described in other studies [14,26-28].

Usability is often defined as the "extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency, and satisfaction in a specified context of use" [29]. Usability testing is a technique that involves testing products or websites with participants drawn from the target population [30]. Usability testing becomes a crucial part of developing novel health information systems and includes evaluating the degree to which technology fulfills basic usability criteria as the participants perform representative tasks [31]. In addition, usability testing is effective at identifying obstacles and system design issues; therefore, it is highly recommended when developing new health information applications [32]. It is not well known how to design a learning portal to best support

XSL•FO
RenderX

patients with T2D in improving their self-care management in an Iranian context—which aspects are important to the target group and how should design trade-offs be managed?

Study Aim

The aims of this study were to (1) draft a framework of design principles for tools for self-management, (2) explore the usability issues of a web-based educational portal for patients with diabetes, and (3) update the framework of design principles for capturing usability issues important for diabetes self-management.

Manuscript Organization

In the "Methods" and "Results" sections, we present the development of a theoretical framework with several design principles for exploring usability issues related to diabetes self-management. Then, we present how usability testing was conducted on a web-based educational portal and the findings that have led us to propose a modified framework with an added design principle. Finally, these findings and the framework are discussed and related to other findings in the literature in the "Discussion" section.

Methods

Approach to Identifying Design Principles for Diabetes' Self-Management

We conducted an analysis of our previous work on designing a web-based educational portal to support diabetes self-management [14,26-28] and the literature considered for its development [14,26-28]. The portal was developed for the local context of Razavi-Khorasan, considering regional health behaviors and user preferences [28]. To derive the design principles, we systematically mapped the portal's functionalities to the 5 layers of influence as outlined in the Ecological Model of Health Behavior [33]: intrapersonal (personalized education and self-monitoring tools to enhance confidence and control), interpersonal (support for family involvement and social engagement), organizational (integration with health care institutions and professional input), community (adaptation to cultural norms and local resources), and public policy (highlighting the need for culturally adapted digital health solutions in low- and middle-income countries). Finally, through a structured, consensus-based approach involving iterative expert panel discussions among the authors and the synthesis of evidence, we consolidated these insights into a set of design principles for web portals that facilitate effective diabetes self-management.

Study Design and Procedure of the Usability Testing

To describe the usability test, we applied the terminology and the checklist proposed in a study by Martins et al [34]. Following the checklist, we detail the usability assessment moderator, participants, usability evaluation method and usability evaluation technique, tasks, and usability evaluation environment. The checklist filled out for our study is presented in Multimedia Appendix 1. MRMH served as the usability assessment moderator and met the inclusion criteria by having prior experience conducting usability tests. He was external to the portal development team, guaranteeing independence from the product's design and development process. Finally, no observers were included in the study, and therefore, no observer responsibilities or characteristics were collected.

A sample size of 10 participants was considered appropriate for this usability evaluation based on previous studies [35-37]. They indicate that a relatively small number of participants is sufficient to uncover most usability issues, with Nielsen and Landauer's model suggesting that 5 participants can identify approximately 80% of usability problems [36]. Extending the sample to 10 participants further increases problem coverage and reliability. Faulkner [37] reported that 10 users can identify approximately 95% of usability issues across typical tasks while maintaining feasibility in formative testing. The inclusion criteria for participation were as follows: having been diagnosed with T2D more than 1 year prior to this study, not having serious diabetes complications, having more than 9 years of formal education, being physically and cognitively able to participate personally in the study, being able to use a computer and internet accessibility, having no experience in using the portal, and, finally, being willing to participate. Participants (ie, patients with T2D) were recruited through convenience sampling from Mashhad Diabetes Clinic. Participant characteristics gathered for the study comprised age, sex, educational level, digital literacy, and the duration of the disease.

We used a single usability testing method using a concurrent think-aloud technique [38], complemented by screen and interaction logging to capture user events (eg, clicks, navigational paths, and errors), without incorporating additional inquiry methods or techniques. In the think-aloud usability test, participants were asked to verbalize their thoughts while completing predefined tasks, allowing insight into their real-time reasoning and difficulties. All sessions were recorded using the computer's built-in microphone, and participants' verbalizations were transcribed verbatim in Persian. To document screen activity and user interactions, we used Camtasia Studio (version 8.4; TechSmith Inc.), which enabled synchronized recording of both the event flow and participants' spoken commentary. Participants completed 9 tasks corresponding to the 9 sections of the web-based educational portal developed by JJ [39], after which they provided severity ratings. Each task targeted a distinct portal section and was performed using the think-aloud technique. Table 1 lists the 9 tasks included in the study. Participants were asked to verbalize their thoughts, feelings, opinions, and experiences while completing the tasks [40]. In individual sessions, participants were first introduced to how the think-aloud method would be used and then received a brief introduction about the portal before the usability test by MRMH. A scenario (Instructions to participants, Multimedia Appendix 2) was prepared based on the results of our previous research [26,27] and was pilot tested with 2 patients prior to the real usability testing. Participants used a laptop running Windows 7, and their activities during the usability tests were video recorded and audio recorded (as abovementioned). During the sessions, the usability assessment moderator (MRMH) sat beside participants to encourage continuous verbalization and to provide assistance if needed—for example, in cases where

XSL•FO
RenderX

instructions were unclear, medical terminology was difficult to interpret, or a technical glitch occurred.

Table . The 9 tasks and their explanations, including the collected data or material.

Task name	Task explanation
Fill in patient information	The user is asked to type or select from a drop-down list. The data are entered into the system using the keyboard and mouse. They include name and surname, gender, age, education level, occupation, address, weight, height, type of diabetes, age of onset of diabetes, and associated specific disease.
Register laboratory results	The user is asked to type laboratory result values and read medical documentation. FBS[a], 2hpp[b], 5PM[c], HbA1c[d], liver function tests (SGOT[e], SGPT[f], ALP[g]), lipids profile (cholesterol and triglyceride), kidney function tests, urine sugar, BUN[h], creatinine, and blood pressure.
Attending educational courses	The user is asked to attend a course aiming to help them improve their diabetes self-management. Eight courses are available, and they were asked to attend one of these courses. Each course contains a short quiz, which is answered before beginning the course.
Read educational material	The user is asked to read educational material about various aspects of diabetes and its effects on organs and the relationship between stress, physical activity, drugs, and disease progression.
Use the “help-me” steps	The user is asked to follow the “help-me” flow or to follow sequential steps to access specific information.
Check health improvement	The user is asked to access data about their current situation based on their medical condition and the laboratory results recorded in the medical record.
Play educational movies	The user is asked to find and watch one short movie about diabetes for at least 1 minute, regarding diabetes complications, diets tailored for patients with diabetes, or other related subjects. Movies are about 3 to 4 minutes long.
Calculate health indices	The user is asked to use a food calorie counter and a calculator to check the BMI and the glycemic index of different types of food. The task was composed of one calculation based on the user’s interest.
Chat with physicians and nurses	The user is asked to use the chat to communicate with physicians or nurses.

[a]FBS: fasting blood sugar.

[b]2HPP: sugar level 2 hours after breakfast.

[c]5PM: 5-afternoon blood sugar.

[d]HbA_{1C}: hemoglobin $_{A1c}$.

[e]SGOT: serum glutamic oxaloacetic transaminase.

[f]SGPT: Serum glutamic pyruvic transaminase.

[g]ALP: alkaline phosphatase.

[h]BUN: blood urea nitrogen.

As for the usability evaluation environment, the study was conducted under controlled conditions in a room located in the Medical Informatics Department of the Faculty of Medicine of Mashhad University of Medical Sciences, Mashhad, Iran. This setting was selected because it provided a quiet, interruption-free environment that ensured consistent testing conditions across all participants.

Data Analysis

The analysis phase integrated quantitative and qualitative components: quantitatively, we computed time on task (summarized with descriptive statistics); qualitatively, think-aloud verbalizations and moderator notes were subjected to qualitative content analysis [41], with iterative code development. A particular focus was on the observations of the participants’ behaviors and their comments related to self-management and the themes of the framework discussed above. Attention was paid to how the web-based educational portal supported or hindered patients’ self-management activities (eg, due to lack of functionality). The time the participants spent on each task and the issues encountered were collected by Camtasia and analyzed. Descriptive statistics, including means and SDs, were calculated for the time taken by participants to complete the tasks. The usability tests were transcribed, and the resulting data were analyzed through qualitative content analysis [41]. Following the completion of the think-aloud sessions, the severity of identified usability problems was assessed by 3 reviewers: 2 members of the team involved in developing the web-based educational portal (AJ and NF; see Acknowledgments) and the first author (JJ). Severity ratings

XSL•FO
RenderX

were assigned using Nielsen's standardized 0 - to 4-point scale [42], where 0 indicates "not a usability problem," 1 indicates "cosmetic problem only," 2 indicates "minor usability problem," 3 indicates "major usability problem," and 4 represents a "usability catastrophe" that must be resolved prior to release. Ratings were based on 3 factors: frequency (ie, how often the problem occurred), impact (ie, the extent to which the problem affected task completion), and persistence (ie, whether recovery was easy or difficult). The 3 reviewers (coders) worked independently, and coding agreement on severity scores was reached by consensus.

Ethical Considerations

All participants received oral and written information about the study and signed a consent form. They were informed about how the gathered data would be used, that their identities would remain anonymous, and that they had the right to withdraw from the study without having to explain why at any time, if they wished to do so. Participants did not receive any compensation. The Ethics Committee of Mashhad University of Medical Sciences approved the study (IR.MUMS.REC. 1395.108; Multimedia Appendix 3).

Results

Overview

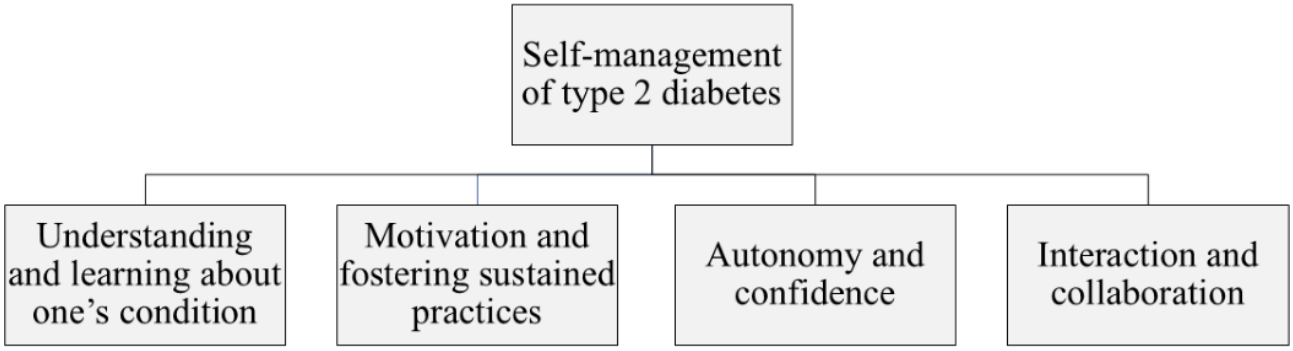
The results are presented in 3 sections. First, the first iteration of the framework ("Design Principles for Diabetes' Self-Management") is outlined, and then, quantitative and qualitative results from the usability tests are explained, and finally, a revised framework is detailed pertaining to design and usability issues in the context of patient self-management of T2D.

Design Principles for Diabetes' Self-Management

Initial Version of the Framework

By the approach explained in the *Methods* section, we proposed 4 design principles for diabetes self-management. The first principle concerns supporting patients' *understanding and learning about the complexities of their condition*. This principle is about creating awareness and supporting patients' learning regarding how to manage their diabetes, including daily measurement routines, diet planning, exercise, medication, illness, alcohol consumption, and stress. When patients do not understand their condition and the importance of managing it, adequate self-management is at risk and is likely to be discontinued. Patients require support on different levels, ranging from performing procedures, such as measurements, to reflecting on how to plan their lives on an overall level to maintain adequate self-management. Patients with diabetes need opportunities to learn specific skills, and environmental and policy contexts influence the psychological factors involved in diabetes management [33]. Opportunities to learn about measuring blood sugar, planning diets, exercising, and addressing challenges specific to diabetes are helpful for supporting self-management and managing diabetes [33].

The second design principle relates to supporting *motivation and fostering sustained practices*. This principle highlights the importance of supporting patients in keeping up their self-management over time and introducing measures to help them avoid skipping self-care practices or giving up entirely. Encouraging, reminding, supporting, and "nudging" can provide the motivation that patients may need to continue their self-management and not become discouraged or distracted. Plans, calendars, schedules, timely reminders, praise, and even rewards could be elements that contribute to keeping patients motivated and supporting them in modifying their everyday practices. Providing updated information, especially information tailored to the individual patient, and giving feedback may maintain patient interest and thereby help them continue to pursue self-management plans over time [33]. Technologies that suggest care activities or adjustments to current treatments based on information on improved care and using these technologies seem to be positive for patients [19]. Mobile apps help patients to self-manage the disease and motivate patients to improve glucose control [4]. Researchers based on numerous studies "recommend designing for continuity in time, space, and the aesthetic dimension and recommend focusing on understandability and learning" [20].



The third design principle concerns the patient's feelings of *autonomy and confidence*. Patients do not only need knowledge and reminders but also need to feel confident and secure when it comes to being able to manage their condition on their own. They need to feel that they can manage their T2D without risking their health and know that they can find and obtain help when needed. It is therefore essential to help patients develop a sense of being in control with clear instructions and, at the same time, help them understand that they have the ability to independently plan their self-management without feeling that their role is just to follow instructions. In previous research, patients with heart conditions have expressed the need to acquire knowledge while also building up their confidence to be effectively involved in decision-making concerning their treatment [43]. Technology, if well designed, can be used to contribute to making patients feel more confident about their disease management, for example, by monitoring patient vitals, giving advice on lifestyle changes, and providing relevant patient education materials [19].

The fourth design principle concerns *interaction and collaboration* with other patients and health care personnel. Supporting contact and communication between patients and health care providers is a key part of supporting patients' self-management [33]. Technology can be a vehicle for sharing information between patients and their caregivers and can provide support. However, technology can also create opportunities for patients to share care activities with informal carers and can contribute to engaging in self-management activities and learning from others with the same chronic condition and enhance collaboration with the care team [19]. Being able to connect with others in a similar situation may be an urgent requirement. Sharing experiences and taking part in

XSL•FO
RenderX

the experiences of others are strong motivators for using social media and are also powerful forces that can be of interest when designing tools for self-management. Figure 1 shows the 4 design principles. These principles draw attention to issues that are relevant for supporting—or hindering—T2D patients' self-management. These principles have served as a background and lens for further developing our framework.

Figure 1. The 4 design principles of diabetes self-management. Results from data collected from the usability testing of the portal.

Description of the Participants' Characteristics

Ten patients from a diabetes outpatient clinic participated in the study. The study participants were 5 males and 5 females with T2D, and the average age was 46.5 (SD 6.4) years. Participants had a mean disease duration of 7.9 (SD 4.5) years from the time of diagnosis. Seven of the 10 participants had received an undergraduate level education (9 - 11 y of education), and 3 had completed postgraduate education (14 - 16 y of education).

Time Spent on Different Tasks and Severity Ratings

The 10 participants completed the usability tests in a mean time of 2068 seconds (34 min and 28 s; Table 2; SD 212.8). The first task, "Fill in patient information," took 513 (SD 131.1) seconds (8 min and 33 s) on average to complete, while it took 442 (SD 33.0) seconds (7 min and 22 s) to complete the second task, "Register laboratory results." The first 2 tasks took longer to complete than the other tasks. Two other tasks on which the participants spent more time were "Calculate health indexes" (task 8) and "Use the 'Help-me' steps" (task 5). Table 2 presents the times that each participant spent completing the tasks and the average time and the SD for each task. In addition, it presents "range" and "range width" for each task completion. As mentioned, participants spent more time on task 1 (mean 513, SD 131.1 s; 25%) and task 2 (mean 442, SD 33 s; 21%) and the least time on task 6 (mean 91, SD 19.7 s; 4%), "Check health improvement," and task 4, "Read educational material" (mean 82, SD 81.5 s; 4%).

[a]Not applicable.

Figure 2 presents a comparison of the duration of task completion for each user.

Figure 2. Comparison of the duration of task completion for each user.

Five tasks were expected to be particularly informative and relevant to the self-management of diabetes:

- Task 3: “Attending educational courses”; take one pretest and look at the courses.
- Task 4: “Read educational material” about diabetes and body organs.
- Task 5: ”Use the ‘Help-Me’ steps” module and follow the steps.
- Task 7: “Play educational movies” and watch one educational video.
- Task 8: “Calculate health indexes,” namely, BMI and daily calorie intake.

Analysis of tasks 3, 4, 5, 7, and 8 showed that participants reflected during task completion (Table 2 and Figure 2) and provided both feedback and opinions. For example, participants pointed out their interest in finding trustworthy and helpful information, educational materials, and short educational videos about diabetes. In addition, they expressed an interest in finding information that could help them solve diabetes-related complications. Participants pointed out the importance of knowing about healthy foods in all food groups and calculating their daily calorie intakes to create healthy-eating plans relevant to their daily activities. These topics are important for diabetes self-management.

Table 3 presents the number of usability problems participants encountered and the problems that were detected in this study according to severity ratings, which range from 0 to 4, determined by the researchers involved. On the basis of the think-aloud method and the qualitative content analysis, 111 problems were detected that show strengths and limitations derived from the usability testing, and some were repeated by participants. Most usability issues (n=46) were classified as minor with a severity rating of 2 (Table 3), whereas 10 issues were rated as severity 4, indicating catastrophic problems. In addition, the participants encountered 14 issues that were not considered usability problems.

XSL•FO
RenderX

Table . Usability problems were identified by users in terms of tasks and their severity ratings.

Tasks	Severity, n (%)					Total usability problems per task, n (%)
	0	1	2	3	4	
Fill in patient information	8 (21)	10 (26)	10 (26)	6 (16)	4 (11)	38 (34)
Register laboratory results	4 (15)	4 (15)	14 (52)	2 (7)	3 (11)	27 (24)
Attending educational courses	1 (20)	1 (20)	1 (20)	2 (40)	0	5 (4)

Participants’ Suggestions for Improving the Portal

In total, 16 suggestions on how to improve the web-based educational portal were noted. In Table 4, the suggestions are sorted in ascending order based on their frequencies.

Table . Suggestions for the improvement of the portal.

User suggestions	Frequencies, n (%)
Need to have a user guide or guideline for the portal	9 (19.1)
Use appropriate messages to interact with the user	8 (17.0)
Embed the list of physicians and nurses in the online chat	5 (10.6)
Use of larger font and readable colors	5 (10.6)
Mark clearly mandatory fields	3 (6.4)
Add more educational content	3 (6.4)
Offer a diet plan	3 (6.4)
Change the titles of the calculator option	2 (4.3)
Do not use medical terms or jargon	2 (4.3)
Classify the content according to patients’ literacy level	1 (2.1)
List specific diseases that a user can select from a list	1 (2.1)
Complete the educational courses	1 (2.1)
Use more pictures and graphs in the educational materials	1 (2.1)
Use simple options to calculate BMI	1 (2.1)
Use more simple options to calculate calories	1 (2.1)
Add an option for booking time to see their physician	1 (2.1)

A Framework of Design Principles

A large number of observations were made regarding the specific complexities and challenges of using the web-based educational portal, which could affect the self-management of patients with T2D. One type of observation concerned difficulties in terms of finding information and following instructions due to poor usability. Another issue related to poor computer literacy adversely affected the possibility of using the portal for self-management due to difficulties with rather basic interactions with buttons, navigation, and finding information in the portal. In some cases, patients needed more time to complete the tasks than expected due to their lack of familiarity with the portal. Various bugs and errors in links, buttons, and forms were also noted, impacting the portal's usability. The first section below presents findings relating to the framework of design principles and is followed by data regarding the time spent on the different tasks (explained in Table 1), severity ratings, and suggestions from participants. In total, 111 codes were derived from analyzing the data that pertained to how the design of the portal supported or hindered self-management behaviors. The results are presented together with the framework of 5 design principles (Figure 1).

Regarding the first design principle about supporting patients in understanding and learning about the complexity of the condition, participants emphasized the importance of finding information and pointed out that interaction within the portal could help them learn more about self-management skills. For example, they expressed that they wanted to learn how to calculate their calorie intake and diets and how to use the BMI calculator. Participants appreciated the educational content as being helpful for dealing with self-management problems but also asked for more information about topics that they would have liked to learn more about, such as diet plans and the role of stress:

> *Here [points to the educational section of the portal], educational content is related to diabetes and body organs that users can [use to] solve their problems.*
>
> *I think it is great; this information helps us know what we have to do because a diabetic patient has a lot of problems.*
>
> *There is nothing written about stress and how it affects the body—I know that stress has a big effect on me.*

While participants appreciated learning about T2D, they pointed out that they had difficulties understanding certain medical terminology, language, and abbreviations on the portal. For 8 of the participants, the term "urine sugar" (glycosuria) was unclear, and for 4 of them, "urea in the blood" (blood urea nitrogen) presented a comprehension problem. All the laboratory items were in English, and it was difficult for participants to enter data about these items. In addition, the use of the abbreviation "BP" for blood pressure was not obvious to users during data entry.

Moreover, participants had difficulties navigating the web-based educational portal to make use of the educational material and in knowing what to do with the information. Six participants had difficulties finding the educational courses and pretest questions on the computer screen. In addition, it was not clear what to do after answering the pretest questions, or, in some cases, the proposed answers were not fully understood. One participant also had an issue with the font size of the text (too small), and 1 patient experienced difficulties accessing the educational course. One participant complained about slow scrolling when studying the educational material. Another participant also complained about the font size during this task. These usability issues risked working against the design principle of supporting understanding and learning. Suggestions from participants included avoiding medical "jargon" and classifying content according to patients' literacy levels.

The second design principle emphasizes supporting motivation and fostering sustained practices. Regarding reminders about how to go about carrying out measurements in their daily lives—such as calculating calories and creating diet plans that are easy to implement—participants expressed that functionalities of the web-based educational portal could help them modify their everyday practices. Features such as reminders, calendars, schedules, rewards, and praise were considered functions that could support participants' motivation by "nudging" them into trying new behaviors and maintaining practices over time. Several participants brought up how educational materials about diabetes could support them in maintaining their interest in the portal. They also expressed how accurate and up-to-date facts about their condition would make them feel that the portal was a place they could return to for resources and advice and something that could assist them in not giving up on self-management. Participants appreciated the idea of finding information about treatments, and knowing that they would find such information on the portal would encourage them to return to consulting the portal. A function that was appreciated was the opportunity to check one's health improvement based on laboratory results, but as the results came from a 3-month data collection period, the participants were not able to see the curve charts on the health progress screen and were therefore not able to test it fully:

> *If that was the case, for example, I would input the food and the site would tell me how much to eat based on my height and weight.*

Several comments and observations highlighted the risks of working against this design principle. As mentioned earlier, participants expressed that they wanted to learn how to calculate their calorie intakes and plan their diets, but they also pointed out that they were hesitant to insert information about their treatment or repeatedly import their weight and height into the BMI calculator, as it was experienced as burdensome. Several interactions, especially relating to inserting data, were in fact experienced as troublesome and referred to as "frustrating." Four participants had difficulties logging in, and 6 participants found it complicated to register, get login codes and passwords, or enter registration information. For all participants, it was unclear what to write in the "patient-specific illness" box in the enrollment portion of the portal, and 4 participants had difficulty entering data into the data entry boxes. Five participants complained about the font size, and 4 of them did not know the date of the onset of their illness, making interaction difficult.

XSL•FO
RenderX

All such experiences were considered annoyances that would lessen their enthusiasm in terms of using the web-based educational portal over time. The participants also experienced difficulties entering laboratory test results, which is a recurring activity that should feel easy to carry out. Eight participants experienced problems entering the value of their "sugar level 2 hours after breakfast (2hpp)." Nine participants had difficulties entering the results of the liver tests such as serum glutamic oxaloacetic transaminase, serum glutamic pyruvic transaminase, and alkaline phosphatase, their five in the afternoon blood sugar (5 PM), and the protein in their urine. Six participants had problems entering the value for serum creatinine, and 3 participants had issues entering their cholesterol and triglyceride levels. A default date was included at the end of the laboratory tests, and it made it difficult for participants to enter the actual laboratory date on the portal.

The third design principle concerned autonomy and confidence. As soon as the participants had understood how to use the web-based educational portal, they explained how it made them feel more secure and willing to continue using it. Participants commented on having mastered carrying out certain steps that they were unable to do before. Being able to use the web-based educational portal without the help of others was reported as satisfying:

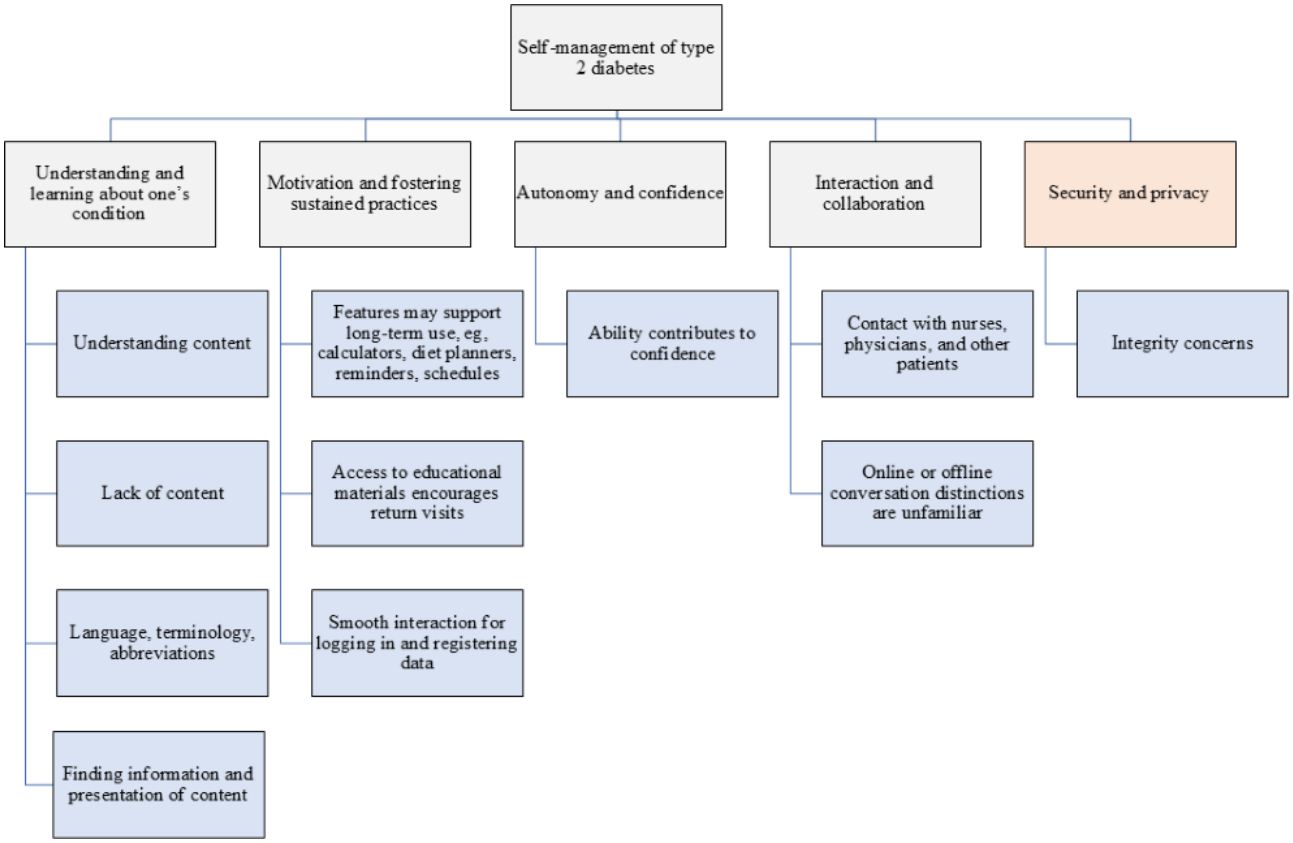
> *I know what I have to do in this step. I did this step and can do the next step; others cannot do the tasks the way I'm doing them.*
>
> *This is the one I can do, and I think it is not difficult for me. It is not necessary to ask someone and get help.*

The step-by-step instructions were appreciated and seen as helpful by the participants in learning how to make use of the portal's features. In contrast, participants were disappointed when they were not able to follow the sequential steps of the Help-Me screen to get the necessary information, and they called for an additional step that would more clearly show them how to complete the task. More user guides were suggested as being potentially helpful for building up competence in fully making use of the intentions of the portal.

The fourth design principle highlights the importance of interaction and collaboration with others. An online chat function is provided by the portal, which enables communication between patients and physicians or nurses. Having the possibility to contact health care professionals was viewed as important, and one of the participants commented as follows:

> *I can find the information that I need on this portal. It is great to have contact with nurses and doctors through this portal.*
>
> *How good it is to be able to contact a nurse online! Well, I do not see anything like a doctor here. It is easier to have the doctor's name. It would also be interesting to talk to people who have the same problem as us.*

Participants suggested extensions regarding how they could get in touch with health care professionals, for example, by adding the ability to book a time to meet their physician through the web-based educational portal. Some participants had difficulties finding the names of the physicians or nurses on the lists that were available online, and one suggestion was to embed such a list in the chat function. One concern that was voiced was that the text-based interaction between nurses and physicians should occur on an appropriate, understandable level. Moreover, the distinction between scheduled online face-to-face meetings and offline, or asynchronous, communication with physicians or nurses was unfamiliar to the participants.



In addition, several observations were made that did not match the framework's 4 principles. A common thread was these observations related to the participants' concerns about their integrity and trusting the system with health data. Participants expressed that they preferred not to share certain information and were uncomfortable being prompted to insert such information. Therefore, the addition of a fifth design principle to the framework relating to security and privacy issues was suggested. Some participants were hesitant about inserting data about their treatments, weight, and height, and there was another aspect to this hesitance. Two participants were unwilling to enter personal information and expressed concerns about security and information privacy and wondered who would be able to see and access the personal data uploaded into the system. The participants referred to the fact that their health information would be in a system that is online as the reason behind their worries. Such concerns, therefore, counter the goal of using the portal. Regardless of whether the users are able to make use of the intended functionalities provided by the system, a lack of confidence in the system risks undermining the overall use of the portal:

> *Is it necessary to enter all this information to register? It would be better if the icons had a star to show which ones are necessary. Because I don't like that, and I don't register myself on some sites that take all my personal information.*

Figure 3 presents the updated framework, which includes 5 principles.

XSL•FO
RenderX

Figure 3. The updated framework.

Discussion

Principal Findings

The principal results are structured as follows: a brief summary of the usability testing is provided first, followed by a detailed discussion of the proposed framework.

The usability testing revealed issues affecting user performance and understanding across the evaluated 9 tasks. Participants successfully completed most tasks, but tasks 1 “Fill in patient information” and 2 “Register laboratory results” required more time and caused confusion about terminology (also because laboratory variables were expressed in English). Think-aloud responses showed that participants reflected on unclear instructions and insufficient system feedback for tasks 3, 4, 5, 7, and 8 (Table 2 and Figure 2). Using Nielsen’s severity rating scale, we identified 46 minor usability problems with a severity rating of 2 and 10 major problems with a severity rating of 4 (Table 3). Minor problems were primarily related to tasks 2, 1, and 9, whereas major problems were related to tasks 1 and 2, related to insufficient support for self-management actions and unclear terminology. Suggestions on how to improve the web-based educational portal were noted (Table 4) and were related to providing a user guide and adopting a suitable terminology for the user. Positive feedback highlighted the usefulness of certain information modules (see section “A Framework of Design Principles”). Overall, these findings guided the refinement of the framework by contributing an additional design principle and providing further detail to existing principles.

This study has proposed a framework of design principles and investigated design and usability aspects of a portal aiming to support the self-management of patients with T2D. The design principles emphasize aspects that are important for the self-management and can guide design work. Design principles have been described as providing a bridge between theory and practice while simultaneously playing several possible roles [44]. They can, for example, be a means of explaining, communicating, and discussing criteria for making selections; suggestions for developing existing practices; a framework for reporting findings; or ideas regarding tool functionalities. In this study, the design principles have fulfilled several of these roles and have provided a way of focusing on aspects of the web-based educational portal that contribute to the overall goals of self-management, as well as to the study and evaluation of the proposed solutions.

These aspects are expected to be crucial to consider when designing tools for T2D self-management, and many have been previously discussed in the literature [4,17-20,33]. Here, the principles have helped us concretize these aspects to empower a specific patient group. The importance of the ideas underlying the principles was in part confirmed by the many observations, but many findings have also added to the understanding of the patient group and its needs. The findings contribute to refining the principles, and negative observations and input from participants have also highlighted the risks and drawbacks of design proposals. Regarding the first design principle, emphasizing the patients’ understanding and learning about their condition, we found overwhelming support for patients’ interest in learning more about their condition and improving their self-management skills. The educational materials that

XSL•FO
RenderX

were provided were appreciated and considered helpful for dealing with self-management problems, but many more topics were called for. Several usability issues also risked countering this design principle, including poorly designed interaction, navigation, presentation, and the use of language and terminology.

The second principle highlights the importance of supporting motivation and fostering sustained practices. Features of the web-based educational portal, such as reminders, calendars, and calculators, which could support, remind, encourage, maintain, and help participants plan their everyday practices, were considered motivating and helpful. However, participants also pointed out that knowing that the portal offers up-to-date educational materials was something that encouraged them to return to it. Poorly designed interaction, especially when registering data, was considered irritating and was identified as a risk when it comes to the sustained use of the portal.

The third principle focuses on patients' autonomy and confidence. Being able to carry out tasks on the portal without help from others was clearly pleasing for participants and contributed to a feeling of confidence. However, there is also a need to educate and guide the patients in how to use the system properly and efficiently. This could be done at the health care centers, where a number of one-to-one sessions with a nurse could be scheduled to direct the patients toward autonomy of use. The usability study shed light on an aspect that we had not previously focused on, namely, the confidence users have in the portal. Confidence in the system and how personal data are handled was a crucial issue for some users, and uncertainty regarding data security was something that risked undermining patients' use of the portal.

The fourth design principle highlights the importance of interaction and collaboration with others and was also confirmed in that participants considered it important and appreciated the possibility to chat with physicians and nurses. In addition, they asked for opportunities to contact other patients and to be able to not only chat with health care personnel but also to book a time to see their physicians. Text-based communication with health care professionals also raised some concerns for those who were unfamiliar with it—what would be an understandable level? In addition, the difference between synchronous and asynchronous communication with physicians or nurses was not clear to all participants.

In addition, as is common to each health information technology application, there are issues associated with security and privacy, which we introduced as a fifth principle because of the usability testing. Patient portals, as clinical information systems, are complex environments that integrate patients' data, information technologies, and human stakeholders. In designing patient portals optimally, it is imperative to protect patient confidentiality and follow health care provider guidelines [45]. Researchers proposed that the privacy principle should be classified into different levels according to importance [46]. To date, in Iran, there is no legal framework in use when it comes to information privacy, but there are legal provisions for cybercrime and protection of personal data [47]. The need to study the European General Data Protection Regulation is also felt in the Iranian legal system. Privacy and individuality are important ethical values and should be respected and protected in the design process [48]. In addition, privacy is gaining more attention in the design of communication technologies [49,50]. Finally, we would like to summarize the elements that support patient engagement. Helpful educational resources, supportive tools for planning and reminders, autonomy in task completion, and easy access to provider communication all encourage and sustain patient portal use for self-management.

Comparison With Prior Work

As designers, there is a need to balance the strengths and weaknesses of a technology [23]. Some of these issues are recognized from previous studies, such as users asking for materials in everyday language without medical jargon while simultaneously requesting accurate and complete information about medical conditions and treatments [28,51]. Such contradictory requirements demand that designers consider the trade-offs. Another such trade-off is, on the one hand, building a web-based educational portal with information about the patient that is as complete as possible, and, on the other hand, burdening patients with having to enter data continuously and also having to worry about the integrity of their personal data, also shown in a study by Derboven et al [24]. Furthermore, the study identified how patients' digital and health literacy and a perception of empowerment were crucial for them to be able to take responsibility for their self-management, which is in line with other studies [14,26-28]. Technology can help patients with chronic diseases take control of their conditions, but research needs to ensure that the technology's design is perceived as safe [23]. In addition, research has previously identified technology as a third agent when generating personalized advice for self-management, which is something that can be automated [24].

This study shows that although design research is time-consuming, usability testing and severity ratings provide invaluable information for design. Going through the scenario and tasks made it possible for participants to indicate which features of the web-based educational portal did not work as intended. It is natural for a usability test to discover problems and glitches—users comment on difficulties rather than when the design works smoothly. A well-known fact in usability design is that users comment more on faults than on features that work well, as the former are unexpected, disturb interactions, and are easier to detect [52]. However, participants also suggested how to improve the design of the portal to better fit their needs. In addition, many of these usability problems can, in most cases, be fixed with a simple redesign, as is reported elsewhere [53]. Inappropriate cultural assumptions and low-level usability issues may, in many cases, lead to nothing more than just annoyance, but seemingly trivial design flaws may ultimately also lead to patient harm [54]. Most of the usability problems that participants encountered in this study concerned entering the data in tasks 1 and 2, which were also found by Mazaheri Habibi et al [55]. Entering personal information and health data on this kind of portal may be a daunting task for patients, and they may also feel insecure about filling in the right data. Developing guidelines to help patients with registration is therefore a necessity [56]. It remains unclear,

XSL•FO
RenderX

especially considering the varying levels of digital and health literacy, whether such guidelines should be provided online, in printed form, or face-to-face. All the participants in this study successfully completed all the tasks, but most of the participants needed help along the way. Similar results were also found in studies of other patient groups [57]. Navigating a health portal is not a straightforward task, and efforts may be needed to produce clearer guidelines in order for portals to be used in practice. A section explaining any changes and improvements regarding the various functionalities can be helpful [15]. One particular difficulty in this case was that while the portal was in Farsi, participants were required to enter their laboratory results in English. Previous studies have shown that patients may find medical terminology on portals difficult [58-60], and they may need more guidance for such interactions. Research has also shown that participants with limited health literacy experience more barriers to using patient portals [56].

Our findings appear to be consistent with prior evaluations of diabetes self-management technologies in similar contexts. Nabovati et al [61] reported high usability for a diabetes app that combined educational content with calculators, reminders, graphical feedback, and physician communication. Our participants similarly endorsed those functions as motivating and practically helpful. Salari et al [62] further showed that personalization guided by behavioral theory and a clinician portal can promote independence and keep users involved. Complementing these results, Ghodousi Moghadam et al [63] demonstrated that a mobile serious game can enhance motivation for diabetes self-management. Together, these studies reinforce our conclusions that educational resources, planning or reminder tools, autonomous task support, and provider communication facilitate sustained portal use, while also reflecting the barriers we found, that is, the need to avoid complex language and to remediate confusing interactions through iterative, user-centered design.

One core aspect of usability is how effectively a design supports users in reaching their desired goal, in this case, self-management. This think-aloud study has investigated aspects that either support or risk being barriers to patients' self-management. Many usability problems and challenges regarding self-management were identified, including negative examples that seem to contradict the design principles. Such observations, however, enable a better understanding of the design principles. The findings enable the principles to be refined to better reach their goals, and the observations from the study, in combination with the input from the participants, have provided several possible ways of addressing these issues.

Limitations

Only literature incorporated in the authors' previous research informed the development of the framework of design principles. Consequently, the range of identified principles may have been influenced by this limited evidence base. Then, this study focused on a group of patients with T2D at a diabetic clinic in one specific city, Mashhad, which may not fully capture the diversity of patients in other settings or geographical locations. This limitation could affect the generalizability of the results. The study also concentrated on specific tasks within the portal's 9 sections, potentially overlooking usability issues or interactions between different sections. To address these gaps, future research should involve more clinical settings and a wider sample of patients. Nevertheless, the research was helpful in refining a framework of design principles pertaining to the design of web-based resources for the self-management of patients with T2D.

Conclusions

A portal designed to enhance patients' understanding, motivation, autonomy, and interaction with health care personnel is likely to be highly appreciated and to effectively support self-management. However, the design must also rigorously address risks that can undermine adoption and sustained use. Poorly designed interactions, such as confusing navigation, unclear workflows, or unintuitive interfaces, can hinder patients' ability to use the portal effectively. Likewise, complex or technical language may reduce comprehension, discourage use, and limit the portal's value for individuals with varying levels of health literacy. In addition, robust safeguards are required to protect patient integrity and data security, as trust in the system is essential for meaningful engagement.

We have proposed a framework of design principles pertaining to the design of web-based resources for the self-management of patients with T2D. Our results imply that usability testing, despite being time-consuming, is necessary when assessing a web-based educational portal, its potential for patients, and its sustained long-term use.

Acknowledgments

The authors received no specific funding for this work. The authors acknowledge the support of the personnel and patients of the Mashhad Diabetes Clinic and Medical Informatics Department at the Faculty of Medicine of Mashhad University of Medical Sciences. The authors would also like to thank Ali Jamali and Niloufar Fouladi, who designed the prototype for the web-based educational portal and participated in the severity analysis.

Funding

The authors declared no financial support was received for this work.

Abstract

Background: Scarce human resources for health and high injury-related mortality coincide with inequities in accessing quality trauma education programs in low- and middle-income countries. Existing observational studies restrict assessments of trauma training program impacts on providers' knowledge. Evaluation of trauma education programs outside clinical trial settings hinders their effectiveness in influencing clinical practice and policy changes for patient outcomes.

Objective: This study aimed to assess the impact of the Rural Trauma Team Development Course (RTTDC) on clinical processes and patient outcomes of motorcycle-accident–related neurological and/or musculoskeletal injuries in selected Ugandan hospitals.

Methods: This was a pragmatic 2-arm, parallel, multiperiod, cluster randomized controlled trial. The participants were trauma care frontline personnel and patients aged 2 - 80 years at 3 intervention and 3 control Ugandan hospitals (1:1 allocation). Hospitals were randomly allocated to intervention or control groups using permuted block sequences. Sequence codes were generated off-site by an independent statistician using Sealed Envelope (version 1.23.1; Sealed Envelope Ltd). Both patient participants and outcome assessors were blinded to allocation. Hospital allocation codes were concealed until the point of assignment. In the intervention arm, 500 trauma care frontliners received RTTDC, whereas patients received standard care. In the control arm, patients received standard care without RTTDC for staff. The primary outcomes were time from accident to admission and from referral to dispatch. The secondary outcomes were all-cause 90-day mortality and morbidity related to neurological and/or

XSL•FO
RenderX

musculoskeletal injuries. We followed the CONSORT (Consolidated Standards of Reporting Trials) guidelines for reporting cluster randomized trials.

Results: We analyzed 1003 participants (501 intervention and 502 control). The intervention arm had a shorter median (IQR) prehospital time of 1 hour (0.50 - 2) and referral-to-dispatch interval during interfacility transfers of 2 hours (1.25 - 2.75). This contrasted with 2 hours (1.50 - 4) and 4 hours (2.50 - 4.10) in the control arm, respectively *(P*<.001). The 90-day mortality was more than halved in the intervention (5%, 24/457) vs in the control arm (13%, 58/430) *(P*<.001). Fewer participants in the intervention group had unfavorable Glasgow Outcome Scale scores (9%, 42/457) vs (20%, 87/430) *(P*<.001). No difference was found in musculoskeletal injury morbidity outcomes *(P*=.57).

Conclusions: Rural trauma team development training demonstrated potential for improved organizational time efficiency and clinical outcomes for neurological injuries without negatively impacting musculoskeletal injury morbidity outcomes. Evidence from this trial supports that locally contextualized, trainee-led rural trauma team development interventional programs are feasible in low- and middle-income countries. However, despite being a multicenter study conducted across 6 geographically distinct hospitals, the research is limited in generalizability due to its focus on a single health care system within 1 country, retrospective trial registration, exclusion of prehospital deaths, and a relatively small number of clusters, which could introduce measurement bias.

Introduction

Background

Globally, access to essential surgical services and trauma education remains restricted. In Africa, shortages of health care workers and their inequitable distribution further impede access to both emergency and elective surgical care. As a result, a substantial proportion of the population in Africa lacks access to these critical services [1].

Optimizing human resource capacity, particularly for trauma care, is critical for strengthening health care systems, alongside infrastructure development [2]. The provision of trauma education for nonspecialist primary care providers remains a potential remedy to address the shortage of health care human resources in Africa [3], but linking such medical education programs to patient outcomes has been underresearched. While several training programs such as the Advanced Trauma Life Support (ATLS) and Primary Trauma Course (PTC) have been introduced, financial barriers and limited assessment of the impact on patient outcomes have hindered the implementation of these education programs, particularly for frontline trauma care providers in low- and middle-income countries (LMICs), who include lay response personnel such as traffic police [3,4]. According to a scoping review of trauma training courses, the average cost of ATLS per participant was US $820 compared to PTC (US $232) and Rural Trauma Team Development Course (RTTDC; US 50 - US $100) [5].

Locally contextualized trauma education programs are needed in LMICs due to resource constraints limiting ATLS uptake [5]. Other existing courses, such as PTC, face criticism for limited international recognition, a relative bias toward trauma technical skills, which limit lay responders' participation, and their impact on patient outcomes has not been rigorously evaluated through clinical trials, warranting further exploration of need-specific alternatives [4].

Evidence from observational studies in the United States suggests that the RTTDC is a well-recognized form of trauma education. RTTDC can be flexibly implemented through a single-day format or a modular structure over approximately 8 hours, with instructors who are trauma specialists, nurses, or paramedics [6]. RTTDC emphasizes technical skills, including primary and secondary surveys, general trauma care, including for specific populations such as children and older adults, while also highlighting a team approach to injury management in rural environments. This is accomplished by evaluating team performance through simulations, didactic lectures, and case scenarios that focus on local injury burden and trauma nontechnical skills such as leadership, communication, coordination, resource management, and decision-making for interfacility transfers [6-8]. These components are vital for trauma teams in rural areas with limited human and infrastructural resources, enabling participation from nontechnical staff and connecting communities to formal trauma systems. Emphasizing trauma coordination, performance improvement, and situational resource awareness helps minimize delays in interfacility transfers for definitive care of injuries that exceed local capacity. While ATLS and PTC provide comprehensive approaches to technical trauma care, RTTDC offers a cost-effective option for training larger groups, including nontechnical staff, in resource-limited settings [5].

The ability of the RTTDC model to improve each trauma team member's performance makes it applicable in LMICs, where team and organizational efficiency are more desirable to mitigate understaffing. However, researchers have primarily evaluated the course's impact on provider performance rather than patient outcomes, as ethical constraints have precluded the evaluation

XSL•FO
RenderX

of RTTDC interventions through individually randomized prospective clinical trials [8]. Furthermore, the need to mitigate potential contamination between treatment arms necessitates a cluster-randomized study design. Evaluation of surgical interventions and trauma education programs outside of randomized controlled settings contributes to research implementation gaps, limiting their utility in clinical practice [9]. Cumulative research findings from emerging contemporaneous studies are necessary to drive practice and policy changes [9].

While prior systematic reviews have identified improvements in clinician knowledge from trauma education programs in LMICs, the next critical step is to evaluate their impact on organizational efficiency and patient outcomes in the clinical setting [3-5]. Therefore, in this cluster-randomized trial, we examined the impact of a locally contextualized RTTDC on hospital processes and clinical outcomes in an LMIC setting, focusing on time efficiency, mortality, and morbidity of motorcycle accident–related neurological and/or musculoskeletal injuries. These injuries were previously identified as critical for strengthening rural trauma systems in Uganda [10]. Motorcycle-related crashes are the leading cause of fatal trauma in Uganda, and the resultant injuries are predominantly neurological or musculoskeletal in 85% of cases [11]. An injury was deemed motorcycle-related if it involved a motorcycle-motorcycle, motorcycle-pedestrian, motorcycle-vehicle, or motorcycle-static object crash. Motorcycle-related injury mechanism was established during the secondary survey in the evaluation of events surrounding the injury.

This study defined rural trauma team development education as the implementation of RTTDC and the establishment of trauma teams in rural Uganda, which were previously nonexistent. In this study, RTTDC was locally contextualized to fit within the interconnected geopolitical, socioeconomic, and health care system challenges in Uganda, and to conform to the 4 domains of the Kirkpatrick framework for evaluating educational interventions [12]. First, we acknowledged the constraints of limited human resources for health in low-income Uganda, political tensions, and internal conflicts; thus, medical interns and traffic law enforcement professionals formed an integral component of our frontline trauma team participants. These cadres provide the first contact to patients with injury in Uganda due to a weak, inadequately funded prehospital and emergency postcrash care system, largely resulting from a shift of resources to the high infectious disease burden and obstetric emergencies [13].

Second, through engagement with local surgical and medical education experts (university medical faculty deans) and the Ugandan Ministry of Health, we fitted our trauma education intervention within the existing framework of medical curricula. We concurrently timed the recruitment of study participants during medical internship placements and surgical clinical rotations to maximize the course uptake.

Third, we assessed participants' satisfaction regarding the course through self-administered surveys (reaction), determined the effect of RTTDC intervention on participants' knowledge through pre-post training trauma-based multiple-choice questions (knowledge gain and retention), and assessed the change in practice using the pre-post training trauma nontechnical skills scale based on customized trauma case scenarios that suited the local injury burden (behavioral change). The impact of RTTDC on participants' knowledge, skills, and behavior was published elsewhere [14].

Finally, we translated classroom knowledge into clinical practice. We used the RTTDC participants to form well-coordinated, real-world rural trauma teams rooted at subcounties, using trained regional traffic police officers as the focal contact persons at the community level, and trained surgical residents at regional referral hospitals. Continuous reinforcement of RTTDC concepts to address team challenges was attained through weekly clinical audits with the trauma teams via Zoom (Zoom Video Communications, Inc). Consequently, these teams were involved in the development of a pilot Motorcycle Trauma Outcome Registry (MOTOR) using comprehensively pretested, refined, and locally customized quality indicators and measurable outcomes based on feedback from patient-public engagements. The data from the MOTOR registry were used in this study to directly link a trauma education intervention to patient outcomes through a trauma registry, thus completing the fourth level of the Kirkpatrick framework for rigorous evaluation of the effectiveness of RTTDC. The trial reporting followed the CONSORT (Consolidated Standards of Reporting Trials) guidelines for cluster-randomized trials, and the exploratory ancillary analyses due to COVID-19 interruptions adhered to the CONSORT and SPIRIT Extension for Randomized Controlled Trials Revised in Extenuating Circumstances (CONSERVE) guidelines [15,16].

Null Hypothesis

We based the specific objectives of this trial on the null hypothesis that RTTDC training has no effect on the clinical process efficiency and outcomes of neurological and musculoskeletal injuries at both the treatment arm and individual levels.

Specific Objectives

The study aimed to (1) determine the effect of RTTDC training on crash-to-admission and referral decision-to-dispatch intervals during interfacility transfers (primary outcomes); and (2) determine the effect of RTTDC training on all-cause 90-day mortality and morbidity of neurological and musculoskeletal injuries (secondary outcomes).

Methods

Overview

This was a pragmatic 2-arm, parallel, multiperiod, cluster randomized trial conducted from 9/01/2019 to 08/27/2023, with a 1-year suspension from 03/01/2020 to 03/01/2021 due to the extenuating effects of the COVID-19 pandemic. Six (6/17, 35%) Ugandan rural regional referral and teaching hospitals functioning as Level III trauma centers, including Jinja, Hoima, Fort Portal, Mubende, Kiryandongo, and Kampala International University Teaching Hospital, were included. Together, these

XSL•FO
RenderX

hospitals serve a total population of 18 million people in 3 cities and 50 rural districts. Following the national standard of care, all patients requiring referral were transferred to the Level I trauma center, Mulago National Referral Hospital, Uganda's comprehensive resource for multidisciplinary tertiary trauma care and rehabilitation.

Trauma centers are categorized into 5 levels based on their capabilities, with Levels IV and V being the lowest, providing initial stabilization through basic emergency facilities before transferring patients to higher-level centers. These correspond to health centers III and IV in Uganda. Levels III and II function as intermediate centers, offering 24/7 emergency assessment, resuscitation, and initiation of definitive care, including emergency surgeries, under the supervision of specialist surgeons, anesthesiologists, and radiologists, along with ongoing education programs for staff. In Uganda, these are typically represented by district hospitals and regional referral hospitals, respectively. While regional referral hospitals host surgical residency and internship programs to address human resource needs, they operate at Level III due to trauma resource challenges. Level I is a tertiary, superspecialized referral center that provides comprehensive care for severely injured patients, including complex microvascular surgeries, rehabilitation, and conducts trauma research, education, and quality assessment programs.

Randomization and Masking

Hospitals (clusters) were randomized in a 1:1 ratio to the intervention or control arm using permuted-block randomization, assuming equal cluster sizes. Blocked randomization lists with 6 random codes were generated off-site by an independent statistician using Sealed Envelope (version 1.23.1; Sealed Envelope Ltd) [17]. Hospital allocation codes were concealed until the point of assignment; local hospital administrators enrolled staff after allocation, and patient recruitment began thereafter.

In the intervention arm (comprising 3 hospitals), 500 trauma care frontline personnel received the fourth edition of the American College of Surgeons RTTDC training, which was administered in a multiperiod manner, whereas in the control arm (3 hospitals), trauma care frontline personnel did not receive the training [6,18]. The training intervention was delivered by a specialist surgeon and 2 senior surgical residents. Outcome assessors were external medical officers or senior residents who were not involved in training delivery and who remained masked to hospital allocation by using deidentified records; patients were not informed of hospital allocation. The training status of specific providers was not revealed to outcome assessors.

Eligibility Criteria

To be eligible to participate, a trauma center had to be a rural teaching hospital offering 24/7 emergency surgical care with access to blood banks and imaging, such as computed tomography (CT), X-ray, and ultrasound scans, as locally available or accessible in a nearby facility. Additionally, each hospital had to be staffed with surgical consultants, residents, interns, and medical students. Six out of 17 (35%) facilities met these inclusion criteria, accepted participation, and were randomized.

The participants in this trial were either trauma care frontline personnel or patients with trauma. The eligible trauma care frontline personnel constituted rural trauma team networks and were either surgery residents, intern doctors, third- to fifth-year medical or allied health students, or road traffic police officers concerned with the emergency evacuation of injured patients. It was not permissible for trauma care frontline personnel to offer their services in a way that would cross the treatment arms.

Eligible patient participants were those aged 2 - 80 years with motorcycle accident–related neurological and/or musculoskeletal injuries presenting within 24 hours at either the intervention or control hospitals during the study period. The rationale for the restriction of the study to these injuries was threefold. First, to minimize confounding due to diverse injury mechanisms during the impact evaluation of the trauma education intervention. Second, to objectively determine 90-day morbidity using standardized, injury-specific, validated tools such as the Glasgow Outcome Scale for traumatic brain injury (GOS-TBI) and Trauma Outcome Measure Score (TOMS) for musculoskeletal injuries [19,20]. Finally, to attain a sample large enough to reach statistical power in subgroup analyses for the specific injuries.

We excluded medical trainees with no previous exposure to surgical clinical rotation; pregnant women; mentally incapacitated individuals due to psychiatric disorders and without legally authorized representatives to provide informed consent; patients with documented stroke; passengers in a car at the time of collision to control confounding for injury mechanism; and deaths before imaging or arrival at emergency departments.

Prehospital deaths were excluded for 3 reasons. First, the health care system design directs such patients to city mortuaries rather than emergency departments, making accurate assessment of the primary outcome impossible, as our case definition of prehospital time was from the scene to the emergency department. Second, sociocultural norms in rural Uganda, where traditional medicine is prevalent, often discourage postmortems for deaths that are not linked to a public health concern, including postmortem CT imaging, which would hinder analysis of secondary outcomes on all-cause mortality, as caregivers typically view this process as lacking value for money. Finally, the absence of structured "on-scene" emergency care in Uganda at the time of the study meant that recording vital signs before hospital arrival could not be guaranteed, as most patients arrived at emergency departments by public transport; yet, vital signs were essential for assessing injury severity and controlling for potential confounding factors. More detailed eligibility criteria are documented in the trial protocol [21].

Patient and Public Involvement

We assessed the feasibility of trial outcome tools through engagement with trauma care frontline personnel and patient caregivers before study commencement. Further engagements were conducted by establishing rural trauma teams rooted at the subcounty level and obtaining bidirectional feedback on

XSL•FO
RenderX

trauma team performance through weekly audit meetings, as detailed in the study protocols [18,21].

Sample Size Determination and Power Analysis

The published trial protocol details the power calculations and methodology [21]. The total sample size of 1003 patient participants (501 intervention and 502 control) was estimated using an R shiny application (RStudio, Inc), accounting for the clustering design effect, 80% power, 5% type I error, intracluster correlation coefficient (ICC) of 0.02 (0.01 - 0.05), cluster autocorrelation coefficient of 0.8, equal cluster size allowing a coefficient of variation of 0.5, and 18% loss to follow-up [22]. The expected mean difference in primary outcomes was 1.02 hours based on an observational study in the United States [23]. Interim analyses were performed by a blinded statistician on August 28, 2022, in which results showed no patient-reported adverse incidents directly attributable to the intervention, which was the preset termination criteria based on harms; thus, the study continued to completion.

Data Collection

Data on the specified variables and outcome measures were collected from a piloted MOTOR created for this study. The data were entered into a secure Research Electronic Data Capture (REDCap; Vanderbilt University Medical Center), hosted by the University of Turku in Finland. Qualified medical doctors with 2 years of clinical experience or senior surgery residents served as blinded outcome assessors and were trained to use the MOTOR registry datasheet and *International Classification of Diseases, 10th Revision (ICD-10*) coding system. These assessors integrated data from clinical observations, patient interviews, and hospital and police records. Follow-up included accident and emergency departments, surgical wards, outpatient clinics, and home visits, as outlined in the study protocol [21].

Study Variables

We captured asymptomatic and symptomatic traumatic brain injury (TBI) based on the National Institute of Neurological Disorders and Stroke case definition. We obtained head CT images for participants who either met the New Orleans criteria or the Canadian CT Head Rule based on local applicable algorithms used at the study sites, whereas we used radiographs to evaluate limb fractures [24]. Based on our baseline study, we obtained variables earlier identified to influence injury outcomes in our settings, including sex, age, comorbidities, injury mechanism, road user category, helmet use, prehospital factors (transportation, first aid, and time), referral decision intervals, head CT results, definitive surgical treatment, multiplicity of injuries, and injury severity based on Glasgow Coma Scale (GCS) and Kampala Trauma Score II (KTS II) [25]. These variables align with the global surgery agenda to improve national surgical care plans in support of universal health coverage and Sustainable Development Goal 3.

Outcome Measures and Methods of Assessment

Detailed outcome measurements, analysis metrics, and assessment time points are illustrated in the published protocol [21]. The prespecified primary outcomes used measures of central tendency to compare between arms (1) prehospital time (from the accident scene to arrival at the emergency department), and (2) referral dispatch interval (from the time a referral decision was made to the time a patient exited the hospital gate to be transferred to a more resourced facility), measured in hours as indicators of process improvement.

The secondary outcomes compared between arms (1) proportions of all-cause 90-day mortality from the time of injury as a measure of physician-centered clinical outcomes, and (2) morbidity of neurological and musculoskeletal injuries at 90 days from the time of admission using the GOS-TBI (hereafter referred to as Glasgow Outcome Scale [GOS]) and TOMS, respectively, as measures of patient-reported functional outcomes [19,20]. Both GOS and TOMS were measured as final values as reported to outcome assessors, although their baseline equivalents, that is, GCS and Trauma Expectation Factor Score (TEFS), were captured to compare morbidity at baseline [19,26]. GOS was stratified into unfavorable (scores 1 - 3) vs. favorable outcomes (scores 4 - 5), whereas TOMS was dichotomized into unfavorable (TOMS < TEFS) vs favorable (TOMS ≥ TEFS) in accordance with previous studies [20,27].

These outcome measures were selected to capture the complex, multidimensional effects of trauma from diverse perspectives, including physical, social, and psychological domains. Both the GCS and the GOS have consistently demonstrated excellent internal validity, reproducibility, and reliability in multicenter trials; moreover, the tools have been validated for use in LMICs, with versions applicable in both adult and pediatric populations [20]. These tools can be administered physically, telephonically, or by post and are sensitive to severity and changes in injury sequelae over time in a diverse population of patients and examiners [28].

Acknowledging the importance of end-user involvement in research, the study used patient-reported outcomes (10-item Likert TOMS scale reported as a percentage) to assess the level of pain, physical function, disability, satisfaction with treatment, and overall life satisfaction at 90 days, compared to baseline expectations at admission (10-item Likert TEFS scale). Negative domains such as pain, disability, and activity reduction were assigned a minus score, while positive domains relating to satisfaction with life post-injury received a positive score, with total scores ranging from −700 to 300. Since injuries are not mutually exclusive in clinical settings, both GCS and GOS, or TEFS and TOMS, were administered for patients with both neurological and musculoskeletal trauma who were able to verbalize. These tools have demonstrated excellent psychometric properties in previous studies, as illustrated in Multimedia Appendix 1. KTS II captured the number of serious injuries to control for confounding due to polytrauma. The KTS II was used for its validity and suitability in predicting mortality in LMICs compared to other trauma scores, in addition to its ability to integrate physiological and anatomical indicators such as age-related comorbidities and multiplicity of injuries [29].

Clinically Meaningful Differences

For prehospital and referral-dispatch intervals, the minimal clinically meaningful difference was established as 1 hour, reflecting the “golden hour” guideline, which stipulates that

XSL•FO
RenderX

patients with trauma should reach definitive care within this timeframe to avoid increased mortality [30]. For the GOS-TBI, a 1-point difference was identified as the minimum clinically important difference, as it can shift an individual from an unfavorable to a favorable outcome category and correlates with a 1-point decline in the Disability Rating Scale [31]. This is deemed sufficient to demonstrate meaningful efficacy for TBI care and clinical research interventions, as outlined by the US Food and Drug Administration [31]. Conversely, for the TEFS and TOMS, assessed in the context of rehabilitation and improvements in functional performance from the patients' perspectives [32], the minimal clinically important difference was defined as the total TOMS score at 90 days meeting or exceeding the patients' TEFS assessed at admission, consistent with previous studies [33].

Statistical Analysis

Analyses were performed for all randomized clusters and participants in both intervention and control groups. We tested the normality of the distribution and equality of variance using the Shapiro-Wilk and Levene tests, respectively. For primary outcomes, a 2-sample Wilcoxon rank-sum test was used to compare the median (IQR) due to the skewed nature of the data despite log transformation. For secondary outcomes, we used an adjusted chi-square test to compare the difference in proportions of all-cause 90-day mortality and proportions of unfavorable GOS or TOMS for neurological and/or musculoskeletal injuries, respectively. The median (IQR) time to event (injury to death) was compared using a 2-sample Wilcoxon rank-sum test and visualized using Kaplan-Meier survival estimates. To explicitly address cluster dependency and to overcome SE bias due to the small number of clusters, we compared primary and secondary outcomes between treatment arms and reported cluster-level summaries and effect sizes within the framework of restricted (residual) maximum likelihood (REML) mixed-effects logistic regression models, using the Satterthwaite method of adjustment for the degrees of freedom. We used the Hussey and Hughes stratum-by-time extension in mixed-effects models to examine the variation in outcomes in both treatment arms across multiple time periods to address residual misspecification, assuming no study interruptions, and validated these results using cluster robust SEs (variance-covariance matrix of the estimators) in random-effects models. ICCs within periods were computed using the ".estat icc" command for each outcome using the mixed-effects REML regression models with Satterthwaite adjustment as the ratio of between-cluster variance of outcome to total variance of outcome between and within cluster.

Preplanned Subgroup Analyses

We performed preplanned subgroup analyses for sex, road user category, injury mechanisms, severity, and multiplicity of injuries. We used the REML mixed-effects logistic regression models, which permitted adjustment for confounding fixed and random effects to examine factors associated with delayed prehospital and referral-dispatch intervals, all-cause 90-day mortality, and morbidity of neurological and/or musculoskeletal injuries. We used the REML mixed-effects models to accommodate variations in baseline characteristics of random variables, intervention effects, and unbalanced data patterns that could have occurred between treatment groups, resulting from loss to follow-up. The random-effects variable was the treatment arm (intervention vs control) as the unit of analysis, with the odds ratios (ORs) and their corresponding 95% CIs as a direct estimate of the effect size. We examined all covariates for confounding and effect modification using the Cochran-Mantel-Haenszel statistics. Confounders were then added to the REML models individually or in blocks, and percentage change in exposure coefficients, Akaike Information Criterion, Bayesian Information Criterion, and log-likelihood for predictive quality were evaluated. Variables with substantial change in exposure effect were retained, and the models with the smallest Akaike Information Criterion and Bayesian Information Criterion were considered best-fitting. All analyses and data visualization were performed in Stata (version 15.0; StataCorp LLC). We considered $P<.05$ as statistically significant. Due to paper length constraints, ancillary studies detailing results of mixed-effects regression analyses for factors associated with mortality and morbidity of neurological and musculoskeletal injuries, barriers to injury care, and the impact of rural trauma team training on providers' knowledge, which constituted the tertiary outcomes of this trial, are reported separately [14,34,35] (preprint).

Additional Analysis

To account for potential confounding due to factors related to the COVID-19 pandemic's socioeconomic impact on emergency trauma services and livelihood, trial investigators conducted exploratory nonprespecified analyses comparing outcomes between participants recruited before and after the pandemic in accordance with the CONSERVE guidelines [16]. These analyses were performed to reflect a study halt, restricted participant access during lockdowns, and newly mandated participant safety requirements. Post hoc power analyses were conducted to assess whether the sample sizes used in the study were adequate for detecting effect sizes associated with the various study outcomes, given predetermined assumptions.

Handling Missing Data

We compared the baseline characteristics of participants who had missing endpoints due to loss to follow-up between the study arms. We conducted sensitivity analyses to assess the robustness of our findings under different assumptions about missing data. First, we performed a complete case analysis, assuming all missing data were completely missing at random. Second, we considered a worst-case scenario where all participants who lost to follow-up in the intervention group experienced the worst (mortality or unfavorable) trauma outcomes, while all those with missing data in the control group had favorable outcomes or survived. Third, we examined a best-case scenario, assuming all participants with missing data in the intervention group survived with favorable outcomes, while those in the control group had unfavorable outcomes or died. Finally, we performed multilevel multiple imputation to account for clustering and mechanisms of missingness and reported how the interpretation of results varied from the complete case analysis.

XSL•FO
RenderX

Ethical Considerations

The study adhered to ethical guidelines outlined by the Declaration of Helsinki and the 2017 Uganda National Council for Science and Technology guidelines. Ethical approval was obtained from the research and ethics committees of Mbarara University of Science and Technology (ref MUREC 1/7; 05/05/2019) and from the Uganda National Council for Science and Technology (ref SS 5082) before study commencement. Written informed consent was obtained from all participants or their legally authorized representatives before recruitment. The principal investigator facilitated data collection and trauma team coordination with airtime and transport reimbursement of US $7.50 per participant. This reimbursement was approved by the research and ethics committee to enable research-related follow-up of participants outside of their routine clinical appointments. This paper does not contain any personally identifying individual data or images. This study used data from the piloted MOTOR. At the time of protocol submission, the ethics committee did not mandate prior registration for academic, non–industry-funded proof-of-concept projects (policy effective December 31, 2023). Following the evolution of local policy, the investigators pursued registration with the Pan African Clinical Trial Registry (PACTR202308851460352). Due to COVID-19 disruptions, registration was completed on 08/17/2023, after recruitment commenced. The full protocol for this study was published under the International Registered Report Identifier: DERR1-10.2196/55297. The authors confirm that all related trials were included in this registration [21]. The specific impacts of the pandemic on this trial, including suspension, were reported according to CONSERVE guidelines, and subgroup analyses were performed appropriately to control for this confounding [16]. Where applicable, retrospective registration and protocol deviations due to the pandemic are cited in the abstract and paper text; for completeness, a detailed list of all deviations is provided in Multimedia Appendix 2.

At the end of the study period, there were 1003 participants (501 intervention and 502 control), with an average cluster size of 167 in both groups (14 individuals per cluster per period). The participant CONSORT flow diagram is summarized in Figure 1.

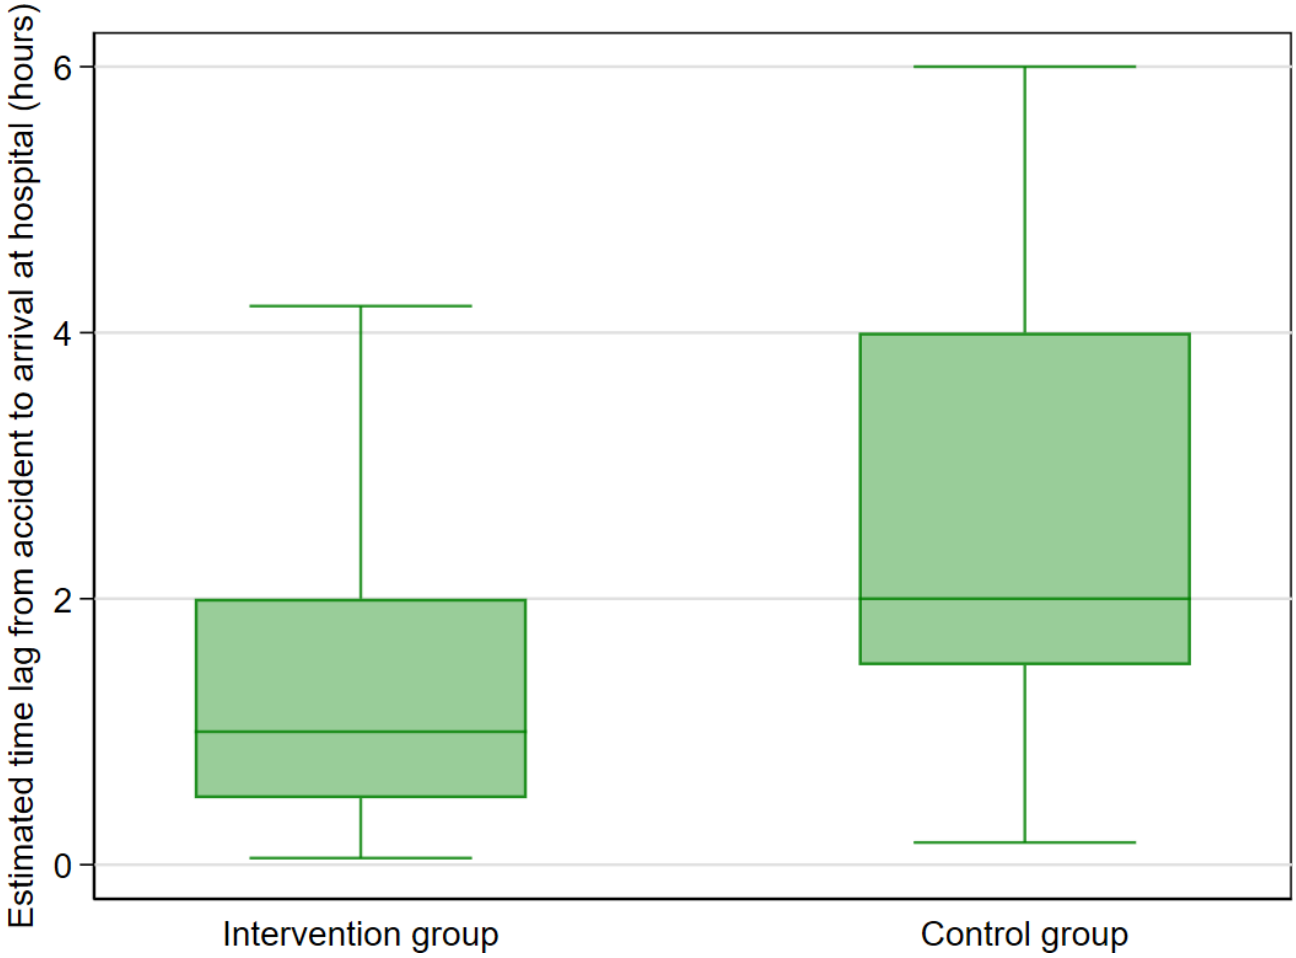
XSL•FO
RenderX

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram. RTTDC: Rural Trauma Team Development Course.

Baseline Sociodemographic and Clinical Characteristics

Cluster- and individual-level baseline sociodemographic and clinical characteristics are summarized in Multimedia Appendix 3. Of 1003 participants, 82% (817) were male and 19% (186) were female (male:female ratio 402:99 in the intervention group vs 415:87 in the control group). The overall median age (IQR) was 28 (22-37) years (median age 28 years, IQR 22-38 years in the intervention group vs median age 28 years, IQR 22-36 years in the control group). There were no significant imbalances in the distribution of baseline characteristics between treatment groups except for 5 out of 37 covariates, namely employment status, proportion sustaining motorcycle-car crash, reported head impact, multiplicity of injuries, and respiratory rate. The overall median injury severity based on KTS II was 8 (IQR 7-9) and did not differ significantly between groups (P=·36).

Most participants (77%, 776/1003) arrived by public means (79%, 398/501 in the intervention group vs 75%, 378/502 in the control group). Helmet use was reported at 25% (254/1003; 23%, 144/501 in the intervention vs 28%, 140/502 in the control group). Irrespective of symptoms, 95% (949/1003) of participants reported head trauma (impact). Symptomatic TBI was present in 70% (699/1003; 69%, 347/501 in the intervention



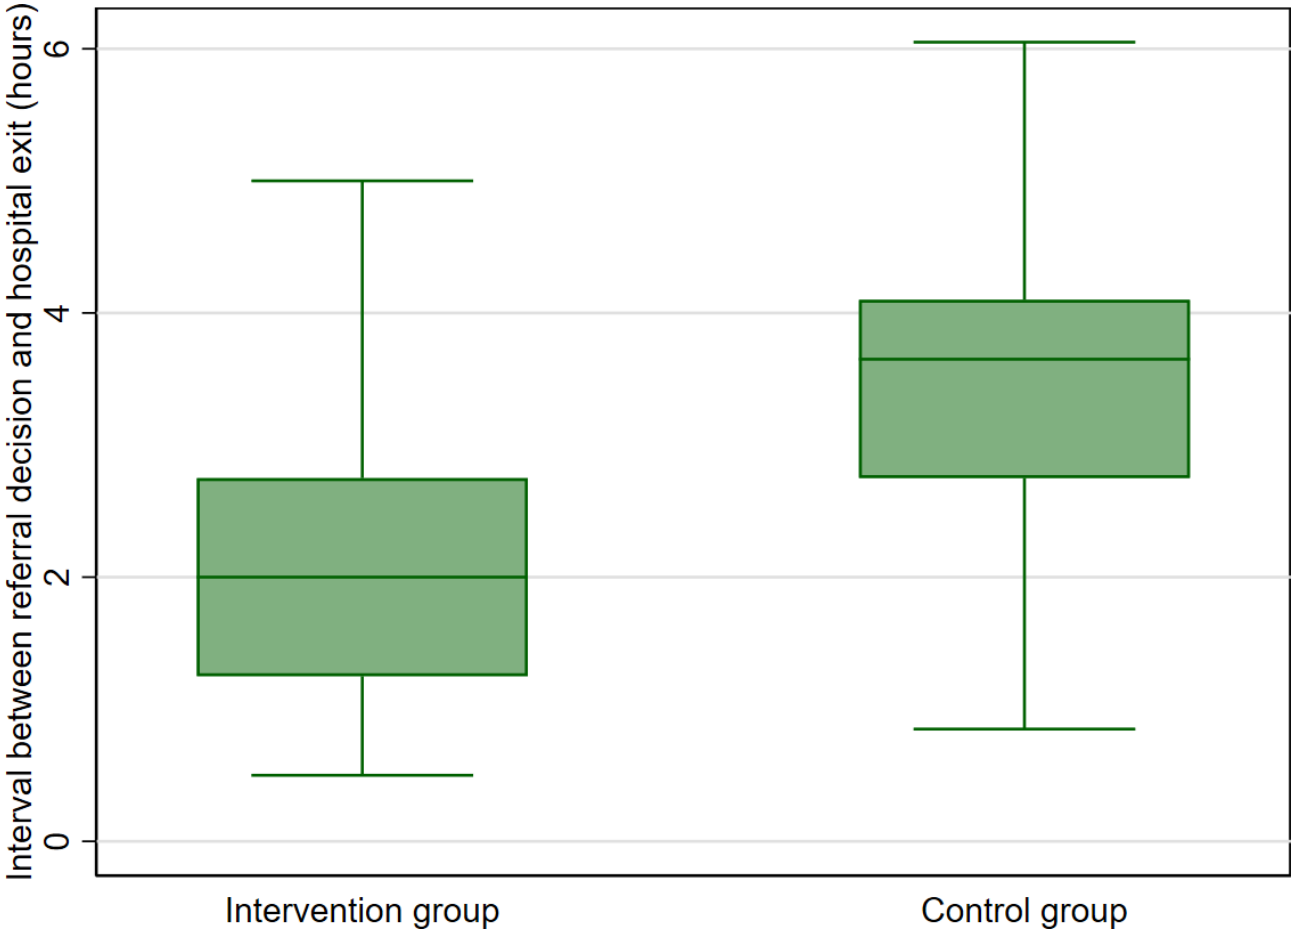
XSL•FO
RenderX

vs 70%, 352/502 in the control group). Over 67% (675/1003) of participants met the head CT criteria (67%, 335/501 in the intervention vs 68%, 340/502 in the control group). Conversely, one-third of the participants did not meet the CT criteria. The median GCS was 14 (IQR 11-15) and did not differ between groups (*P*=.12). The admission systolic blood pressure was ≥90 mm Hg in 82% (822/1003), with oxygen saturation >90% in 80% (802/1003) of participants. Loss of consciousness and posttraumatic headache were the most reported clinical presentations. Acute epidural hematomas were the most observed radiological pathology (17%, 175/1003), followed by subdural hematomas (10%, 95/1003). Emergency craniotomy was the most performed neurosurgical intervention (24%, 236/1003). On the other hand, musculoskeletal injuries were present in 80% (799/1003) (80%, 400/501 in intervention vs 80%, 399/502 in control), of which 27% (268/1003) had limb fractures (27%, 134/501 in intervention vs 27%, 134/502 in control).

Primary Outcome I: Comparison of Prehospital Time

For the 1003 participants, the overall median prehospital time was 2 (IQR 1.00 - 3.00) hours and was shorter in the intervention compared to the control group (1 hour, IQR 0.50 - 2.00 hours vs 2 hours, IQR 1.50 - 4.00 hours; *P*<.001) (Figure 2). Adjusted predictions of prehospital time between arms across study periods are provided in Multimedia Appendix 4. Factors that contributed to delayed prehospital arrival beyond the optimal 1 hour were commute distances longer than 5 km, being a survivor of motorcycle-static object collisions, needing first aid before arrival at emergency departments, and requiring craniotomy, whereas patients' age and head CT findings were the most significant determinants of delayed referral-dispatch execution (Multimedia Appendix 5).

Figure 2. Comparison of median prehospital time lag from accident scenes to arrival at emergency departments.

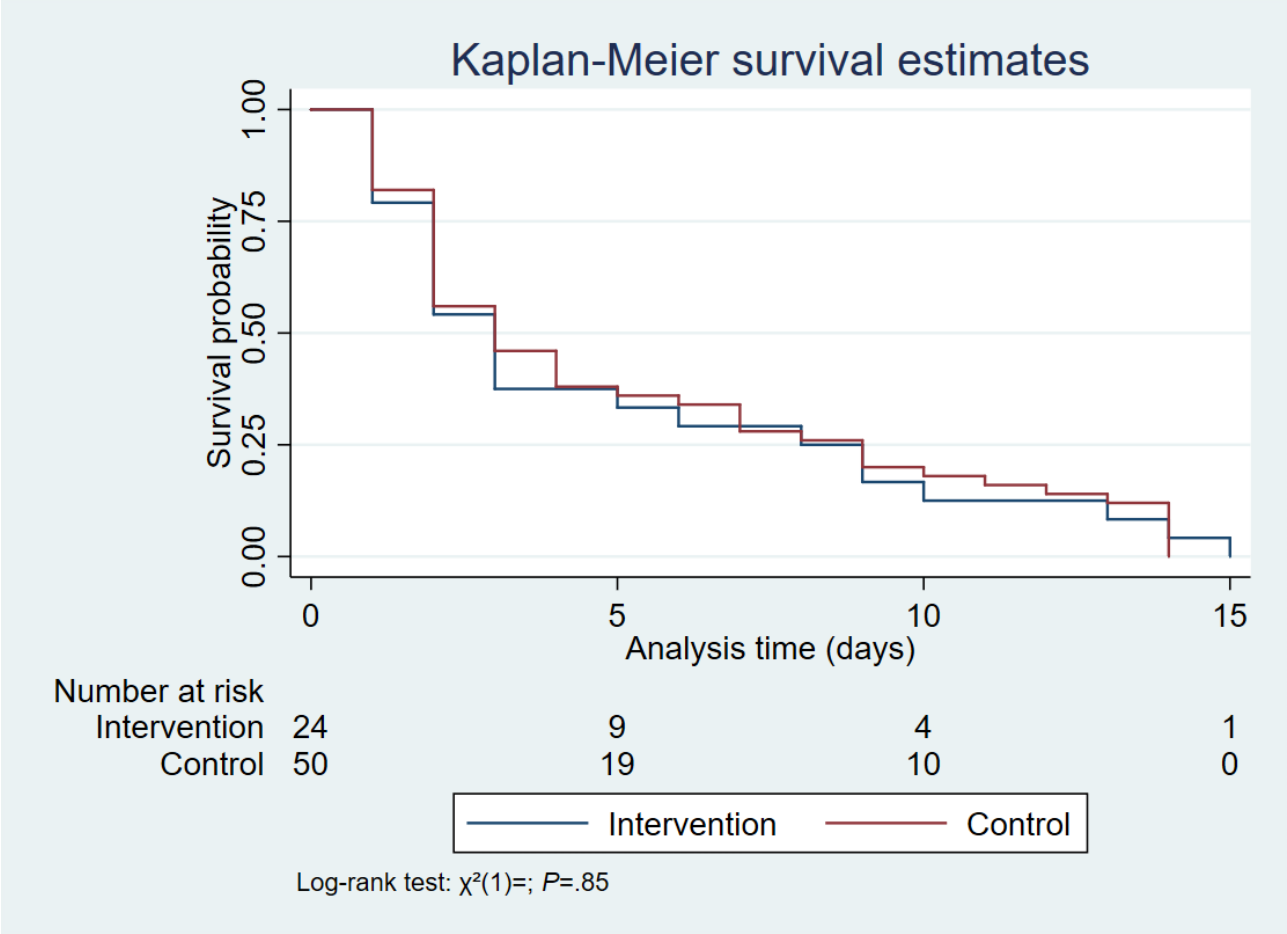


Primary Outcome II: Comparison of Referral Decisions to Dispatch Interval During Interfacility Transfers

For 69% (691/1003) of patients whose care demands exceeded local resources and warranted referral, the overall median referral decision to dispatch interval was 3 hours (IQR 1.75 - 3.85 hours). As provided in Figure 3, the referral decision to dispatch interval was shorter in the intervention (2 hours, IQR 1.25 - 2.75 hours) vs the control group (4 hours, IQR 2.50 - 4.10 hours; *P*<.001]. Adjusted stratum-by-time predictions of referral-dispatch intervals between arms across study periods are provided in Multimedia Appendix 6.

XSL•FO
RenderX

Figure 3. Comparison of referral decision to dispatch interval between groups.



Secondary Outcome I: All-Cause 90-Day Mortality

Of the 88% (887/1003) participants who completed the 90-day follow-up, the overall 90-day mortality was 9% (82/887). Mortality was lower in the intervention at 5% (24/457) compared to the control group at 13% (58/430) (χ^2_1=17·9; *P*<.001). Of the 82 deaths, 8 (9.8%) occurred in the emergency departments of the control group vs 0 (0%) in the intervention group. Figure 4 demonstrates that the overall median survival time among the remaining 74 deaths was 3 (IQR 1-8) days and did not differ significantly between groups (*P*=.48). Stratified Cox regression analysis showed that the only determinant of time to event (death) was receiving a craniotomy (*P*=.01), but the proportions that required this procedure did not differ between groups (*P*=.17) (Multimedia Appendix 7). Although more males (84%, 69/82) died than females (16%, 13/82), preplanned subgroup analyses showed that the median survival time did not differ significantly across study periods by sex (*P*=.71) (Multimedia Appendix 8) and by road user category (*P*=.46) (Multimedia Appendix 9).

XSL•FO
RenderX

Figure 4. Comparison of Kaplan-Meier survival time (days) between groups.

Secondary Outcome II: Comparison of Morbidity of Neurological Injuries

Of the 887 out of 1003 participants who completed the 90-day follow-up, 86% (758/887) had a favorable GOS, with a median of 5 (IQR 4-5). The proportion of participants with favorable outcomes was significantly higher in the intervention group (91%, 415/457) compared to the control group (80%, 343/430) (χ^2_1=21·7; *P*<.001). The median GOS (IQR) was 5 (4-5) in both arms, with the intervention group showing a slightly higher median compared to the control group (*P*=.003). The results of all GOS subcategories among participants are summarized in Multimedia Appendix 10.

Secondary Outcome III: Comparison of Morbidity of Musculoskeletal Injuries

Of the 637 out of 799 patients with musculoskeletal injuries whose TEFS and TOMS were complete at 90 days, the majority (75%, 478/637) had a favorable outcome (TOMS ≥ TEFS). As provided in Figure 5, the proportion of patients whose trauma outcome equaled or exceeded their initial expectations was comparable between the intervention (76%, 262/345) vs the control group (74%, 216/292) (χ^2_1=0.6; *P*=.57).

The OR of unfavorable to favorable patient-centered trauma outcomes for musculoskeletal injuries did not differ significantly between intervention (OR 0.952, 95% CI 0.804 - 1.128; *P*=.57) vs control (OR 1.073, 95% CI 0.907 - 1.269; *P*=.57). This finding remained consistent after preplanned subgroup analyses for limb fractures in the intervention (OR 1.009, 95% CI

XSL•FO
RenderX

0.716 - 1.368; *P*=.95) vs in the control group (OR 0.990, 95% CI 0.716 - 1.368; *P*=.95) and for isolated tibial fractures in the intervention (OR 0.992, 95% CI 0.740 - 1.332; *P*=.96) vs in the control group (OR 1.008, 95% CI 0.726 - 1.400; *P*=.96) (Multimedia Appendix 11). Adjusted predictions of TEFS and TOMS across study periods are illustrated in Multimedia Appendix 12. The cluster-level summary and comparison of all outcomes using nonparametric Wilcoxon rank-sum tests are provided in Table 2, with the number of clusters in the intervention arm=3; number of clusters in the control arm=3; total number of clusters: 6; number of discrete decay periods=12.

The results of nonparametric tests were congruent with those of mixed-effects regression (REML) comparisons after adjustment for small-sample correction using the Satterthwaite method (Table 3). The corresponding residual estimates are provided in Multimedia Appendix 13.

Table . Per-protocol comparison of primary and secondary outcomes across study periods after adjustment for small-sample correction.

Outcome variable (number of observations)	Average cluster size per period, n (min-max)	Average sample per period, n (min-max)	SE	Satterthwaite adjusted df	Coefficient (intervention arm; 95% CI)	*P* value	Residual ICC[a] at level of study period (95% CI)

[a]ICC: intracluster correlation coefficient.

Adverse Events

There were no crossovers between arms, but there were 8 deaths at the emergency department in the control arm, which can be considered as an adverse injury outcome. At 90-day disposition among 805 retained survivors, a total of 16 (2%) participants were still hospitalized due to pressure ulcer sequelae to neurological injuries. These ulcers required long-term debridement and plastic reconstruction alongside physiotherapy and rehabilitation, which all took longer than 90 days. However, the proportions of those retained (7/433 in the intervention vs 9/372 in the control group; χ^2_1=0.6; *P*=.43) and those discharged home (426/433 in the intervention vs 363/372 in the control group, χ^2_1=0.01; *P*=.94) did not differ significantly.

To examine the extenuating circumstances of COVID-19, we performed exploratory analyses to probe any differences in outcomes, and our results showed no differences in the prehospital interval, referral decision to dispatch interval, and all-cause mortality before and after the COVID-19 pandemic. However, participants who were seen after the onset of the pandemic were twice as likely to report TOMS below their baseline expectations (OR 2·019, 95% CI 1.178 - 3.460; *P*=.01), and this association remained significant even after adjusting for confounding due to age, employment status, marital status, injury mechanisms, injury severity, and multiplicity of injuries (adjusted OR 2.095, 95% CI 1.199 - 3.659; *P*=.01). A detailed account of the pandemic effects and other factors that influenced mortality and morbidity is provided here [34].

Missing Data

Our data quality and handling protocols in REDCap have been previously described in the study protocol [21]. On evaluation of lost to follow-up, the primary outcomes with missing end points (prehospital time or referral dispatch interval) were less than 0.1% (1/1003), whereas 12% (116/1003) were lost to follow-up and had missing secondary outcomes (90-day mortality, GOS, and TOMS). The proportion of loss to follow-up

XSL•FO
RenderX

was lower in the intervention (9%, 44/116; *P*=.001) vs in the control group (14%, 72/116*; P*=.001), but the baseline sociodemographic and clinical characteristics of those lost to follow-up did not differ significantly between the 2 treatment groups (all *P*>.05; Table 4).

Given the statistically significant differential attrition in loss to follow-up between arms, we simulated the base, worst-, and best-case scenarios. We found that overall, missing data did not impact the interpretation of results of both primary and secondary outcomes under the different scenarios except for mortality (14%, 68/483 in the intervention vs 12%, 58/470 in the control group; *P*=.34) and morbidity based on unfavorable GOS (1-3) for neurological injuries (14%, 68/483 in the intervention vs 19%, 87/470 in the control group; *P*=.06), which did not reach statistical significance in the worst-case scenario (Multimedia Appendix 14). However, the results from multiple imputations were congruent with complete-case analysis, with all primary and secondary outcomes (mortality and GOS) reaching statistical significance (all *P*<.01; Table 5). Note that the estimates for random effects parameters were computed in mixed effects restricted maximum likelihood (REML) regression models using the Satterthwaite method of adjustment of degrees of freedom for small sample correction. Number of study arms=2 (intervention vs control); number of discrete time decay study periods=12; total number of clusters=6; number of clusters per treatment arm=3; sample size may vary due to variation in study outcomes. All analysis variables were included in the model regardless of completeness. The summary presented is a pooled analysis of 20 imputations. Imputed is the minimum across "*m*" of the number of filled-in observations. Imputation method: Multiple imputation by chained equation (MICE). Number of imputations (*m*)=20. Assumption: Missing at random or completely missing at random. . The corresponding imputed variables with loss to follow-up (missing data) are provided in Multimedia Appendix 15, whereas the residual estimates after multiple imputation are provided in Multimedia Appendix 16.

[a]ICC: intracluster correlation coefficient.

Posthoc Power Analyses

The posthoc analyses indicated that, except for secondary outcomes related to the TOMS for musculoskeletal injuries, the sample sizes used in the study were sufficient for detecting effect sizes associated with the various study outcomes at a power level of 80%, based on both predetermined and observed ICC and study assumptions (Multimedia Appendix 17). We did not apply corrections for multiple testing, as the study used marginal rather than disjunctive power. However, with our 5 key study outcomes at a significance level of $P<.05$, the differences in primary outcomes (prehospital time and referral-dispatch interval) would remain statistically significant at $P<.01$ if the Bonferroni method (ie, 0.05/5) were used. Furthermore, in our exploratory analyses of secondary outcomes with distinct constructs (ie, mortality, GOS, and TOMS), the risk of missing a potentially significant finding was deemed a greater concern than the occurrence of false positives.

Discussion

Principal Findings

To our knowledge, this study represents a pioneering cluster-randomized trial assessing the impact of a medical education program (RTTDC) on clinical processes and patient outcomes in an LMIC setting. This trial found that RTTDC training significantly reduced prehospital time, highlighting its potential for improved budget allocation for prehospital logistical systems aimed at enhancing care for neurological and orthopedic injuries in these settings. Prior research, primarily observational or quasi-experimental, has indicated similar reductions in referral decision times and transfer intervals; for instance, a 1.91-hour decrease was reported in Western Virginia hospitals compared to control groups [36]. Further findings from this trial indicated a reduction in the interval from referral decision to hospital dispatch for patients who required interfacility transfer ($P<·001$). These results align with a recent study involving 472 trauma patients in the United States, which documented a similar decrease in emergency department dwell time [7]. However, these studies often faced limitations due to small sample sizes and potential biases. Poor interhospital coordination, dysfunctional referral systems, and transportation were the most important contributing factors to delayed emergency surgical access in rural settings, alongside human, financial, and infrastructural resource challenges, as this trial demonstrated that most trauma patients arrived by public means, which may apply to other LMICs.

The trial's overall 90-day mortality rate was comparable to prior Ugandan studies but higher than rates reported in the US and European cohorts [37,38]. Notably, the intervention group exhibited significantly lower mortality rates than the control

XSL•FO
RenderX

group in both complete-case analysis and best-case scenarios, suggesting that RTTDC implementation and the coordination of rural trauma teams may effectively minimize mortality associated with prolonged referral decision times. In this trial, referral decision to dispatch time of more than 1 hour was associated with a fourfold increase in mortality after controlling for confounding due to injury mechanisms and severity. This finding is particularly relevant given that delays in care have been shown to exacerbate injury-related mortality in both LMICs and high-income countries [37]. Consistent outcomes were observed in previous studies, including a notable 50% reduction in mortality rates associated with RTTDC training in the United States [23]. Despite these potential positive results, variations in mortality outcome rates across studies exist and may stem from different methodological approaches, sample sizes, and settings [7]. In this study, the mortality rate and operative neurosurgical interventions were relatively high, partly due to the restriction of the study to motorcyclists in rural settings where helmet usage and speed limits are poorly regulated, resulting in severe TBI. In the case of 8 deaths in emergency departments of control centers, it was determined that patients were awaiting head CT scans at the request of trainee general surgery residents to decide on transfers for neurosurgical evaluation. However, no local neurosurgeons were available to address potential surgical needs based on the CT results. This highlights the lesson from RTTDC that investigations should not be requested without the requisite human resources to act on the findings.

In our settings, the impact of RTTDC was driven by the actualization of physical trauma teams through pairing junior and senior medical trainees, effective communication and coordination at the community level, facilitated by trained volunteer traffic police, and guided by interns and surgery residents in emergency departments. This collaboration ensured proper selection of destination hospitals, prearrival preparations, and swift interfacility transfers for injuries exceeding local capacity. Key strengths of RTTDC included emphasizing teamwork, closed-loop communication within trauma teams, and optimizing local resources based on facility capabilities. These are elements that other trauma education courses in LMICs should replicate. Recognizing that forgetting is a barrier to skill application, we reinforced knowledge transfer through weekly clinical audits and regular feedback to trauma teams, which helped maintain focus on course objectives. This decision-making support was critical, as previous research indicated that only 31% of district and regional referral hospitals in Uganda had emergency unit protocols [39].

Additionally, prior trauma education interventions, such as the Kampala Advanced Trauma Course, showed limited impact on facility-wide best practices when specialist surgeons and experienced medical officers were the main participants due to inadequate skill transfer to junior faculty [40]. Our experience in audit meetings revealed that local consultant surgeons, although willing to assist, were sometimes unreachable when surgical residents required their expertise in emergency situations. We found the “train the trainer” approach effective for fostering team cohesion by pairing third-year medical students with fifth-year students, interns, and residents during night duty calls. Therefore, a comprehensive understanding of the strengths and weaknesses of the health care system for which a trauma course or a medical education program is to be implemented is critical for its effectiveness. Our study underscores the importance of involving frontline workers, such as trainee surgeons, in trauma training initiatives. To address this gap, 3 local universities in Uganda have initiated postgraduate medical education programs in emergency medicine, although these roles are not yet integrated into the national civil service staffing structure by the government. Long-term local trauma fellowship programs can accelerate this goal and address issues of sustainability.

Knowledge reinforcement through support audit meetings also emphasized the necessity of routine community engagement with traffic police, as there was no structured approach to enhancing community awareness or providing emergency care at accident scenes in Uganda during the study. Ideal Level II and III trauma centers should implement trauma quality assessment and outreach programs for their communities. The meetings revealed practical insights into team dynamics and technological resource challenges, including network connectivity and difficulties in locating ambulances. These issues were addressed by coordinating with volunteer taxi drivers who facilitated rescue evacuations under the guidance of traffic police, general surgery trainees, or intern physicians. This strategy improved the selection of destination facilities and enabled concise handover reports from police, who are first responders in most emergencies, since only 25% of Uganda’s 48 million population had access to ambulances [13].

These lessons highlight the urgent need for investment in surgical education, emergency medical services (EMSs), telemedicine, and remote monitoring systems such as edge computing to address connectivity issues, including the establishment of toll-free emergency numbers that link police to hospitals and ambulances. Additionally, further medical training for lay responders and efforts to increase the number of paramedics are essential. Uganda’s national EMS policy, launched in 2021, aims to enhance emergency care capacity, but fixed staff occupancy in district hospital emergency departments remains below 50% [39,41]. Integrating artificial intelligence–enabled triage, referral decision support, and imaging prioritization into rural trauma workflows may overcome some of the human resource constraints to reduce delays in the trauma care continuum in low-resource settings. However, enhancing patient outcomes through artificial intelligence in these contexts necessitates robust ethical oversight, fair dataset representation from LMICs, and ongoing validation via prospective clinical trials [42].

Contemporaneous evidence indicates that community responders play a significant role in both current and future EMS, even in countries with established prehospital care systems, such as the United Kingdom, due to their timely responses and reduced maintenance costs [43]. The Ugandan EMS policy acknowledges the potential contributions of community responders [41]. However, to actualize these contributions, it necessitates a separate budget to reimburse costs associated with communication and transportation, support training that bridges lay responders to clinicians, and facilitate medical interns and

XSL•FO
RenderX

residents who work overtime to address staffing shortages in emergency departments (resource optimization). Moreover, it is essential to design legal protections for community responders through Good Samaritan laws, establish clear standard operating procedures with decision support algorithms for trainee physicians, develop referral protocols with automated workflow, and implement performance measurement frameworks for improvement. These measures would prevent fatalities during transport, including auditing incidents that occur before ambulance arrival [44]. Consequently, it is crucial for medical training institutions, public-private partnerships, ambulance and insurance companies, and civil society organizations to consider investing in this area.

In addition to mortality, the study explored morbidity outcomes, wherein the intervention group had a lower proportion of unfavorable GOS-TBI scores compared to controls, indicating improved recovery trajectories. However, the analysis of TOMS for musculoskeletal injuries was inconclusive, possibly due to the study being underpowered for this particular outcome, a higher proportion of polytrauma cases, and higher initial trauma outcome expectations among intervention participants. Existing literature corroborates the increased morbidity associated with polytrauma, emphasizing the need for future research into the long-term outcomes of RTTDC interventions in the context of multiple injuries [45]. On the other hand, the nonsignificant results for musculoskeletal injuries may stem from the inherent focus of the RTTDC on life-saving resuscitation measures and the immediate transfer of critical cases such as neurotrauma, which require high care demands. Alternatively, it may be that the evaluation tools (TEFS and TOMS) are less sensitive to assessing outcomes related to musculoskeletal injuries within the trauma education context. To resolve this uncertainty, further investigation is warranted with a larger number of clusters and cluster sizes.

Policy Implications

The implications of our findings are threefold. First, while RTTDC training shows promise for enhancing clinical processes and patient outcomes in LMICs, local and regional evaluations of its impact are essential for effective implementation. Establishing regional continuing medical education certification centers and long-term postgraduate trauma training programs for trauma care providers could facilitate this goal and address concerns about sustainability. Second, the development of context-specific rural trauma transfer guidelines is critical, incorporating local norms and logistical realities. This may necessitate broader participation from various health care professionals, including medical trainees, private ambulance companies, and lay traffic police who provide immediate crash responses, to strengthen rural trauma systems. Finally, a tailored needs assessment for each LMIC is crucial to adapt trauma education programs, ensuring they address specific cultural, technological, and systemic challenges while promoting sustainability. Existing trauma education programs in LMICs lacked robust impact evaluation, cohesive local contextualization, and common outcome metrics for reporting [3]. This trial provided critical clinical processes and patient-reported indices that could constitute a core outcome set for interventions linking medical education to patient outcomes in a trauma context.

Study Strengths and Limitations

This trial offers significant strengths in evaluating a locally contextualized trauma education program and linking it to clinical outcomes in resource-limited rural settings. It effectively demonstrates that training trauma care frontline workers, such as voluntary traffic police officers and medical trainees, can enhance clinical practices and patient outcomes. We previously highlighted the impact of RTTDC on care providers' knowledge and behavioral change [14]. This trial builds on that foundation by showing the translation of acquired classroom knowledge into improved clinical processes. Early engagement with frontline workers ensured that the trial was relevant, and the findings may inform future core outcome sets for similar trials in LMICs, where this study forms an integral component of pioneering efforts to evaluate the real-world impact of an education program (RTTDC) in controlled clinical settings. Studies of this nature are topical for the global surgery community. This study provides an ideal example of how equitable South-West partnerships in global surgery should be implemented. A detailed statement regarding how partnerships and collaborations were actualized is available in Multimedia Appendix 18. There are no previous large-scale cluster randomized controlled trials that have evaluated the effect of trauma education programs on patient workflows and clinical outcomes, but a recent feasibility trial evaluating ATLS course and PTC against standard care in India found justification for full-scale cluster randomized trials [46], thus our publicly available data in the Multimedia Appendix 19 is timely [47].

However, this study has 6 notable limitations. First, a higher loss to follow-up in the control group may introduce potential systematic attrition bias, which must be addressed in future studies by assuming the worst-case situation during sample size computation. Although the overall dropout rate (11.6%) remains within acceptable limits, the conclusions regarding mortality and morbidity must be cautiously interpreted in this context. The differential attrition could suggest that missingness was likely related to the effectiveness of the intervention, with plausibility that participants in the control group without perceived improvement due to unfavorable trauma outcomes or other unmeasured postrandomization experiences were more likely to be lost to follow-up. Furthermore, the ICC was estimated based solely on primary outcomes, which may not accurately reflect variations in cluster sizes for secondary outcomes, as observed with TOMSs for musculoskeletal injuries. This is a common issue in cluster-randomized trial design.

Second, some patients at intervention sites may not have received care from trained providers, limiting the intervention's individual-level impact. Due to significant shortages of health care personnel in Uganda, we set the trained staff capacity in emergency units at 80%, as complete participation in training was not feasible at any given time. This strategy addressed human resource constraints while minimizing ceiling effects associated with training and fostering information sharing among trauma team members in our train-the-trainer model. Given our trauma "team approach" to injury care, which deployed a

XSL•FO
RenderX

5-member in-hospital team for each patient, it was not feasible to provide cluster-level proportions of trained providers and their association with outcomes. However, 80% coverage may result in occasional individual-level exposure misclassification, with a 1:4 likelihood that a patient may encounter 1 untrained vs 4 trained providers during the continuum of care within a typical 5-member trauma team at the same intervention hospital. Consequently, any potential biases in estimates are likely to trend away from the null.

Third, the generalizability of findings is constrained to those who underwent head CT scans in a single country's health care system, excluding emerging prognostic factors for neurological injuries such as blood-based biomarkers.

Fourth, although exploratory analyses indicated no significant changes in prehospital time due to the COVID-19 pandemic, its broader social effects on hospital surroundings, resuscitative capability, injury patterns, and patient-reported morbidity outcomes remained challenging to quantify. Moreover, COVID-19's extenuating effects on the trial, including study halt, retrospective registration, and need for posthoc data stratification by pandemic status, which was not hypothesized beforehand, could introduce bias. However, we are unaware of any other events that could have influenced referral decisions and morbidity outcomes.

Fifth, the absence of preintervention data at the study sites represents a limitation. Ideally, if data had been available before training, a comparison of injury outcomes before and after the training would have been preferable to the current approach of making parallel comparisons. Moreover, the data constraints on prehospital deaths may systemically bias estimates of prehospital time and mortality outcomes, introducing survivor bias. For instance, we could not establish if the intervention reduced prehospital deaths, an issue the Ugandan government can address by mandating all unnatural prehospital deaths to undergo postmortem and forensic analysis to determine the cause of death. Although there were 8 mortalities in the emergency department of control hospitals vs zero in the intervention group, and the principal determinant of time-to-event (death), that is, requiring a craniotomy, did not differ between groups, which would trend any biased estimates away from the null; the authors recommend that the study conclusions should only be applied to patients surviving up to hospital arrival.

Finally, despite sensitivity analyses, we are aware that the relatively smaller number of clusters and cluster sizes, and aggregating intracranial lesions as axial or extra-axial or dichotomizing the GOS and TOMS tools as favorable vs unfavorable outcomes, could have led to loss of information and left unmeasured residual confounding that can potentially contribute to some of the observed associations. Moreover, we were also unable to account for the heterogeneity across the considerably wide range of our participants' age groups, despite trauma not being segregative, an issue future studies should address.

Conclusions

This trial provided reasonable evidence to suggest that rural trauma team development training potentially decreased prehospital time and referral decision intervals, lowering motorcycle accident–related mortality from neurological and musculoskeletal injuries, without negatively impacting patient-reported morbidity. Despite potential measurement biases from the exclusion of prehospital deaths due to data constraints and the relatively smaller number of clusters, these findings highlight the importance of enhancing rural trauma team capabilities and supporting ongoing investment in global trauma education programs. Future research should focus on large, multicountry studies using long-term trauma registries with diverse injury mechanisms and patient-centered quality-of-life outcome measures tailored to local contexts in LMICs.

Acknowledgments

We are grateful to Asiimwe Daniel, Namutosi Esther, Kabarokole Annet, Mwine David, Ssekabembe John, Japheth Comfort, Nalumansi Hilda, and Rwamukaga Nasurudin for their invaluable assistance in the data collection process and for consenting to the publication of their names. Additionally, we thank Mary Nnabagulanyi for her support in the off-site administration and coordination of this trial and appreciate our research participants for their commitment and time dedicated to the study. The authors declare the use of generative artificial intelligence (AI) in the research writing process. Under full human supervision, Microsoft CoPilot and Poe Assistant were used during proofreading, editing, and refinement of grammatical errors. Responsibility for the final paper lies entirely with the authors. Inequalities in access to injury care and trauma training in rural low- and middle-income countries (LMICs) stem from a lack of specialized workforce, trauma resources, and technological advancement. To address this, the principal investigator (PI), a specialist surgeon and perioperative fellow at the Centre for Health Equity in Surgery and Anesthesia at the University of California, San Francisco, was stationed at local trauma centers in Uganda during recruitment. The PI built capacity through the Rural Trauma Team Development Course (RTTDC) training for surgical residents, who then trained interns. This work is part of a broader doctoral project at the University of Turku in Finland, which examines the potential role of allied health and law enforcement trauma teams and registries as underused resources for trauma care. This project underscores the importance of high-fidelity interdisciplinary collaborations in educational and trauma research, as well as the value of community presence in areas designated for global surgery interventions.

Funding

HL was supported by the University of Turku Graduate School, Turku University Hospital (TYKS) Foundation, TYKS Neurocenter, and the University of California, San Francisco (UCSF)–Center for Health Equity in Surgery and Anesthesia (CHESA) through participation in fellowships. JPP was supported by the Academy of Finland (grant nos 17379 and 60063) and the Maire Taponen Foundation. The funders has no role in the study design, implementation, or reporting. All authors had full access to the data and accept responsibility to submit for publication.

Data Availability

The datasets generated or analyzed during this study are available in the MendeleyMendeley repository [47], and are included in this published article. Further details are available in the study protocol and trial registry sections.

Authors' Contributions

HL contributed to conceptualization, data curation, investigation, methodology, project administration, resources, formal analysis, software, visualization, writing (original draft), writing (review and editing), and funding acquisition. BO, AK, HML, RS, and PK contributed to data curation, investigation, validation, and writing (review and editing). MM, AA, and AD contributed to formal analysis, software, visualization, validation, and writing (review and editing). FJW contributed to investigation, validation, and writing (review and editing). TB contributed to investigation, validation, writing (review and editing), and funding acquisition. JPP and MLW contributed to investigation, funding acquisition, supervision, validation, and writing (review and editing).

Conflicts of Interest

The authors declare that no competing interests exist. Early results of this work were shared with stakeholders at the Safety 2024 World Conference on Injury Prevention and Safety Promotion in New Delhi. The views expressed in this report are solely the authors' responsibility and do not represent the official views of their affiliated institutions.

Editorial Notice

The trial used data from the piloted Motorcycle Trauma Outcome Registry (MOTOR) project. At the time of protocol submission, the ethics committee did not mandate prior registration for academic, non–industry-funded proof-of-concept projects (policy effective December 31, 2023). Following changes in local policy, the investigators pursued registration with the Pan African Clinical Trial Registry. Due to COVID-19–related disruptions, registration was completed after recruitment had commenced.

Abstract

Background: Patient autonomy through informed consent is a foundational ethical principle for health care practitioners. Online consent processes risk producing "consent in name only," using manipulative or confusing user interfaces to extract consent artificially. This presents a significant danger for safe and ethical remote consultations for primary care providers, which often extract significant amounts of sensitive personal data.

Objective: This study aims to examine the quality of consent obtained through both currently used and novel consent acquisition interfaces for remote e-consultations between a patient and a primary care provider.

Methods: A total of 55 adult participants in the United Kingdom completed an interaction with a mock-up e-consultation system's consent interface for data processing, with 54 completing the full study protocol. The participants were then asked questions regarding what they had provided consent for and the usability of the interface. These responses led to the calculation of an industry-standard System Usability Scale (SUS) score and a novel Quality of Informed Consent Collected Digitally (QuICCDig) score.

Results: Users perceiving interfaces to be more usable (with a greater SUS score) were statistically significantly (n=54; *P*=.004) correlated with an increase in the quality of consent collected from those users (with a higher QuICCDig score). Nonetheless, both existing and novel user interfaces for collecting e-consultation consent were rated poorly, achieving a maximum SUS letter grade of "F." In total, 45% (25/55) of all the participants reported not recalling making a privacy-related decision at all during their consultation, and 87% (48/55) did not recall being offered any alternatives to e-consultation.

Conclusions: The findings demonstrate that current methods for collecting consent in telemedical applications may not be fit for purpose and potentially fail to collect valid informed consent. However, increased usability scores from users do appear to drive improvements in the quality of consent collected. Therefore, decision-makers should place importance on high-quality interface design when building or procuring these systems. We have also provided the QuICCDig score for further use.

Introduction

Remote electronic systems for consultations between patients and their primary care providers have been growing rapidly in use since they were first conceptualized—growth that was accelerated by the pressures of the COVID-19 pandemic on the health care system [1]. These systems allow patients to obtain medical advice without having to physically travel to a clinic or speak to a primary care provider over the phone by answering questions and uploading images to an online system for a health care professional to review, thereby expanding access to health care. They allow for rapid symptom triage, which may increase primary care operational efficiency [2]; among some patient populations, they may also lead to increased honesty with health care providers when consulting about symptoms perceived to be embarrassing [3].

Adoption of these systems has varied across international primary care environments. Around the world, asynchronous primary care "e-consultations" conducted via online platforms are known to be used in Norway, Spain, Sweden, the United Kingdom, and the United States [4,5]. In the United Kingdom, access to online consultations from patients to their general practitioner (GP) has been compulsory for GP practices since the April 2021 financial year's contract [6], as part of the National Health Service (NHS) Long Term Plan from 2019 [7]. However, partly owing to unforeseen pressures of the COVID-19 pandemic to implement the technology in a crisis-driven fashion, the success of the rollout has been variable, with some practices seeing substantial efficiency improvements, while others have since reverted to a "strategically traditional" model for meeting the needs of their patient population [8].

Ethical challenges relating to informed consent in telemedicine are nothing new—home monitoring systems have faced them for some time [9]. However, despite the increased uptake of e-consultations [10], issues of safety and consent have not been well evaluated in existing literature [4]. This lack of focus on safety, combined with technocentric policymaking, risks leading clinicians and technologists alike to be overeager to implement new technologies without adequate consideration of the implications for patients' bioethical and legal rights [11]. Regulators and lawmakers internationally have been slow to respond to advances in telemedicine, muddying the waters further [4]—even as disparities in patient understanding of digital health information across age groups and health numeracy have been demonstrated [12].

In the development of websites more broadly, impetus for collecting consent from users for data processing largely comes from regulatory requirements rather than ethical frameworks. Standards for ethical practice for software engineers have been described as "toothless" and criticized for "ethics-washing" without actually changing corporate incentives [13]. Perhaps unsurprisingly, many examples exist of users' data being collected on a "legal minimum" basis or even without proper consent at all [6,7]. Bollinger et al [14] found that, of approximately 30,000 websites studied, 94.7% contained potential European Union General Data Protection Regulation violations related to cookie consent, although that figure is based on automated detection without human verification. In some cases, interfaces are deliberately designed so that users do not remember their choices, even when they regret them upon being reminded of them [9]; however, this has become such standard practice that users simply consider it part and parcel of their internet experience [15].

This resigned acceptance of poor ethical standards in the context of the internet presents a challenge for facilitating ethical telemedical interactions, as the ethical and legal standards for consent in medical contexts are substantially more stringent. Notably, for example, guidance in the United Kingdom consistently highlights the need for clinicians to obtain informed consent from patients for examination and assessment and not just subsequent treatment [16-19]; indeed, government guidance makes it clear that even implied consent for measuring blood pressure by a patient holding out an arm may require the patient "receiving appropriate information" first [20]. The courts have confirmed this; in *R v Hallstrom*, Mr Justice McCullough writes "it goes without saying that, unless clear statutory authority to the contrary exists, no one is […] even to submit himself to a medical examination without his consent" [21]. Failure to collect consent appropriately may be considered a reportable adverse event [22].

There are no currently accepted systems that evaluate clinical informed consent collected through entirely digital systems with no human-in-the-loop involvement. Usability, defined by International Organization for Standardization 9241-11:2018 as the "extent to which a system, product or service can be used by specified users to achieve specified goals with effectiveness, efficiency and satisfaction in a specified context of use" [23], is measured using well-established metrics such as the Post-Study System Usability Questionnaire or the System Usability Scale (SUS) [24,25]. However, these metrics, when used alone, could, for instance, result in high scores for interfaces that are extremely user-friendly but fail to convey important information, as patients' feelings of being informed in the context of clinical consent may not actually relate to objective measures of knowledge [26]. Therefore, a clear gap exists for a metric to assess the quality of digitally collected informed consent.

This work analyzed the quality of consent that can be collected through remote patient–primary care provider e-consultations. To do this, we (1) developed a scoring system by which consent gathered for electronic patient–primary care provider medical consultations can reliably be evaluated, (2) established an understanding of the validity of current strategies for consent acquisition in remote patient–primary care provider e-consultation via the internet, and (3) evaluated whether changes in user interface design could impact the quality of consent collected.

Methods

Overview

This research developed a novel questionnaire and scoring system, Quality of Informed Consent Collected Digitally (QuICCDig), for evaluating the quality of health care informed

XSL•FO
RenderX

consent collected digitally, based on a synthesis of existing systems from health and technology consent research. A selection of real online consultation systems was then evaluated, using both QuICCDig to evaluate the quality of the consent collected and the industry-standard SUS to evaluate the perceived usability of the interface.

QuICCDig Development

In this study, we synthesized QuICCDig from an analysis of multiple existing criteria for consent evaluation across both health care and digital technology. A narrative literature review was conducted, investigating current methods used for evaluating the quality of consent collection in medical consultations and digital interactions. PubMed, Google Scholar, and HeinOnline were searched for terms including "quality of informed consent," "digital consent evaluation," "medical consent evaluation," "digital consent quality," and "medical consent quality" without restricting to a particular date range, location of publication, or format of publication.

Search results were then assessed for relevance. In particular, results with no full text available to the researchers were excluded as were results whose full text did not contain evaluation methodologies for consent quality or whose methodology was based on parameters such as refusal rate rather than the quality of the consent process itself. Methodologies that were specific to the consent process for a particular subspeciality were excluded, but methodologies used for the evaluation of consent for clinical research were included, as it was hypothesized these might relate to more relevant data-sharing exercises. Where results were already referenced in a broader piece of work, such as a systematic review, the original work was excluded in favor of the broader work to simplify identification of themes.

Interface Evaluation Study Design

To understand how well existing digital consultation systems manage the challenge of acquiring informed consent, we (1) reviewed existing consultation systems approved for use in the United Kingdom to evaluate what consent interfaces they use, (2) created a series of interactive mock-up interfaces (defined as midfidelity interactive prototype user experiences that allow users to complete a specific interaction as relevant for the study) for consent collection in the context of a digital consultation, and (3) provided participants with the interface and subsequently administered the SUS and QuICCDig questionnaires to evaluate the usability of the interface and the quality of the consent collected through it.

All 9 online consultation systems approved for use in the United Kingdom NHS Digital Buying Catalogue [27] as of January 2023 that supported "self-help and signposting" or "symptom checking" were reviewed, of which 7 were noted to be suitable for primary care patient-provider remote consultation use. Only 2 contemporary practices for consent were identified in these 7 systems: either "link and checkbox," in which users are shown a checkbox to confirm their acceptance of privacy information or "summary and checkbox," in which users are shown a checkbox to confirm their acceptance along with a brief explanation of what they are providing consent for and a link to read more. The design of these interfaces reflects different modalities of user interaction as well as different amounts of content presented initially to the user; these differences may reflect attempts to promote user recognition of familiar interaction paths within known user interface paradigms while also allowing appropriate use of users' background knowledge, mapping to the Nielsen design heuristics of "recognition rather than recall" and "match between system and real world" [28].

On the basis of these real consultation systems, 9 mock-up user interfaces were designed, with 2 based on contemporary "link and checkbox" or "summary and checkbox" consent practices and the remainder being novel interfaces not seen to be used in existing approved software (Table 1; for screenshots, refer to Multimedia Appendix 1). Checkbox, drag-and-drop, and swipe interfaces were investigated, as previous research has shown that the quality of consent collected and the perceived usability of the interface may vary across these interface types [29,30].

Participants' demographic data were collected, and they were then presented with a brief to complete a simulated consultation related to a low-acuity mental health presentation. This presentation was chosen because it may result in greater concerns about privacy and confidentiality than a physical health presentation [31,32]. Participants were randomized by computer to interact with 1 of the 9 interfaces, and metadata regarding interactions, such as click heat maps and interaction times, were recorded by the system. The only differences between the interfaces were their consent collection techniques—the other elements were identical. Each participant was only shown the single interface to which they were randomly allocated.

After completing the interaction, participants were presented with a survey evaluating their impressions. First, participants were asked to complete the standard "SUS" questions [24]; they were then presented with the QuICCDig questionnaire described earlier.

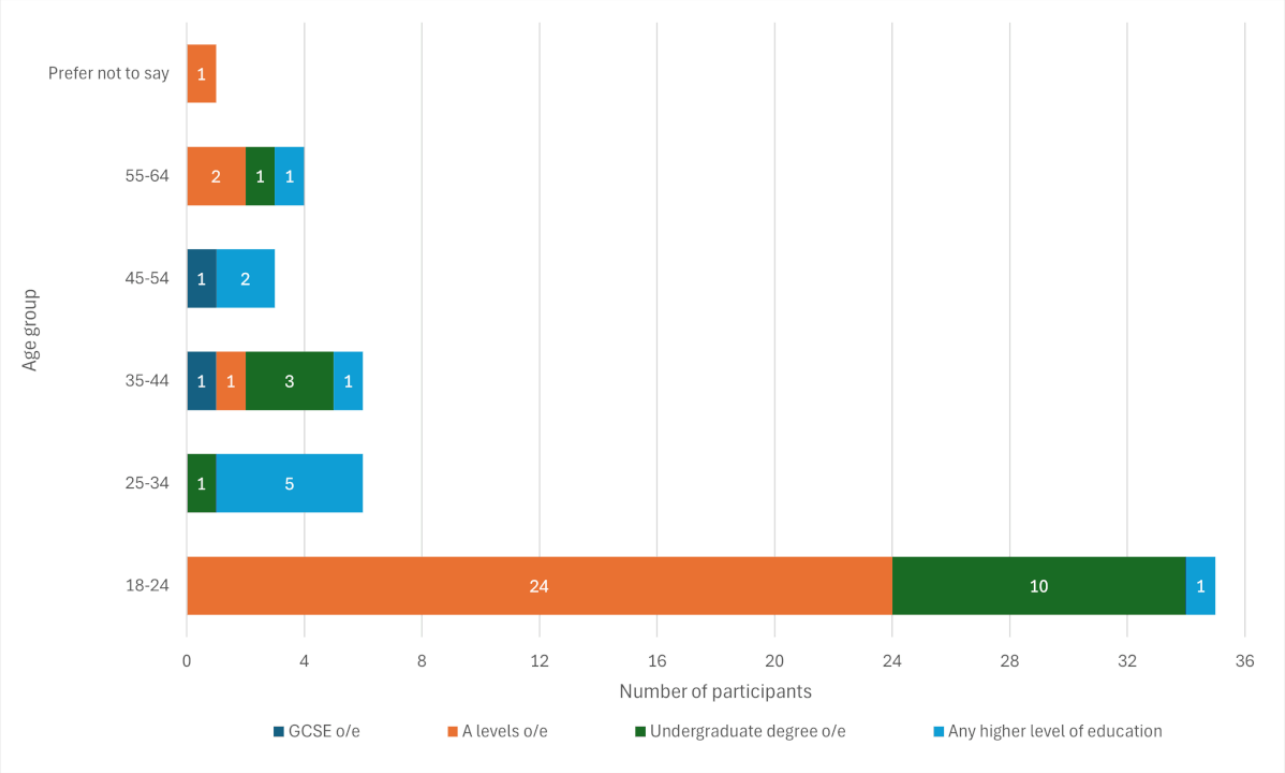
Ethical Considerations



This research was approved by the University of Southampton Faculty of Engineering and Physical Sciences Ethics Committee (FEPS/ERGO/78443). Participants were presented with signposting information for support if the study caused any discomfort or distress and informed of the voluntary, anonymous nature of the study. Informed consent was gained from all participants before their participation, and participants were reminded of their ability to opt-out at any time. Participants were not compensated for their participation. No personal data were used in the analysis.

Recruitment and Statistical Power

Participants aged 18 years or older who had previously interacted with a GP were recruited via snowball sampling from an initial set of posts on social media as well as from advertisements placed on a university campus. A target of 113 participants was set based on a planned linear multiple regression analysis (with an anticipated f^2 value of 0.15, an α value of .05, and a power of 0.8). In actuality, 93 participants were recruited; 66 (71%) completed their interactions enough to answer at least the SUS questions, and 55 (59%) completed the survey well enough to calculate a QuICCDig score. Of these 55 participants, 45% (25/55) had formal computer science-related education, 27% (15/55) had formal medical education, and 76% (42/55) had been prior users of e-consultation technology.

In total, 1 (1%) participant who completed the QuICCDig questionnaire could not have their SUS score calculated due to a technical issue, leaving 54 (58%) of the recruited participants with valid scores for both SUS and QuICCDig. Demographic breakdowns of participants are included in Figure 1.

Figure 1. Demographic breakdowns of participants. GCSE: General Certificate of Secondary Education; o/e: or equivalent.

Results

QuICCDig Synthesis

A total of 11 key papers were identified, and their content was then reviewed for themes. After excluding themes that were either impossible to measure reliably without a human in the loop and were thus impractical to include in an online primary care patient-provider e-consultation system, such as the use of repeat-back testing [33,34], or items that could automatically be collected in a digital system without having to ask a patient (and therefore did not need to be explicitly asked), such as time to complete a consent process or parts of a website that were consulted, 14 key themes were identified as being used in current evaluation criteria. From these themes, corresponding questions were synthesized for inclusion in the QuICCDig metric. The themes included and the questions produced are presented in Table 2, while themes identified but excluded are detailed in Table 3. The scoring metric for these questions is detailed in Multimedia Appendix 2.

XSL•FO
RenderX

Table 2. Quality of Informed Consent Collected Digitally (QuICCDig) themes and questions produced.

Theme	Study	Question
Ability to complete the task	[29,35]	• "Were you able to successfully complete your e-consultation?"
Perceived ease of use	[14,15]	• "How easy did you find it to complete your e-consultation?"

Perceived quality of description and explanation of processes and how they work	[34-37]	• To be asked before the main body of the study, alongside the demographic questions
		  • "What do you think happens during an e-consultation, and where does the information go?"
		• Asked with the rest of the QuICCDig questions after the main body
		  • "Did you get an explanation of what an e-consultation involves?"
		  • "How well do you feel you understand e-consultations now?"
		  • "Did your understanding change from what you thought happened in an e-consultation before? If so, what changed?"

Objective understanding of processes and how they work	[35,38]	• "How long will your consultation data be stored?" • "Which of the below might have access to some data collected during the consultation? [Select multiple: Me, my healthcare provider, other healthcare providers, the company that runs the consultation software, Google, Facebook]."
Why it is being done and the benefits to the patient	[35-38]	• For each group identified in the question about who will have access to consultation data • "Why will NAME have access to your data?"
Risks to the patient inherent to the procedure	[34,36-38]	• "Which of the below are risks involved in the e-consultation process?"
Alternatives	[34,36-38]	• "Do you remember being told about the alternatives to using an e-consultation?" If yes, "What alternatives were there?"
Recollections of consent	[34,35]	• "Do you remember making any privacy-related decisions during your e-consultation?" If yes, "What do you remember deciding?"
Effect on privacy and confidentiality	[37]	• "What impact will this e-consultation have on the confidentiality of your medical records?"
Degree of satisfaction with the decision-making and consent process	[34,37,39]	• "How satisfied with the decision-making process for whether you wanted to continue with an e-consultation were you?"
Whether the patient knew who to ask questions to	[34,37]	• "If you had questions about how your e-consultation would work, or how your data would be used, who would you ask?"
How to revoke consent	[35]	• "If you wanted to change your mind about your e-consultation data being used, what would you do?"
Patient's feeling of involvement with the process	[34,35,39]	• "To what extent did you feel informed and involved with the process of consenting for your e-consultation? [Select one: Not at all, Somewhat, Enough, More than enough, Too much]"
Anything the patient felt was missing	[35]	• "Was there anything else you would have liked to have known that you weren't told about?"

XSL•FO
RenderX

Table 3. Themes identified in the literature but not included in the Quality of Informed Consent Collected Digitally (QuICCDig) scoring system.

Theme	Study	Justification for lack of inclusion
Whether the patient was asked for consent	[34]	In the context of an interaction that is guaranteed to present a prominent consent screen, asking users whether they were prompted for consent would not be expected to yield useful data compared to an in-person medical interaction, where it could be forgotten or made nonobvious.
Timing of information being given	[34,36]	Specific times at which consent information is presented can be automatically collected from an online system but are also less likely to be relevant in the context of an asynchronous patient–primary care provider interaction.
Who gave the information to the patient	[34]	Consent information in online systems, such as primary care patient-provider e-consultation systems, is consistently provided through an automated online interface.
Whether the patient was asked to repeat the explanation	[34]	Assessing repeated explanations for coherence and relevance would be essentially impossible to achieve without the involvement of a clinician, which is not practical for the purposes of a patient-provider e-consultation in primary care.
Questions relating to research consent	[37]	The scope of the QuICCDig score is limited to clinical consent for consultation and assessment.
Questions relating to ignoring consent dialogues and continuing use of the application in any event	[35]	In all the interfaces used and identified, it is not possible for the user to proceed with the consultation without interacting with the consent interface.
Questions relating to specific fine-grained control of (eg, cookies)	[35]	Control of specific aspects of the technical function of the system is outside the scope of the QuICCDig score; rather, the overall consent process is evaluated.
Questions about which parts of the website were consulted	[35]	In this study and in most similar interfaces identified in real-world use in the National Health Service Digital Buying Catalogue, interfaces are presented as single-page applications rather than multipage websites with multiple interaction paths.
Time to complete the consent and consultation process	[29]	This can be captured automatically by online systems.

Interface Evaluation Study

Among participants for whom both a QuICCDig and a SUS score could be calculated, a statistically significant moderate positive correlation was identified (n=54; ρ_{52}=0.388; *P*=.004; 95% CI 0.120-0.604) between a user's calculated SUS score and QuICCDig score (Figure 2). There was no statistically significant difference in the number of study completions between mock-up interfaces (n=93; $F_{8,84}$=1.122; *P*=.36), amount of information presented (n=93; $F_{2,90}$=1.719; *P*=.19), or consent interface type used (n=93; $F_{2,90}$=0.271; *P*=.76). The calculated QuICCDig scores ranged from –0.775 to 0.775 with a mean of 0.371 (SD 0.305); the SUS scores ranged from 13 to 40 with a mean of 32.11 (SD 6.864).

While there were substantial numerical differences in the mean scores between interfaces, as shown in Figure 3, an ANOVA across the different mock-up interfaces for average QuICCDig score (N=55; $F_{8,46}$=0.946; *P*=.49) and average SUS score (n=54, $F_{8,45}$=1.629; *P*=.14) found that these differences were not statistically significant, although the averages did indicate some superiority of the first 2 information levels compared to all information being contained on the same page (Tables 4 and 5). Likewise, no significant difference was found in either SUS or QuICCDig scores based on previous e-consultation use (SUS: n=54; Mann-Whitney *U*=228.0; *P*=.44; QuICCDig: N=55; Mann-Whitney *U*=248.0; *P*=.62). Time elapsed interacting with the interfaces is shown in Table 6 but was not statistically significantly different between experiments (N=55; $F_{8,46}$=0.895; *P*=.53).

Across the board, only 13% (7/55) of the participants recalled being offered alternatives to e-consultation, something presented only in the policy text itself. No correlation was observed between the number of participants who recalled being offered alternatives and the mock-up interface shown. Of the 7 participants who did remember alternatives and stated which ones they remembered, 6 correctly recalled at least 1 alternative option presented by the privacy notice, although only 1 recalled both alternatives (NHS 111 or speaking to the GP by another means), and 1 also produced an alternative which was not included in the notice (NHS 999).

A total of 55% (30/55) of the participants recalled making a privacy-related decision during their e-consultation. Of the 26 participants who responded when asked what they recalled deciding, 12 (46%) referenced the idea of their data being processed; 9 (35%) wrote that they had to agree to privacy information, while 6 (23%) recalled deciding not to read the privacy information. Only 5 (19%) participants gave a specific decision they had to make, for example, "agree [sic] to google analytics," or "if I should use e-consultation at all […] as I was worried about data breaches."

When asked about the impact that the use of e-consultation would have on the confidentiality of their medical records, of the 37 respondents who wrote a response, 3 (8%) gave a response identifying a specific change ("It'll be visible to my medical provider"; "Only the transport risk"; and "The information […] may be accessible to the software company and Google"); 15 (41%) stated they did not believe there to be any change. Some participants (n=8, 22%) also expressed feeling that their data would be generically "more" or "less" secure, while 11 (30%) stated they did not know.

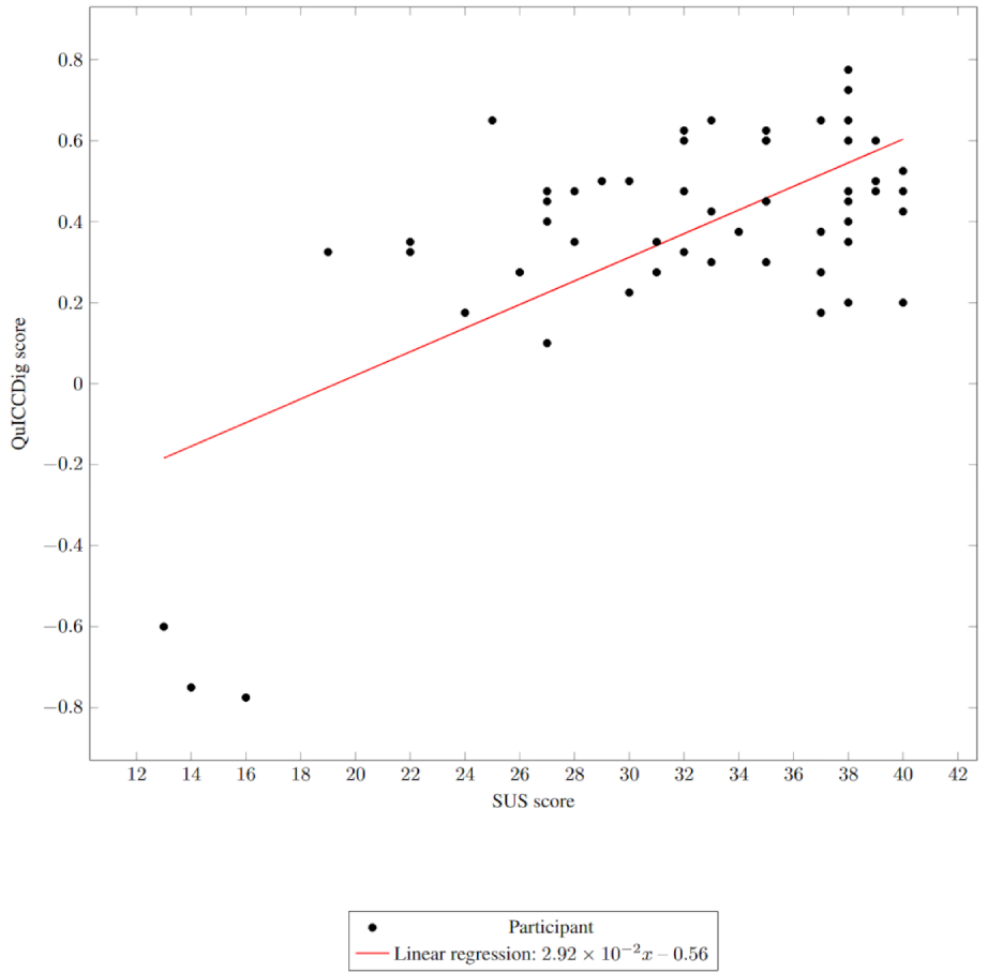

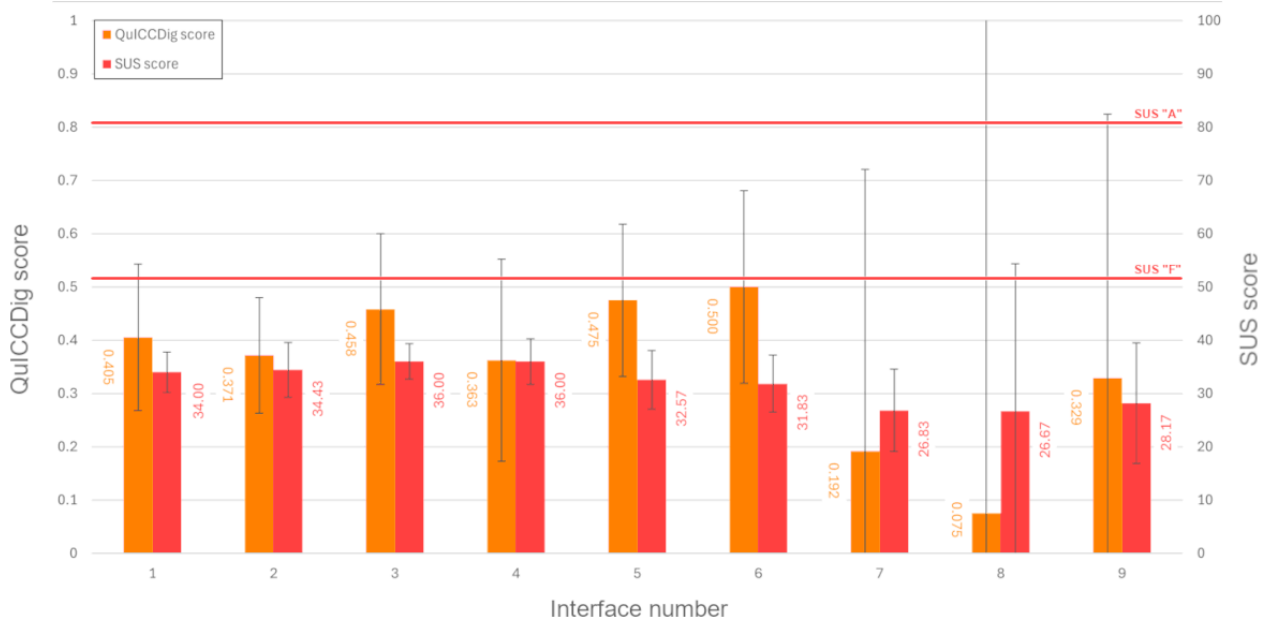

Figure 3. Mean Quality of Informed Consent Collected Digitally (QuICCDig) and System Usability Scale (SUS) scores by interface; 95% CIs for both are displayed in error bars. Grade boundaries for the SUS score are taken from the work of Sauro and Lewis [40].

Notably, 29% (2/7) of the participants from interface 2 (the drag and drop group was presented with a simple privacy policy link) wrote in free text that they would have liked to have what they described as a "simplified" or "short" version of the legal information before providing consent. No participants from any of the other groups made such a comment.

XSL•FO
RenderX

Most of the participants who responded when asked in free text whether their understanding of what an e-consultation was had changed after completing the consultation stated that their understanding did not change (13/23, 57%), while a plurality stated that they thought the mock-up interface was too simple for a full e-consultation (10/23, 43%).

Table 4. Mean System Usability Scale scores per experiment.

	Blanket with privacy policy, mean (SD)	Summary and details page, mean (SD)	All policy information contained on a single page, mean (SD)
Checkbox	Interface 1 34.00 (5.249)	Interface 4 *36.00 (1.732)*[a]	Interface 7 26.84 (7.360)
Drag and drop	Interface 2 34.43 (5.563)	Interface 5 32.57 (5.940)	Interface 8 26.67 (11.150)[b]
Swipe	Interface 3 *36.00 (3.162)*	Interface 6 31.84 (5.115)	Interface 9 28.17 (10.815)

Table 6. Median interaction duration for each mock-up interface.

Interface number	Interaction duration (s), median (IQR)
1	53.3 (35.9-72.4)
2	61.0 (52.7-64.4)
3	61.0 (59.2-62.8)
4	57.9 (32.0-77.2)
5	84.0 (56.1-89.7)
6	69.3 (40.8-79.8)
7	52.0 (39.2-71.1)
8	95.3 (67.7-103.9)
9	86.0 (53.2-97.2)

Discussion

Principal Results

The link found between the quality of consent and perceived interface usability is a significant novel result and strongly supports the importance of high-quality interface design when building remote-access consent collection systems, such as those used for e-consultations. Designers of these systems should consider using user testing with the SUS, QuICCDig, and/or similar scoring systems to evaluate the effectiveness of their designs for gathering informed consent from users. Likewise, organizations responsible for their implementation should consider high-quality user interface design to be a requirement of such systems to effectively gather consent from patients and not merely a “nice-to-have.”

Nonetheless, across all user interfaces tested, both SUS and QuICCDig scores were objectively low. The maximum average SUS score attained by any of the interfaces was 36 for interfaces 3 and 4 (SDs 3.162 and 1.732, respectively), which is between

XSL•FO
RenderX

the fourth and sixth percentile of raw SUS scores and would equate to a letter grade of F [40]. Likewise, the maximum theoretical QuICCDig score is 1, yet the highest attained score by any of the interfaces presented was 0.5. A total of 17% (9/54) of the participants who completed the full study admitted in free text, choosing not to read privacy information thoroughly or at all, even in the context of a study in which participants were informed beforehand of the aim to assess the informedness of consent, which may have had an impact on the SUS scores obtained. An interface required to complete a task that is a prerequisite but ancillary to the user's intended goal in the consultation may therefore always receive low scores. Equally, participants' broader attitudes to privacy and medical consent may have impacted perceived usability or desire to interact with the interface at all. The low number of participants conveying understanding of either positive or negative changes in the confidentiality of their medical records may have arisen for similar reasons. Alternative novel designs may warrant exploration, such as those incorporating voice-over or slideshow interfaces, to examine whether different modalities can deliver improvements.

Fewer than 1 in 7 participants remembered being offered alternatives to completing an e-consultation, even when every design included them in the presented information. This lack of awareness may be particularly concerning for patients less confident in completing their health interactions online, such as older patients, or for patients with what they perceive to be more serious conditions, who may feel less comfortable with online contact with their health care provider [41]. Further research should be conducted targeting these groups specifically. Real-world patients may be aware of existing alternatives anyway, such as out-of-hours services or calling their medical practice by telephone [42]. However, some patients feel pushed into e-consultation use by their primary care provider to avoid alternative methodologies such as face-to-face appointments, which may affect their trust in the service [43]. One study conducted in Norway in 2025 found that 9.5% of the patients who used a primary care e-consultation platform said that sending an e-consultation was not their first choice [42]; clear display of alternative options as part of the process of beginning a consultation may benefit these patients. Similarly, while some patients who are not English speakers may feel more confident completing an e-consultation than a telephone or face-to-face consultation [44], others may prefer to be seen in person [45]; challenges among this patient group with understanding how to contact primary care providers have been specifically highlighted in focus groups conducted by the NHS [46], underscoring the importance of this information being properly conveyed.

Both the drag-and-drop summary and swipe summary interfaces had higher average QuICCDig scores, but lower average SUS scores, than all other interfaces except for the ones containing the entire policy on the consent page. This could potentially indicate a priming effect: perhaps seeing a small amount of information begets interest in more, owing to an increased level of concern, akin to the bulletproof glass effect identified by Brough et al [47]. However, this study's low sample size makes drawing any strong inference from this difficult; future work could investigate this effect in greater detail, perhaps through a more qualitative analysis.

Comparison to Prior Work

Easier-to-use user interfaces appear to be associated with increased quality of consent in this study. This builds on the findings of Lindegren et al [29], demonstrating the effect of consent design patterns on usability and user attention. Habib et al [35] further found that different user interfaces could result in substantially different patterns in recall of consent information, although they did not test the usability of the interfaces they examined.

Research has previously highlighted issues surrounding a lack of reporting on the safety and quality of electronic health care consent collection. Ramos [48], writing in the context of an HIV clinic setting, pointed out that although guidelines clearly assess the accessibility of medicolegal consent information provided in paper form, no standard has existed for evaluating patients' consent following interactions with a digital consent collection user interface. This was once again raised as an important gap in a 2024 systematic review by Leighton et al [4], noting poor reporting on safety— underscoring the fact that in nearly a decade, there has been little progress in this field.

In research medicine, many studies have evaluated the use of technological consent acquisition user interfaces. By virtue of the fact that the end users of these systems are research volunteers, they are likely to have more time and inclination to read consent information than members of the general public accessing health care services, yet even in this group, few definitive findings relating to usability exist [49]. However, usability as measured by SUS scores in research participants appears to be far better than that found in this study [50]. It is possible that participants view providing consent as the primary task in a research consent collection platform, whereas they view it as an ancillary one in a patient–primary care provider consultation interaction, and that this difference is reflected in the reduced SUS scores in this study. This would mirror the findings of Utz et al [51] that some users provide consent for cookies to be placed by websites simply as the easiest path to completing the objective of their visit, obviously with concerning implications for the quality and validity of medical consent.

This study focuses on traditional user interfaces and has not addressed the potential of conversational user interfaces (CUIs) to impact consent. Previous research has shown that users may accept or even prefer information given in this form [52]. CUIs can evoke feelings of social presence [53], and while this has been shown to feel intrusive in the e-commerce context, personal connection to clinicians during consent conversations has been shown to reduce anxiety and improve clinical outcomes [54]. Some research suggests that "chatbot" interfaces that appear overtly as a bot may produce equal perceptions of expertise as those that present themselves as a physician [55]. However, unless a bank of preset responses is used, presenting privacy information this way risks eventual "inevitable" errors [56], potentiating invalid consent based on invalid information. Further research is required in this area to evaluate the safety

XSL•FO
RenderX

and efficacy of modern CUI systems in privacy-related decision-making interfaces.

Limitations

The interpretation of these results should be tempered by the nature and size of the sample and the snowball method of acquisition. While the positive findings are still significant, the negative results may have limited generalizability, owing to the underpowering of the study—the lower-than-targeted sample size may, for instance, have prevented the detection of actual differences in the SUS or QuICCDig scores between the interface types. The sample achieved is also heavily biased toward young, well-educated participants, including those with health care– or computer science–related education. Well-educated participants appear to consistently have higher levels of comprehension and better quality of consent as a consequence [57,58]; education may also have a more direct influence on privacy-protective behavior [59]. Results have varied internationally with respect to the effect that age has on measures of consent quality and recall, although older patients, underrepresented in this study, are known to have higher rates of neurocognitive impairment than younger patients, which presents unique issues for ensuring informed consent is collected effectively wherever possible [60]. Furthermore, some evidence suggests older people may have greater privacy concerns on average than younger people [61].

The variability of health systems' uptake of asynchronous e-consultation systems internationally and the apparent heterogeneity of different populations' digital health literacy [62] may also limit this study's relevance outside of the UK NHS context. The effect of using a simulated clinical interaction in which participants were aware that consent and privacy were being studied, as opposed to using real-world patients, is also unknown and limits the direct applicability of this study to clinical practice. With rigorous ethical safeguards in place, future trials conducted directly in primary care settings with larger, more representative populations should consider using real patient interactions to evaluate these systems and explore in more detail the potential for an intention-behavior gap in these interactions with respect to informed consent.

The QuICCDig scoring system has not been formally externally reviewed, and this is not a formal validation study. There is currently no clear gold-standard metric in the field to validate against, which makes designing a robust validation study challenging. Future research could consider validating against clinician-perceived informedness, although it is important to be mindful of the biases this could introduce, or perhaps simultaneously against validated scores for digital consent, clinical consent, and/or health care research consent. However, this may be difficult to orchestrate in practice.

Conclusions

We find that contemporary user interfaces for collecting informed consent in remote electronic consultations for primary care may not reliably collect fully informed consent from patients. Furthermore, we find the perceived usability of a user interface to be significantly (P=.004) correlated with the quality of consent acquired through that interface. However, even in a study where participants knew consent was being studied, we find that almost half (25/55, 45%) of the participants did not remember making a privacy decision, and more than 87% (48/55) of the participants did not remember being offered alternatives to agreeing to complete their consultation. We recommend that primary care decision-makers consider the quality and usability of a remote consultation and triage application's consent interface when making procurement decisions.

Acknowledgments

The authors thank Dr Reinder Broekstra of the Faculty of Medical Sciences at the University of Groningen in the Netherlands for his input concerning medicolegal aspects of digital consent and Dr Laura Carmichael of the School of Electronics and Computer Science at the University of Southampton for her input in the field of data protection and privacy law.

This study makes use of the System Usability Scale. The System Usability Scale was developed as part of the usability engineering program in integrated office systems development at Digital Equipment Co Ltd, Reading, United Kingdom.

This work is partially supported by the National Institute for Health Research Southampton Biomedical Research Centre.

Abstract

Background: Grip strength is a crucial indicator of muscle deterioration, recovery, sarcopenia, and neurological disorders. However, conventional measurement requires a dedicated dynamometer, which limits accessibility and requires specific movements.

Objective: This study aimed to propose and validate a method for estimating grip strength using standard smartphone operations, thereby eliminating the need for specialized equipment.

Methods: Data were collected from 21 young adults in the main experiment, who performed standard smartphone tasks (tapping, flicking, and dragging) after measuring their grip strength with a dynamometer. A predictive regression model was developed using touch and inertial sensor data. The model was first evaluated using a random split of the entire dataset (random split evaluation). To further assess practical feasibility and generalizability, we conducted leave-one-user-out validation and a few-day calibration validation; the latter simulated a calibration scenario by incorporating 1 to 4 days of user-specific data into the training set.

Results: The regression analysis using a random split of the dataset demonstrated high accuracy, with a mean absolute error of 2.62 (SD 0.18) kg, a mean absolute percentage error (MAPE) of 8.91% (SD 0.57%), and a coefficient of determination of 0.802 (SD 0.036). In the validation of practical scenarios, the leave-one-user-out validation resulted in a MAPE of 15.08% (SD 5.40%). However, the personalized few-day calibration model showed significant improvements as calibration days increased, with the MAPE decreasing to 13.96% (SD 5.57%) after 1 day and reaching 11.64% (SD 5.80%) after 4 days. Furthermore, the National Aeronautics and Space Administration Task Load Index assessment indicated a low overall subjective workload (mean 3.04, SD 2.23 on a scale of 10), confirming the method's suitability for daily use without a significant burden on users.

Conclusions: The proposed method demonstrates that smartphones can serve as a viable, pervasive tool for daily grip strength monitoring, offering a convenient alternative to traditional dynamometers.

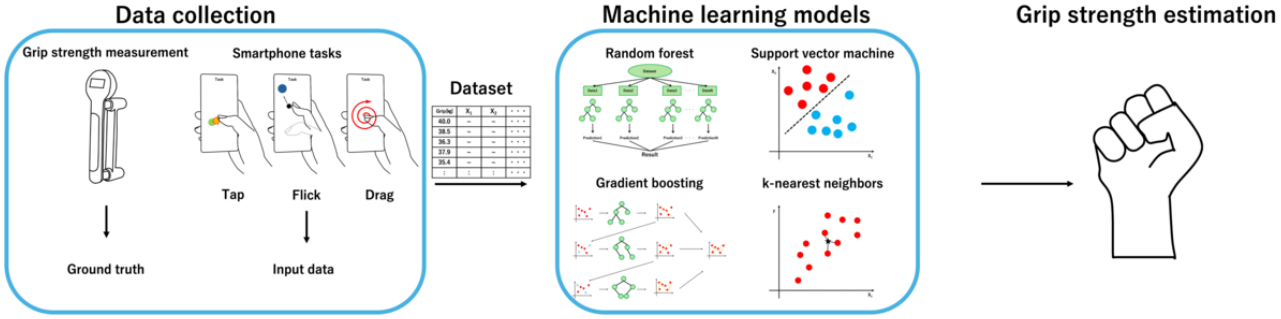
KEYWORDS

grip strength; mobile health; smartphone; machine learning; human computer interaction

Introduction

Muscle strength is known to decline with aging [1,2], and this decline is used as a diagnostic indicator of sarcopenia and frailty [3,4]. Among various muscle strength measures, grip strength is widely used in medical settings for treatment and rehabilitation [5-7]. Additionally, grip strength has been linked to chronic diseases, with several studies reporting a decline in grip strength among patients with diabetes [8-11]. Furthermore, reduced grip strength has been associated with an increased risk



XSL•FO
RenderX

of falls and fractures, highlighting its relevance in assessing overall musculoskeletal health [12]. Therefore, regularly measuring grip strength and monitoring daily variations are essential for health management and disease risk assessment.

However, grip dynamometers are not widely available to the general public, and high-precision devices used in medical settings are expensive, making them difficult to obtain for personal use. Furthermore, electronic grip dynamometers require maintenance and are not easily portable, making measurements outside clinical settings challenging. These limitations hinder the feasibility of continuous and routine monitoring, potentially posing a barrier to effective health management.

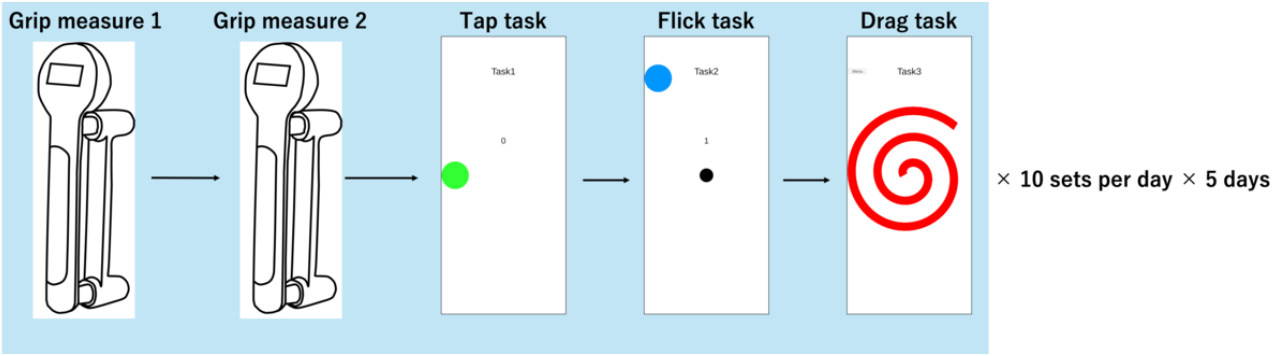
We propose a method for estimating grip strength that leverages the widespread availability of commodity smartphones (Figure 1). Specifically, it uses simple and quick touch input tasks to provide practical and accessible grip strength measurements. For model construction, grip strength is first measured using a Jamar-style dynamometer to obtain the ground truth, followed by a smartphone task to collect the corresponding input data. This task involves common smartphone input gestures, such as tapping, flicking, and dragging, during which input coordinates, time stamps, contact area, and sensor data—including acceleration, angular velocity, and orientation—are recorded as feature variables. A regression model is then constructed using the measured grip strength as the target variable and the extracted features as explanatory variables. In total, 21 participants took part in the experiment, and the analysis results showed that the best-performing model had a mean absolute error (MAE) of 2.62 (SD 0.18) kg, a mean absolute percentage error (MAPE) of 8.91% (SD 0.57%), and a coefficient of determination of 0.802 (SD 0.036).

Figure 1. Overview of the proposed grip strength estimation method. Grip strength measurements and smartphone tasks were conducted, and the resulting data were used to construct a machine learning model. Grip strength values were set as the ground truth, while input coordinates, time, and sensor data were used as the input, enabling estimation through regression analysis.

This method enables grip strength estimation using a regular smartphone without the need for specialized equipment, making daily measurements more accessible, enabling use in unsupervised environments, and requiring only a short amount of time (approximately 30 seconds per set of smartphone tasks). A brief overview of the study, including the experimental tasks and key results, is provided in Multimedia Appendix 1.

Methods

Recruitment



This study included 21 participants (n=16, 76.2% male and n=5, 23.8% female participants), aged 20 to 24 (mean 21.5, SD 1.00) years, with no functional impairments in their hands. All participants were right-handed. We provided participants with a prior explanation of the study and obtained their informed consent before participation.

Procedure

Figure 2 shows an overview of the data collection experiment. Each day, participants performed a set of grip strength measurements and smartphone tasks (tap, flick, and drag tasks) 10 times. There were no breaks between the grip strength measurements and tasks, ensuring continuous execution; this design was deliberately implemented based on previous findings [13] that report a decrease in grip strength immediately after using a handgrip dynamometer, thereby intentionally inducing variability in grip strength over the 10 consecutive task sets. The measurements were conducted over 5 separate days, with at least a 2-day interval between each measurement day. The experimental procedures were standardized across all participants and measurement days.

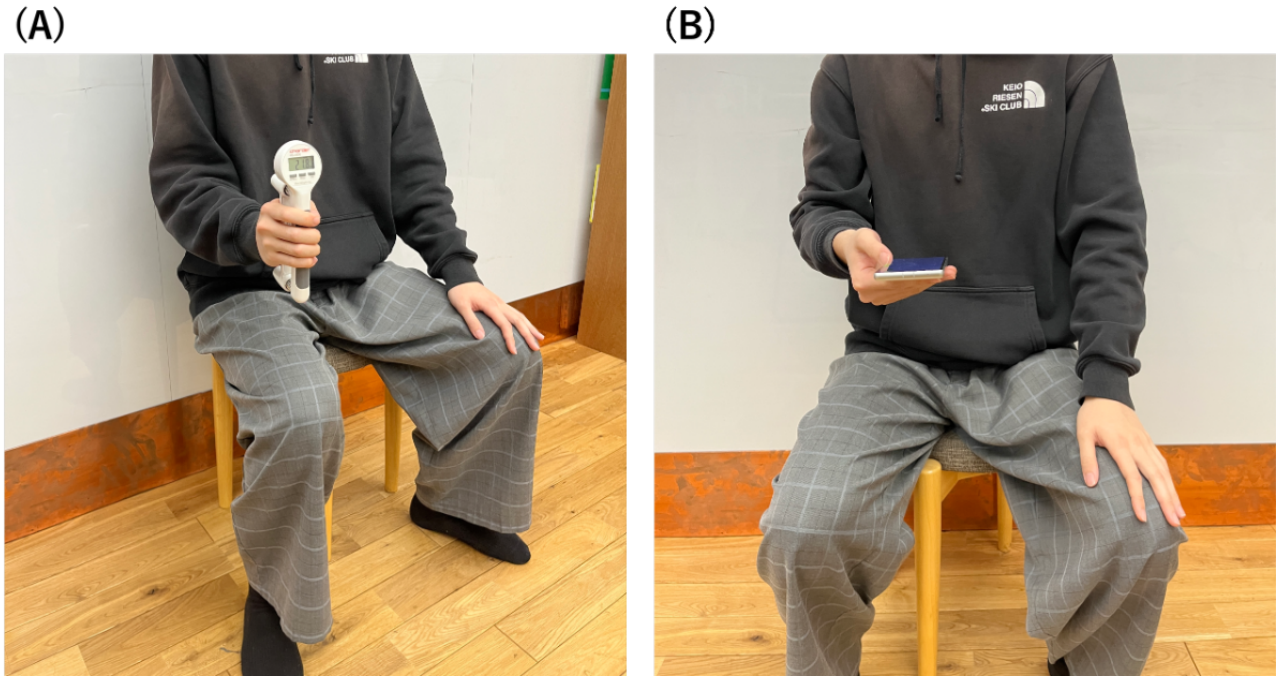

Figure 2. Overview of the data collection experiment. The experiment consisted of grip strength measurements and smartphone tasks (tap, flick, and drag).

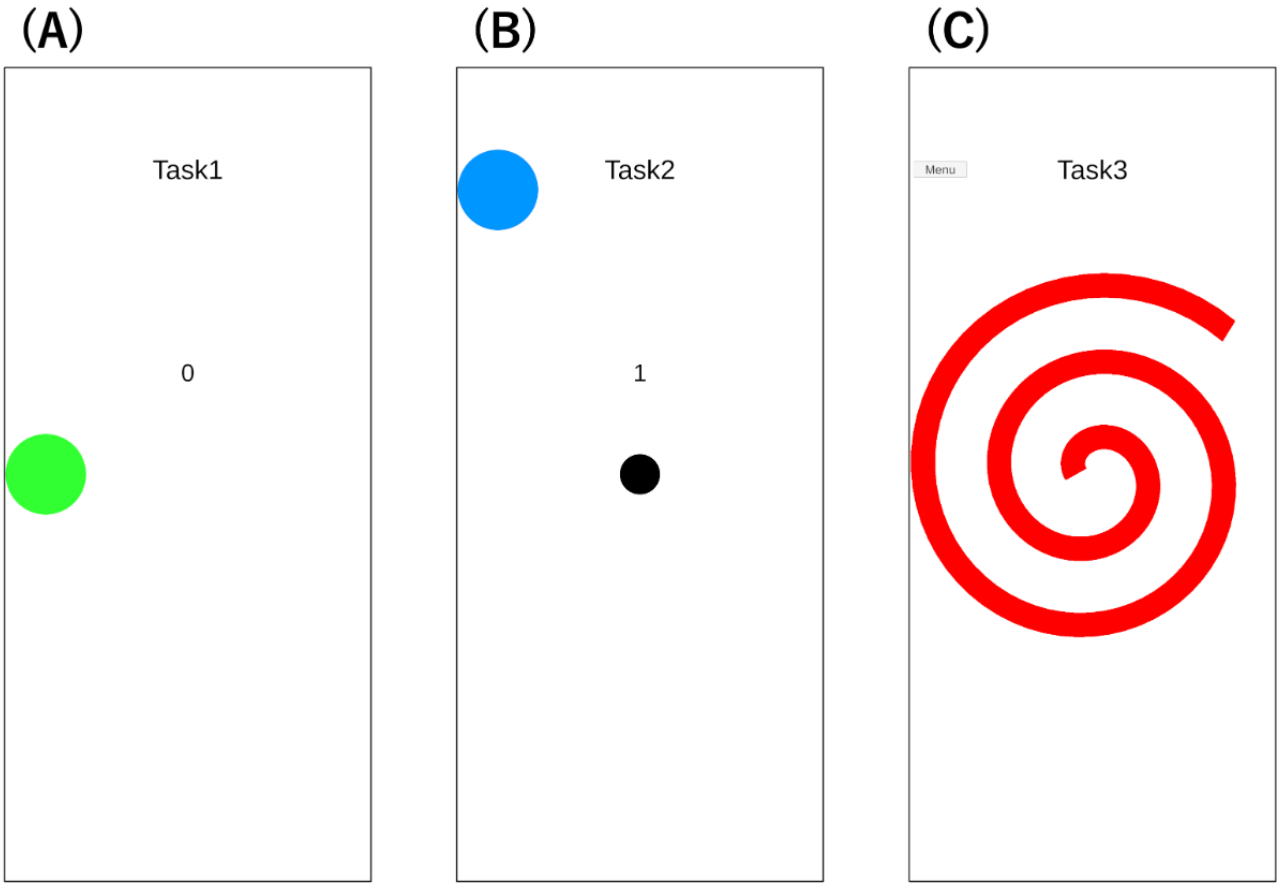
Grip Strength Measurement

We used a Jamar-style dynamometer with a standard procedure to measure grip strength. Participants sat on a stable chair without armrests in a relaxed state during the measurement. During the measurement, they kept their upper limb on the measurement side aligned with their body and maintained a posture with the elbow joint flexed at 90° (Figure 3A). The measurement was conducted only on the dominant hand. After the first measurement, a second measurement was taken following a 10-second interval.

Figure 3. Postures used for (A) grip strength measurement and (B) smartphone tasks.



Smartphone Task

A Google Pixel 7a (72.9 mm × 152.0 mm × 9.0 mm) was used for the task, and a custom-developed app built with Unity (version 2022.3.9f1; Unity Software Inc) was used. During the task, data from the device's accelerometer, gyroscope, and orientation sensor were recorded at 60 Hz. Participants sat on a stable chair without a backrest, held the smartphone in their dominant hand, and operated it using their thumb. They were instructed to keep their hand elevated, ensuring that they did not touch the table or their lap (Figure 3B). Additionally, they were asked to perform the following three tasks with careful and deliberate movements: tap task, flick task, and drag task (Figure 4).

XSL•FO
RenderX

Figure 4. Screenshots of the experimental app used for data collection, illustrating (A) the tap task, (B) the flick task, and (C) the drag task.

Tap Task

Participants tapped on a green target (14.6 mm diameter) displayed on the screen. When the target was tapped, a new target appeared at a different location. The task ended after 10 targets were tapped (Figure 4A).

Flick Task

Participants flicked a black circle (7.3 mm diameter) in a specified direction to make it collide with a blue target (14.6 mm diameter). When a successful collision occurred, a new target was generated. The task ended after 10 correct flicks in the designated direction (Figure 4B).

Drag Task

Participants traced a spiral (4.4 mm width) displayed on the screen from the center outward. When using the right hand, a clockwise spiral was used, whereas a counterclockwise spiral was used for the left hand. The task ended after tracing the spiral once (Figure 4C).

Features

We extracted specific behavioral features from each task—tap, flick, and drag—to capture the kinematic characteristics associated with grip strength. For the tap task, the extracted features included the spatial accuracy, defined as the distance between the input coordinates and the center of the target, as well as temporal metrics, such as the time taken to eliminate the target and the duration of the touch interaction. The finger contact area during the tap was also recorded. In the flick task, we calculated the direction of the flick input (represented by x- and y-components), the time taken to eliminate the target, the finger contact area, and the duration of the touch interaction from the start to the end of the flick. For the drag task, features included tracing accuracy, measured as the average distance between the input coordinates and the nearest point on the reference spiral centerline. Additionally, we derived input velocity and acceleration based on the coordinate movement, along with the finger contact area and the total duration of the drag interaction.

Common to all tasks, we used inertial sensor data, including acceleration, angular velocity, and orientation. Linear interpolation was applied to handle any missing values. To capture the hand movement dynamics surrounding the interaction, sensor data were extracted from 3 specific temporal windows: “preinput” (the 10 frames immediately preceding the input event), “during-input” (the average value recorded at the time of input), and “postinput” (the 10 frames immediately following the event) windows. Subsequently, we performed statistical calculations on these extracted data streams to derive the final feature set. These calculations included the differences between consecutive frames to capture the rate of change, as well as the maximum, minimum, range, and mean values to summarize the signal characteristics over the period of interest.

Data Processing

The target variable for our predictive models was the grip strength value, derived by averaging the 2 measurements taken within each set. We then constructed 4 distinct regression

XSL•FO
RenderX

models by pairing this grip strength data with the extracted behavioral features. First, we developed task-specific models, which were trained exclusively on data from each interaction type—namely, the tap, flick, and drag tasks. These models allowed us to evaluate the predictive power of each gesture independently. Second, we constructed a unified model trained on a combined dataset incorporating features from all 3 tasks. By integrating multimodal features across different interaction styles, this unified approach aimed to enhance overall prediction accuracy and establish a comprehensive model capable of estimating grip strength from a variety of daily smartphone gestures.

In this study, we used all the extracted features (touch interaction features, device motion features, and temporal metrics) for model training without applying dimensionality reduction or exclusion techniques. We relied on the inherent feature importance evaluation capabilities of nonlinear models (eg, random forest) to handle potential multicollinearity.

To remove high-frequency noise from the raw sensor data, we applied a low-pass filter with a cutoff frequency of 20 Hz. Before being used as input for the machine learning models, all extracted features were normalized using StandardScaler (scikit-learn; version 1.2.2) to ensure that each feature contributed equally to the model training. For each machine learning model, we performed a grid search to identify the optimal hyperparameters. This systematic search allowed us to select the best-performing configuration for each algorithm, ensuring the robustness of our grip strength estimation.

Model Training and Validation Scenarios

To estimate grip strength, we implemented 4 regression models using the scikit-learn library in Python. The random forest model was configured with 200 estimators, a maximum depth of 20, and the square root of features used for splitting, with the random state fixed at 42 for reproducibility. For support vector regression, we used the radial basis function kernel with a regularization parameter C of 100 and a “scale” kernel coefficient. The gradient boosting (GB) model used 100 estimators, a learning rate of 0.1, and a maximum depth of 5. Finally, the k-nearest neighbors (k-NN) model was set with 9 neighbors, using distance-based weighting and the Manhattan distance metric. Model evaluation was performed using 5-fold cross-validation, comparing performance based on the MAPE and the coefficient of determination.

To evaluate the feasibility of a practical deployment scenario, we assessed the model’s performance when trained on a combination of data from other participants supplemented with varying amounts of the target user’s specific data. Specifically, we conducted evaluations using 2 approaches: leave-one-user-out validation, in which 0 days of the target user’s data were included in the training set, and a personalized calibration approach using 1 to 4 days of the target user’s data (few-day calibration). This experimental design simulates a real-world scenario in which a generic model is calibrated with user-specific data collected during the initial period of use to improve estimation accuracy.

Ethical Considerations

The study protocol was approved by the Research Ethics Committee of Keio University (2025-041). Prior to the experiment, the detailed purpose and procedures of the study were explained to all participants, and written informed consent was obtained. Participants were informed that they could withdraw from the study at any time without penalty. Regarding the exclusion criteria, individuals with preexisting hand impairments or pain were excluded from participation due to safety considerations. As the data collection involved repeated muscle exertion for maximum grip strength measurement, this exclusion was strictly enforced to prevent any risk of injury or symptom exacerbation. All participant data were anonymized and stored on a secure server. Each participant received a cash compensation of ¥2000 (approximately US $13) for their time and participation in the study.

Results

Collected Data

In total, 1050 data points (10 repetitions × 5 days × 21 participants) were collected during the measurements for each tap, flick, and drag task. We used grip strength measured before each task as the ground truth, and we mapped this value onto the data collected in each of the 10 executions of the task. Therefore, each data point consisted of a ground-truth grip strength value and data collected through 1 execution of the task. The average time taken for each task was 6.11 (SD 1.37) seconds for the tap task, 7.45 (SD 1.26) seconds for the flick task, and 3.84 (SD 1.88) seconds for the drag task.

Random Split Cross-Validation Result

Table 1 shows the MAE, Table 2 shows the MAPE, and Table 3 shows the coefficient of determination. In all tasks, the support vector machine (SVM) achieved the best results in terms of both MAPE and coefficient of determination. Additionally, the unified model, which combined features from different tasks, showed a lower MAPE than single-task models. It also achieved the highest coefficient of determination. Figure 5 illustrates a scatter plot of the true values (x-axis) and the estimated values (y-axis) for the test data of the unified model. SVMs, GB, and k-NNs had an average error of approximately 3 kg. For random forest, there were many data points with prediction errors of ≥5 kg for both low and high true values.

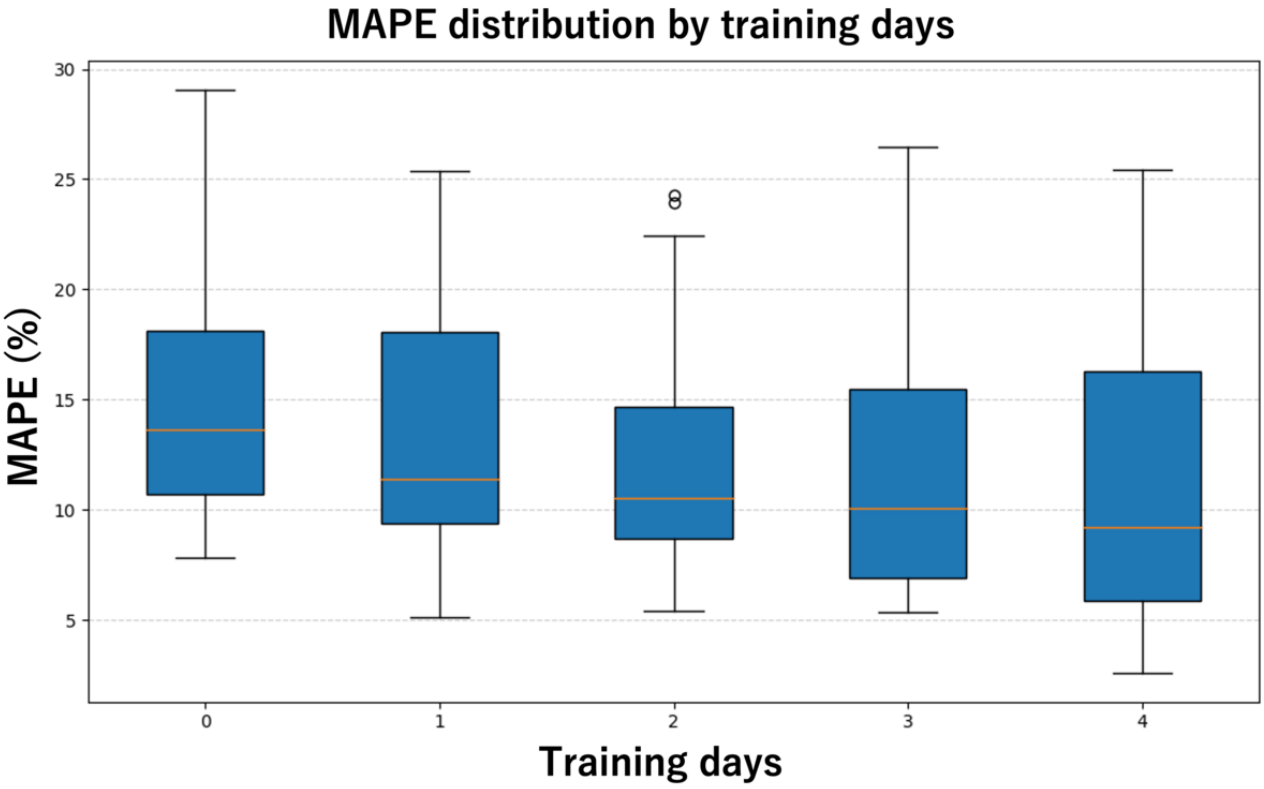
Leave-One-User-Out and Few-Day Calibration Validation Results



For the leave-one-user-out and few-day calibration validations, the SVM model was used and evaluated based on the MAE and MAPE for each participant. As shown in Table 4 and Figure 6, the estimation accuracy consistently improved as more days of the target user's data were incorporated into the training set. In this evaluation, the case with 0 training days corresponds to leave-one-user-out validation, while the cases with 1 to 4 training days represent the few-day calibration validation.

Table 4. Comparison of mean absolute error and mean absolute percentage error by number of training days.

Variable	Day 0	Day 1	Day 2	Day 3	Day 4
Mean absolute error (kg; SD)	5.03 (2.65)	4.39 (2.28)	3.96 (2.11)	3.80 (2.04)	3.56 (2.23)
Mean absolute percentage error (%; SD)	15.08 (5.40)	13.96 (5.57)	12.60 (5.54)	12.23 (5.68)	11.64 (5.80)

XSL•FO
RenderX

Figure 6. Distribution of estimation errors from the initial state to 4 days of calibration. The box plots illustrate the mean absolute percentage error (MAPE) of the support vector model as the number of user-specific training days increases from 0 to 4. The case with 0 days represents leave-one-user-out validation, while cases with 1 to 4 days represent few-day calibration validation. The horizontal line within each box represents the median error, and the box edges represent the IQR.

Subjective Workload Assessment

To evaluate the subjective workload of the measurement tasks using our proposed method, we administered the National Aeronautics and Space Administration Task Load Index (NASA-TLX) questionnaire to 9 participants. Prior to the assessment, participants were instructed on how to use the app and performed the tap, flick, and drag tasks once. Subsequently, they completed the questionnaire. Following the raw Task Load Index method, participants rated 6 subscales on an 11-point scale ranging from 0 (low) to 10 (high). The results are summarized in Table 5. The overall workload score (mean of all subscales) was 3.04 (SD 2.23), indicating a low level of workload overall. Among the subscales, mental demand (mean 1.89, SD 2.02), effort (mean 1.78, SD 2.10), and frustration (mean 1.78, SD 2.10) were rated particularly low. In contrast, temporal demand showed the highest mean value at 5.11 (SD 3.14).

Table 5. National Aeronautics and Space Administration Task Load Index scores.

Subscales	Descriptions	Mean (SD)
Mental demand	How much mental and perceptual effort did the task require?	1.89 (2.02)
Physical demand	How much physical activity was required?	4.22 (2.86)
Temporal demand	How much time pressure did you experience while performing the task?	5.11 (3.14)
Performance	How successful were you in accomplishing the task?	3.44 (2.50)
Effort	How hard did you have to work?	1.78 (2.10)
Frustration	How irritated, stressed, and annoyed did you feel?	1.78 (2.10)
Overall workload	Average of the 6 subscales	3.04 (2.23)

Discussion

Model Performance and Estimation Characteristics

In the model comparison, SVMs achieved the highest accuracy, followed by GB, k-NNs, and random forest. SVMs and GB effectively captured nonlinear relationships in the data, enabling them to achieve high estimation performance despite the limited dataset. In contrast, k-NNs tend to suffer from decreased accuracy in distance calculations when applied to high-dimensional data, leading to lower overall precision. Additionally, random forest does not focus on reducing errors in the same way as boosting methods, which may result in suboptimal feature selection.

XSL•FO
RenderX

Furthermore, there was a tendency for grip strength to be overestimated when the true value was low and underestimated when the true value was high. This may be attributed to distributional bias in the original data. Most of the data were concentrated between 25 kg and 35 kg, while values >40 kg or <20 kg were relatively scarce. Consequently, the model was likely influenced toward the mean, reducing the estimation accuracy for extreme values.

The observed reduction in estimation errors as the number of calibration days increased suggests that user-specific data significantly enhance the model's ability to account for individual variability. Compared to the leave-one-user-out validation, which yielded the highest error rate, the introduction of even a single day of user data led to a notable improvement. The most substantial improvement occurred between the initial state and the first 2 days of calibration, after which the error rate continued to decrease more gradually. This indicates that while initial personalization is critical to overcoming the limitations of a purely generic model, the system reaches a state of relative stability with approximately 3 to 4 days of data.

The primary dataset involved university students aged 20 to 24 years. To assess the applicability of our framework to broader demographics, we conducted a preliminary case study with a 53-year-old participant (middle-aged adult). We trained a model using the participants' data from 1 day, combined with the entire dataset from the younger group, and tested it on the participants' data from other days. The model achieved an estimation error with an MAE of 1.87 kg (MAPE 11.19%), which is comparable to the accuracy levels obtained from the younger participants. Regarding participants with hand disabilities, we were unable to include them in this study due to ethical considerations. As the data collection tasks involve repeated muscle exertion and impose a certain physical load on the hand, recruiting individuals with existing hand impairments posed a potential risk of exacerbating their conditions.

Practical Applications and Future Directions

In the future, we will implement the proposed model on a smartphone and evaluate its practicality for daily grip strength monitoring. Specifically, we plan to develop a system that inputs data obtained after certain operations into the model and provides feedback on the estimated results. The goal is to track changes in grip strength and use the data for health management and exercise. To achieve this, maintaining accuracy on actual devices and assessing usability will be crucial challenges.

For daily grip strength monitoring, we believe that ease of measurement is one of the most crucial factors. When using the unified model (ie, conducting all tasks), the required time is approximately the same as that for completing one set of smartphone tasks in the data collection experiment. The average completion time for these tasks in our experiment was approximately 30 seconds, which we consider short enough to avoid burdening users in everyday use.

Furthermore, numerous studies have reported on the relationship between smartphone use and grip strength variations, revealing that individuals who spend more time using smartphones daily tend to have lower grip strength [14-16]. Excessive smartphone use can affect hand function and may lead to conditions such as tenosynovitis [17,18]. By using this system, it may be possible to detect grip strength decline during smartphone use, estimate hand fatigue, encourage appropriate use, and reduce the risk of orthopedic disorders.

Subjective Workload and Usability

To evaluate user fatigue and task burden during daily monitoring, we conducted a subjective workload evaluation using the NASA-TLX with 9 participants. The overall workload score was low at 3.04 (SD 2.23) (on a scale of 0 to 10). Specifically, the physical demand score averaged 4.22 (SD 2.86). Given that the task inherently involves physical muscle exertion to estimate grip strength, a moderate level of physical load is expected. However, this value indicates that the task does not impose excessive fatigue compared with maximum voluntary contraction tasks typically performed with a conventional dynamometer.

Notably, the mean temporal demand score was relatively high at 5.11 (SD 3.14), even though participants were explicitly instructed to perform the tasks at their own self-selected pace. This perception may be attributed to the app's feedback design, specifically the display of elapsed time upon task completion. Although participants were instructed to prioritize their own pace, the visualization of a time metric likely created an awareness of *being timed*, inducing a psychological pressure to perform quickly. Consequently, to mitigate this unintended pressure, we plan to redesign the user interface by removing the explicit display of elapsed time in future versions of the app.

Crucially, however, the frustration score remained extremely low at 1.78 (SD 2.10). The clear dissociation between high temporal demand and low frustration implies that this time pressure was not perceived as negative stress or panic but potentially as a gamified element or a source of positive engagement to complete the task efficiently. These results confirm that our proposed method is suitable for continuous daily use without causing significant user burden or stress.

Limitations

To evaluate the generalization of the proposed model across different participants, leave-one-user-out validation was performed. As reported in the Results section, this approach yielded a relatively large estimation error, with an MAE of 5.03 (SD 2.65) kg and an MAPE of 15.08% (SD 5.40%) for the SVM. These results, particularly when contrasted with the improved accuracy observed after just 1 to 4 days of calibration, highlight the significant impact of individual variability in grip strength and smartphone interaction patterns. The high error rate in leave-one-user-out validation suggests that a purely generic model struggles to adequately capture the unique features of each individual's operations. Consequently, our findings indicate that while the model provides a strong foundation, an individual calibration process is currently essential to bridge the gap between a general estimation and the high precision required for practical, personalized health care monitoring.

The accuracy of the proposed model may depend on the smartphone model used. The extracted features, such as device acceleration and angular velocity, could vary due to differences

XSL•FO
RenderX

in device size, weight, and screen dimensions. Consequently, the model may not achieve the same level of accuracy when applied to a different smartphone model. Additionally, the participants in this study used different smartphone models in their daily lives. Some participants struggled with input due to differences in size and shape compared with their usual devices. Their unfamiliarity with the device may have affected task performance. Therefore, it is necessary to explore methods to mitigate the impact of device-related constraints on model performance.

In our experiment, participants were required to hold the smartphone with 1 hand and use their thumb for input. This setup was chosen considering the ease of one-handed operation and the need for consistency in analysis. Meanwhile, factors such as finger length and hand size were not examined in this study. However, because these elements are known to influence touch input accuracy [19], factoring in such variations may improve the accuracy of grip strength estimation across diverse users.

Additionally, using 1 hand with the thumb was the primary interaction style in our experiment. Consequently, the current model is optimized exclusively for this specific posture. We recognize that users often use alternative styles, such as holding the device with 1 hand and operating it with the index finger of the other, which can significantly alter sensor data profiles. To ensure data consistency in a practical deployment, we propose implementing on-screen instructions or a brief tutorial to explicitly guide users to adopt the required one-handed thumb posture during the measurement tasks. Expanding the model to accommodate diverse interaction styles remains an important direction for future work.

In this study, data collection was conducted exclusively with right-handed participants operating the smartphone with their dominant (right) hand. To extend the applicability of our model to left-handed users operating with their dominant hand, we propose a geometric transformation approach. As the anatomical structure of the hands is symmetrical, left-hand interaction data can be mapped to the right-hand feature space by mirroring the horizontal coordinates (x-axis) of touch points and reversing the rotation direction of the spiral drag task (ie, treating counterclockwise input as clockwise). This preprocessing allows the model trained on right-dominant data to be directly applied to left-dominant users.

However, the validity of estimating grip strength using the nondominant hand (regardless of whether it is the left or right hand) remains unverified, as differences in dexterity and motor control may significantly alter sensor patterns compared with the dominant hand.

Consequently, to ensure valid estimation in a real-world deployment, the app requires an input interface where the user explicitly specifies two parameters before use: (1) which hand is currently being used (left or right) and (2) whether it is their dominant or nondominant hand. On the basis of these inputs, the system can determine whether to apply geometric transformations (for left-dominant input) or to notify the user that the current condition (nondominant input) is outside the verified scope of the model.

We acknowledge that this study used a single smartphone model (Pixel 7a). As inertial sensor data (acceleration and angular velocity) are physically influenced by the device's weight and dimensions, verifying reproducibility on different devices is crucial. However, the Pixel 7a (weight 193.5 g; display 15.5 cm) represents a standard form factor in the current smartphone market. Therefore, we anticipate that the fundamental physical interactions between grip strength and device motion would remain consistent, and the influence on estimation accuracy would be limited for devices with similar specifications.

To strictly address the issue of varying sensor characteristics (eg, bias or sensitivity) across different hardware in the future, we propose 3 potential approaches. First, sensor calibration could be introduced as a preprocessing step to identify and correct for device-specific sensor characteristics, thereby standardizing the input data across different models. Second, we suggest focusing on robust feature extraction, which prioritizes features that are independent of raw sensor hardware variations, such as relative motion patterns, rather than relying on absolute sensor values. Finally, if a large-scale dataset across multiple devices becomes available, device-specific features—such as model ID, weight, or screen size—could be explicitly incorporated as input variables to train a more generalized and hardware-agnostic model.

Comparison With Prior Work

Several studies have explored methods for estimating grip strength without using a grip dynamometer. Matsumoto et al [20] proposed a method for estimating grip strength by capturing an image of a hand gripping a soft tennis ball using a monocular camera on a smartphone and analyzing changes in the angle of finger joints. Yamamoto et al [21] proposed a grip strength measurement method using capacitive touch sensors on smartphones, which does not require any electronic components on the measuring device itself. Although these methods offer alternative approaches to measuring grip strength, they still require external equipment beyond a smartphone, and the measurement results may be influenced by the user's posture. In this study, our objective is to estimate the grip strength using only the smartphone, with the aim of establishing an easy and convenient measurement method without specialized equipment.

This study examines the estimation errors of the proposed grip strength model. The Jamar dynamometer manufacturer recommends a measurement error within 5% [22], whereas the error rate in this study slightly exceeds this threshold. We also evaluated the clinical relevance of our estimation accuracy. The minimal clinically important difference for grip strength is reported to be between 5.0 kg and 6.5 kg [23]. Our model achieved an MAE of 2.62 (SD 0.18) kg in the random split and 4.39 (SD 2.28) kg in the single-day case of the few-day calibration, both falling within this minimal clinically important difference range. This indicates that our method is effective for detecting meaningful changes in muscle strength over time, such as recovery or decline. However, a critical limitation arises when applying this method to disease screening based on specific thresholds. For instance, the Asian Working Group for Sarcopenia 2019 defines diagnostic cutoffs of <28 kg for male and <18 kg for female individuals [24]. Given our estimation

XSL•FO
RenderX

error of approximately 2.6 kg to 4.4 kg, there is a risk of misclassification (false positives or false negatives) for individuals whose grip strength lies near these borderline values. Consequently, we position our method not as a replacement for clinical-grade dynamometers for definitive diagnosis but rather as a pervasive tool for daily longitudinal monitoring and initial screening to identify at-risk individuals who should seek professional assessment.

The accuracy of the proposed model is compared with previous grip strength estimation studies. Park et al [25] used national survey data from >20,000 participants, where grip strength was measured using a digital grip strength dynamometer. Their analysis used age, sex, hand preference, height, weight, waist circumference, and 5 physical activity levels (vigorous or moderate work, vigorous or moderate recreation, and travel) as input features, achieving a coefficient of determination of 0.717 with Extreme Gradient Boosting. Hwang et al [26] developed a deep learning model trained on data from 164 participants, incorporating various postures, demographic information, and anthropometric data as input, achieving a coefficient of determination of 0.88. This study, in contrast, focuses on estimating grip strength using everyday smartphone interactions, making the input data fundamentally different from those used in previous studies. However, the limited number of participants and the small training dataset present challenges in terms of reliability and accuracy. Additionally, further investigation into user-independent models is necessary. Future work should aim to expand the dataset and improve the model to enhance estimation accuracy.

Conclusions

In this study, we proposed a model for estimating grip strength using smartphone input data. First, grip strength was measured, followed by the execution of smartphone tasks, during which sensor data from the device were collected. On the basis of the obtained data, multiple machine learning models were constructed and evaluated. The results showed that the model using SVMs achieved the highest accuracy. Furthermore, integrating features obtained from different tasks improved estimation accuracy. In the future, we aim to implement the model on a smartphone to enable real-time grip strength estimation. To achieve this, further accuracy improvements and evaluations under various conditions will be necessary.

Data Availability

The source code for the smartphone app developed in this study and the data analysis scripts are available in the GitHub repository [27].

Abstract

Background: Mobile health (mHealth) apps are useful tools for research and disease management. However, implementation of mHealth apps is lacking in many areas. While mHealth apps offer various advantages to researchers and patients, their effectiveness depends on their actual use. Barriers to using mHealth apps are often due to human factors such as usability or technology acceptance. Although prior studies have examined the acceptance of mHealth apps in patient treatment, the key factors driving or hindering the use of mHealth apps in research remain unclear.

Objective: This study explores user perceptions of 2 mHealth apps in the setting of an observational technology evaluation study using the unified theory of acceptance and use of technology. We aim to evaluate the technology acceptance of these specific apps and to investigate challenges in choosing suitable mHealth apps in research. The apps were intended for data collection; no effect on health was expected.

Methods: Patients with chronic diseases as well as healthy participants used a symptom tracking app and a cognitive test app over the course of 4 weeks within the feasibility study of the project “Identifying Digital Endpoints to Assess Fatigue, Sleep and Activities of Daily Living in Neurodegenerative Disorders and Immune-Mediated Inflammatory Diseases.” Thereafter, 61

XSL•FO
RenderX

qualitative interviews were conducted, recorded, and transcribed. A qualitative content analysis using the unified theory of acceptance and use of technology was performed.

Results: An important aspect of motivation for participants was feedback on their health data and performance in the cognitive tests. Effort played a significant role in app use. Patients rated the apps as easy to use and quick. Using the app multiple times per day at fixed times was perceived as disruptive. Participants preferred using their own phone. Social influence as well as facilitating conditions played a lesser role in intention to use the apps. Data security was no concern for most participants. They stressed the importance of good relations with the study team.

Conclusions: In choosing suitable apps, one size will certainly not fit all. For medical research, pretesting of all materials with the potential users is of utmost importance. If the positive effects of the app on users' health are not immediately apparent, other factors may motivate use, for example, feedback, gamification, adjustable functions, applicability on all smartphone operating systems, and good relations to the study team.

mobile health care; mobile health; mHealth; digital health; technology use; neurodegeneration; app; user experience; mixed method study

Introduction

Technology has become increasingly important in maintaining our health and treating illness [1]. This affects not only care providers but also individuals who take advantage of technologies such as websites, smart devices, and apps. Mobile health (mHealth) apps, for example, monitor users' health, remind themselves of their medication, and connect with other patients and their care providers [2-4]. The increase in use has led to an increase in the availability of these services [2,5-7]. mHealth apps can be useful tools for patients as well as medical staff. They can be particularly effective in the self-management of patients, collection of health data, support of diagnosis, and disease management [2-4,7,8]. In clinical research, mHealth apps deliver convenient access to large amounts of real-time health data from users' everyday lives [2]. This combination of advantages highlights the growing significance of mHealth apps in patient care and medical research [9].

Although a large number of mHealth apps are available and their advantages seem obvious, implementation is still lacking in many areas. Barriers that prevent the implementation of mHealth apps are often due to human issues, such as user acceptance, low familiarity with technology, and resistance to change [10]. A prerequisite to the successful implementation of an mHealth app is its usability. Technology acceptance and the ability to implement the technology in daily life are further requirements [11]. The effectiveness of a new mHealth app depends on its actual use [5]. Therefore, the experiences and opinions of users and patients must be taken into account when evaluating mHealth apps. Understanding what aspects of mHealth apps facilitate or hinder user acceptance is an important step to promote their implementation.

The concept of technology acceptance was originally used in organizational contexts [12], such as the adoption of new technology in the workplace. However, its importance in health research has increased with the growing use of health technology such as mHealth apps [10]. Different models have been used to explain the intention and use of a technology [6], such as the theory of reasoned action or the technology acceptance model [12-14]. The unified theory of acceptance and use of technology (UTAUT) was developed to unify these different models [14] and has been widely used in mHealth research [6,15]. It postulates that the actual use of a technology can be predicted by the behavioral intention to use a technology. The behavioral intention is determined by 4 constructs: performance expectancy, effort expectancy, social influence, and facilitating conditions [13]. Performance expectancy is defined as the degree to which a user expects a technology to help him or her. Several studies on mHealth services find positive effects of performance expectancy on behavioral intention to use a technology [6,16-18]. Effort expectancy describes the assumed ease of use of a technology and has been strongly associated with a greater intention to use in an mHealth context, especially in older populations [6,16]. Venkatesh et al [13] defined social influence as "the degree to which a person perceives that important others believe he or she should use the new system." Social influence also has a positive effect on behavioral intention in mHealth contexts [6,16]. Facilitating conditions describe the perceived organizational and technical infrastructure in support of using a technology, such as instructions or assistance [16].

A number of studies have been conducted on the technology acceptance of mHealth apps using the UTAUT or related models. Many of these studies focus on mHealth apps designed to help patients with self-management of their health such as hypertension or weight management apps [17,19,20]. Studies on diabetes management apps point out the importance of trust, particularly regarding data security and perceived disease threat [21,22]. Similar results were found regarding technology acceptance on COVID-19 contact tracing apps [23]. Technology acceptance of mHealth apps focusing on health information has also been investigated. Intention to use a prenatal care app has been investigated using the UTAUT [24]. Alsyouf et al [25] stressed the importance of data security on intention to use a personal health record system. However, the majority of these studies focus on mHealth apps that provide direct benefits to their users, such as support in health management or providing health information. The notion of perceived usefulness or performance expectancy is a well-described predictor of intention to use mHealth apps [6,7,18]. This influence might

XSL•FO
RenderX

be diminished in the context of research-focused mHealth apps because they do not offer direct benefits for the user.

Here, we report the results of a study on the technology acceptance of 2 mHealth apps developed for research purposes. Patients with Parkinson disease, Huntington disease, rheumatoid arthritis, systemic lupus erythematosus, primary Sjögren syndrome, and inflammatory bowel disease as well as healthy participants used 2 mHealth apps over the course of 4 weeks. This study was part of a larger evaluation study with the goal to examine usability of these mHealth apps as well as other digital technologies. The symptom tracking app included questionnaires regarding the patient's state of health, that is, sleepiness, fatigue, and mood. The cognitive test app included 3 different cognitive tests.

In short, this study serves 2 purposes. First, we assess the technology acceptance of these apps to evaluate their usability for a follow-up study. Second, we explore the specific challenges involved in selecting suitable data-gathering mHealth apps for medical research. We hope these insights will be helpful for researchers in planning future studies using mHealth apps and help prevent data loss due to low technology acceptance.

Methods

Study Overview

Study Design of the IDEA-FAST Feasibility Study

We conducted qualitative semistructured interviews with participants of the feasibility study (FS) of the IDEA-FAST project ("Identifying Digital Endpoints to Assess Fatigue, Sleep and Activities of Daily Living in Neurodegenerative Disorders and Immune-Mediated Inflammatory Diseases"). IDEA-FAST investigates whether digital parameters can be used to assess fatigue and sleep disturbances. The FS was an observational study, in which different technologies and mHealth apps were assessed for their suitability for the larger clinical observation study. The FS included 2 mHealth apps, a symptom tracking app [26] and a cognitive test app. Quantitative and qualitative measures were used to evaluate the suitability of the mHealth apps. For the qualitative evaluation, patients as well as healthy participants were interviewed after using the apps for 4 weeks.

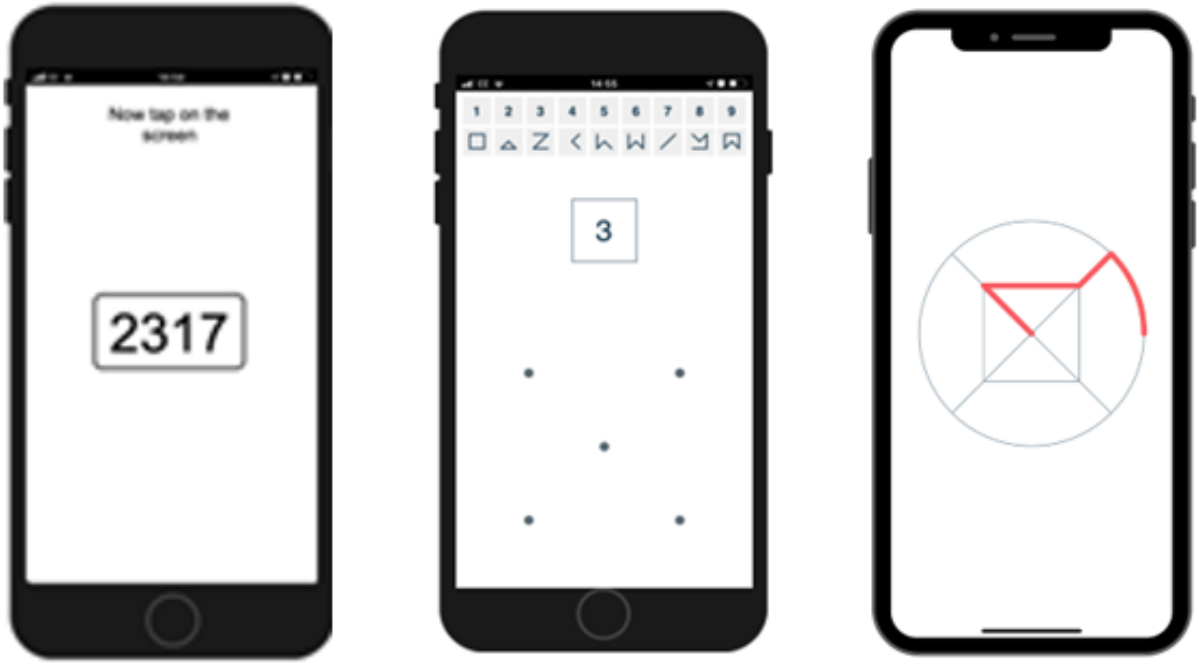
The design and rationale of the FS as well as baseline characteristics have been described previously [27]. In short, digital technologies, including symptom tracking and cognitive test apps, were implemented alongside surveys and patient-reported outcome measures. The FS was conducted from August 2020 until June 2021 at 4 study sites: Erasmus University Medical Centre, Rotterdam (the Netherlands), Newcastle University (the United Kingdom), University Medical Centre Schleswig-Holstein, Kiel, and George Huntington Institute GmbH, Münster (Germany). Participants were introduced to the mHealth apps at a baseline visit with their local site. Afterward, participants used the apps for 4 weeks, each week consisting of a 5-day wearing period and a 2-day rest period. Taken together, the apps were used for 20 days. Additional information and support were offered by clinical staff either via support materials, tutorials, telephone, and/or in-person visits.

mHealth Apps

Overview

Both apps could be installed either on participants' personal phones or on a study phone provided by the research staff. The symptom tracking app was available for Android operating systems, and the cognitive test app for both Android and IOS operating systems.

Symptom Tracking App



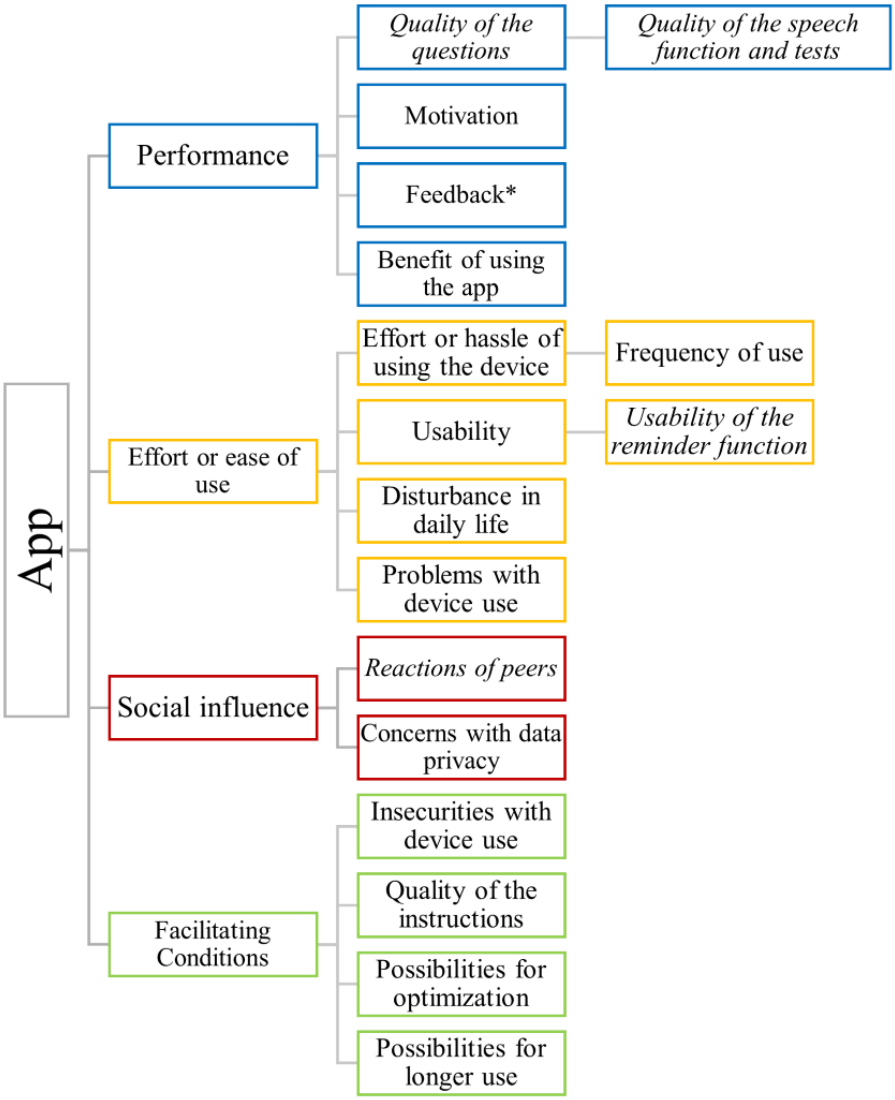
The symptom tracking app has been developed by VTT in accordance with the study design. It was scheduled to be filled out 4 times a day, at 9 AM, 1 PM, 5 PM, and 9 PM. Participants received notifications to answer questions and were given a time frame of several hours for each action within the app. Each action consisted of several questions specially designed for the study regarding current fatigue, sleepiness, mood, and pain. In the morning, users answered additional questions regarding sleep duration, sleep disturbances, and sleep quality. In the evening, physical and mental activity during the day was assessed. In addition, the study team decided to add a voice feature to allow participants to verbally share information about their day. Furthermore, 2 speech tests were included in the app for study purposes: an oral motor skill task, in which participants had to make certain sounds; and a temporal orientation task, where participants stated the time of day. The app is equipped with a reminder function using sounds, which can be turned off.

Cognitive Test App

The cognitive test app has been developed by Cambridge Cognition, also in accordance with the study design. It required participants to complete a cognitive task twice a day. The psychomotor vigilance task (PVT) was administered in the first week, followed by the digit symbol substitution test (DSST) in the second week, and the n-back task (NBX) during weeks 3 and 4 [28]. The tests can be seen in Figure 1. The PVT measures reaction time, alertness, and attention. As participants look at the screen of their smartphone, a number appears, and as soon as they see the number, they have to touch the screen as quickly as possible. The DSST measures cognitive ability and takes 1.5 minutes. Participants see abstract symbols associated with numbers at the screen of their smartphone. When a particular number appears on the screen, they have to draw the corresponding symbol. Participants are asked to draw as many symbols as possible. The NBX measures attention and working memory and takes up to 2 minutes. Participants see a stream of abstract symbols. They must touch the screen whenever a visible symbol matches the one that appeared 2 symbols previously [29].

XSL•FO
RenderX

Figure 1. The 3 tests of the cognitive test app.



Qualitative Interviews

The general implementation and transcription procedures of the interviews have been described previously [27]. In short, an interview guideline based on the UTAUT model was developed. After an introduction including verbal consent, some basic demographic questions followed. Participants were asked about each app separately. First, participants were asked to describe their general experiences with the app, followed by more detailed questions to cover all aspects of UTAUT. Participants in the FS were contacted during the study to assess their willingness to take part in an interview. Interviews were conducted between October 2020 and June 2021, mostly via videoconference. Written consent to participate in the interviews was obtained beforehand. Interviews were conducted in the first language of the participants and recorded with their consent. They were transcribed verbatim or pseudonymized by a transcription service. Interviews in Dutch were translated into English with an online translation tool and double-checked by a native speaker. Quotations used in this paper were slightly edited for readability without altering their meaning. All interviews were analyzed using content analysis following Mayring [30] with MAXQDA 2022 (version 22.8.0; VERBI GmbH). Overall, 59 complete interviews and 2 summaries of interviews (where recording had not worked) were included in the analysis. Initially, 4 broad top-level codes were defined to classify the interview content according to the 4 constructs of technology acceptance. In the next step, potential subcodes were delineated on the basis of the interview guide. Subsequently, the interviews were analyzed using these preexisting codes, with the additional step of using an inductive method to derive new codes. Applying this method to both apps resulted in comparable coding systems that still account for individual differences. The resulting code system is illustrated in Figure 2.

XSL•FO
RenderX

Figure 2. General code system of the apps. Codes present in italics format are only used for the symptom tracking app, and feedback* is only used for the cognitive test app.

While the UTAUT model was used as a foundation for both the interview guideline and the analysis, it was slightly adapted to fit this study. As participants in a medical study, users did not expect the devices to be personally useful and were unable to judge their usefulness to the study team. In addition, as we interviewed participants after their use of the device, “expectation” seemed to be an inaccurate term in this case. Therefore, we decided to use the terms “performance” and “effort or ease of use” instead of performance expectancy and effort expectancy, respectively.

Participants

Interviews were conducted separately for each participant group until data saturation was reached. To ensure a diverse sample, we conducted at least 1 interview per patient group and research center. When new interviews in a patient group did not lead to new valuable insights, we assumed data saturation. This approach led to different sample sizes. A total of 61 interviews were conducted. As only 1 patient with systemic lupus erythematosus could be interviewed and therefore data saturation is not clear, this interview was excluded from analyses.

Ethical Considerations

Ethics approval was granted by the ethics committee of Kiel University, Germany (Ethikkommission der Medizinischen Fakultät der CAU zu Kiel, approval D491/20) and the Health Research Authority and Health and Care Research Wales (IRAS project ID 282329, REC reference 20/PR/0185). Participants gave written and verbal informed consent before taking part in the study. Interviews were voluntary for participants of the larger FS. To ensure participant privacy, participants were assigned a random code. The code key is stored, encrypted, and password-protected. Interview transcripts were pseudonymized. Voice and video recordings are stored separately in accordance with the General Data Protection Regulation.

Results

Overview

Table 1 provides an overview of the number of interviews per group and site, while Table 2 shows the demographic characteristics of the sample.

[e]RA: rheumatoid arthritis.
[f]IBD: inflammatory bowel disease.

Figure 2 shows the general code system used for both apps. Some of the second- and third-level codes were only used for one of the apps. *Quality of the questions*, *quality of speech function and tests*, as well as *usability of the reminder function* and *reactions of peers* were only needed for the symptom tracking app, while *feedback* was only used for the cognitive test app.

Symptom Tracking App

Overview

Most participants used the symptom tracking app throughout the whole study period, though many participants mentioned missing several appointments. Three participants did not use the app at all. For one participant, it did not work, and some participants only got the notifications a few times for unknown technical reasons. One participant dropped out of the study due to perceived distress caused by the questions.

Performance

While most users rated the quality of the questions specially designed for the observational FS study as “fine,” there were some complaints. A few participants said that they had problems rating their experiences, and others criticized the questions as vague. A few users felt that there were not enough possibilities to answer, especially an option to answer “not at all” was missed. Some users felt that the questions did not fit their symptoms or experiences. In addition, a few participants were unsure about the meaning of some words: “I did not know, what Fatigue is. [...] And after I googled it, I was still unsure whether I had answered it correctly” (translated from German). One participant felt burdened by answering the questions:

> *At some point I said I didn’t want these questions anymore, I felt really bad about it. So for me, such questions don’t work, they also have to be positive. It’s a bit of a self-fulfilling prophecy, in that I always*

XSL•FO
RenderX

> *ask [myself] negative questions. So, I really found that I felt really, really bad afterwards.* [Translated from German]

Many participants found the questions boring or not well-suited to their situation, as they experienced little variation in their symptoms.

Some participants reported not liking the speech function researchers designed for the observational FS study, as they were unsure what to talk about or were embarrassed talking about their day: "I didn't know exactly how precise I was supposed to talk about that" (translated from German). Other participants reported feeling silly while performing the speech tests:

> *The only thing I didn't quite understand was that in the evening you either had to say "papapam" all the time or say "A" for a very long time and I didn't quite understand the point of that, but I'm sure there's a reason for that. [...] I just thought it was a bit silly.* [Translated from Dutch]

Some users pointed out that it was hard to stay motivated to answer the questions: "They were virtually the same questions. You just got fed up with them." On the other hand, some users reported that they enjoyed monitoring their own data:

> *Comparing the beginning of the day to the end of the day [...]. And then looking at how I slept the night before. So, yeah, I enjoyed doing that part.*

A few participants reported that they benefited from using the app, as it raised their awareness of their feelings and symptoms: "I found that very informative to me, to actually stop and think [...]. It was thought-provoking." Another participant said:

> *I actually didn't think the questions were bad at all, because you first had to deal with the question, 'How am I actually doing in this area today?' at that moment. And I also noticed how it changes during the day. When you are tired in the evening, you click on completely different values than in the morning when you have had a good night's sleep.* [Translated from German]

Effort or Ease of Use

Many participants agreed that answering the questions was quickly done, though some still perceived the effort as high. This was mainly due to the number of times it came as a part of study design or because they had to keep 2 phones with them: "If I were going out, having to take two phones out with me [...] was a bit of a nuisance."

While many users were comfortable with the apps' use frequency, a lot of participants found it too frequent. Many users were unable to respond consistently, and some described the timing of the app interactions as incompatible with their daily schedules: "It's a burden for the fixed time that's involved in those things. I've missed [answering the questions] a number of times, because you're in a meeting or whatever" (translated from Dutch), reported one participant.

Using the app was described as easy by most participants. Some users reported problems with opening the app, which could only be done using the notifications on the phone: "That is a bit hidden. You have to scroll down first. I actually didn't find it at first" (translated from German), reported one participant.

A few users reported problems with setting the time with a dial. Most reported not using the reminder function, though some found it quite useful. Some mentioned that remembering to answer the questions was bothersome. Others felt bothered by the reminder.

While most participants did not feel disturbed by using the app, some reported that it disrupted their schedules. "To a certain extent, it almost drove your day," reported one user. It was perceived as more disturbing at work, as there was not always time to use the app: "When I'm at work, in the car or on my bike, I can't just open the app and [answer the questions], so sometimes you get [...] a kind of guilty feeling, those kinds of negative feelings" (translated from Dutch).

There were some technical problems reported with the symptom tracking app. Some participants received the notifications not often enough or not for the whole period—not knowing why. Two users reported not getting any notifications at all. Others reported the questions to be in a mix of English and German: "The questions [were] only in English, it took a few days until we had it [in German]" (translated from German).

Social Influence

While no participants reported concerns regarding reactions by their peers, many said that they avoided answering questions when in company, running errands, or working: "When you are in the car or somewhere in a store, you can't just start taking your phone out" (translated from German). There were no reports about concerns regarding data privacy.

Facilitating Conditions

There were some insecurities mentioned regarding the symptom tracking app. As mentioned in the performance section, some users were unsure what to include during the speech function. Some participants were unsure how long after the scheduled time point they could still respond, which led them to miss some questions. A few suggestions to improve the study design and app use were to personalize the timing of the notifications, increase the time frame, or indicate how long the time frames were. Many participants would have preferred getting the questions less often. Others said that there should be the possibility to go back to correct their inputs. While some users said that the app could be used following the same schedule for a longer time, others said that they would not like that, or that it would only fit for people with more severe symptoms.

Cognitive Test App

Overview

Most participants used the cognitive test app, though some users stopped during the NBX. Others reported that they did not always have time for the tasks. One participant did not use the app.

XSL•FO
RenderX

Performance

Regarding the PVT and DSST, most participants felt positive and motivated. “I enjoyed those little quiz things,” reported one user. A few participants disliked the PVT and described it as boring: “The first one got a bit laborious because you’re doing the same thing all the time.” In contrast, the NBX was disliked by most participants. Many found it too hard, which led to frustration or annoyance. “I just said, I got two right, I thought they’d be thinking I’m the village idiot here. [...] The [NBX] was by far the most frustrating,” said one participant. They reported feeling unmotivated, as they did not see any improvement: “But to actually not feel as if [...] this was really achieving anything. You got to the stage sometimes where you just said, well, I’m just going to press a button.” Only a few participants reported liking this task, seeing it as challenging or fun.

Some participants commented that they would have liked feedback on their performance, which might have improved motivation: “If it would show afterwards whether you had gotten better or worse, or whether that was depending on the time of the day, that would have interested me” (translated from German).

A few participants reported feeling like they benefited from the tasks and could use them for training and getting better. Others reported not feeling any training effect: “I’m not under the impression that I got faster or more experienced [...]. Consistent, probably age-appropriate, I think” (translated from German).

Effort or Ease of Use

Most participants agreed that it was not too much effort, though some said that the tutorial for new tasks was too long. While most participants agreed that the frequency of using the app chosen for the study was appropriate, some reported to have missed a few tests. Other users mentioned that the times were not fitting to their schedules.

Participants generally found the app easy to use. They liked the design as a chat: “It’s a nice way of being greeted: ‘Hello, are you ready for your next exam,’ and concentrate, and off you go. That’s all you have to do,” said one user.

Some participants reported disruptions to their daily routines, as they sometimes had difficulty fitting the app’s scheduled assessments into their workday, especially when tasks required concentration: “You really have to go into the corner, because during the day, when you’re at work, you can’t really do it” (translated from German).

Some technical problems with the app were mentioned. For a few participants, the notifications did not come regularly twice a day, but only once or only at the beginning of their trial period. In other cases, not all tasks were available. A few users had problems solving the tasks because another app notification covered a part of their screen.

Social Influence

No participant reported having concerns regarding data privacy. One user stated:

> *That sort of thing crosses your mind but obviously, the paperwork you’re given beforehand tells you how it’s going to be stored, who will have access, whether it’s being anonymized. [...] If I participate in some sort of medical research then [...] I expect it to be absolutely fine.*

Nobody mentioned any reaction of peers.

Facilitating Conditions

Some participants reported feeling insecure whether they understood the instructions for the third task correctly. While some participants found the instructions sufficient, others felt that the instructions for the last task were vague. Regarding optimization, a few suggestions were made. Some participants suggested to make the NBX easier. Others reported wanting more variety in the tasks: “I would like to have more variety. So, maybe today like this and tomorrow like this, or maybe sometimes more difficult and sometimes easier, so that you are a bit [more] motivated” (translated from German), suggested one participant. While some study participants did not want to use the cognitive test app longer following this study-specific schedule, others reported that they would have liked to do more tasks.

Discussion

Principal Findings

This study considers the technology acceptance of 2 different apps in the context of the IDEA-FAST FS. We interviewed participants who used a symptom and activity app as well as a cognitive test app over 4 weeks. Using the UTAUT [13] model, we identified different themes of technology acceptance in the use of these apps.

For the users, performance played a less crucial role in technology acceptance, whereas the aspect of effort gained importance. Both facilitating conditions as well as social influence seemed to play minor roles in the acceptance of the apps.

Performance

When users expect an mHealth app to be helpful to them, they show more willingness to use it [1,6,16]. This perceived usefulness has been shown to be a good predictor for the intention to use mHealth apps [17,18,21,23]. In this study, the apps did not provide an apparent impact on the participants’ health. Therefore, motivation and adherence to the schedule were issues with both apps. Some participants did not see value in answering the questions of the symptom tracking app and saw it as a burden, while others enjoyed the opportunity to track their behavior and symptoms. The cognitive test app varied in popularity among participants. Some users found the PVT boring, but it was well liked by most, as was the DSST. However, many participants disliked the NBX, found it too hard or frustrating. This led to compliance problems, such as randomly clicking through the test, ignoring or missing scheduled sessions, or ceasing to answer it altogether. A possible reason for this could be that the task was developed for healthy users. The cognitive impairments of participants with Parkinson

XSL•FO
RenderX

disease and Huntington disease, along with the relatively high average age of the sample, contributed to the task being perceived as too difficult. As a result, the task was adjusted during the FS. However, since the adjusted NBX was still perceived as too difficult, it was not included in the subsequent clinical observation study.

An important aspect of motivation for participants seemed to be feedback on their data. While not many participants reported interest in the results from the symptom tracking app, those who enjoyed the app used it as a tool to track their behavior and symptoms, especially fatigue. Possibly, these were patients who were concerned about their fatigue before joining the study. In contrast, many participants voiced a wish for feedback from the cognitive tests. Feedback could help increase motivation if participants were able to see their performance over time. If an mHealth app itself does not seem inherently helpful to the user, feedback might serve as a useful way to engage them. At the same time, feedback could be considered as an intervention, which researchers might wish to avoid. Feedback can be a helpful or interesting resource users can gain from their app use.

Effort or Ease of Use

People tend to use mHealth apps they perceive as easy to understand and to use. This effect has been shown in previous studies [1,6,16,18] and can be observed here as well. While users agreed that the apps did not take too much time, the frequency of use required by the study design was more problematic. Especially having to use the apps at specific time points was seen as disruptive and led to missing data. The 2 apps described in this study had to be used several times per day. Even though the sessions were short, these numerous sessions meant a considerable amount of extra effort, especially since the participants had to adhere to certain time constraints. It was not surprising that almost all participants reported they had not been able to attend all sessions, especially those who were more active or working. Participants suggested adjustable time frames as a solution to account for differences in daily routine or to find individual times they would be able to handle the apps, which should be considered by the clinical team to find a compromise between the patient's needs and study goals. When choosing an app for a scientific study, it is beneficial if it is available for all common smartphone operating systems. Often, participants prefer using their own phone rather than a study phone. Study phones constitute an additional device participants have to familiarize themselves with, charge regularly, carry around, and keep in mind to use. They tend to be forgotten or ignored more easily.

Social Influence and Facilitating Conditions

Both social influence and facilitating conditions did not seem to have significant impact on the acceptance of the apps in this study. An explanation could be the study context. As participants were using the apps without expected impact on their health, it is not surprising that family members and peers did not have specific expectations or motivating sentiments regarding app use. Therefore, opinions of peers seem to have had only a slight impact on their willingness to use the apps. This finding is not entirely inconsistent with the literature, as some studies have found no influence of social influence on the intention to use a technology [20,31]. Other studies have shown that opinions of peers influence the decision to use an mHealth app [21,23]. In the context of study-related apps, social influence may affect the decision to participate in the study rather than the use of the app itself. Another interesting finding was that participants did not voice major concerns regarding data privacy. Data privacy and security have previously been reported as a valid concern for users of mHealth apps [10,16,25,32], though others did not find that privacy concerns predicted intention to use mHealth apps [17,18,21]. As the symptom tracking app gathers quite personal information, concerns regarding data privacy had to be expected. When asked about data privacy, many participants cited trust in the study team and medical data security standards as reasons to feel safe.

Regarding facilitating conditions, salient factors such as costs for the use of mHealth apps or availability [16,23,33] were not an issue in this case. Both apps as well as study smartphones were provided for the participants. It seems that the provided support in the form of instructions and the study team was sufficient for most participants to feel confident about the correct use of the apps. There were some uncertainties concerning the symptom tracking app, like not knowing what to report using the speech function and not knowing how much time there was for answering the questions. Facilitating conditions have been found to be very influential on the intention of using a technology in several studies [1,33], while others did not find a connection [6]. It seems probable that due to the high amount of support and lack of limiting factors, the positive impact of facilitating conditions on the use of the apps was present. This assumption is supported by the fact that many participants stressed the good support during the study and voiced their appreciation for the study team.

Some aspects of these apps were controversial among participants. While many participants disliked the NBX of the cognitive test app, some voiced their appreciation for feeling challenged by the task. Many participants described the frequent documentation of their well-being as tedious, although some appreciated the possibility to track their symptoms. While studying the opinions and experiences of users is a valuable tool to ensure acceptance, users have different desires and needs. In choosing suitable mHealth apps, one size will most certainly not fit all. While some aspects of these apps are necessary for study success, such as the documentation in the symptom tracking app, others might be customizable. An example is the reminder function of the symptom tracking app, where users can decide for themselves if they want to be reminded or not.

Limitations and Strengths

Limitations and strengths of this study align with those previously described [27]. In short, due to the design of the study, participants used multiple devices as well as the mHealth apps at the same time, which might have influenced their opinions. Due to the different number of interviews in each group, disease-specific aspects might not have been entirely captured. In addition, the COVID-19 pandemic might have had an influence on the acceptance of the 2 apps, since participants were partly living in lockdown or had altered their normal

XSL•FO
RenderX

routines. We are also aware that these qualitative interviews primarily reflect app modifications made specifically for this FS, including support provided by the clinical team. Thus, the findings cannot be generalized to the assessment of app use in different contexts. The results represent the experiences of the FS participants with the apps implemented in a specific study with its own design choices. The requirements of apps can be different, depending on their context of use.

This study represents the opinions and voices of a large and diverse sample on the acceptance of 2 mHealth apps with different aims and uses. This enables us to draw conclusions, which might also be useful for other studies planning to use mHealth apps, as well as help in the development of new apps. Conducting these interviews during the duration of the FS helped us to improve and select suitable apps for use in the clinical observation study. As described earlier, the NBX of the cognitive test app was adjusted to fit better to the study population. Its use was discontinued for the clinical observation study. Our experience underlines the importance of involving users and patients in the development and design of mHealth apps in order to achieve a user-friendly and meaningful result [11].

Recommendations

The choice of appropriate mHealth apps for a research project can be a challenging decision to make. The efficacy of any data collection app is contingent upon the extent to which its users actually use it. Consequently, when developing or selecting an mHealth app for a research project, it is essential to consider technology acceptance. The effort expended by the user should be considered as an integral component of the evaluation process. The ideal app is one that is straightforward and intuitive to use [24]. Patients will have divergent preferences regarding the impact of the study on their lives. Consequently, the integration of customizable features, where feasible, may enhance technology acceptance. These may encompass adjustable reminder functions, time points, and time frames for use of the app. The minimization of user effort is also relevant to the decision regarding the use of study phones. Many patients may prefer their personal smartphones as opposed to designated study phones. Therefore, ensuring that the app is available for all common smartphone operating systems might be beneficial [23]. The necessity of carrying 2 phones is thus eliminated, and the potential for patients to forget the phone at home and miss vital data is also minimized. Evidently, the time expended in using the app constitutes a significant proportion of the overall effort involved. Most cognitive testing and symptom tracking apps require patients to use them for a fixed period of time. Should this be required on a daily basis, or several times per day at designated times, it would necessitate a significant degree of effort. To minimize effort, it is vital to keep the required app time as short and infrequent as possible.

Considering the role of performance in technology acceptance, the pivotal question pertains to the extent to which the technology benefits the patient. The use of cognitive testing and symptom tracking apps within the context of research studies may not necessarily result in tangible health benefits for the patient. This is particularly relevant in cases where apps are used over an extended period of time. In such cases, consideration should be given to alternative factors of motivation. These elements may include gamification mechanisms or feedback on data in noninterventional studies. In the context of cognitive testing apps, the motivational factors of enjoyment and challenge can be leveraged. A task that is perceived as too easy may quickly become tedious to the user, while those that are too challenging may result in demotivation over time. The process of identifying an appropriate level of difficulty for the target population can be a difficult yet rewarding endeavor.

The role of social influence in the technology acceptance of mHealth apps in the context of medical studies may be less significant. It is possible that the opinion of significant others may influence patients' decisions regarding participation in the study, thereby reducing the impact of social influence during the actual use of the apps. Data security could be a cause of concern for patients. The provision of information regarding data security measures during the recruitment process is therefore a valuable use of time [25].

Some salient factors that are typically considered facilitating conditions of technology acceptance, such as costs or availability [23], are typically negligible in the context of medical studies. Nevertheless, the pivotal role that technical and organizational support play in facilitating patient compliance has to be taken into account. The provision of adequate instructions and support should be considered a prerequisite [21]. The establishment of positive relations between patients and the study team can be a significant motivating factor, as well as enhancing satisfaction with the study itself.

Conclusions

This study describes the technology acceptance of 2 mHealth apps. The primary objective of this study was to assess the usability of these apps in a follow-up investigation. As part of a larger evaluation study, potential issues were identified. They include demotivation due to the level of difficulty experienced with one of the cognitive tasks and challenges with adhering to the stipulated time schedule for the symptom tracking app. These issues were addressed through a variety of approaches. For instance, the challenging task was set aside for use in the follow-up. To support adherence, time points were limited to those essential for the study's success while allowing as much flexibility as possible. The second objective of this study was to assess the specific challenges researchers encounter when selecting suitable mHealth apps for their own research, and what characteristics an app must possess to be considered a useful tool for health research. The incorporation of patient perspectives in the device selection process has been demonstrated to be beneficial and valuable. The findings of this study provide a valuable contribution to the field of medical research by offering insights that may inform the selection of appropriate mHealth apps. The study emphasizes the importance of effective communication and testing of all materials used in conjunction with patients and intended users prior to the commencement of research studies.

Acknowledgments

The authors would like to thank the participants for their time and contribution to the feasibility study and the interviews. In addition, the authors would like to thank the IDEA-FAST (Identifying Digital Endpoints to Assess Fatigue, Sleep and Activities of Daily Living in Neurodegenerative Disorders and Immune-Mediated Inflammatory Diseases) consortium, consisting of Newcastle University, University Medical Center Schleswig-Holstein, University of Brescia, Erasmus University Medical Center Rotterdam, University of Glasgow, University of Limerick, ECRIN European Clinical Research Infrastructure Network, Queen Mary University of London, Imperial College London, Byteflies NV, DREEM, University of Cambridge, Lixoft SAS, Asociación Parkinson Madrid, Stichting MLC Foundation, TMF eV, Medibiosense Ltd, empirica GmbH, FCiências.ID, Pluribus One Srl, Instituto de Medicina Molecular Joao Lobo Antunes, Teknologian tutkimuskeskus VTT Oy, Cambridge Cognition Ltd, Universidad Autonoma de Madrid, Institut Mines-Télécom, McRoberts BV, George-Huntington-Institut GmbH, Instytut Psychiatrii Neurologii, Medical University Innsbruck, Helse Stanvanger Hf, iXscient Ltd, European Federation of Crohn's and Ulcerative Colitis Association, Leids University Medical Center, University of Manchester, Janssen Pharmaceutica NV, Takeda Development Centre Europe Ltd, AbbVie Inc, AstraZeneca AB, Eli Lilly & Co Ltd, CHDI Foundation, Parkinson's Disease Society of the United Kingdom, Pfizer Ltd, F. Hoffmann-La Roche AG, Sanofi Aventis Recherche et Développement, UCB Biopharma SPRL, Biogen IDEC Ltd, Orion OYJ, and Let it Care.

Funding

The IDEA-FAST (Identifying Digital Endpoints to Assess Fatigue, Sleep and Activities of Daily Living in Neurodegenerative Disorders and Immune-Mediated Inflammatory Diseases) project has received funding from the Innovative Medicines Initiative 2 Joint Undertaking (grant 853981). The Joint Undertaking receives support from the European Union's Horizon 2020 research and innovation program, European Federation of Pharmaceutical Industries and Associations, and Parkinson's Disease Society of the United Kingdom LBG. This communication reflects the view of the authors, and neither the Innovative Medicines Initiative nor the European Union and European Federation of Pharmaceutical Industries and Associations is liable for any use that may be made of the information contained herein.

Authors' Contributions

WFN, WM, JG, and HK conceived the study and were involved in protocol development with KE. WM, WFN, JG, and KE were involved in gaining ethics approval. JG, EW, KD, VM, SA, RR, and JD were responsible for patient recruitment. Interviews were conducted by JG, EW, HK, and VM. Data analysis and the first draft of the manuscript were completed by JG. A detailed revision was done by JD. All authors reviewed and edited the manuscript and approved the submission version of the manuscript.

Conflicts of Interest

RR is the founding director and owner of the George-Huntington-Institute, a private research institute focused on clinical and preclinical research in Huntington disease, and QuantiMedis, a clinical research organization providing quantitative motor services in clinical trials and research. RR served as an elected member of the Steering Committees of the European Huntington Disease Network and the Huntington Study Group, cochair of the Task Force on Huntington's disease, and member of the Task Force on Technology of the International Parkinson and Movement Disorder Society. He has provided consulting services, advisory board functions, clinical trial services, quantitative motor analyses, and/or lectures for Actelion, Alnylam, Amarin, Annexon, AOP Orphan Pharmaceuticals, AskBio, Cure Huntington Disease Initiative Foundation, Desitin, Hoffmann-La Roche, IONIS, Ipsen, Lundbeck, MEDA Pharma, Medivation, Mitoconix, Neurosearch, Novartis, Omeros, Pfizer, Prana Biotechnology, Prilenia, PTC Therapeutics, Raptor, Siena Biotech, Temmler Pharma, Teva, uniQure, Vaccinex, Voyager, Wave Life Sciences, and Zevra. He has received grant support from the Bundesministerium für Bildung und Forschung, the Cure Huntington Disease Initiative Foundation, the Deutsche Forschungsgemeinschaft, the Deutsches Zentrum für Neurodegeneration und Entzündung, the European Union's 7th Framework Program, Horizon 2020 Innovative Medicine Initiative 2 program, the European Huntington Disease Network, the High-Q-Foundation, the National Institute of Health, and the National Science Foundation. NVM is an employee of Johnson & Johnson and may hold company stocks or stock options. WFN provided consultations for Asahi Kasei Pharma, Amgen, Argenx, Bristol Myers Squibb, EQT, IQVIA, Johnsons & Johnsons Innovations, Novartis, Quotients, Resolves Therapeutics, Sanofi & Veloxis.

Abstract

Background: Web-based and mobile phone–based apps have become widely available for dietary self-monitoring; however, their use may increase the risk of disordered eating. College students frequently demonstrate poor nutrient intake despite consumption of sufficient calories. One way to improve diet quality may be via the use of a smartphone app that encourages intuitive eating.

Objective: The purpose of this study was to improve diet quality among college students through the use of a novel smartphone app that promotes intuitive eating rather than calorie counting and weight loss.

Methods: The In2Eat iOS mobile app was developed in SwiftUI and stored user data in a Firebase database. A total of 45 college students completed assessments of intuitive eating, diet quality, and disordered eating before and after 4 weeks of using the In2Eat app. Users evaluated the usability of the app with the System Usability Scale (SUS). Engagement with the app was recorded as the total number of days a meal was logged, the total number of meals logged, and the average number of meals logged per day.

Results: After our 4-week intervention, dietary qualities that protect against chronic disease increased by 28%, fruit consumption increased by 63%, and skin antioxidant levels increased by 6.1% (Hedges g=0.16; mean difference 0.33, 95% bias corrected and accelerated [BCa] CI 0.04-0.61; P=.03). Global intuitive eating did not change during the user study; however, the unconditional permission to eat subscale increased (Hedges g=−0.28; mean difference 0.28, 95% BCa CI 0.07-0.49; P=.01, adjusted P=.07). Overall, disordered eating also did not change with app use, although dietary restraint decreased (Hedges g=−0.23; mean difference 0.30, 95% BCa CI −0.61 to −0.04; P=.04, adjusted P=.22). The average SUS score for the In2Eat app was 67.2 (SD 15.5). The number of days a meal was logged was positively correlated with SUS scores (r=0.28; P=.06), and the total number of meals logged had a monotonic association with app usability (ρ=0.31; P=.04). When divided according to the low (mean 10.2, SD 5.3), medium (mean 26.3, SD 2.8), and high (mean 33.6, SD 3.8) number of days logging meals, participants with higher days of logging reported the app as more usable (H=6.75; P=.03). A regression analysis showed that 8% of the variance in system usability (R^2=0.080; P=.31) was explained by app use; however, none of the individual predictors contributed substantially to the variance.

Conclusions: An intuitive eating smartphone app can improve diet quality without increasing disordered eating. Results suggest that participants who logged more meals tended to rate the app as more usable. Further research is needed with a greater sample size after incorporating features to improve the app's usability.

KEYWORDS

disordered eating; nutrition; college age; intuitive eating; mobile app; natural language processing; recommendations; recipes; physical activity

Introduction

Web-based and mobile phone–based apps have become widely available for dietary self-monitoring, with some incorporating recent technological advances, such as speech recognition for logging meals with voice and computer vision for food image understanding to reduce user burden [1-3]. In our prior work, we developed an iOS app called COCO Nutritionist that used natural spoken language understanding and machine learning to automate mapping of self-reported meal logs to the US Department of Agriculture (USDA) food codes and portion sizes, and we demonstrated in a pilot study that there was no significant difference in 3-day reported energy intake between our method and gold-standard 24-hour recalls [4].

Previous research shows that lifestyle habits developed as a college-aged young adult have a lasting influence on physical health, mental health, and general well-being [5,6]. Despite this, there is ample literature demonstrating inadequate nutrient intake among college students [7,8]. Malnutrition exists when there is a lack of calorie intake (ie, undernutrition) and when dietary intake is excessive. Of particular concern is a high intake of calories lacking in nutritional quality, increasing risk for chronic disease. Vitamin and mineral deficiencies can occur even when the diet is abundant in calories; hence, the need to assess diet quality, not just calorie intake [9]. Diet quality assesses the extent to which a diet has sufficient health-promoting foods to avoid vitamin and mineral deficiencies and protect against chronic disease while avoiding overconsumption of dietary factors that increase risk for chronic disease.

One way to improve diet quality may be via the use of a smartphone app that encourages healthy eating. However, research suggests that use of smartphone apps that track calorie intake is related to disordered eating symptoms [10,11]. Repetitive monitoring of calorie intake may lead to obsessive behaviors, anxious feelings, and unhealthy dietary restrictions. Intuitive eating is a conceptual eating behavior that emphasizes the use of internal cues for hunger and satiety to guide food choices [12]. Preoccupation with food, restriction, and rigidity are commonly observed with disordered eating. However, an intuitive approach to eating encourages achieving satisfaction without overeating by using interoceptive awareness while allowing unconditional permission to eat. The 10 principles of intuitive eating include rejecting diet culture, honoring hunger, making peace with food, discovering satisfaction, feeling satiety, challenging diet “rules,” coping with emotions, respecting bodies, joyful movement, and honoring health [12]. Research has found that the use of intuitive eating principles may counteract disordered eating behaviors [13-16].

The purpose of this study was to improve diet quality among college students via a smartphone app designed to encourage intuitive eating and recommend personalized healthy recipes. We hypothesized that consistent use of our smartphone app over 4 weeks would improve diet quality without increasing disordered eating.

Methods

This paper describes the design, development, and evaluation of, to our knowledge, the first mobile app for automated self-report of dietary intake via natural spoken language that promotes intuitive eating principles.

App Development

The In2Eat iOS mobile app was developed by a team of undergraduate computer scientists at Loyola Marymount University. In the preliminary design phase, 2 other apps were found to promote intuitive eating—MyTummy and MEAL. However, neither of these apps supported the kind of self-reported dietary intake and detailed nutrient information that was common among popular diet-tracking apps such as MyFitnessPal, Noom, and Weight Watchers. In2Eat is unique in that it both supports low-burden diet logging and promotes intuitive eating. Diet tracking is required for improving diet quality, which is our goal and is associated with health and disease prevention. However, our intuitive eating approach aims to avoid fostering disordered eating that can occur with apps that emphasize weight loss and calorie counting [10,11].

In2Eat’s natural language processing technology for easily logging meals with voice or text was originally developed for the COCO Nutritionist research prototype [4]. COCO used machine learning, specifically convolutional neural networks (CNNs), to accomplish 2 tasks: parsing a user’s natural language meal description into foods and quantities and mapping the user’s food descriptions to a matching entity in the validated USDA food database using learned embeddings. The CNN automatically learned semantic vector representations, or embeddings, of the user’s unstructured natural language meal description through a binary classification task where the model learned to detect which pairs of USDA foods and meal descriptions were a match. With In2Eat, the 2-step approach of parsing a user’s meal description, followed by database mapping with embeddings, is still the same, but the implementation now uses large language models (LLMs) for parsing meal descriptions and embeddings from LLMs instead of CNNs.

We built our In2Eat app in SwiftUI and stored user data in a Firebase database. A key component of our intuitive eating design is that the app does not display caloric information and instead focuses on diet quality by reporting consumed macro and micronutrients. In addition, there is a daily push notification with an intuitive eating quote of the day, which is drawn from intuitive eating content that we curated. This intuitive eating quote of the day is also displayed on the main dashboard screen upon opening the app. In2Eat supports food logging via written or spoken natural language, along with a hunger satiety check-in at each meal. Several principles of intuitive eating can be fostered by increasing awareness of feelings of hunger and

XSL•FO
RenderX

satiety before or after eating occasions. Thus, experts coach intuitive eating by using a scale of 0 to 10 to represent primal or painful hunger (as 0) and painfully full or stuffed (as 10) [12]. The macronutrients are shown in a pie chart on the dashboard, and the micronutrients are shown as green, yellow, or red progress bars toward reaching the recommended amount based on the user's sex and weight. The recommended targets were based on the Dietary Reference Intakes established by the Institute of Medicine [17]. In2Eat's recipe book recommends healthy recipes, defined as at least 5 g of fiber and no more than 5 g of saturated fat per serving that align with the user's self-reported dietary restrictions, when applicable. Users can save favorite recipes and search for specific recipes as well as filter by cooking and preparation time, cuisine, price, and allergens. Finally, there is a screen for logging the number of minutes of physical activity, without having to label the type of exercise, which aligns with the "joyful movement" principle of intuitive eating.

Recruitment

College-aged adults were recruited via flyers and classroom announcements at a primarily undergraduate institution in an urban setting. Advertising flyers were specifically placed on the walls in the on-campus food pantry, which is available for access 24 hours a day, 7 days per week. Inclusion criteria included being aged 18 years or older and having access to an iOS smart device.

A total of 47 volunteers enrolled in the study; however, 2 (4.3%) were lost to follow-up because they did not use the app and were unresponsive when attempting to schedule follow-up testing. Therefore, 45 (95.7%) participants were included in this analysis. At the time of enrollment, participants completed several online questionnaires and came into the laboratory for measurements of height, weight, and skin antioxidant levels. During the first laboratory visit, participants downloaded the In2Eat app onto their smart device and were given brief instructions on how to use the app. Volunteers were instructed to use the app for the next 4 weeks. After 4 weeks of app use, participants repeated the online questionnaires, as well as height, weight, and skin antioxidant level assessments. Incentives of US $50 grocery store gift cards were provided to participants who completed the baseline and follow-up testing sessions.

Measures

System Usability

The System Usability Scale (SUS) was used at follow-up to assess the app's usability on a scale from 0 to 100. The average SUS score is 68, with 68 through 80.3 considered good and greater than 80.3 considered excellent [18,19]. The instrument consists of 10 questions (eg, "I thought the app was easy to use"), each with 5 options ranging from strongly agree to strongly disagree.

App Use

To investigate the relationship between app engagement and perceived usability, we computed 3 use metrics: LogCount (total number of days a participant logged at least 1 meal), TotalMealsLogged (total number of meals logged throughout the study), and AvgMealsPerDay (mean number of meals logged per day, calculated as TotalMealsLogged divided by LogCount). These metrics capture both breadth and depth of engagement with the app.

Intuitive Eating

Intuitive eating was assessed using the Intuitive Eating Scale version 3 (IES-3) established for reliability and validity [20]. Possible results for the IES-3 range from 1 to 5 with higher scores indicating greater intuitive eating. Scoring the survey provides an overall global score for intuitive eating as well as scores on 4 subscales: unconditional permission to eat, reliance on hunger and satiety cues, eating for physical reasons, and body food choice congruence.

Disordered Eating and Mental Health

The Eating Disorder Examination Questionnaire (EDE-Q) was used to assess disordered eating patterns. This validated and internally consistent questionnaire provides a global disordered eating score and 4 subscales for dietary restraint, eating concern, body shape concern, and weight concern [21,22]. Dietary restraint reflects a tendency to consciously restrict or limit dietary intake. Eating, body shape, and weight concern are subscale scores that reflect an unhealthy preoccupation or worry with these features of the diet or body. The EDE-Q results range from 0 to 6, with higher scores indicating greater disordered eating. Volunteers were also asked to complete the Kessler Psychological Distress Scale (K10) with 10 prompts, scored from 1 to 5 and summed. Results from the K10 range from 10 to 50 with higher scores indicating severe mental disorder [23,24].

Diet Quality

Volunteers submitted the Diet Quality Questionnaire (DQQ), which is validated for use by adults in more than 100 countries [25]. This categorical survey uses food group indicators to calculate how well the diet achieves a global dietary recommendation (possible scores range from 0 to 18) and the degree to which dietary intake on the previous day protects against noncommunicable diseases (NCD-Protect, possible scores range from 0 to 9) and increases risk for noncommunicable diseases (NCD-Risk, possible scores range from 0 to 9). The DQQ also quantifies the proportion of the study group who ate at least 1 serving from all 5 of the food groups recommended in global food-based dietary guidelines (vegetable, fruit, pulse, nuts and seeds, animal-source food, and starchy staple). Diets of high quality also exhibit diversity; thus, the dietary diversity score ranges from 0 to 10 to reflect the average score for the study group, with a higher score indicating the presence of more food groups. Finally, the DQQ quantifies the proportion of the study group who consumed at least one fruit and one vegetable on the preceding day. Data from our investigation were compared against results collected from adults in the Global Diet Quality Project between 2021 and 2023 [26].

As an objective measurement of diet quality, antioxidant levels in the skin were evaluated using a handheld spectrophotometer (Konica Minolta CM-700d). More specifically, fruits and vegetables contain carotenoids that act as antioxidants to reduce

XSL•FO
RenderX

inflammation and cell damage [27]. Carotenoids, and specifically β-carotene, present as a yellow color and typically absorb light in the 450-nm frequency [28]. A spectrophotometer can be used to measure light reflection at specific wavelengths as an indicator of carotenoids, and therefore fruit and vegetable consumption. Using a previously documented noninvasive approach, we recorded the tristimulus b* value at the 450-nm frequency to assess carotenoid levels in the skin [29]. After daily calibration, the thenar eminence of the palm of the hand for each participant was scanned twice with the spectrophotometer. An average of the 4 scans was calculated and used for statistical analysis. As carotenoids are found in fruits and vegetables, measuring skin carotenoid levels is an accurate and less invasive measurement of dietary intake compared with self-reported data or blood tests.

Food Security

Much research has suggested that food security is directly related to diet quality [30]. Thus, we used the USDA Food Security Survey to assess whether our participants had limited or uncertain availability of nutritionally adequate foods [31].

Statistical Analysis

We examined associations between these metrics and SUS scores using correlation and regression analysis. Correlation (Pearson and Spearman) and ordinary least squares regression were conducted using Python (version 3.11; Python Software Foundation) with the Pandas, SciPy, Seaborn, and Statsmodels libraries. To assess the combined predictive value of use behaviors, we included all 3 use metrics as predictors in the regression model. Paired sample, 2-tailed *t* tests were performed using SPSS software (version 29; IBM Corp) to evaluate differences between variables at baseline and after 4 weeks of app use. Bootstrapping was performed with 5000 samples and bias corrected and accelerated (BCa) CI were calculated. Cohen *d* and Hedges correction were calculated as measures of the effect size. The Holm-Bonferroni adjustment was made to correct for multiple comparisons. Assumption testing was performed for outcomes yielding statistically significant results using the Shapiro-Wilk test and Q-Q plots. Where the normality assumption did not hold, a Wilcoxon signed-rank test was conducted as a sensitivity analysis. Missing data were excluded.

Ethical Considerations

Participants were fully informed of the study protocol and provided written informed consent before enrolling. This study was approved by the Loyola Marymount University Institutional Review Board (protocol number 2024FA16-R) according to the Declaration of Helsinki. Participants were assigned an identification number to protect privacy and ensure confidentiality.

Results

Overview

Demographic data for the 45 participants who completed the study are displayed in Table 1. This college-aged group was made up primarily of female participants (n=33, 73.3%) from diverse ethnic and racial groups, with approximately half living on campus (n=22, 48.9%) and using the campus-offered meal plan (n=24, 53.3%). Of the 45 participants in the study, 5 (11.1%) reported low (n=4, 8.8%) or very low (n=1, 2.2%) food security at baseline and follow-up. Food security measures did not correlate with intuitive eating, disordered eating, or diet quality in this population.

System Usability

The average overall system usability score for the In2Eat app at the end of the 4-week pilot study was 67.2 (SD 15.5), which is similar to the commonly cited SUS benchmark score of 68 [18,19]. As shown in Figure 1, the questions with the highest scores were those concerning ease of use, specifically that users thought people would quickly learn to use the app, the app was very easy to use, and they felt confident using the app. By contrast, the questions with the lowest scores were those related to not finding the app cumbersome to use, wanting to use the app frequently, and not finding too much inconsistency or complexity in the app.

XSL•FO
RenderX

Figure 1. System Usability Scale (SUS) scores for each of the 10 survey questions, ranging from the lowest score of 1 (“Strongly disagree”) to the highest score of 5 (“Strongly agree”).

App Use

Figures 2 and 3 visualize the associations between system usability scores and app use using both scatterplots and group-wise boxplots. Pearson and Spearman correlations showed modest and mostly nonsignificant associations between use metrics and SUS scores. LogCount was positively correlated with SUS scores (Pearson r=0.28; P=.06), though this did not reach conventional significance. Notably, TotalMealsLogged had a statistically significant monotonic (but not linear) association with SUS scores (Spearman ρ=0.31; P=.04), suggesting that participants who logged more meals tended to rate the app as more usable.

Table 2 presents descriptive statistics for app use across the full study sample as well as within low, medium, and high use groups (tertiles based on LogCount). As expected, participants in the high use group demonstrated consistently greater engagement across all metrics compared with those in the medium and low use groups. Specifically, high use users logged meals more frequently, entered a greater total number of meals, and maintained a higher average number of meals logged per day. The medium use group showed intermediate values across all engagement metrics. These results confirm a clear separation between groups, capturing both the breadth and intensity of app engagement across the cohort.

Tertile grouping was used to provide an interpretable comparison of usability across distinct levels of engagement (low, medium, and high) and to examine potential nonlinear patterns in the relationship between app use and perceived usability that may not be captured by correlation analyses alone. In addition to group-based comparisons, we report both Pearson and Spearman correlations between use metrics and SUS scores. These analyses showed modest associations, with a statistically significant monotonic relationship observed between TotalMealsLogged and SUS scores (Spearman ρ=0.31; P=.04), indicating that greater meal logging was associated with higher perceived usability.

We further explored differences in usability scores across low, medium, and high use groups (tertiles based on LogCount). A Kruskal-Wallis test revealed a significant difference in SUS scores across LogCount groups (H=6.75; P=.03), indicating that participants with higher day-level logging frequency perceived the app as more usable. No substantial group differences were observed for TotalMealsLogged or AvgMealsPerDay.

Finally, we performed an ordinary least squares regression, including all 3 use metrics as predictors of SUS scores. The overall model explained only 8% of the variance (R^2=0.080; P=.31), and none of the individual predictors were statistically significant. While LogCount had the largest coefficient (β=.55), its contribution was not statistically robust (P=.31). These results suggest a trend toward more consistent engagement being associated with higher usability ratings, but the effect sizes are modest and should be interpreted cautiously given the limited sample size.

XSL•FO
RenderX

Figure 2. Relationship between app use metrics and perceived system usability. Each panel shows a scatterplot with a linear regression line, comparing (A) the total number of days users logged meals (LogCount), (B) the total number of meals logged, and (C) the average number of meals per day with the System Usability Scale (SUS) scores. Across all 3 use metrics, greater engagement with the app tended to be associated with higher perceived usability.

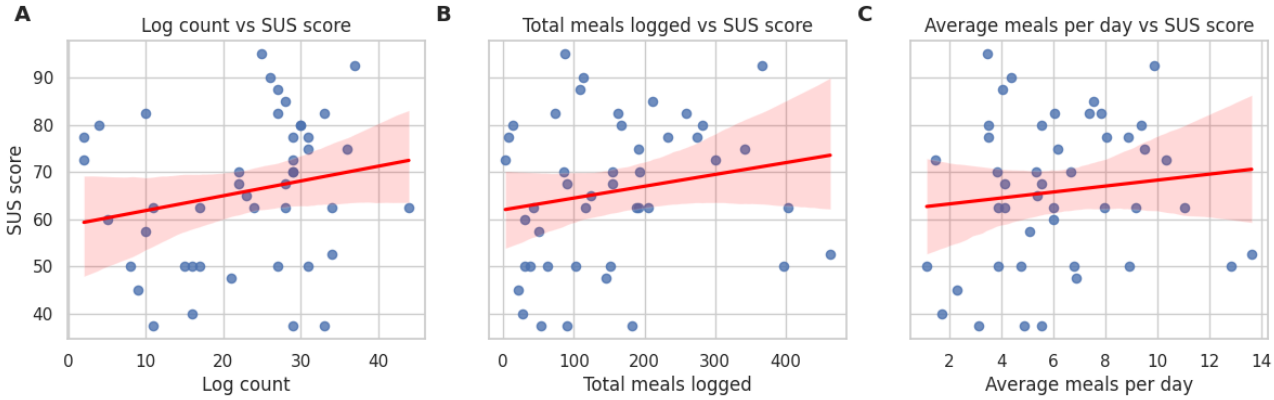

Figure 3. Distribution of System Usability Scale (SUS) scores grouped by use level (low, medium, and high) for each app engagement metric. Participants with higher app use more frequently reported higher usability scores, particularly those with higher LogCount values.

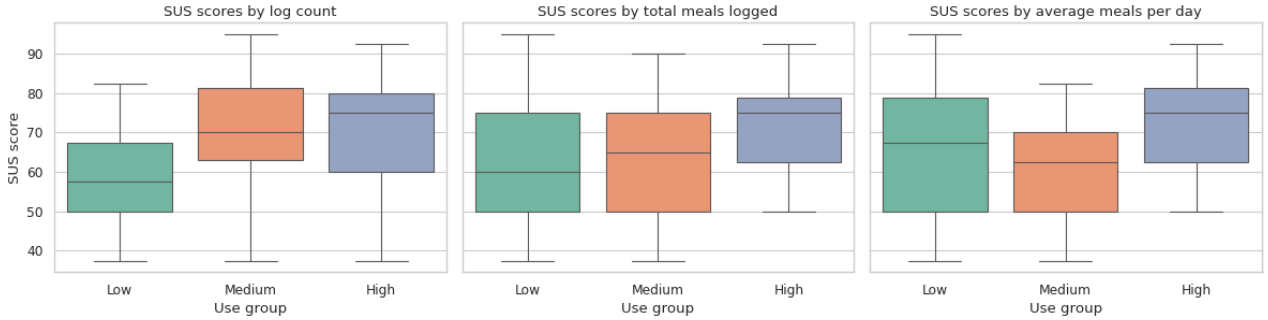

Table 2. App use metrics among the 45 participants overall and by group.

Use metrics	Overall, mean (SD)	Low, mean (SD)	Medium, mean (SD)	High, mean (SD)
LogCount	23.11 (10.34)	10.2 (5.28)	26.28 (2.76)	33.62 (3.8)
TotalMealsLogged	157.09 (115.43)	57.8 (52.95)	144.17 (64.41)	289.54 (96.13)
AvgMealsPerDay	6.19 (2.85)	5.02 (2.66)	5.45 (2.2)	8.57 (2.59)

Intuitive Eating

The global score for intuitive eating did not change after 4 weeks of using the In2Eat app (Table 3); however, the unconditional permission to eat subscale of the IES-3 did increase significantly (P=.01), though with a small effect size (Hedges g=−0.28) and not after Holm-Bonferroni adjustment to control for type I error across related outcomes with multiple comparisons (adjusted P=.07). Normality assumptions were met.

Disordered Eating and Mental Health

Internal consistency at baseline was excellent for the EDE-Q scale ($\alpha=0.95$) and the K10 ($\alpha=0.89$). Baseline and follow-up assessments of disordered eating via the EDE-Q revealed no major changes during app use, except for dietary restraint which decreased significantly ($P=.04$), though with a small effect size (Hedges $g=-0.23$) and not after Holm-Bonferroni adjustment to control for familywise error (adjusted $P=.22$). For dietary restraint, the normality assumption did not hold due to an S curve in the Q-Q plot and the Shapiro-Wilk test result ($P<.001$); however, the Wilcoxon signed-rank sensitivity analysis ($P=.03$) confirmed the finding, indicating that the result was robust to nonnormality.

Diet Quality

Diet quality among app users also appeared to improve during the study (Table 4). Dietary features that are known to protect against noncommunicable diseases (NCDs) increased by 28%, while there was a negligible decrease (4%) in dietary features that increase the risk for NCDs. Of particular note is the 63% increase in fruit consumption during the app intervention. Furthermore, paired *t* tests (N=47) revealed a significant increase in skin antioxidant levels ($P=.03$) with a small effect size (Hedges $g=0.16$).

We additionally examined whether outcomes differed between students living on campus and those living off campus. No significant differences were observed between groups across all primary outcomes, including diet quality (global dietary recommendation score, NCD-Protect, and NCD-Risk), intuitive eating (IES-3), disordered eating (EDE-Q), and skin antioxidant levels (all $P>.05$). Similarly, SUS scores did not differ between groups ($P=.36$). These findings suggest that residential status did not meaningfully influence study outcomes.

Qualitative Feedback

We collected qualitative feedback from 17 study participants via a Qualtrics survey to inform future strategies for improving the app and to investigate why participants did not frequently use the app despite the monetary incentive. The survey asked 2 free-response questions, one about why they may not have used the app often, and the second about how we could improve the In2Eat app. The final question asked them to select which of 12 hypothetical new features would make them more likely to use the app more often. As shown in Figure 4, by far the most popular new feature was computer vision—13 (76.5%) out of 17 respondents selected the ability to log photos of their meals, and 12 (70.6%) selected the ability to take a photo of a nutrition facts label.

Patterns emerged from the free-response questions as well. Four (23.5%) respondents each mentioned forgetting to log meals and that reminders would be helpful, that they would like incentives or rewards for logging meals, and that the data entry was too time-consuming and/or annoying. Three (17.6%) respondents each mentioned wanting computer vision; worries about their own logging precision, especially portion size, as well as the accuracy of the app itself; and the app missing foods, including non-American cuisines. Other feedback included speeding up meal logging with “quick add” of common foods or meals; making the interface more interactive, visual, and informative; adding a social tab to see friends; helping them to track and achieve their nutrition goals; and adding a barcode scanner. This qualitative data analysis strongly supported our current work on incorporating computer vision as well as gamification features (ie, incentives, goals, and friends).

Discussion

Principal Findings

The overarching goal of this study was to investigate whether the use of a mobile phone app that promotes intuitive eating principles (through hunger satiety checks at each meal and push notifications with daily intuitive eating quotes of the day) would improve diet quality, without increasing disordered eating symptoms as often occurs when using other diet-tracking apps [10,11]. Our results from a 4-week user study with 45 college students demonstrated that diet quality improved, as measured by a significant increase in skin antioxidant levels [27], a 63% increase in fruit consumption, and a 28% increase in dietary features known to protect against NCDs. Compared with data reported for American adults, a smaller proportion of our college-aged participants consumed all 5 food groups, 1 fruit, 1 vegetable, and showed a lower dietary diversity score. On a positive note, the global dietary recommendation score for our population was above the national average for US adults, while the NCD-Protect score became closer to the national average after 4 weeks of app use. Notably, the NCD-Risk score among our participants was lower than national norms, indicating a diet with fewer contributing factors to disease. The unconditional permission to eat subscale of the intuitive eating IES-3 increased significantly. Finally, unlike existing diet-tracking apps, ours did not increase disordered eating; rather, for every disordered eating metric, the mean slightly decreased after the intervention, and there was a significant decrease in dietary restraint. However, due to the small sample size, the effects were small, and Holm-Bonferroni adjusted *P* values were not significant.

Strengths

This work has several strengths. First, our study is the first intervention that we know of to provide a validated alternative to the expensive and time-consuming current approach of working one-on-one with a registered dietician, without the harm caused by most apps that emphasize weight loss and calorie counting. Second, our results demonstrated significant improvement in diet quality after a 4-week intervention using our app. Improved diet quality is associated with health promotion and disease prevention. Finally, our research used validated measures of intuitive eating, disordered eating, and psychological distress, as well as robustness checks, including bootstrapped CIs and nonparametric sensitivity analyses to strengthen confidence in the findings.

Comparison With Prior Work

Prior work demonstrated the accuracy of logging meals via natural language within a mobile app [4] and showed that the use of intuitive eating principles may counteract disordered eating behaviors [13-16]. Our work builds upon this literature by investigating the use of a new mobile app that not only allows users to log meals with natural language but also promotes intuitive eating principles and asks users to log their hunger satiety.

Limitations

Limitations of the study include the small sample size (n=45), which resulted in small effect sizes, and the lack of diversity because we only recruited college students, who have been shown in prior work to have inadequate nutrient intake [7,8]. Another limitation is the wide range of app use, resulting in study participants who did not use the app often despite the monetary incentive. Other limitations include the lack of a control group, the inclusion of participants with eating disorders and medically supervised diets, and the absence of socioeconomic data.

Future work on In2Eat will focus primarily on improving the app's usability and engagement, as well as incorporating more intuitive eating features. On the basis of feedback from our study participants, we are currently adding computer vision and nutrition facts label scanning so users can more easily log their meals with photos of meals or nutrition facts labels. We are also adding tooltips with explanations for each nutrient and more

XSL•FO
RenderX

useful feedback and visualizations, including a detailed analysis after logging a meal and a weekly diet quality score with feedback for improvement. Furthermore, we are expanding from iOS to the Android platform.

Conclusions

To our knowledge, our In2Eat iOS app is the first mobile app to combine diet tracking with intuitive eating, and ours is the first study to demonstrate that the use of a diet-tracking app with a focus on intuitive eating instead of calorie counting improves diet quality without increasing disordered eating.

Acknowledgments

This study would not have been possible without the support of the Seaver College of Science and Engineering at Loyola Marymount University through an interdisciplinary seed grant.

The authors thank undergraduate computer science students Catalina Barnes, Lauren Campbell, Funmilola Idowu, and Ngoc Kim Ngan Tran, who designed and developed the In2Eat iOS app, and undergraduate health and human sciences students Alexis Arle, Gabrielle Besio, Samantha Chuakay Lim, and Cameron Sumaquial, who conducted the user study and analyzed the data. The authors also thank undergraduate computer science student Natasha Cordova-Diba for her preliminary work on the In2Eat website and Riley Kehoe for his assistance with the development of the recipe recommender system.

Abstract

Background: After the emergence of telemedicine as a major health care delivery mode during the COVID-19 pandemic, Sheba Medical Center (SMC) rapidly transitioned its outpatient clinics to telemedicine. A postimplementation satisfaction study revealed that while nearly 90% of patients reported a positive experience, only 38% of clinicians expressed high satisfaction. SMC soon established Sheba BEYOND, a dedicated virtual hospital. This initiative was accompanied by extensive efforts to improve the telemedicine experience. In 2025, a follow-up survey addressing clinician satisfaction and acceptance was conducted.

Objective: This study aimed to explore whether clinician satisfaction improved and which barriers to clinician engagement persisted.

Methods: An anonymous survey was distributed via a link to the staff of SMC's outpatient clinics. The survey inquired about user experience with the telemedicine digital platform, integration in workflow, barriers to use, perceived benefit to patients, and overall satisfaction. Clinicians who never or rarely perform telemedicine visits were classified as nonusers; all others were classified as users. The questionnaire included 21 questions, 2 additional questions for nonusers, and 5 additional questions for users. Overall satisfaction was ranked on a 10-point Likert scale. Descriptive statistics were calculated using SPSS (version 29.02; IBM Corp) and Microsoft Excel. A chi-square test of independence was used for categorical variables. We used a 2-tailed *t* test, with a probability of <.05 considered statistically significant.

Results: The survey was sent to 2735 clinicians, and 274 (10%) responded. Telemedicine users accounted for 52.6% (144/274). Among all respondents, 54.4% (149/274) were physicians, 30.3% (83/274) were paramedical staff, and 15.3% (42/274) were nurses. Clinical specialties across all respondents were internal medicine (36/274, 13%), psychiatry (34/274, 12%), pediatrics (36/274, 13%), oncology (31/274, 11%), and other specialties (137/274, 50%). Compared to the 2020 survey, a 41.9% increase was recorded in the number of users reporting a high level of satisfaction, from 37.7% (61/162) to 53.5% (77/144; *P*=.006). This increase was largely driven by a significant improvement in the oncology clinic, where users reporting a high level of satisfaction rose from 23.3% (10/43) to 63.6% (14/22; *P*=.01). In total, 64.4% (176/274) of respondents believed that telemedicine was advantageous for patient care and 66% (95/144) of users reported that telemedicine reduced their workload. Among the 103 video-visit users who answered the technical feedback questions, 62.1% (64/103) experienced problems in connecting to the patients' network and 32% (33/103) experienced connectivity problems in SMC. In fact, 80.6% (83/103) reported that they had to switch to the telephone at least once. Most of the 98 nonusers (80/98, 81.6%) stated that they did not perform telemedicine because it was mostly clinically inappropriate.

XSL•FO
RenderX

Conclusions: This study demonstrates the positive impact of institutional change management strategy in promoting clinician engagement with telemedicine. However, persistent technical barriers and varying engagement highlight opportunities for refinement.

KEYWORDS

telemedicine; telehealth; health personnel attitudes; clinician engagement; clinician satisfaction; video consultations; implementation barriers; virtual hospital; change management

Introduction

The COVID-19 pandemic catalyzed an unprecedented transformation in health care delivery worldwide, with telemedicine emerging as a vital solution to maintain continuity of care during lockdowns and social distancing mandates [1]. At Sheba Medical Center (SMC), outpatient services rapidly transitioned to telemedicine in early 2020. A postimplementation survey revealed a definite contrast in satisfaction levels: while nearly 90% of patients reported a positive experience, only 38% of clinicians expressed high satisfaction, citing technical challenges, administrative burden, and difficulty integrating telemedicine into clinical workflows [2]. This discrepancy echoed broader global trends observed at the time: a high level of patient satisfaction [3-5] with usability challenges on the clinicians' side [6]. Although these studies examined short-term satisfaction during the pandemic, there is limited evidence on whether sustained institutional change can lead to durable cultural shifts in clinician engagement with telemedicine.

Soon after the onset of the pandemic, the SMC established Sheba BEYOND, a dedicated virtual hospital that launched new telemedicine-based, hybrid care services, including home hospitalization, remote rehabilitation, and chronic patient management. In addition to ensuring continuity of care during the pandemic, Sheba BEYOND was established as part of a broader organizational strategy aimed at improving accessibility to specialist care, reducing geographic barriers, enhancing timeliness and continuity of ambulatory services, and supporting long-term digital transformation through hybrid models of care delivery. This initiative was accompanied by extensive efforts to facilitate clinician engagement and improve the telemedicine experience through the establishment of a video telemedicine helpdesk for technical support, frequent technical upgrades, interoperability improvements, administrative streamlining, and leadership training and incentives for telemedicine adoption.

Between 2020 and 2024, the number of yearly telemedicine visits at SMC more than doubled, increasing from approximately 60,000 in 2020 to >114,000 in 2024. Yearly patient experience surveys have continued to show high levels of patient satisfaction, with minor fluctuations over the years. In 2025, we conducted a follow-up survey addressing clinicians to assess whether the organizational efforts to facilitate telemedicine adoption translated into increased clinician satisfaction and acceptance over time.

Unlike prior studies focused primarily on short-term telemedicine implementation during the acute pandemic phase, this study examines long-term clinician engagement several years later within the context of an institutional virtual hospital framework and sustained organizational change efforts and explores whether the significant increase in telemedicine visits reflects a true cultural shift or if barriers to clinician engagement persist.

Methods

Overview

To assess the experience of telemedicine clinicians, an anonymous survey link was distributed through both text message and email to SMC's outpatient clinic staff. The survey questions assessed users' experiences interacting with the telemedicine digital platform, integration of telemedicine in clinician workflow, barriers to use, perceived benefit to patients, and overall satisfaction and thoughts on potential improvements to the service. Clinicians who reported that they never or rarely perform telemedicine visits were classified as nonusers; all others were classified as users. The questionnaire included 21 questions for all respondents, 2 additional questions for nonusers, and 5 additional questions for users. Three reminders, sent through both text message and email, spaced 1 week apart, were sent to the clinicians who had yet to respond to the survey.

Eligibility

The study did not define formal patient-level inclusion or exclusion criteria, as the survey focused on clinician experience across existing outpatient telemedicine services routinely performed at the institution. Decisions regarding telemedicine appropriateness were made according to specialty-specific clinical judgment and institutional practice.

Surveys

Overall satisfaction was ranked on a 10-point Likert scale [7]. Satisfaction ratings of 8 to 10 were considered as a high level of satisfaction, ratings of 4 to 7 as an intermediate level of satisfaction, and ratings of 1 to 3 as a low level of satisfaction. Responses to operational questions such as ease of use and adherence to appointment schedule were rated on a 5-point Likert scale, with scores of 4 to 5 considered high, 3 considered intermediate, and 1 to 2 considered low. For patient benefit, ratings of 4 to 5 were considered as a high level of support, 3 was considered as an intermediate level of support, and 1 to 2 were considered as a low level of support. Several survey items were adapted from the previously published institutional telemedicine survey conducted in 2020, while additional questions were developed by the investigators to assess workflow integration, operational barriers, and modality-specific experiences [2]. Comparison to the 2020 survey was made only

XSL•FO
RenderX

when questions were similar in the 2025 survey. The questionnaires (translated from Hebrew) are presented in Multimedia Appendix 1.

Statistical Analysis

Descriptive statistics were calculated with Microsoft Excel and SPSS software (version 29.02; IBM Corp). A chi-square test of independence was used for categorical variables. We used a 2-tailed *t* test, with a probability of <.05 considered statistically significant.

Ethical Considerations

The study received approval from SMC's institutional review board for retrospective analysis of prospectively collected data (2516-SMC-D). Participation in the survey was voluntary and anonymous. Completion of the questionnaire was considered implied informed consent. No identifiable personal information was collected.

Results

The survey was distributed to 2735 clinicians and 274 responded, representing a 10% response rate. Of the 274 respondents, 61% (n=167) accessed the survey link via text message. Telemedicine users accounted for 52.5% (144/274) of the respondents. Clinical characteristics and mode of communication are presented in Table 1.

Table 1. Clinician characteristics and mode of communication (n=274).

	Clinicians, n (%)
Clinician characteristics (n=274)	
Clinical specialty	
Internal medicine	36 (13)
Psychiatry	34 (12)
Pediatrics	36 (13)
Oncology	31 (11)
Other specialties	137 (50)
Clinician type	
Physicians	149 (54.4)
Paramedical staff	83 (30.3)
Nurses	42 (15.3)
Mode of communication (n=143[a])	
Mostly video visits	69 (48.3)
Both telephone and video	56 (39.2)
Primarily telephone	14 (9.8)
Alternative modes	4 (2.8)

[a]Notably, of the 143 clinicians who responded to the question regarding the mode of communication, none of the 19 psychiatrists indicated telephone visits as a significant feature of their telemedicine practice; 36.8% (7/19) of the psychiatrists engaged predominantly in video visits, while 63.2% (12/19) exclusively conducted video-based telemedicine visits.

User Satisfaction: Comparison to 2020

There was a 41.9% increase in users reporting a high level of satisfaction, from 37.7% (61/162) in 2020 to 53.5% (77/144) in 2025 (*P*=.006). Additionally, the proportion of respondents reporting a low level of satisfaction decreased from 11.1% in 2020 to 4.2% in 2025 (*P*=.02; Figure 1).

The observed overall increase in satisfaction was largely driven by a significant improvement among clinicians in the oncology clinic, where users reporting high satisfaction increased from 23.3% (10/43) in 2020 to 63.6% (14/22) in 2025 (*P*=.01). A high level of satisfaction in other clinics, including internal medicine, psychiatry, pediatrics, and other specialties, remained largely unchanged during the same period (Figure 2).

Changes in overall satisfaction levels across different sectors were predominantly nonsignificant. However, the high level of satisfaction among paramedical staff increased from 40.3% (29/72) to 59.3% (32/54; *P*=.03), while a low level of satisfaction among physicians decreased from 21.8% (19/87) to 9.5% (7/74; *P*=.03).

When queried about the perceived benefits of telemedicine for patients overall, 64.4% (176/274) of respondents expressed the belief that telemedicine was advantageous for patient care. No significant variation was observed across medical disciplines. Among telemedicine users, the proportion who considered telemedicine beneficial for their patients remained high and unchanged over time, at 87% (141/162) in 2020 and 86.6% (123/142) in 2025. In contrast, among nonusers, this proportion decreased from 68% (34/50) in 2020 to 41.9% (49/117) in 2025 (*P*<.001).

Efficiency and Integration Into Workflow

The majority of users (95/144, 66%) reported that telemedicine reduced their workload and only 9% (13/144) felt their workload increased when performing telemedicine visits, with no significant differences observed across clinics. Nurses experienced the greatest benefit, with 90.5% (38/42) reporting reduced workload, compared to 63.8% (95/149) of physicians (P>.05) and 61.4% (51/83) of paramedical staff (P=.04).

Half of the users (73/144, 50.7%) felt that telemedicine visits were shorter and only 3.5% (5/143) of clinicians felt they were longer. Most internal medicine (16/21, 76.2%) and oncology (15/22, 68.2%) clinicians felt telemedicine visits were shorter, and most psychiatric (17/20, 85%) and pediatric (11/19, 57.9%) clinicians felt it took the same time as in-person visits.

Overall, 63.2% (91/144) of telemedicine users reported that patient appointments typically began on time. Punctuality rates were significantly higher in psychiatry (17/20, 85%) and pediatrics (15/19, 78.9%) compared to other specialties (37/62, 59.7%; P=.01). Clinicians who reported having delays (53/144, 36.8%) identified several factors contributing to the delays in telemedicine visits, including clinician-related delays (23/53, 43.4%), patient unavailability at the scheduled time (5/53, 9.4%), technical issues (12/53, 22.6%), and other miscellaneous reasons (13/53, 24.5%).

Video Visits

Of the 143 users performing video visits, 51.7% (n=74) reported actively using SMC's telemedicine platform (Datos Health), while 13.3% (n=19) indicated they had previously used it but discontinued and 35% (n=50) stated they had never used the platform. The most commonly used alternative video platforms were Zoom (Zoom Communications, Inc; 36/104, 34.6%) and WhatsApp (Meta Platforms, Inc; 18/104, 17.3%), with multiple responses permitted. Among the 103 video-visit users who answered the technical feedback questions, the Datos platform was considered very easy to use by 53.4% (55/103) of users, intermediately easy by 23.3% (24/103), and hard to use by 23.3% (24/103).

The proportion of clinicians performing video visits reporting technical or connectivity problems was high. Most clinicians (64/103, 62.1%) experienced problems in connecting to the patients' network, 32% (33/103) experienced connectivity problems in SMC and only 7.8% (8/103) reported never having connectivity problems, with no significant differences among specialties. In fact, 80.6% (83/103) reported that they had to switch to telephone conversation at least once, and 23.3% (24/103) stated that it occurred at least half of the time. Only 19.4% (20/103) of users never had to switch to telephone.

A third (83/274, 30.3%) reported that they had contacted SMC's helpdesk regarding technical difficulties with the video platform; 86.9% (238/274) stated that they were satisfied with the service they received from the helpdesk staff.

Nonusers

In total, 20% (26/130) of nonuser respondents reported they had previously performed telemedicine and stopped. The proportion of clinicians who ceased to perform telemedicine visits was higher in psychiatry compared with other clinics although the absolute numbers were small (6/14, 42.9%). When asked for reasons for not performing telemedicine, of the 98 respondents who answered this question, 81.6% (n=80) stated that it was mostly clinically inappropriate, 23.4% (n=23) stated that they had experienced difficulties, 15.3% (n=15) thought it would interfere with their workflow, 9.2% (n=9) reported that they did not know how to perform telemedicine visits, and 8.2% (n=8) believed that patients would find it less convenient (multiple responses were allowed).

Discussion

Principal Findings

This study aimed to examine clinician engagement and satisfaction with telemedicine following institutional efforts to enhance uptake through technical improvements, administrative streamlining, and clinician support initiatives at SMC's virtual hospital, Sheba BEYOND. The findings demonstrate that while significant progress has been made in improving clinician satisfaction, persistent obstacles continue to affect overall adoption.

The results demonstrate a significant improvement in clinician satisfaction with telemedicine services, with users reporting a high level of satisfaction increasing from 37.7% (61/162) in 2020 to 53.5% (77/144) in 2025 (P=.006), alongside a notable decrease in low levels of satisfaction.

The doubling of telemedicine visits between 2020 and 2024, along with a significant increase in clinician satisfaction levels, highlight a fundamental cultural shift in clinician attitudes toward telemedicine, reflecting the success of Sheba BEYOND's robust infrastructure and multifaceted change management strategies. Similar interventions in other health care systems have successfully increased clinicians' confidence in telemedicine platforms by addressing usability and logistical challenges and providing appropriate support [8]. Oncology clinicians showed the most substantial improvement in satisfaction (from 10/43, 23.3% to 14/22, 63.6%; P=.01), likely due to improvements to interoperability in the oncology clinic. It is possible that the increase is also due to exceptional receptiveness to telemedicine by oncology patients [9]. Satisfaction in psychiatry remained high; prior research has shown that psychiatrists believe most patients to be good candidates for telemedicine and that it is useful as a means to encourage patient engagement [10]. Satisfaction in pediatrics did not see meaningful change. Pediatric physicians may be suspicious of their ability to provide care and build rapport with patients when using telemedicine, a perception reported in other studies on pediatric telemedicine [11,12]. The greater improvement observed by paramedical staff may reflect the longitudinal nature of their clinical activities, which often include patient education and rehabilitation support that may integrate more naturally into telemedicine workflows. Physicians, in contrast, may remain more affected by limitations related to physical examination requirements and diagnostic complexity.

XSL•FO
RenderX

The sustained increase in telemedicine visits and improved satisfaction mirror findings from previous studies highlighting the importance of institutional frameworks in fostering a cultural shift toward telemedicine. For example, the study by Ramaswamy et al [4] reported similar trends in higher satisfaction and increased adoption when supported by extensive training, workflow compatibility, and leadership-driven initiatives. Sheba BEYOND's multifaceted strategies align closely with global approaches to managing change in telemedicine adoption after the COVID-19 pandemic [8].

The results highlight a significant disparity in perceptions between telemedicine users and nonusers, with 87% (141/162) of users believing telemedicine benefits their patients compared to only 41.9% (49/117) of nonusers. Interestingly, confidence in telemedicine's utility among nonusers decreased significantly, from 68% (34/50) in 2020 to 41.9% (49/117) in 2025 (P<.001). This decrease may not reflect a true change in perspective but rather be related to the fact that over time, clinicians who believe in the utility of telemedicine have gradually embraced it, leaving the "nonuser" group with those who continue to be skeptical about this mode of health care delivery. Nonusers repeatedly cited clinical inappropriateness (80/98, 81.6%), difficulties with workflow integration (15/98, 15.3%), and technical problems (23/98, 23.5%) as primary reasons for opting out of telemedicine services. The literature supports these concerns, noting that telemedicine may be less applicable to high-complexity or tactile specialties such as surgery or certain subspecialty consults [13].

These findings align with barriers highlighted in the study by McMaster et al [14], which identified difficulties in integrating telemedicine into traditional workflows and its appropriateness for certain specialties as key obstacles to clinician adoption. Two-thirds (95/144, 66%) of telemedicine users reported reduced workloads, and 50.7% (73/144) perceived telemedicine visits as shorter than in-person consultations. Internal medicine (16/21, 76.2%) and oncology (15/22, 68.2%) clinicians were particularly likely to report shorter visits, whereas psychiatry (17/20, 85%) and pediatrics (11/19, 57.9%) found visit durations comparable to in-person care. Such efficiency gains are consistent with studies showing that telemedicine facilitates streamlined care delivery [15].

However, adherence to scheduled appointment times remained a challenge, with only 63.2% (91/144) of telemedicine users reporting that visits typically began on time. Punctuality rates varied across specialties, with psychiatry (17/20, 85%) and pediatrics (15/19, 78.9%) performing better than others. Clinician-related delays (23/53, 43.4%) and technical problems (12/53, 22.6%) were identified as the main contributors to scheduling inefficiencies, emphasizing the need for ongoing optimization of workflows and technology.

A significant proportion of telemedicine users performing video visits reported connectivity issues, with 62.1% (64/103) experiencing problems with patients' networks and 32% (33/103) encountering connectivity problems within SMC's network. This constrained user experience led to 80.6% (83/103) of clinicians resorting to telephone consultations at least once, undermining the platform's reliability. While SMC's telemedicine platform was deemed very easy to use by 53.4% (55/103) of users, alternative platforms such as Zoom and WhatsApp enjoyed widespread use, albeit with varying consistency. SMC encourages the use of its institutional telemedicine platform but does not restrict clinicians from using alternative video communication platforms. The study design did not allow assessment of the reasons underlying clinicians' preference for telephone versus video consultations. We speculate that some clinicians may have favored telephone visits due to their simplicity and reduced vulnerability to connectivity issues, while others may have preferred video visits because visual interaction was important for clinical assessment and patient communication.

The literature emphasizes the importance of stable and user-friendly telemedicine platforms in ensuring clinician satisfaction and adoption. A systematic review by Pogorzelska and Chlabicz [3] identified platform usability and seamless integration into clinical workflows as critical factors influencing telemedicine success during the pandemic. For institutions with large-scale telemedicine implementation, customized solutions that address specialty-specific needs, such as pediatric consultations or psychiatric evaluations, can significantly enhance adoption.

Institutional efforts to support telemedicine adoption must go beyond technology upgrades and training. Telemedicine adoption may be encouraged or hindered by specialty-specific concerns. To ensure wider engagement, there is a need to address clinician skepticism regarding the clinical appropriateness of telemedicine and to tailor solutions to their specialty needs and circumstances. SMC's institutional efforts to expand telemedicine adoption, specifically in the nonuser group, continue to focus on specialty-specific workflow adaptation, training initiatives, and hybrid care model development, while recognizing that telemedicine may remain less suitable for certain clinical scenarios and specialties.

Additionally, addressing technical barriers is paramount. Streamlined software platforms, increased access to stable internet connections, and ongoing support are essential to improving reliability and user satisfaction [8]. Patient education and technological assistance can also mitigate connectivity issues, helping reduce clinician workload related to troubleshooting technical problems during visits.

This study has several limitations. Its 10% response rate may limit representativeness, as clinicians more actively engaged with telemedicine may have been more likely to respond. The study was conducted at a single tertiary medical center, which may limit generalizability. In addition, the study design did not allow correlation between clinician satisfaction and objective telemedicine use metrics at the individual level. Furthermore, patient experience was outside the scope of this clinician-focused survey. Future studies should aim to address these gaps with broader sampling and data regarding clinician uptake.

Conclusions

This study demonstrates the positive impact of institutional change management strategy in promoting clinician engagement with telemedicine services. The doubling of telemedicine visits

XSL•FO
RenderX

and significant improvements in clinician satisfaction reflect an adaptive cultural shift, driven by organizational commitment and infrastructure development. However, persistent technical barriers and varying specialty-specific engagement highlight opportunities for refinement. Addressing these challenges through targeted interventions is crucial to achieve sustained engagement and maximize telemedicine's potential in outpatient care.

Abstract

Background: Neonatal mortality remains a leading contributor to under-5 deaths globally, particularly in low- and middle-income countries (LMICs). While machine learning (ML)–based risk prediction models show promise for identifying high-risk neonates, published evidence describing the real-world usability and practical implementation of ML-derived neonatal risk prediction tools within routine clinical workflows in LMIC neonatal units remains limited.

Objective: This study aimed to evaluate the usability, user experience, and perceived clinical utility of a paper-based neonatal risk predictor tool derived from an ML model and implemented across 3 Kenyan health facilities.

Methods: A postimplementation, cross-sectional usability evaluation was conducted following a 4-month implementation period from August through November 2025. The study was embedded within a longitudinal mixed methods project. Frontline neonatal health care workers (n=10) completed standardized usability instruments, including adapted global usability items (System Usability Scale [SUS]), selected Questionnaire for User Interaction Satisfaction (QUIS) domains, and the Post-Study System Usability Questionnaire (PSSUQ), alongside a project-specific Post-Study Neonatal Utility Questionnaire (PSNUQ). Descriptive statistics (medians, IQRs, and category percentages) were computed. A total of 3 purposively selected neonatal unit leaders participated in semistructured key informant interviews (KIIs), which were analyzed using thematic analysis. Quantitative and qualitative findings were triangulated to contextualize perceptions of usability.

Results: Among participating frontline health care workers, overall perceptions of usability were generally favorable. Around 75% (6/8) of respondents reported being willing to use the tool frequently, and 55% (5/9) indicated confidence in using it independently. Around half (5/10) disagreed that the tool was complex, while 22% (2/9) agreed, indicating moderate polarization in perceived complexity. Median PSSUQ composite scores were below 3 across subscales, reflecting positive usability ratings. Overall, 8 of 10 (80%) respondents agreed that the tool supports early identification of high-risk neonates and improves care prioritization within the first 48 hours. However, workflow integration was workload-sensitive: 40% (4/10) reported an increased documentation burden during periods of high patient volume. KIIs identified staffing shortages, parallel documentation systems, and the importance of administrative endorsement as key structural influences on adoption.

Conclusions: The neonatal risk predictor tool demonstrated acceptable usability, learnability, and perceived clinical relevance across 3 diverse Kenyan facilities. However, variability in perceived complexity and workload sensitivity highlights the importance of structured onboarding, workflow-aligned integration, and context-aware implementation planning. These findings underscore that translating ML-derived predictor models into clinical practice requires not only technical validity but also strong usability and system-level readiness within routine neonatal care settings.

Introduction

Neonatal mortality remains a major global health challenge, accounting for almost half of all under-5 deaths worldwide, with an estimated 2.3 million newborn deaths in 2022 [1]. Despite global progress in reducing child mortality, declines in neonatal deaths have been slower and progress uneven across regions, making early identification and management of high-risk newborns a priority for achieving Sustainable Development Goal (SDG) Target 3.2 [2,3].

Structured, timely risk identification at birth and during the first 48 hours is critical because many life-threatening conditions (such as prematurity-related complications, intrapartum injury, and early-onset infection) present within this window [3]. In low- and middle-income country (LMIC) settings, reliance on subjective clinical judgment and inconsistent documentation often reduces the reliability of early triage, contributing to delays in escalation of care [3]. These realities create a pressing need for practicable risk-stratification tools that fit routine neonatal workflows and improve early detection of clinical deterioration.

Machine learning (ML) and other data-driven approaches show promise in neonatal risk prediction, with systematic reviews demonstrating that ML models can predict neonatal mortality and other adverse perinatal outcomes using routinely collected predictors [4-6]. However, most published ML models remain limited by modest external validation, variable predictor availability across settings, and sparse evidence on real-world deployment [4,5]. This gap between technical model development and safe operational deployment has also been documented in broader health information technology (HIT) literature, where system functionality issues, configuration errors, and workflow misalignment have resulted in unintended care disruptions [7-10]. Consequently, translating ML predictors into clinical practice requires 2 parallel lines of evidence: (1) demonstration of acceptable technical performance, and (2) evidence that the predictor tool is usable, acceptable, and practically feasible for frontline health care workers within the constraints of their working environments [6,11-13].

Usability and user experience (UX) are central determinants of health-technology adoption: internationally recognized standards define usability in terms of effectiveness, efficiency, and satisfaction in a specific context of use [9,14], and empirical work shows that poor usability undermines both uptake and the intended effect of clinical decision-support tools [14,15]. Evidence from national incident-report analyses indicates that poorly integrated digital systems often cause workflow disruptions, documentation inconsistencies, and patient safety risks when usability and contextual fit are not adequately addressed [8-10,16]. In health care, and especially in high-stress, time-sensitive clinical areas such as neonatal units, even small frictions in interface clarity, learnability, or workflow fit can materially reduce consistent use and thereby erode potential clinical benefit [9,14,15].

User-centered design (HCD) approaches that iteratively involve end-users in design, testing, and refinement increase the probability of adoption and sustained use of digital health tools in LMICs [17,18]. Prior work examining digital health testbeds and system configuration failures underscores the importance of early-stage contextual testing and iterative refinement to prevent downstream operational disruptions [9,10]. HCD emphasizes aligning an intervention's information architecture, terminology, and workflow demands with the cognitive load and priorities of frontline staff, an especially important requirement when staffing shortages and high nurse-to-patient ratios constrain the time available for documentation [17]. For neonatal risk predictors, HCD therefore implies not only designing an accurate predictor tool but also ensuring the tool's presentation, learning curve, and integration into routine tasks are acceptable to users [18-20].

Despite the theoretical consensus, there remains remarkably little real-world evidence on the usability and perceived utility of neonatal risk predictor tools in LMIC neonatal units [11]. Existing studies of ML-based neonatal prediction largely focus on model building and internal validation, with few studies examining frontline user perceptions, interface quality, and the practical trade-offs staff make when integrating new documentation tasks into busy clinical workflows [3,5]. This gap is consequential: without evidence that frontline users can and will use a predictor tool reliably, implementation at scale risks failure even if the underlying model performs well on retrospective data [3,5].

This study presents the completed user-centered evaluation of a neonatal risk predictor tool derived from an ML model [4] and implemented as a paper-based risk tool across 3 Kenyan health facilities, following the methodology outlined in the previously published study protocol [21]. Our objectives were to (1) assess perceived usability and user experience using validated instruments and bespoke UX items, (2) describe perceived usefulness and likely impact on routine neonatal workflows, and (3) identify design and training priorities to strengthen adoption in resource-constrained neonatal units. By focusing on frontline user perspectives and practical workflow constraints, the paper aims to provide the implementation-oriented evidence needed to move from ML model development toward safe, usable, and context-appropriate deployment.

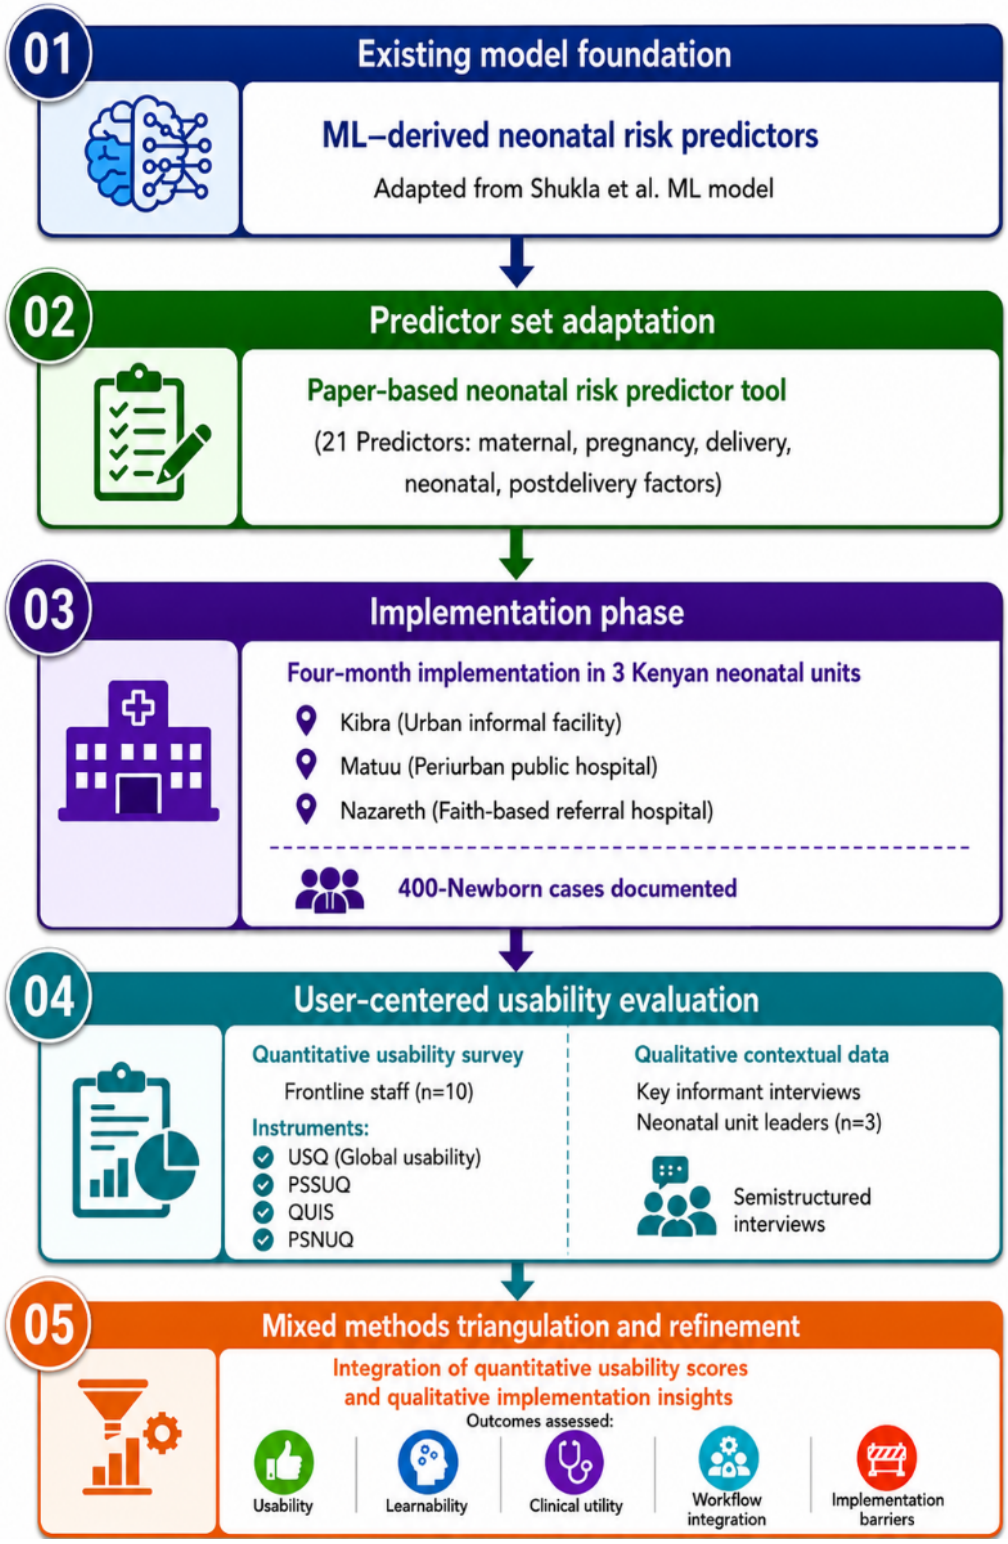
Methods

Overview

The study adhered to good practices for pragmatic usability assessment in clinical settings. The study is reported in accordance with the Good Reporting of A Mixed Methods Study (GRAMMS) recommendations [22], and the completed GRAMMS checklist is provided as Multimedia Appendix 1.



Study Design

This study used a postimplementation, cross-sectional usability, and UX evaluation embedded within a longitudinal mixed-methods project. The use of mixed methods triangulation aligns with established approaches for evaluating complex health care interventions, combining quantitative usability metrics with qualitative contextual insight to enhance interpretive depth [23-25]. The evaluation combined standardized usability instruments with a project-specific Post-Study Neonatal Utility Questionnaire (PSNUQ) and semistructured key informant interviews (KIIs) to triangulate frontline users' perceptions with contextual implementation data. The quantitative usability component reported here was administered after a 4-month implementation period of the paper-based neonatal risk predictor tool. The study followed good practice for pragmatic usability assessment in clinical settings [14].

This study represents the completed user-centered usability evaluation described in the previously published study protocol [21]. This paper reports the implementation and postimplementation usability findings from that protocol-defined study. Preintervention key informant interviews were conducted in August 2025, followed by implementation of the paper-based neonatal risk predictor and newborn data collection from August through November 2025. The postimplementation usability survey was administered in December 2025. The overall study design and mixed-methods usability evaluation framework are illustrated in Figure 1.

XSL•FO
RenderX

Figure 1. Study design and mixed methods usability evaluation framework. ML: machine learning; PSNUQ: Post-Study Neonatal Utility Questionnaire; PSSUQ: Post-Study System Usability Questionnaire; QUIS: Questionnaire for User Interaction Satisfaction; USQ: Usability Scale Questionnaire.

The ML–derived neonatal risk predictor tool was implemented as a paper-based documentation instrument across 3 Kenyan neonatal units over a 4-month period. Following implementation, usability and user experience were evaluated using a mixed methods approach that combined standardized usability questionnaires (System Usability Scale [SUS], Post-Study System Usability Questionnaire [PSSUQ], Questionnaire for User Interaction Satisfaction [QUIS], and PSNUQ) completed by frontline neonatal staff (n=10) with qualitative KIIs with neonatal unit leaders (n=3). Quantitative and qualitative findings were triangulated to assess usability, learnability, clinical utility, workflow integration, and implementation context.

Study Setting

The study was conducted in 3 Kenyan health facilities representing distinct service contexts: an urban informal

XSL•FO
RenderX

settlement facility in Kibra (Nairobi County), a periurban public hospital in Matuu (Machakos County), and a faith-based referral hospital in Nazareth (Kiambu County). Facilities were located in Nairobi County (Kibra), Machakos County (Matuu), and Kiambu County (Nazareth). Contextual details and facility characteristics are described in the project report and site summaries.

Participants and Sampling

The published study protocol specified a purposive sample of 10 health care workers across the 3 participating facilities, with a planned allocation of 4 participants from Kibera, 4 from Matuu, and 2 from Nazareth [21]. In the completed study, however, recruitment was based on the availability of eligible frontline neonatal health care workers during the implementation period. All eligible and available staff involved in the implementation were invited to participate, and 10 frontline staff completed the postimplementation survey.

The protocol's prespecified allocation of 4 participants from Kibra, 4 from Matuu, and 2 from Nazareth was intended to ensure representation across the 3 participating facilities. The allocation was a planned recruitment target rather than a statistically derived proportional allocation. In the completed study, the final numbers of participants from each facility corresponded to these planned numbers, although recruitment was based on the availability of eligible frontline neonatal health care workers during the implementation period.

A total of 2 participant groups contributed to the usability evaluation:

1. Key informants (qualitative KIIs): Purposive sampling was used to select senior neonatal unit leaders (one per facility) for semistructured interviews exploring implementation context, governance structures, workflow integration, and perceived barriers and enablers to adoption. A total of 3 KIIs were conducted across the participating facilities. These interviews have also been reported in a separate published analysis examining governance and health system determinants of scalability and institutionalization of the neonatal risk stratification tool [26]. In this study, the same interview data were used to contextualize the user-centered evaluation, with analysis focused specifically on perceptions of usability, workflow integration, and implementation-related factors relevant to the frontline use of the paper-based predictor tool. The semistructured interview guide is provided in Multimedia Appendix 2.
2. Frontline neonatal health care workers (quantitative postsurvey): The 3 participating facilities had a combined workforce of 43 neonatal health care workers: 11 at Kibra, 15 at Matuu, and 17 at Nazareth. All eligible neonatal nurses and midwives involved in the 4-month implementation of the tool were invited to complete the post-implementation survey. Due to staff availability during the study period, 10 frontline health care workers participated in the survey. Participants were distributed across the 3 facilities as follows: 4 from Matuu, 4 from Kibra, and 2 from Nazareth.

All participants provided information and consent for the use of anonymized aggregate responses in research outputs.

Development of the ML-Derived Neonatal Risk Predictor

The paper-based neonatal risk predictor evaluated in this study was derived from a previously developed and validated ML model for neonatal mortality prediction reported by Shukla et al [4]. The original model was developed using routinely collected maternal, obstetric, delivery, neonatal, and early postnatal variables and demonstrated good predictive performance in LMIC settings (area under the receiver operating characteristic curve >0.80). Rather than evaluating the predictive performance of the ML algorithm itself, this study focused on the feasibility, usability, user experience, and workflow integration of a paper-based implementation of the predictor set within routine neonatal care across 3 Kenyan health facilities.

The complete list of predictor variables and the paper-based neonatal risk predictor form used during implementation are provided in Multimedia Appendix 2.

Intervention and Exposure

The object of evaluation was a paper-based neonatal risk predictor tool (the "predictors set") that had been integrated into routine documentation for newborns at delivery (Day 1) and at a postdelivery check (Day 2). The tool captured 21 candidate predictors, organized into 5 domains: maternal characteristics, pregnancy-related factors, delivery characteristics, neonatal clinical indicators, and early postdelivery observations. The complete list of predictors and the paper-based neonatal risk predictor form are provided in Multimedia Appendix 2 to enhance transparency and reproducibility. During the 4-month implementation period, the tool was used prospectively within routine neonatal care, resulting in 400 newborn cases recorded across the 3 participating sites: 100 at Kibra, 100 at Nazareth, and 200 at Matuu. These site-specific totals represent the cases captured during the implementation period and were not determined through a statistically derived per-site sampling allocation.

Instruments

Standard Instruments

We combined well-established usability measures to capture complementary aspects of usability and user experience:

1. PSSUQ: The PSSUQ (James R Lewis) is a validated instrument designed to measure users' perceived system usability after task completion; the most commonly used short form has 16 items across dimensions such as system usefulness, information quality, and interface quality, typically scored on a 7-point Likert scale (lower scores = better perceived usability). The PSSUQ has been psychometrically evaluated and widely used in health technology research [15,27]. PSSUQ scores were summarized using the standard System Usefulness, Information Quality, and Interface Quality subscales, together with the overall score.
2. QUIS: The QUIS is a user satisfaction instrument developed by Chin et al [28] that measures overall reaction and

XSL•FO
RenderX

multiple interface dimensions (eg, screen factors, terminology, and learnability). We used QUIS items to assess interaction satisfaction and perceptions of content and layout [28]. Selected QUIS domains assessed overall user satisfaction, ease of use, interface characteristics, and learning.

3. SUS: While our project labels one instrument "SUS" in the field documents, the SUS is the canonical short usability scale commonly used to obtain a global usability score (10 items and 5-point Likert) [29]. In our implementation, we used a short version of SUS, adapted from standard global usability measures (SUS and PSSUQ constructs), to capture overall perceived ease of use and willingness to reuse.

Project-Specific Instrument Content (PSNUQ and SUS Items)

The PSNUQ includes domains on perceived usefulness, learnability, task support, content quality, interface quality, and perceived productivity and impact. The SUS items in the survey covered willingness to use, perceived complexity, need for assistance, and overall ease of use. The QUIS subscales assessed overall reaction, layout and text clarity, terminology, and interaction satisfaction.

Questionnaire Administration and Data Collection Procedures

Postsurvey questionnaires were administered face-to-face by the research team to frontline neonatal staff at the end of the implementation period. Respondents completed the combined instrument (SUS+QUIS+PSNUQ) in a private setting; the survey took approximately 20-30 minutes. KIIs with neonatal unit leads were conducted using a semistructured guide, with audio recording with permission; interview transcripts were used for thematic analysis and triangulation.

The complete questionnaires, including all item wording, response anchors, scoring procedures, and the PSSUQ subscale allocation, are provided in Multimedia Appendix 2. The SUS, PSSUQ, and selected QUIS domains are validated usability instruments, whereas the PSNUQ was developed for this study to evaluate perceived clinical relevance, feasibility, and implementation considerations of the neonatal risk predictor tool.

Scoring and Quantitative Analysis

Survey items used Likert-style ordinal response scales (typically 5- or 7-point, depending on the instrument and item). For standardized instruments (PSSUQ, QUIS, and SUS-derived items), we followed canonical scoring procedures where applicable (eg, SUS scoring and PSSUQ subscales) and computed descriptive statistics (median, IQR, and category percentages) for each item and subscale. Given the small sample size (n=10), analyses were descriptive, focusing on response distributions, identifying polarized items, and cross-tabulations by facility or cadre where numbers allowed. We also computed simple case-level completeness and item-level missingness for the survey dataset. These methods align with pragmatic usability evaluation approaches in clinical contexts [14,15].

Qualitative Analysis and Triangulation

KIIs were audio-recorded with participant consent and transcribed verbatim. The transcripts were analyzed using thematic analysis through an iterative coding process, with coding conducted manually using a structured coding framework informed by the interview guide and patterns emerging from the data [30,31]. EK and FS conducted the initial coding, while RDN and MSRJ independently reviewed the coding and emerging themes. Coding discrepancies were discussed among the coders and resolved through consensus. The analysis focused on identifying themes relevant to usability, workflow integration, and implementation context, with the qualitative findings used primarily to contextualize and triangulate the quantitative usability findings rather than as a standalone qualitative outcome analysis. In particular, qualitative insights helped explain divergent or polarized survey responses, including concerns related to staffing shortages, documentation duplication, workload pressure, infrastructure limitations, and resistance to workflow changes. The researchers acknowledged that interpretation of the qualitative data was informed by their experience in digital health and neonatal care, and efforts were made to minimize interpretive bias through regular discussion of emerging themes. Given the exploratory nature of this pilot study and the inclusion of one key informant from each participating facility, thematic saturation was not formally assessed. Representative deidentified quotations supporting the themes are provided in Multimedia Appendix 3. Findings from the quantitative postsurvey (SUS, QUIS, and PSNUQ components) and the qualitative KIIs were then triangulated to generate integrated interpretations. This triangulation enabled identification of both tool-specific usability issues (eg, clarity, learnability, and layout) and system-level constraints affecting adoption (eg, staffing capacity, governance processes, and infrastructure readiness). The triangulated findings informed practical recommendations for design refinement and implementation planning.

The reporting checklist, complete postimplementation survey instrument (SUS, selected QUIS domains, PSSUQ items, and PSNUQ), semistructured interview guide, and the paper-based neonatal risk predictor form are provided as Multimedia Appendices 1-3 to support transparency and reproducibility.

Ethical Considerations

Ethical approval (SU-ISERC2949/25) was obtained from the Strathmore University Institutional Scientific Ethics Review Committee (SU-ISERC), Nairobi, Kenya, on 28 July 2025, prior to commencement of the study. All participants provided informed consent before participation after receiving information about the study aims, voluntary participation, confidentiality protections, and data management procedures. Interview transcripts were anonymized before analysis to protect participant confidentiality and institutional privacy. The study adhered to established ethical principles for qualitative health systems research throughout data collection, analysis, and reporting.

XSL•FO
RenderX

Results

Participant Characteristics

A total of 10 frontline neonatal health care workers completed the postintervention usability evaluation across the 3 study sites. The majority of respondents were mid-career nurses with diploma-level qualifications, reflecting the cadre primarily responsible for routine neonatal documentation and triage. The characteristics and study-site distribution of the participating frontline neonatal health care workers are summarized in Table 1.

Table 1. Characteristics of frontline neonatal health care worker participants (n=10).

Characteristics	Values, n (%)[a]
Study site (n=10)	
Kibra	4 (40)
Matuu	4 (40)
Nazareth	2 (20)
Professional cadre (n=10)	
Nurses	8 (80)
Midwives	2 (20)
Age (years; n=9)	
18-30	2 (22.2)
31-40	6 (66.7)
51-60	1 (11.1)
Educational qualification (n=9)	
Certificate	7 (77.8)
Bachelor's degree	2 (22.2)

[a]Percentages are calculated using the number of respondents for each characteristic. One participant had missing responses for age and educational qualification; therefore, the denominator for these variables is 9 rather than 10.

Overall Usability Perception: Global Usability (SUS Items)

Among participating frontline health care workers, overall perceptions of usability were generally favorable. Most respondents reported positive overall perceptions of the neonatal risk predictor tool's usability. Specifically, 75% (6/8) reported a willingness to use the tool frequently in routine practice, and 55% (5/9) indicated confidence in using it independently. Regarding perceived complexity, around half (5/10) disagreed that the tool was complex, while 22% (2/9) agreed. Together, these findings suggest the tool's overall acceptability, with moderate variability in users' perceptions of complexity.

PSSUQ Composite Scores

PSSUQ subscales were computed using canonical scoring procedures (lower scores indicate better usability). Median scores across all subscales were below 3, indicating favorable perceptions of usability.

Information quality and interface quality showed slightly greater dispersion, reflecting variability in respondents' perceptions of clarity and layout. Median PSSUQ subscale scores are presented in Table 2. All median scores were below 3, indicating generally favorable perceptions of system usability.

Table 2. PSSUQ subscale scores.

Subscale	Values, median (IQR)[a]
System Usefulness	2.1 (1.5-2.8)
Information Quality	2.3 (1.7-3.0)
Interface Quality	2.4 (1.8-3.2)
Overall PSSUQ[b] score	2.3 (1.6-3.0)

[a]PSSUQ responses were available for 10 participants (n=10). Scores are presented as median (IQR). Lower scores indicate greater perceived usability.
[b]PSSUQ: Post-Study System Usability Questionnaire.

RenderX

User Experience Domains (QUIS and PSNUQ)

Content and Layout Clarity

A majority of respondents (8/10, 80%) agreed that the content of the tool was clearly structured, and the same proportion (8/10, 80%) indicated that the terminology was understandable. Additionally, 7 respondents (7/10, 70%) agreed that the information was logically grouped. However, 3 respondents (3/10, 30%) expressed concerns regarding potential redundancy with existing documentation forms.

Learnability and Confidence

A total of 8 respondents (8/10, 80%) agreed that the neonatal risk predictor tool was easy to learn after initial exposure, whereas 2 respondents (2/10, 20%) reported some initial difficulty during early use. Regarding confidence in using the tool independently, 6 respondents (6/10, 60%) indicated that they felt confident completing the tool without assistance following the implementation period, while 4 respondents (4/10, 40%) reported requiring occasional clarification or support during early stages of use.

In addition, 7 respondents (7/10, 70%) reported that their comfort level with the tool increased over the 4-month implementation period, suggesting progressive familiarization with the structured documentation format. These findings indicate that while initial onboarding may require guidance for a subset of users, perceived learnability improved with continued exposure.

Perceived Clinical Utility

PSNUQ responses demonstrated high perceived clinical utility of the neonatal risk predictor tool. A total of 8 respondents (8/10, 80%) agreed that the tool supports early identification of high-risk neonates, while 7 respondents (7/10, 70%) agreed that it enhances structured clinical thinking during neonatal assessment. Additionally, 8 respondents (8/10, 80%) reported that the tool may improve care prioritization within the first 48 hours of life.

Workflow Integration

Although the tool was perceived as clinically helpful, integration into the routine workflow was described as dependent on staffing capacity. Overall, 6 respondents (6/10, 60%) indicated that the tool was manageable under normal staffing conditions, whereas 4 respondents (4/10, 40%) reported that high patient volumes increased the perceived documentation burden. Among those reporting higher-workload environments, 3 respondents (3/10, 30%) specifically noted that competing clinical priorities made consistent completion more challenging.

Polarization and Divergent Perceptions

Item-level distribution analysis demonstrated moderate polarization on complexity-related items. Item-level responses demonstrated moderate variation in perceptions of tool complexity. A total of 5 respondents (5/10, 50%) disagreed or strongly disagreed that the tool was complex, 3 (3/10, 30%) selected a neutral response, and 2 (2/10, 20%) agreed or strongly agreed.

Triangulated Interpretation

Qualitative insights from KIIs provided contextual interpretation of the usability findings. All 3 informants (n=3, 100%) identified staffing shortages as a structural factor influencing perceived documentation burden. A total of 2 informants (n=3, 67%) reported that parallel documentation requirements contributed to concerns about duplication, particularly in facilities where existing paper records must be maintained alongside new tools. Additionally, 2 informants (n=3, 67%) emphasized that visible administrative endorsement influenced staff motivation to adopt and consistently use the tool.

Triangulation of quantitative survey findings with qualitative themes indicates that perceived usability was shaped not only by interface clarity and learnability but also by broader structural workflow conditions within the neonatal units.

In Summary, the neonatal risk predictor tool demonstrated favorable usability performance across multiple domains. Survey responses indicated generally positive global usability ratings, acceptable learnability following initial exposure, and strong perceived clinical relevance for the early identification and prioritization of high-risk neonates. At the same time, item-level distribution revealed moderate variability in perceptions of complexity, with a subset of respondents reporting increased burden under high-workload conditions. These patterns collectively reflect broad usability across participants, alongside measurable differences in experience related to workflow intensity and staffing context.

Discussion

Principal Findings and Interpretation

This pilot, multisite usability evaluation suggests that the neonatal risk predictor tool was generally perceived as usable, learnable, and clinically relevant by participating frontline neonatal health care workers across the 3 Kenyan facilities. Most respondents reported willingness to use the tool regularly and increasing confidence with continued exposure; median composite usability scores were in the favorable range. At the same time, item-level responses revealed measurable polarization on perceived complexity and workload sensitivity, with a minority of users reporting initial difficulty and persistent concerns about documentation burden under high patient loads. These findings suggest that while the tool is broadly acceptable to users, its successful integration into routine neonatal workflows will depend on workload-aware implementation strategies and structured onboarding.

Our results align with broader evidence emphasizing the importance of usability and contextual fit for clinical decision-support tools in LMICs. The neonatal period remains the most vulnerable window for child survival globally, and interventions that improve early identification of high-risk neonates must be operationally feasible at the point of care to affect outcomes [1,3]. The finding that frontline health care workers value clinically relevant predictors (eg, Appearance, Pulse, Grimace, Activity, and Respiration [APGAR], gestational age, and vital signs) is consistent with prior ML prediction reviews that identify these variables as strong, widely used

XSL•FO
RenderX

predictors of neonatal outcomes [5]. However, systematic reviews and expert commentaries have repeatedly highlighted that technical model performance alone is insufficient for impact: external validation, predictor availability, and deployment logistics are essential for translation [5]. Our triangulated usability and KII data confirm this; technical validity must be matched by usability and health-system readiness for effective adoption [3,5].

Our findings are also consistent with previous usability evaluations of digital health interventions in maternal and neonatal care. For example, Balderas-Díaz et al [32] demonstrated that user-centered design, iterative proof-of-concept evaluation, and usability testing are essential for promoting user acceptance and successful implementation of adaptive mHealth systems in perinatal care. Consistent with their findings, our study highlights that, beyond technical performance, successful adoption depends on usability, workflow integration, and alignment with users' clinical needs.

Usability Implications and Standards

The observed variability in perceived complexity and information-quality dispersion highlights the need to follow established usability standards and HCD principles when refining and scaling the tool. ISO 9241-11 defines usability as effectiveness, efficiency, and satisfaction in a specified context of use; our findings show acceptable satisfaction and improved efficiency with use, but situational constraints reduce effectiveness in high-workload settings [14]. Similarly, reviews of usability instruments in mHealth underline the importance of combining standardized psychometric measures (eg, PSSUQ, QUIS, and SUS) with context-specific items that capture workflow and documentation interactions [15]. Our approach, combining standardized scales with a project-specific PSNUQ and KIIs, therefore, aligns with recommended practice for pragmatic usability evaluation in health settings [14,15].

Interpretation of Variability and Polarization

The observed polarization in perceived complexity is not merely noise—it is a signal that the intervention interacts with heterogeneous user contexts, capacities, and expectations. Some frontline staff found the tool intuitive and readily incorporated it into routine care, while others experienced friction that increased perceived burden. This pattern commonly appears in early-stage usability evaluations and often reflects differences in prior exposure to structured documentation, individual triage strategies, and local workflow realities (eg, staffing and shift patterns). Interpreting polarization, therefore, requires moving beyond averages to examine subgroups (by facility, cadre, or prior digital familiarity) and to identify threshold conditions: small increases in caseload or complexity may flip a user from "comfortable" to "overloaded," producing bimodal response distributions. Empirically, such subgroup heterogeneity is a cue for targeted refinements (eg, simplified pathways for high-workload contexts) rather than wholesale redesign [33].

From a theoretical perspective, polarization can also reflect differences in cognitive load and schema availability: users with established mental models for structured documentation experience lower intrinsic and extraneous cognitive load and therefore report lower perceived complexity; those lacking such schemas are more affected by extraneous load and report higher complexity (cognitive load theory). Targeted training that promotes rapid schema formation (eg, worked examples and supervised practice) is therefore likely to reduce polarization by elevating baseline competence across the team [34].

Finally, polarization carries implementation implications: rather than treating the tool as binary (adopt vs reject), implementation plans should include adaptive pathways, for example, a "light" checklist for high-pressure shifts and a richer version for less busy times, to maintain fidelity while accounting for context. This approach preserves core clinical value while lowering the activation energy for use under strain (implementation outcomes and feasibility guidance) [35].

Translation Gap Between ML and Clinical Workflow

The literature on ML for neonatal prediction is clear: many models demonstrate high retrospective performance but fail to translate into routine care due to gaps in predictor availability, data quality, and workflow fit (external validation, calibration, and deployment are often missing). In other words, algorithmic accuracy is necessary but not sufficient for clinical impact; the "last mile" is practical integration into health care workers' daily tasks [9,10]. This study therefore complements previous model-development research by evaluating the implementation of an ML-derived predictor set under routine clinical conditions rather than reassessing algorithmic performance. Consistent with broader analyses of health information technology incidents, system-level fragilities often emerge not from algorithmic logic itself but from workflow integration failures, configuration issues, and documentation burdens.

Our findings reinforce this translation gap: frontline staff valued clinically relevant predictors (APGAR, gestational age [GA], and vitals), but even clinically sensible predictors must be routinely and rapidly available in usable form for an ML-based tool to function in practice. This reinforces calls in the literature for deployment-focused research that explicitly couples model development with operational capture and usability testing [5,36].

Operational requirements for ML deployment, therefore, extend beyond model metrics to include measures of data completeness, real-time availability, and process fit. Our mixed results, reasonable data capture for many predictors but workload-sensitive usability, illustrate why ML systems often falter post deployment: data pipelines may look good in retrospective datasets but break when frontline realities impose delays, missing fields, or inconsistent recording habits. Addressing this requires co-designed data workflows, automated data extraction when possible, and continuous monitoring of data quality during deployment [5,37].

Although the neonatal risk predictor evaluated in this study was derived from a validated ML model, participants were not asked to evaluate or compare the underlying algorithm. Instead, the usability evaluation focused on frontline users' experiences with the paper-based implementation of the predictor set within routine clinical workflows. Consequently, the findings should be interpreted as evidence regarding implementation and

XSL•FO
RenderX

usability rather than perceptions of algorithmic transparency or trust in specific ML approaches.

Cognitive and Workflow Load Considerations

Clinical tasks in neonatal units are time-pressured and cognitively intensive. Cognitive load theory highlights that working memory is limited and that extraneous load (poorly designed interfaces, unnecessary duplication) reduces the capacity available for core clinical reasoning. Our results, which showed that some users reported perceived complexity and workload-related friction, map precisely onto this theory. In practice, design choices that reduce extraneous cognitive load (prefilled defaults, binary checkboxes rather than free-text, and minimized decision branches) and scaffold intrinsic load (clear prompts and quick-reference thresholds) are most likely to improve consistent uptake. Empirical work on electronic health records (EHRs) and clinical decision support system **(**CDSS) shows that poor interface design increases cognitive load and error risk; conversely, simplified, context-aware interfaces reduce time-on-task and decision fatigue [34,38].

From a workflow standpoint, the tool must respect "attention budgets." During high-volume shifts, health care workers have very limited time to document; even an additional 30 seconds per baby can be prohibitive. Therefore, interventions should be evaluated in terms of marginal time cost under realistic caseloads (time-motion studies), and design should aim to minimize per-case time through automation, task reallocation, or condensed item sets for critical screening. This attention to microeconomics of time turns usability into an outcome (time cost and adherence), not just a perception metric [38,39].

Our findings can also be interpreted through the Systems Engineering Initiative for Patient Safety (SEIPS) framework, which conceptualizes health care quality and patient safety as emerging from interactions among people, tasks, tools, and technologies, the physical environment, and organizational conditions [40,41]. From a SEIPS perspective, the documentation burden reported during periods of high workload reflects a work-system issue rather than a limitation of the neonatal risk predictor itself. Similarly, the qualitative findings regarding staffing shortages, parallel documentation systems, and organizational support indicate that successful implementation depends not only on the tool's usability but also on optimizing the broader clinical work system and integrating workflows. In low-resource settings, these considerations extend to the availability and reliability of the infrastructure supporting digital health implementation; evidence from Kenyan health facilities has highlighted the importance of addressing electricity and connectivity constraints and considering context-appropriate approaches to maintain continuity of digital health services [42,43].

Implementation Science Perspective

Implementation science provides conceptual tools to interpret our findings and plan next steps. The Implementation Outcomes Framework (Proctor et al [35]) identifies acceptability, feasibility, appropriateness, and adoption as proximal outcomes that must precede penetration and sustainability. Our data show reasonable acceptability and perceived appropriateness, but feasibility and adoption are conditional on staffing and documentation realities, precisely the intermediate implementation outcomes that predict later penetration and sustainability. Framing results in this taxonomy clarifies operational priorities (eg, improving feasibility via workflow changes) and defines measurable implementation end points for subsequent trials.

Normalization process theory is also useful: it articulates how new practices become embedded through coherence (sense-making), cognitive participation (engagement), collective action (operational work), and reflexive monitoring [44]. Our KIIs and survey data indicate that coherence exists (staff see the value), but cognitive participation and collective action are hindered by workload and governance barriers, meaning that embedding will require active facilitation, local champions, and adaptive workflows to transform individual acceptance into routinized practice. These theoretical lenses suggest concrete implementation strategies (champion identification, cocreation, iterative feedback loops, and fidelity monitoring) that align with our empirical patterns [45].

Contribution to LMIC Digital Health Literature

This study contributes, both practically and conceptually, to the emerging LMIC digital health literature in several ways. First, it presents real-world usability evidence from neonatal units, a high-impact but under-studied clinical domain in LMICs, and ties usability to operational capture metrics, bridging a common gap between model-focused and deployment-focused work [39]. Second, by triangulating standardized usability instruments with context-specific qualitative insights, the work demonstrates a pragmatic mixed methods evaluation blueprint that other LMIC implementers can replicate. Third, it underscores that pilot usability samples (n≈5-15) are methodologically defensible for early user-centered design validation while pointing toward necessary next steps (larger trials and psychometric validation), thereby setting realistic methodological expectations for the field. Finally, it emphasizes implementation equity: without attention to staffing, governance, and data burden, digital tools risk widening care quality gaps across facilities [46]. Digital inequities and differential adoption across populations have been documented in other contexts, where infrastructure, governance, and sociocultural factors shape digital uptake [47,48]. These contributions respond directly to calls in recent mHealth and implementation reviews for context-sensitive, deployment-oriented evidence.

Implications for Practice

Based on our findings, implementers and facility managers should consider the following practical steps before scaling:

1. Structured onboarding and mentorship: Provide brief, practical training sessions with supervised use during the initial weeks and ongoing mentorship for new or rotating staff to reduce early-use errors and perceived complexity [49]. Evidence from health care quality improvement and digital training interventions demonstrates that structured onboarding and supervised adoption phases improve implementation fidelity and long-term usability outcomes [23,50,51].

XSL•FO
RenderX

2. Workflow-sensitive adaptation: Integrate the tool into existing delivery registers or consolidate parallel documentation forms to reduce duplication; where duplication is unavoidable for regulatory reasons, design the tool to minimize additional data entry (eg, checkboxes and prefilled fields) [52].
3. Task allocation and scheduling: Assign clear responsibilities (eg, primary recorder during delivery and secondary verifier) to ensure consistent completion during peak periods [53].
4. Hybrid implementation planning: For facilities with unreliable IT and infrastructure, maintain a hybrid approach (paper with planned digitization) and plan for offline digital options with synchronization capability [52,54].
5. Monitoring and iteration: Embed short feedback cycles (weekly and monthly) to capture user problems and quickly iterate on interface or process changes [54,55].
6. User engagement and co-design: Actively involve frontline health care workers in iterative refinement of the tool through feedback sessions, participatory design workshops, or pilot discussions. Engaging end users in the adaptation process can enhance local ownership, improve contextual fit, and increase the likelihood of sustained adoption within routine clinical workflows [17,20].

These pragmatic steps align with implementation science principles and can increase the likelihood that technically valid predictor models translate into practice improvements.

Strengths and Limitations of the Study

Several features increase the study's utility to researchers and implementers: (1) real-world exposure, that is, the usability assessment followed a 4-month implementation period rather than a short laboratory test, increasing ecological validity); (2) multisite design, that is, 3 diverse facility contexts (urban informal, periurban public, and faith-based referral) enhance transferability of implementation insights across LMIC delivery settings; (3) triangulated methods, that is, combining standardized usability instruments (SUS, QUIS and PSSUQ-derived items) with KIIs provided depth and helped explain quantitative polarization; and (4) operational realism, that is, the usability evaluation was explicitly tied to routine documentation and staffing realities, yielding actionable recommendations for onboarding and workflow adaptation.

We must acknowledge several limitations that constrain the generalizability and strength of conclusions. First, the postsurvey sample size was small (n=10), limiting statistical power and precluding robust inferential testing; this study should therefore be understood as a pilot usability evaluation rather than a definitive validation. Accordingly, the findings should be interpreted as preliminary evidence intended to inform future larger-scale usability and implementation studies rather than to support broad generalization. Second, although multi-site, qualitative key informant data were limited to 3 senior health care workers (n=3), which constrains claims about saturation for broad thematic generalization; however, those informants were purposively selected leaders with facility-level oversight, increasing the relevance of governance and workflow insights.

Third, the usability measures relied on self-report; objective measures of time on task, error rates, or direct observation could provide complementary evidence of efficiency and effectiveness. Fourth, the PSNUQ instrument is study-adapted; while combining it with validated scales strengthens construct coverage, formal psychometric validation (eg, reliability and factor structure) was not possible with this sample. Finally, the study used a paper-based implementation of the predictor tool; findings may differ with a fully digital interface and therefore should not be assumed to directly generalize to other delivery modalities. These limitations should guide the interpretation and design of future studies.

Future Research Recommendations

To build on these pilot findings, we recommend:

1. Larger multisite usability and effectiveness trials: Expand sample sizes across more facilities and include objective time-motion measures, task completion rates, and downstream clinical process outcomes (eg, time to antibiotic administration, referral timeliness) [56].
2. Psychometric validation of PSNUQ: With a larger sample, assess internal consistency (Cronbach α) and factor structure to formally validate the adapted instrument [37].
3. Compare delivery modalities: Evaluate differences between paper, hybrid, and fully digital interfaces for the same predictor tool to identify modality-specific strengths and weaknesses [57].
4. Implementation trials linked to process outcomes: Conduct stepped-wedge or cluster-randomized evaluations to test whether increased usability and workflow integration translate into measurable improvements in neonatal care processes and, ultimately, clinical outcomes [58].
5. Cost-effectiveness and sustainability analysis: Assess the resource and financing implications of scaling, including staff time, training costs, and information communication technology (ICT) investments. These analyses will help policymakers weigh trade-offs between manual and digital approaches [59].

Conclusions

This pilot usability evaluation suggests that participating frontline neonatal health care workers generally perceived the neonatal risk predictor tool as usable, learnable, and clinically relevant, while also identifying workflow-sensitive barriers, particularly staffing pressures and documentation duplication, that may influence implementation. These findings support proceeding to larger, methodologically rigorous evaluations while simultaneously investing in pragmatic onboarding, workflow integration, and infrastructure planning to maximize the potential for real-world impact. Given the global priority of reducing neonatal mortality, pragmatic usability evidence such as ours is a necessary step toward responsibly translating ML into safer, more timely neonatal care.

Acknowledgments

The authors would like to thank all health care professionals and facility leaders who participated in this study for their time, insights, and contributions. We are particularly grateful to the participating health facilities in Kenya for their collaboration and support during data collection and implementation activities. We also acknowledge the contributions of research assistants and local coordinators who supported data collection, transcription, and field logistics. Their efforts were essential to the successful completion of this study. The authors used OpenAI to assist with language editing, manuscript refinement, and figure refinement for publication. All AI-assisted outputs were critically reviewed, verified, and edited by the authors, who take full responsibility for the accuracy, integrity, and final content of the manuscript.

Data Availability

The datasets generated and analyzed during the current study are not publicly available due to ethical and confidentiality restrictions. The data include deidentified qualitative interview transcripts collected from healthcare professionals within specific health facilities in Kenya. Given the small sample size and context-specific nature of the facilities, public sharing could potentially compromise participant confidentiality. Deidentified data may be made available from the corresponding author upon reasonable request, subject to institutional and ethical approval and applicable data protection requirements.

Funding

A Frontiers Seed Funding (Grant number FS-2425-23-127) from the Royal Academy of Engineering has been received to support this study.

Abstract

Background: Digital microinterventions are increasingly used to support stress self-management in everyday life. While previous research has examined their feasibility, adherence, and preliminary effectiveness, much less is known about how these interventions are experienced over extended periods of real-world use.

Objective: This study used collaborative autoethnography (CAE) to examine the everyday experience of living with MINT (Micro-Interventions for Navigating Tension), a Telegram-based chatbot for stress management. Our goal was not to evaluate clinical outcomes but to understand how scheduled microinterventions fit into everyday life, when they were ignored, and when people relied on other ways of coping instead, and to identify implications for the design of future digital mental health tools.

Methods: We conducted a 4-week CAE involving 5 digital mental health researchers, who used the MINT chatbot as both participants and researchers. The experience was documented through multiple qualitative and quantitative sources, including reflective diaries, ecological momentary assessments (EMAs), workshop discussions, and wearable data, and analyzed collaboratively using reflexive thematic analysis (RTA).

Results: Six interconnected themes described how MINT was experienced in everyday life: (T1) the importance of timing and emotional receptivity, (T2) the need for reciprocity and relational continuity, (T3) the tendency to favor existing coping strategies over suggested exercises, (T4) the meaning of nonengagement during periods of high stress, (T5) the collapse of self-initiated use after reminders were removed, and (T6) how everyday experiences with consumer wearables and general-purpose large language models reshaped expectations of digital mental health systems.

Conclusions: Our findings show that CAE complements conventional evaluations of digital mental health interventions by revealing aspects of everyday use that are difficult to capture through feasibility studies, large-scale trials, or looking at usage data. Beyond the specific case of MINT, they suggest that future stress-management systems should better account for users' receptivity, provide greater continuity across interactions, build on existing coping strategies, and help users move from externally prompted engagement to autonomous self-management.

Introduction

Stress is a pervasive challenge that affects psychological well-being, cognitive functioning, and overall quality of life [1]. Despite its prevalence, individuals often lack accessible, personalized tools to help them recognize and regulate stress. Digital mental health interventions (DMHIs), including mindfulness apps [2], chatbots [3], ecological momentary interventions (EMIs) [4], and wearable devices [5], have attempted to fill this gap by delivering support outside clinical environments. One approach that has attracted growing attention is the use of digital microinterventions. Microinterventions are short, structured therapeutic activities, such as cognitive reappraisal [6], guided breathing [7], positive imagery [8], or mindfulness exercises, that can be completed in under a few minutes [9]. Their brevity and adaptability make them well suited for real-world stress self-management, where users often have only small windows of time available. Research has already explored several ways of delivering microinterventions in

XSL•FO
RenderX

everyday settings. For example, Microsoft researchers [10] have developed a just-in-time adaptive intervention (JITAI) system for workplace stress management, showing that context-triggered support, derived from indicators, such as email load, meeting frequency, time of day, facial expression cues, and heart rate, can be feasibly delivered and meaningfully integrated into daily activities. Other work [11] has focused on wearable-based approaches, where smartwatches periodically prompt users to report how they feel and then offer brief, breathing-oriented microinterventions to support emotional regulation during moments of elevated arousal. Further analysis [12] has evaluated a range of cognitive behavioral therapy (CBT)–based techniques to identify particularly promising exercises and examine how different stress levels may align with specific intervention strategies. Finally, a study [13] conducted a microrandomized trial with parents using the commercial mindfulness app Headspace to assess the feasibility and acceptability of delivering mindfulness-based microinterventions for stress regulation in daily life.

However, most field evaluations focus on feasibility, adherence, or preliminary outcomes and not on the lived experience of interacting with microinterventions across an extended period. As a result, while many of the practical challenges surrounding engagement with digital microinterventions have already been identified, we still know comparatively little about how these challenges play out in everyday life: how such interventions fit (or fail to fit) into daily routines, how users make sense of the activities, how emotional context shapes engagement, or how motivation fluctuates across weeks. This limitation reflects a broader concern in digital mental health research. Large trials and log-based analyses, while valuable for quantifying use, often miss how engagement is shaped by everyday contexts and circumstances, making it difficult to explain why people sustain or abandon DMHIs. Prior work [14] on "trial bias" further suggests that engagement observed in controlled studies may not reflect real-world use, underscoring the need for methodologies that foreground real-life contexts and subjective experiences. To better understand these everyday dynamics, researchers have increasingly turned to methods that foreground lived experience. This shift has prompted researchers both to involve users as collaborators, helping to interpret how digital mental health tools shape and are shaped by identity, emotion, and daily routines [15,16], and to turn the analytic lens inward, using autoethnographic methods to generate richly contextual insights from their own experiences [17]. This growing interest is reflected in recent work. Authors of the study [18], for example, used autoethnography to explore how low-tech event-logging can be used for smartphone disengagement. Another study [19] tracked 16 weeks of sleeping with a companion robot, highlighting how emotional and relational dynamics emerge through extended use. More recently, the authors of the study [20] used a duoethnographic design to examine how wearable-triggered prompts and large language model (LLM)–based interventions unfold in daily life.

This paper presents a collaborative autoethnography (CAE) [21] of MINT (Micro-Interventions for Navigating Tension), a Telegram chatbot delivering brief stress-management exercises through scheduled prompts and user-initiated access. Our goal was not to evaluate clinical efficacy or stress-contingent delivery. Instead, we used MINT as a formative case to examine a more basic design problem: how scheduled microinterventions are taken up, resisted, or displaced in everyday life. Over 4 weeks, 5 researchers used the system while documenting their own experiences as both users and designers. Through this case, we explore the conditions under which scheduled microinterventions fail to become part of a person's own coping repertoire and derive implications for the design of future stress-management systems.

Methods

Overview of the MINT Prototype

MINT is a Telegram chatbot designed to support stress self-management through brief, evidence-based microinterventions. The system aims to provide immediate stress relief while helping users develop skills for everyday resilience by teaching exercises that foster resilience. Users can log mood, stress, sleep, physical activity, and coping strategies, as well as record reflections in a diary-style format (Figure 1). Exercises (microinterventions) are available both through scheduled ("push") delivery and user-initiated ("pull") access, allowing users to actively select both the exercise and its delivery style. MINT's interventions are grounded in CBT techniques and include cognitive reappraisal [6], controlled breathing [7], positive mood induction [8], smiling [22], and guided visualization of one's best possible self [23]. Each exercise lasts under 5 minutes and can be tailored to match the user's preferred learning style according to the visual, aural, read/write, kinesthetic (VARK) framework [24], adapting its delivery as a visual diagram, audio guide, written instructions, or kinesthetic prompt (see an example in Multimedia Appendix 1). VARK variants were intentionally introduced to support learning and skill acquisition and to eventually help users internalize stress-management techniques. The flows of exercises were designed by the research team and delivered through scripted conversations in the chatbot interface.

XSL•FO
RenderX

Figure 1. Screenshots of the MINT (Micro-Interventions for Navigating Tension) Telegram chatbot illustrating core interaction types: (A) delivery of a scheduled microintervention, (B) manual stress and mood recording, (C) menu for user-initiated ("pull") selection of any exercise, and (D) ecological momentary assessment (EMA). All information related to real people has been censored. All remaining conversations are fictional; therefore, consent is not required.

A B C D

At the start, MINT collects an initial user profile, including personality (Big Five Inventory-10 [BFI-10; 25]), coping style (COPE-28 [Coping Orientation to Problems Experienced-28; 26]), cognitive style (Rational Experiential Inventory-13 [REIm-13; 27]), and learning style preferences (VARK v8.01 [28]); while most measures are used for research purposes, only the VARK preference guides personalization. Optional wearable integration is also supported and enables passive monitoring of physiological signals, such as electrodermal activity (EDA), heart rate variability (HRV), and skin temperature, to gather exploratory insights into the feasibility of wearing a smartwatch for multiple weeks and user perceptions of such data. Architecturally, MINT was developed as a rule-based conversational agent using Node.js and the grammY framework for Telegram API integration. Interventions and ecological momentary assessment (EMA) delivery followed scripted, finite-state decision trees, with user responses, logged metrics, and interaction timestamps stored in a MongoDB database. Scheduled push notifications were triggered via automated background cron jobs on a dedicated self-hosted server.

Study Design

As anticipated in the *Introduction*, we chose CAE to explore our lived, day-to-day experiences of using the MINT chatbot. The CAE [21] is a qualitative methodology in which researchers document and interpret their own experiences in a systematic and collective way, making visible aspects of everyday experience that are difficult to capture otherwise.

Participants and Researcher-Participant Positionality

All 5 authors served as researchers-participants (RPs; Table 1), engaging with MINT over a 4-week period in June 2025 while reflecting on its role in our daily lives. Each of us had prior experience studying or designing digital mental health technologies, and 1 (RP2) had led the development of the MINT prototype. Recognizing that this shared expertise inevitably shaped our expectations and interpretations, we paid explicit attention to positionality throughout the study, regularly discussing in debriefing sessions how our disciplinary backgrounds, design knowledge, and personal histories influenced our experiences and sensemaking of MINT.

Procedures

We interacted with MINT through the Telegram bot for 28 consecutive days following a structured weekly progression (Table 2), with each week focusing on different modes of engagement and intervention delivery to introduce frictions, sustain learning, and elicit responses under different conditions.

Table . Overview of the 4 experimental phases (weeks 1 - 4) and their respective intervention delivery strategies.

Week	Phase name	Description	Key focus/purpose
#1	Preferred modality delivery	One daily afternoon microintervention delivered in the participant's dominant VARK[a] learning preference.	Establish a baseline of "comfortable," intuitive, and preferred engagement.
#2	Nonpreferred modality delivery	Daily interventions continued but were intentionally mismatched with the participant's VARK preferences.	Create mild friction; explore resistance, adaptability, and emotional reactions to nonpreferred formats.
#3	Participant-selected activities	No specific exercises suggested; participants received only 1 daily prompt inviting them to choose any intervention themselves.	Shift responsibility to the user; emphasize autonomy and the cognitive/emotional effort of self-selection.
#4	Free-use period	All scheduled prompts removed; participants could interact (or not interact) with MINT[b] entirely on their own terms.	Capture fully self-directed patterns of engagement and disengagement.

[a]VARK: visual, aural, read/write, kinesthetic.

[b]MINT: Micro-Interventions for Navigating Tension.

XSL•FO
RenderX

Each weekday, we received an EMA in the morning at 9:15 AM, another EMA in the afternoon at 7:15 PM, and a microintervention at 6:15 PM (Table 2). To reduce burden, we received no interventions on weekends, and on these days we only completed the morning and afternoon EMAs. At the end of the 4 weeks, we hosted 2 in-person postintervention reflective workshops [29] (each approximately 90 min long) to revisit our experiences and develop a shared interpretation of the 4-week journey. The sessions were audio-recorded and transcribed to support subsequent analysis.

Ethical Considerations

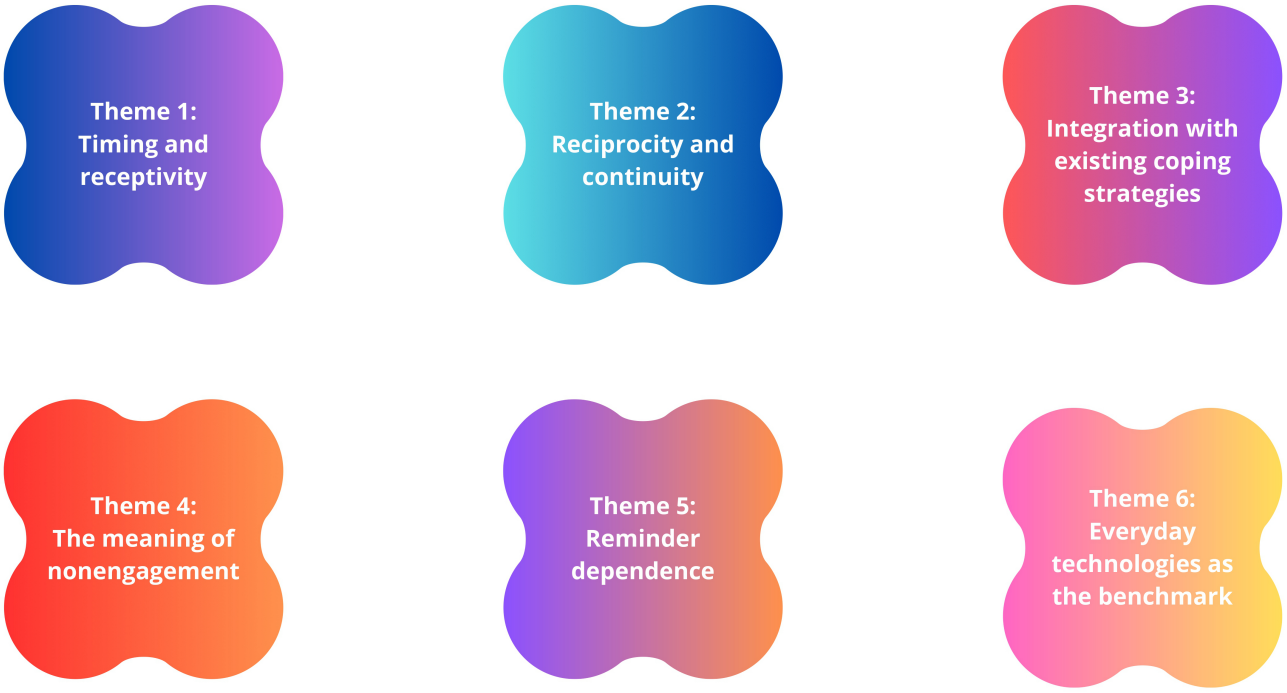
This study was conducted in full accordance with the Declaration of Helsinki and with current Italian regulations governing research involving human participants. In this case, in line with Italian Law No. 3/2018 [30] (Art. 2, paragraphs 7 and 10), formal ethics committee approval was not required because the investigation focused exclusively on the usability and lived experience of a prototype digital intervention, did not involve patients or vulnerable individuals, and did not entail any clinical treatment. Nevertheless, all RPs provided voluntary, written informed consent before enrollment, were free to withdraw from the study at any time without consequence, and were fully informed about data handling procedures.

Data Collection

To capture our experiences from different perspectives, we collected multiple forms of data throughout the 4-week study period. Each of us kept a personal diary, noting episodes of stress, how the chatbot fit into our daily routines, and our emotional reactions to each interaction (eg, comfort, resistance, irritation, or relief). These diaries served as our primary narrative record that captured not only what happened but also how it felt to navigate ordinary routines with the system in the background. Alongside these individual accounts, we maintained a shared reflexive log where we posted brief observations, patterns we noticed, or questions we wanted to revisit later. These shared notes often prompted new reflections in our personal diaries, creating a fluid back-and-forth between private and communal sense-making. The interactions with MINT also generated an additional source of data. Our EMA responses and free-text messages, collected through the chatbot, provided brief snapshots of mood and stress that enriched the corpus of personal reflections. Finally, 3 of us used wearable devices for continuous physiological monitoring: RP2 wore an EmbracePlus (Empatica Inc) [31], RP4 wore a Galaxy Watch 4 (Samsung Electronics) [32], and RP3 wore a Watch SE2 (Apple Inc) [33]. These devices generated continuous physiological data throughout the study, complementing our subjective accounts while also revealing what it was like to live with continuous stress monitoring.

Data Analysis

All qualitative data were analyzed through reflexive thematic analysis (RTA) [34], following the 6-phase analytic process described by Braun and Clarke [35]. Consistent with the logic of CAE, the 2 postintervention workshops served as the primary site of analysis, providing a space for collective sense-making through which researchers reflected on, interpreted, and negotiated the meaning of their experiences. These discussions served as the main point of theme generation, capturing shared and divergent experiences with the MINT chatbot. The resulting themes were then revisited across the broader dataset, including personal diaries, the shared reflexive log, stress entries, EMAs, and summaries of wearable data, to refine and contextualize the emerging interpretations. All materials were stored in a shared Google Drive folder, cleaned for clarity, and anonymized using nonidentifying placeholders (eg, [NAME] to replace actual names of people cited in the notes/transcripts) and participant codes (RP1-RP5). Throughout the analysis, we documented emerging themes and analytic decisions in a shared codebook. The final themes reported in this paper reflect what emerged through this collaborative process of integration, shared discussions, and individual reflections across all data sources.



Results

Themes Identified Through Interactions With MINT

Over the 4 weeks, our collective engagement with MINT evolved in ways that were often surprising and sometimes frustrating. Across the entire corpus analyzed, 1 pattern became clear: our responses to the chatbot were not simply reactions to individual exercises. They depended just as much on when the prompts arrived, what we were already doing to cope, how much effort the interaction required, and whether the system seemed able to give anything back. We identified 6 interrelated themes (Figure 2) that describe core design challenges that emerged through interaction with MINT (more details on themes, subthemes, and coding instances are reported in Multimedia Appendix 2).

XSL•FO
RenderX

Figure 2. Overview of the 6 themes identified through collaborative reflexive thematic analysis (RTA).

Theme 1: Timing and Receptivity

From the first few days, the timing of MINT's notifications made a noticeable difference in how we received its exercises. There were moments when an intervention arrived just as we were settling into routines we had intentionally carved out for ourselves, like cooking dinner or finally sitting down to relax. RP2 captured this most vividly: "Very often [notifications from MINT] arrived when I was doing something else… For example, one day I had just turned on the Xbox, I was finally relaxing, and the reminder came. At that moment the bot was stealing the only space of peace I had managed to carve out." That feeling of intrusion was shared by all of us: even brief prompts could turn a low-stress moment into a jolt of irritation, not relief. But it was not only the schedule that mattered; our emotional state at the moment of delivery was equally decisive. Exercises framed with positivity, like visualizing the best possible self or the smiling exercise, were polarizing. When we were relatively calm, these exercises could feel energizing or pleasant. But on days when tension was high, the same prompts sometimes backfired. RP4 put it perfectly: "The best possible self is a perfect example of a double-edged tool… when I was already feeling down it made me feel worse, because I was imagining a version of myself that was completely unreachable at that moment." Smiling exercises could feel hollow or even irritating under stress, while other exercises, like controlled breathing, felt neutral and safe, something we could do without pretending that everything was fine. They demanded little emotional effort and could be accessed regardless of mood. These experiences showed us how timing and emotional alignment worked together as gatekeepers. The same exercise could either be welcomed or rejected depending on when it arrived and how we felt. For instance, even an exercise we normally enjoy could trigger annoyance if it appeared at a moment when our attention or emotional bandwidth was low. As the weeks went on, we noticed this pattern more clearly. We started anticipating how we might feel before even opening MINT, sometimes ignoring notifications in advance, preemptively judging the exercise's fit with our current state. Over time, we realized that acceptability was not just about content, but about context, about how each exercise intersected with the unpredictable rhythms of daily life.

Theme 2: Reciprocity and Continuity

Another recurring experience concerned the balance between effort and return. Using MINT required regular attention: daily EMAs, diary entries, exercise completion, and occasionally syncing wearables. Yet, despite investing this energy, there was little sense that the bot responded to us or incorporated our input in any meaningful way. RP5's reflection expressed this plainly: "You give the chatbot a lot of data but you get nothing back… no real insight." This sentiment resonated across the group. At times, the bot felt like an "empty box" (RP2) or "just another sequence of homework," (RP5), with no acknowledgment of what we had already done. Over time, we realized how much relational cues mattered. Small conversational touches, such as brief comments, acknowledgment of previous entries, and even light humor, could have made exercises feel less transactional. RP2 captured this perfectly: "The role of small talk is fundamental… Those circumstantial chats are what unblock everything in in-person counselling sessions. If you arrive at the therapy room and the counselor immediately applies a cognitive-behavioural technique, you feel you are only receiving directives." We noticed that without any sense that the bot "knew" us or remembered our past engagement, its exercises sometimes felt cold, prescriptive, and burdensome. Some of us also wanted visible feedback as evidence that our engagement mattered. RP1 wrote in her notes, "I would have loved a simple dashboard, even just a weekly message saying 'Last week you felt better on the days you walked more … shall we use that?'… something that shows the bot is actually doing something with everything I'm giving it." Without this, even well-designed

XSL•FO
RenderX

exercises sometimes felt like chores. Over time, this shaped how and when we engaged, as the perceived effort of participation without visible reciprocity began to weigh more heavily than the potential benefits of the exercises themselves.

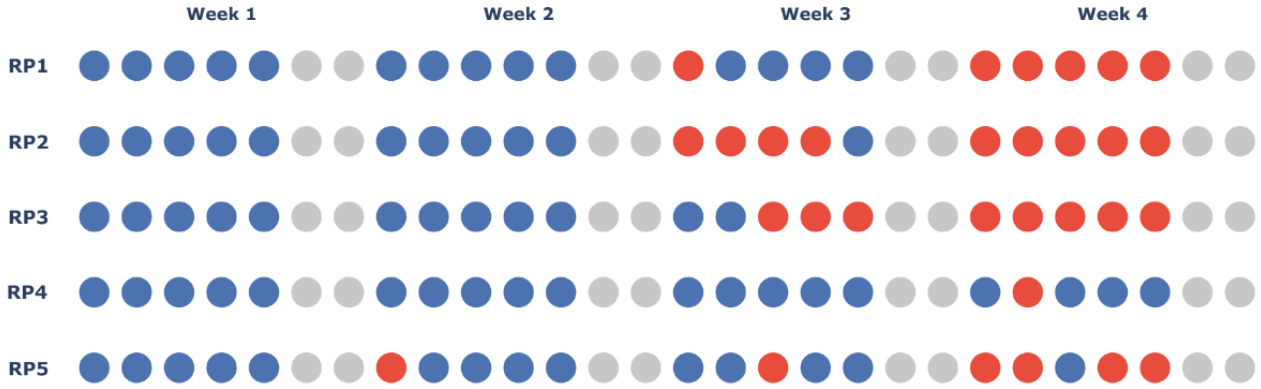
Theme 3: Integration With Existing Coping Strategies

The moments when we truly felt the tension dissolve rarely lined up with finishing a MINT exercise. More often, relief arrived through small, familiar things we reached for on our own, like going for a run (RP1), walking the dog in the evening light (RP3), turning the car into a private concert hall and singing at the top of our lungs while stuck in traffic (RP2), curling up with a novel for 10 quiet pages (RP4), sketching, or simply loading a favorite video game. These strategies also shared another characteristic: they worked quickly and intuitively. RP1 noted, "I already know what works for me … running gives me the endorphins, loud rhythmic music settles my breathing, a few pages of fiction melt the noise in my head… it just does." Even when MINT exercises were tailored to our VARK preferences, they often felt slower or more effortful compared with strategies we had already internalized. We noticed ourselves comparing the 2: the structured exercises vs our own spontaneous coping tactics. The comparison was stark: while the exercises were often interesting or novel, they did not always provide the immediate, visceral relief that our own strategies did. Over time, we started to integrate MINT exercises selectively, favoring moments when our usual strategies were unavailable or when we wanted to experiment with a different approach. This realization prompted deeper reflection on how we individually manage stress and how digital interventions fit into those practices. It became clear that while MINT offered structured, evidence-based exercises, the most meaningful support often came from us and the routines we had developed over years of trial and error. Over the weeks, our engagement with the bot shifted from following instructions to observing, reflecting, and occasionally experimenting, blending our spontaneous coping strategies with its prompts when it seemed useful.

Theme 4: The Meaning of Nonengagement

One pattern became impossible to ignore over the 4 weeks. Our engagement, or lack of it, was closely tied to moments of stress. The periods when we did not interact with MINT often turned out to be the most informative. On low-stress days, we were conscientious, completing EMAs, logging diary entries, and experimenting with exercises. Yet, when stress peaked, our interactions dropped sharply. RP2 described this clearly: "My engagement pattern made me think of missing not at random [MNAR] … the classic example to understand MNAR is the alcoholic who doesn't fill in the questionnaire when he drinks. Here, when I was really overwhelmed, I simply didn't record anything." This was true for all of us: periods of silence were rarely accidental; they were protective withdrawals from additional effort or exposure to stress. For instance, one of us (RP3) missed every EMA on the day of a major work crisis, while another (RP2) did not engage with interventions and left diary entries blank for 3 consecutive days, later recalling them as "the worst [part] of the entire month." In these moments, engaging with MINT felt like adding friction rather than offering relief. As we revisited our diaries, EMAs, and workshop discussions, the blank spaces themselves became meaningful signals. They came to represent moments when the support we most needed was, paradoxically, the hardest to access. We began to treat missing entries as informative, signaling not a failure of adherence but the contours of our emotional landscape. Interestingly, these gaps also shaped how we thought about the system's design. We realized that MINT had no way to detect absence or adapt when we withdrew. In contrast to times when engagement was high, peak stress moments were invisible to the system, and its push notifications often went unanswered, further emphasizing the mismatch between system design and lived reality. By the end of the study, we collectively understood that these silences were not just "missing data" in a technical sense; they were data in themselves, communicating both our states of mind and our coping capacity. Recognizing this made us reflect differently on the metrics of success for digital interventions: completion rates alone were insufficient. The pattern of nonengagement became a story in itself, narrating where MINT could not reach us and where the system might have needed to adapt.

Theme 5: Reminder Dependence



Week 4 was revealing for us in a way we hadn't anticipated. We made a provocative and deliberate choice: at the start of the week we switched off every scheduled notification overnight. No gentle tapering, no transitional phase, just silence. In real-world deployments, this would be unusual and potentially harmful, but for us, it was intentional. We wanted to force the question: once the external scaffolding disappears, what remains? The answer came within hours and could not have been clearer.

Within 2 days, 4 of the 5 participants had essentially abandoned the bot (Figure 3). As RP2 summed it up in the second workshop, "Without reminders the intervention crashed… we all crashed, except you RP4." RP4 was the quiet exception. She continued to use controlled breathing and deliberate walking at genuine moments of tension. The techniques had become hers; the bot had successfully faded away. For the rest of us, when the prompts vanished, so did any impulse to seek the bot out. The radical week 4 switch acted like a stress test that exposed a truth we would otherwise have discovered only after months of gradual disengagement: the first 3 weeks had trained dependence, not independence. We had inadvertently built a system that functioned like a daily pill, something you take because it arrives, not because you have learned to live differently. Curiosity and our duty as researchers had kept us compliant, but MINT had never become a companion in genuine behavior change. This realization hit hard. Microintervention systems are often conceived as short-term analgesics: deliver evidence-based techniques, reduce symptoms, repeat. But week 4 showed that symptom relief without skill transfer is little more than digital pharmacology: effective only as long as the external dose keeps coming. True behavior change companions, by contrast, must do the opposite of a pill: they must work themselves out of a job by helping the person internalize new patterns until the tool itself becomes optional. RP2 articulated how we should have used those crucial early days instead: "The week should be a protected onboarding and alliance-building

XSL•FO
RenderX

phase. The bot should be deliberately present, even chatty, but with one clear message: 'For the next week I'll be around a lot, not to give you homework, but so we get to know each other and so you learn exactly how to use me when you actually need me.' It teaches transparently: how stress works in the body, why breathing is an instant reset, why movement is medicine. It gives three or four one-word commands ('BREATHE,' 'WALK,' 'PAUSE,' 'VENT'). Every evening it asks one gentle question: 'One thing that helped today?' or 'Anything you want me to remember?' By the end of that week the user trusts the bot, feels seen, and knows precisely how to call for help. Only then do you start fading the prompts." The abrupt week 4 silence was therefore not a flaw; it was the perfect diagnostic. By removing the external "dose" all at once, it revealed that we had built a pharmacological tool rather than a behavior change companion. It proved that genuine autonomy is cultivated from day 1 through transparency, psychoeducation, felt understanding, and explicit pathways for self-initiation. In other words, our prototype taught us how to design another version of it that, like the best therapist or coach, eventually makes itself proudly obsolete.

Figure 3. Participant timeline showing daily engagement patterns (completed microinterventions) with the MINT (Micro-Interventions for Navigating Tension) chatbot. Red indicates that the RP did not engage with MINT, whereas blue indicates that the RP engaged with MINT. RP: researcher-participant.

Theme 6: Everyday Technologies as the Benchmark

Finally, 3 of us (RP2, RP3, and RP4) wore wearable devices to capture physiological signals during the study. In practice, the data provided by those devices proved far less useful than we had hoped. Signals were noisy and frequently mismatched with how we actually felt. As RP2 recalled a frightening moment on the road, "A car almost hit me on a bend… I expected a massive peak [in EDA]… instead I saw nothing at all." RP4 regularly experienced the reverse: "I felt calm and it said I was super stressed…" Practical difficulties added to the disappointment. Two of us (RP1 and RP4) developed skin irritation within the first week, even with the medical-grade device, and daily charging became another small but persistent hassle. By the second workshop, we agreed that, for the moment, wearable-derived stress metrics remain too inconsistent and burdensome to serve as a reliable foundation for everyday intervention. They generated interesting patterns for post hoc reflection but could not be trusted in real time. Wearables, however, were not the only benchmarks that shaped how we experienced MINT. An even more unexpected comparison emerged from our own everyday habits. We ourselves, while testing MINT, began turning to general-purpose LLMs for the emotional support that the prototype was not providing. As RP4 admitted with a half-smile, "I write everything I'm feeling on ChatGPT… it helps just to put the words down… it's my free psychologist … well, cheap psychology anyway. [laugh]" The joke landed because it was true for several of us (RP2, RP3, and RP4). During the same 4 weeks we were dutifully completing MINT's EMAs and exercises, we were also quietly opening ChatGPT (OpenAI) to vent after a hard day, draft angry messages more calmly, externalize racing thoughts, or simply to feel heard when the structured bot stayed silent. These parallel conversations were never part of the protocol; they happened spontaneously, often late at night or in moments of peak frustration. Some exchanges were brief check-ins, others long, meandering threads that continued over days. We noticed the same patterns: the model remembered what we had said before, asked gentle follow-up questions, and responded with a warmth that, however simulated, felt caring. A few of us also observed that, at times, chatting with an LLM could have downsides, like enabling prolonged rumination rather than gently interrupting it. Instead of recognizing the loop and helping the person close or rework the situation, the model simply kept the conversation going. We had deliberately designed MINT to be short, focused, and emotionally neutral in order to respect time and clinical rigor. In practice, we found ourselves seeking out something more verbose, curious, and unmistakably human-like. Current openly available LLMs, tools never intended for therapeutic use, quietly showed us the level of continuity, attentiveness, and conversational space that users now expect from any digital companion. The unreliable wearables and our own unsolicited use of LLMs reminded us that users (even when the users are the designers) do not evaluate a new intervention in isolation. We compare it, consciously or not, with everything else already in our hands.

Discussion

Principal Results and Comparison With Prior Work

Contribution of CAE

Digital mental health research has already identified many of the challenges discussed in this paper, including issues related

XSL•FO
RenderX

to timing, engagement, personalization, attrition, and the limitations of current sensing technologies. We do not present these themes as entirely new findings. Their value lies instead in the level of detail with which CAE allowed us to examine them from the inside: not only as design problems but also as experiences that unfolded, accumulated, and changed meaning across ordinary days. As anticipated in the *Introduction*, traditional trials, log analyses, and feasibility studies can show when engagement drops, which prompts are completed, and which features are preferred. CAE allowed us to ask a different question: what does it feel like when those patterns happen, and how do users make sense of them while they are living with the system? These forms of evidence are complementary rather than competing. In this discussion, we therefore use the literature as a point of orientation but focus on what the CAE perspective added to each theme: the mechanisms, tensions, and lived interpretations that are often flattened in aggregate engagement metrics.

Theme 1

The first example is about timing. JITAI research has already shown that receptivity depends strongly on when support is delivered [36]. Poorly timed prompts can reduce engagement, while better-timed ones can make digital support feel more relevant. What our CAE made visible, however, was the deeper meaning of "poor timing." A mistimed prompt was not simply inconvenient. At times, it interrupted a moment participants had actively created to recover from stress. This matters because the system was not only competing with work, distraction, or busyness; it was also sometimes competing with users' own successful attempts at restoration.

This also aligns with the occupational psychology literature on the importance of psychological detachment and psychological restoration, which underscores the importance of preserving personal downtime for the recovery of depleted cognitive and emotional resources [37,38]. From this perspective, the design issue is not just interruption management; it is the risk that an intervention aimed at supporting regulation may disturb an ongoing act of self-regulation.

The CAE also helped us distinguish need from receptivity. In everyday use, higher stress did not automatically translate into greater openness to support. Some exercises required a degree of emotional availability that was absent precisely when stress was high. Others, especially lower-effort regulation strategies such as breathing, felt easier to access across a wider range of states. This points to a narrow and unstable window: enough distress for support to matter, but enough attentional and emotional bandwidth to engage with it. Current wearable approaches often equate physiological arousal with need [39-41], but our experience suggests an inverted-U pattern: too little arousal yields little or no benefit, whereas excessive arousal triggers protective withdrawal; this underscores why linear "more arousal equals more need" algorithms risk delivering interventions precisely when users are least able or willing to receive them.

Theme 2

Findings on the perceived lack of reciprocity and relational cues instead extend previous work showing that relational agents support sustained engagement [42,43]. Our experience suggests that the issue goes beyond conversational style. Throughout the 4 weeks, participants rarely questioned the quality of the exercises themselves. Instead, frustration accumulated because the effort invested in the interaction seemed to disappear into the system. Logging moods, completing EMAs, and recording reflections gradually came to feel like one-way transactions, with little indication that MINT was doing anything with that information. Seen in this light, reciprocity is not simply about making a chatbot warmer or more socially engaging. It is about making users feel that their contributions have consequences. Even small signals (eg, a reference to a previous interaction, a brief acknowledgment, or a simple synthesis of recurring patterns) could have changed how participants interpreted the same interaction. The absence of these cues shifted the perceived balance between effort and value, until the exercises themselves began to feel increasingly transactional. This resonates with previous work showing that users disengage when conversational agents fail to establish a sense of relationship or continuity [44,45]. Reading back the workshops, what stood out was that we rarely asked for a more empathic chatbot. We asked for signs that the chatbot was listening. Those are related ideas, but they are not the same. The issue was less the absence of warmth than the absence of evidence that previous interactions had shaped subsequent ones.

Theme 3

Theme 3, on the other hand, resonates with longitudinal studies showing that people rarely adopt the full repertoire of techniques offered by mindfulness or CBT apps, instead selecting only those that fit their everyday lives [46,47]. Our experience suggests that this selectivity is not simply a matter of personal preference. Throughout the study, participants seemed to evaluate each proposed exercise against an already existing repertoire of coping strategies that had been built through years of experience. The decision was rarely "Is this exercise good?" It was closer to "Is this more useful than what I would naturally do right now?" Familiar activities such as walking, running, reading, or listening to music were not necessarily perceived as more evidence-based or therapeutically sophisticated. They simply required little deliberation, carried no learning cost, and already belonged to participants' habits. Structured microinterventions, therefore, entered an environment where effective coping strategies were already in place, rather than an empty space waiting to be filled. This perspective is consistent with the person-based approach to intervention development [48], which emphasizes understanding how interventions fit within people's existing lives rather than expecting people to adapt to the intervention. Our findings reinforce this principle by suggesting that future systems should explicitly discover and build upon users' own coping repertoires from the outset. This does not reduce the value of evidence-based exercises. Instead, it positions them as additions to an existing repertoire, introduced when they genuinely expand what users can already do rather than asking them to replace or take the place of strategies that already work.

XSL•FO
RenderX

Theme 4

Nonengagement during periods of elevated stress is a phenomenon that has already been described as a form of MNAR data in digital mental health research literature [49], and similar patterns have been reported in studies of depression and bipolar disorder, where drop out often coincides with symptom worsening [50,51]. Even in this case, our experience did not challenge this interpretation. It added something more specific: the opportunity to understand what those missing moments actually represented from the participant's perspective. Looking back together at diaries, workshop discussions, and EMA records, we found that periods of nonengagement rarely appeared as simple lapses in adherence. They reflected moments in which interacting with the system itself had become one demand too many. This perspective echoes recent calls to treat nonuse as meaningful data rather than simply as adherence failure [49,52,53]. Our findings suggest that the next step is not only to detect these patterns computationally but also to understand the circumstances that produce them. From a design perspective, prolonged silence should perhaps be interpreted less as disengagement from the intervention itself and more as a potential indicator that the demands of engaging with the intervention have temporarily exceeded the user's available capacity.

Theme 5

Similarly, the sharp decline in self-initiated use after scheduled reminders were removed reflected a challenge that is increasingly being documented across many DMHIs. Longitudinal evaluations of commercial apps consistently report high initial engagement followed by substantial attrition over time [54,55]. Our experience suggests that this transition deserves attention not only as an engagement problem but also as a question of learning (in the sense of internalizing intervention strategies). What remains once the external structure disappears? Considering this theme alongside theme 3 offers 1 possible interpretation. Throughout the study, participants continued to rely on coping strategies that had become part of their everyday routines through years of personal experience. By contrast, most of the chatbot exercises remained closely associated with the chatbot itself. They were completed when prompted, but they rarely became something participants reached for independently. RP4 was the only participant who continued using exercises after the reminders had disappeared. In her case, the strategies had become detached from the chatbot that had introduced them and had entered her everyday coping repertoire. This distinction may be more important than continued use of the chatbot itself. A successful intervention is not necessarily one that people keep opening indefinitely but one whose underlying strategy gradually becomes part of their own repertoire. When that transfer does not occur, engagement risks remaining dependent on the external structure that originally sustained it.

Theme 6

Finally, theme 6 broadens the lens beyond the chatbot itself. As we reflected on our experience, it became increasingly clear that we were not evaluating MINT against an abstract idea of a digital intervention. We were comparing it, often implicitly, with technologies that had already become part of everyday life and had quietly reshaped our expectations. General-purpose LLMs were the clearest example of this shift. We did not expect MINT to become an open-ended conversational agent, nor did we see that as its purpose. Instead, interacting daily with LLMs had changed what a conversational system was expected to do. When read alongside theme 2, the issue was not simply conversational warmth. It was continuity. We expected signs that previous interactions still mattered: that the chatbot remembered, connected, and built on what had already been shared. As these behaviors become commonplace in everyday AI systems, their absence becomes more noticeable even in highly structured digital health interventions. Recent work is beginning to document similar shifts in users' expectations of specialized mental health tools [56-58].

Just as LLMs have changed our expectations of conversation, the increasing presence of wearable devices in our lives has also shaped our expectations of physiological sensing. Simply wearing a device that continuously monitors physiological signals creates the expectation that the system will recognize meaningful changes in one's state. Across our reflections, the critical issue was not occasional inaccuracies themselves but what happens after repeated mismatches between sensed data and lived experience. Those moments gradually weaken confidence that the system can recognize when support was actually needed. Previous work has extensively discussed the technical challenges of using consumer wearables for stress detection in everyday settings [59-61]. Our experience suggests an additional consequence that is less often examined: repeated mismatches may gradually erode users' willingness to rely on physiological sensing as the basis for intervention delivery. From the user's perspective, sensing is not evaluated signal by signal but through the accumulation of moments in which physiological measures either correspond or fail to correspond with lived experience.

Design Implications and Directions for Future Research

Designing DMHIs often begins with deciding what support to provide. Our experience suggests that just as much attention should be given to what happens after that support is introduced into everyday life. Many of the design implications that emerged from this study concerned not the content of the interventions themselves but the conditions that shaped how they were experienced and, over time, whether they became part of everyday routines. To translate these observations into practical guidance for both the further development of MINT and the design of future digital stress-management interventions, Table 3 synthesizes the key design challenges emerging from our findings together with their corresponding design implications.

XSL•FO
RenderX

Table . Design implications for digital microintervention systems for stress management derived from the 6 collaborative autoethnography (CAE) themes.

Design focus	Key empirical insight	Design implication
Receptivity-aware intervention delivery	Theme 1	Develop receptivity-aware triggering that goes beyond physiological arousal, estimating not only when support is needed but also when users are likely to have sufficient emotional and attentional capacity to engage with it.
Relational continuity and reciprocity	Theme 2	Treat continuity across interactions (eg, remembering previous inputs and acknowledging earlier exchanges) as a core design feature rather than a conversational enhancement.
Integration with existing coping strategies	Theme 3	Design microinterventions to extend users' existing coping repertoires rather than compete with or replace them.
Accounting for nonengagement	Theme 4	Redefine nonengagement patterns as meaningful signals (MNAR[a]) that should inform adaptation and evaluation, rather than interpreting them only as adherence failure.
Transition to autonomous use	Theme 5	Design explicit pathways through which users gradually move from prompted engagement to self-initiated coping, allowing reminders to fade as strategies become part of everyday life.
Appropriate use of wearable sensing	Theme 6	Use wearable sensing primarily to enrich contextual understanding rather than as the sole trigger for intervention delivery in everyday settings.
Balancing everyday AI expectations with evidence-based interventions	Theme 6	Recognize that users increasingly expect continuity across interactions and explore architectures that can provide it while remaining clinically appropriate.

[a]MNAR: missing not at random.

Several questions naturally follow from these observations. One concerns receptivity: future work should explore how multimodal sensing and lightweight contextual information can better estimate when support is both needed and welcome. Another concerns learning over time. Combining microrandomized trials with longer qualitative follow-up could help clarify how people move from externally prompted engagement to genuinely self-initiated use. Finally, the widespread adoption of everyday generative AI raises new design questions. Hybrid scripted-generative architectures [62,63] offer one promising direction for exploring how conversational continuity can be achieved while preserving the structure and safety of evidence-based interventions.

Limitations and Role of CAE in Digital Health Research

Before concluding, it is important to acknowledge several limitations of this study. First, our RPs were all digital mental health researchers, and this inevitably shaped both the usage of the prototype and the depth of interpretations. Compared with the broader population, we were likely more attentive to design decisions, more accustomed to reflecting on our own engagement, and more familiar with stress-management strategies. The study also lacked, by definition, cultural, socioeconomic, and clinical diversity, and RP2's dual role as a prototype developer may have influenced parts of the collective sense-making despite our explicit attention to positionality throughout the study. The research lasted 4 weeks, longer than most feasibility pilots but still short relative to the development of longer-term habits. Importantly, because our analysis of nonengagement (theme 4) relies on retrospective self-reports and collaborative reflections, the study design cannot conclusively determine the causes of nonuse or distinguish whether missed interactions were driven by emotional overload or by competing daily demands, participant burden, and reduced motivation over time. These observations should therefore be understood as subjective participant interpretations rather than empirically established causal claims. In addition, MINT relied on scheduled rather than stress-contingent intervention delivery. This was an intentional design choice, as our goal was to understand how scheduled microinterventions are experienced in everyday life rather than to evaluate JITAI algorithms. Likewise, the abrupt removal of reminders during the final week was designed to probe self-initiated engagement and whether participants had integrated the strategies into their everyday coping repertoire, not to simulate a realistic deployment strategy. As a result, the observed decline in engagement cannot be attributed solely to reminder dependence but should instead be interpreted as highlighting the need to better understand how users transition from externally prompted support to independent use, including within more context-aware intervention designs. At the same time, this study also illustrates what CAE can contribute during the early stages of designing digital health interventions. Several of the insights discussed in this paper did

XSL•FO
RenderX

not emerge from single interactions but from returning to the same experiences over time and discovering that they acquired a different meaning once considered alongside later events. What initially felt like isolated moments of frustration, comfort, or disengagement gradually became interpretable as recurring patterns. This depth of interpretation depended not only on prolonged engagement with the system but also on the collective sense-making that sits at the heart of CAE. Revisiting experiences together allowed us to question initial interpretations, surface alternative readings, and gradually build richer explanations than any one perspective could have produced alone. Perhaps the most valuable aspect of this process was not that it generated more data but that it gave us repeated opportunities to elaborate on what those data meant. For us, this reinforces the role of CAE as a complementary approach within the broader evaluation of digital health interventions, particularly during the early stages of design, where understanding how design decisions are experienced can meaningfully inform what is tested next.

Conclusions

This study used CAE to examine the everyday experience of using a stress-management chatbot over 4 weeks. Using MINT as part of our daily routines allowed us to look beyond individual microinterventions and consider how they were experienced over time: how expectations developed, how support was interpreted in different situations, and how the strategies introduced by the chatbot related to our existing ways of coping. The study also illustrates what CAE can contribute to the evaluation of digital health interventions. Returning to the same experiences over time and making sense of them collectively often enriched our initial interpretations. Experiences that initially seemed unrelated acquired a different meaning when revisited alongside later events, revealing patterns that were difficult to recognize in the moment. Instead of introducing entirely new design challenges, this process helped us develop richer interpretations of familiar ones, moving beyond description toward explanations and hypotheses that can inform subsequent stages of intervention design and evaluation. We see this as complementing more established evaluation approaches, particularly during the formative stages of design. More broadly, this experience reminded us that design features rarely have a single, fixed meaning. The same feature can be reassuring, frustrating, motivating, or simply irrelevant depending on when it is encountered, what has happened before, and how it fits within the broader context of everyday life.

Generative AI Use

ChatGPT (OpenAI) was used in the preparation of this manuscript to assist with English-language editing and phrasing. All scientific content, study design, data collection, analysis, interpretation, and final decisions remain the sole responsibility of the human authors.

Abstract

Background: Hospital-based makerspaces have emerged as collaborative environments for technical innovation, where designers cocreate with health care professionals and patients to resolve specific problems experienced in practice. As end users, patients can offer unique insights that could drive the development of patient-centered health care services or research. However, cocreation with patients within a makerspace environment is still rare—representing a missed opportunity to use their insights to develop innovations that meet their needs. Patient-designer interactions are underaddressed in the literature, and a deeper understanding could enhance their effectiveness.

Objective: The study aimed to explore the experiences of designers and patients (or their carers) cocreating in an academic hospital–based makerspace, using a bottom-up approach.

Methods: A generic qualitative study was conducted using semistructured individual interviews based on the Sunnybrook team–based competencies and design thinking methodology. A heterogeneous sample of 12 participants was recruited from a makerspace in an academic hospital in the Netherlands, comprising 6 with a designer's perspective and 6 with a patient's perspective. Most participants were involved in collaborative pairs, representing both perspectives within the same innovation project. Data were analyzed thematically.

Results: Four key themes emerged from the data: (1) dealing with the patient's situations, (2) integrating different perspectives, (3) feeling valuable and useful, and (4) dynamic interplay and engagement. Collaboration with patients in this hospital-based makerspace was perceived as valuable for innovation development, benefiting from diverse perspectives. However, the degree of patient involvement varied, influenced by factors such as the patient's health status, reachability, and interest in innovation development.

Conclusions: This study highlights the complexity of developing technical innovations that involve hospitalized patients. It offers valuable insights into how both patients and designers generally viewed their collaboration in the makerspace positively. Practical recommendations for hospital-based makerspaces include respecting patient autonomy, involving patients early and consistently throughout all development phases, maintaining communication beyond the formal collaboration period, and actively seeking feedback.

Introduction

Over the past decade, makerspaces in hospitals have contributed to a new movement in health care known as Health 4.0 [1-3]. This movement uses modern technology to improve the quality, accessibility, and cost-efficiency of health care [4,5]. Such improvement is needed to address the increasing health care demand and to enhance staff empowerment and the work environment in the face of nursing workforce shortages [6-8]. However, technical innovations designed for health care may fail to meet the needs of nurses and patients [9]. These end users themselves may need to develop innovations that align with their daily practice, and makerspaces can assist in this process.

XSL•FO
RenderX

A makerspace is a collaborative physical department equipped with prototyping facilities, including 3D printers and laser cutters [9]. Professionals such as industrial product designers, user experience designers, software engineers, and researchers are employed to facilitate innovation development. Hospital-based makerspaces aim to find suitable solutions to problems experienced in health care practice, such as poor ergonomics and time-consuming tasks. These problems are identified using a bottom-up approach, meaning that nurses and patients address their problems and cocreate with the makerspace staff to remedy the problem or develop innovations to solve them [10,11]. By recognizing patients or their carers as end users, involving them in a cocreation process offers valuable insights to address issues and develop innovations that could improve patient-centered health care [12-15].

For conceptual clarity, this study adopts the definition of cocreation proposed by Pearce et al [16], who identified 4 interrelated collaborative processes—coideation, co-design, coimplementation, and coevaluation—as the core components of cocreation in health interventions. These 4 processes align closely with the stages of design thinking: inspiration (problem identification), ideation (prototyping and testing), and implementation (diffusion of innovations). The design thinking approach is commonly used in makerspaces and provides a structured lens for examining stakeholder involvement [17].

In health care, cocreation approaches are widely promoted as a means of strengthening patient involvement, improving the relevance of interventions, and bridging the gap between knowledge generation and practice. A systematic review by Grindell et al [18] found that cocreation fosters shared understanding, responsibilities, and decision-making among stakeholders, and enables diverse types of knowledge, including patient experience, to shape innovation. Moreover, a qualitative study by Voorheis et al [19] shows that patient and public involvement does not merely inform isolated design choices but influences the broader direction and viability of an innovation, including the implementation and long-term relevance of innovations. Their study also highlights that participating in cocreation can be empowering for patients themselves. At the same time, the authors emphasize that without clear roles, sustained engagement, and supportive structures, much of this potential value remains underused. A scoping review found that patient involvement is often limited to the first 2 phases of innovation development [20,21]. Excluding patients and their carers from all phases represents a missed opportunity and could be due to a mismatch in perception of the usefulness of solutions or a lack of public awareness and guidance on how to effectively collaborate with patients in technological innovation development [22,23].

While concepts such as public and patient involvement and community-based participatory research offer valuable insights into patient involvement, they are structured around research-oriented participation models and projects focusing on the public, where larger groups of stakeholders are included. Therefore, they differ from the makerspace context, where innovation emerges through bottom-up, practice-driven problem-solving; patients are involved due to an intrinsic motivation to solve their experienced problems and are part of a smaller team within the hospital.

Although the importance of involving patients throughout innovation processes is repeatedly emphasized in the literature, empirical research examining how patients and designers actually experience cocreation within hospital-based makerspaces remains scarce. Most existing studies focus on how makerspaces function organizationally and their role, rather than on the human interactions that shape cocreation [2,3,20,24].

Understanding the collaborative experiences of collaborations between designers and patients (or their carers) is essential. Gaining insight into the barriers and facilitators of such collaboration can improve future cocreation efforts within hospital makerspaces. Therefore, this study aims to explore the experiences of designers and patients (or their carers) cocreating in an academic hospital-based makerspace, using a bottom-up approach.

Methods

Study Design

A generic qualitative study was performed using semistructured interviews and thematic analysis. This approach enabled an in-depth understanding of how designers and (carers of) patients perceived the cocreation and what could be learned from their experiences, rather than testing or producing a theory or explicating the essential structure of a single phenomenon [25]. The study was conducted between February 2024 and June 2024 and adhered to the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist (Checklist 1) [26].

Setting

The study was conducted at a makerspace with a professionally equipped prototype studio, housed within an academic hospital, including a large children's hospital in the Netherlands. The makerspace is financed through the hospital's internal funding. The staff comprises industrial product designers, user experience designers, electrotechnicians, a quality adviser, a manager, and a coordinator who is also an academic researcher. The staff collaborates with individuals who identify a problem, such as patients, to develop technical innovations that address the experienced problem. Cocreation is embedded throughout all phases of the design thinking process. Depending on the situation, patients either visit the makerspace studio or designers meet them at the hospital ward. This makerspace aims to deliver functional prototypes that comply with relevant regulatory requirements. It operates in accordance with the Medical Device Regulation and produces medical devices for in-house use under the hospital's quality management system, which includes preparing required documentation such as an innovation justification statement, a statement of requirements, and risk analyses. The makerspace has successfully produced over 30 innovative products for use in daily practice. The makerspace staff proactively disseminates their knowledge and products within the hospital and beyond.

Patients or carers typically approach the makerspace with a specific problem and cocreate with the makerspace staff to develop a solution. Examples of innovations include a silicone

XSL•FO
RenderX

cover designed to fit the rigid connection piece of a kidney drain, reducing discomfort during daily activities and sleep (Figure 1A); an easily accessible emergency bag to support rapid response when a child's tracheostomy tube becomes obstructed (Figure 1B); a pillbox enabling hospitalized patients to manage their own medication while allowing nurses to maintain oversight of medication administration (Figure 1C); a waterproof shower cape for patients with a Port-a-Cath for intravenous chemotherapy; and a bedside table that can be positioned over the bed to facilitate play, homework, or family meals.

Figure 1. Examples of technical innovations developed in cocreation with patients within the makerspace: (A) Silicone cover kidney drain, (B) Emergency bag tracheostomy tube, and (C) Pillbox for hospitalized patients.

Population and Recruitment

To gain insight into the perspectives of both designers and end users, a heterogeneous group of designers and patients was selected using purposive sampling [27]. The first perspective, referred to as the "designer" perspective, included makerspace staff such as industrial product designers and user experience designers. The second, the "patient" perspective, included individuals involved in cocreating innovations addressing problems experienced by patients. This group included patients and representatives such as informal caregivers (eg, parents in the case of young children) and professionals who supported patients during the cocreation process and were able to describe their experiences with patients from their perspective. Eligible participants were individuals who had participated in a collaborative project with the hospital's makerspace to develop an innovation addressing issues experienced by patients and who represented either the designer or patient perspective. Designers who had no direct interaction with patients during collaborative projects were excluded. Additionally, patients under the age of 18 years or those who were hospitalized and in a delicate condition at the time of the study were excluded, as they were considered unable to participate adequately in an interview or participation could impose an undue burden.

Eligible designers and patients (or their representatives) were identified through the makerspace's network of previous collaborations. For recruitment, individuals who had cocreated innovations at the makerspace, preferably pairs who had collaborated on projects, were approached and informed about the study by the makerspace's coordinator, who is also senior researcher OH. Eligible participants had to actively make contact with the study's first researcher, JVDG, via email. Once contact was initiated, they were sent the participant information letter and informed consent form (ICF). JVDG then scheduled an interview with those who had confirmed their willingness to participate.

Data Collection

Researcher JVDG conducted individual face-to-face and online interviews to collect the data. With a background in nursing and no affiliation with the hospital, JVDG brought relevant experience while maintaining impartiality. A semistructured interview guide was developed, based on the Sunnybrook team–based competencies [28] and the design thinking [17,29] approach to innovation development (Multimedia Appendix 1). The guide was chronologically structured around the phases of innovation: inspiration, ideation, and implementation. A single interview guide was developed, reflecting the equal role of patients within interprofessional teams as emphasized in the Sunnybrook model [28]. The content and language of the interview guide were reviewed by an external expert in patient-driven innovation and senior researchers OH and TVH. It was pilot-tested in 1 interview and subsequently refined to ensure relevance and clarity. After the first 4 interviews, the guide was further adjusted based on emerging insights.

At the beginning of each interview, participants completed a brief demographic form, which included categorical questions about age, innovation experience, and professional perspective based on their employment. All interviews were audio-recorded. A constant comparison method was applied during data collection and analysis, leading to iterative adjustments to both the interview guide and the codebook (for further details, see the "Data Analysis" section). Data collection stopped once data saturation was confirmed.

Data Analysis

Researcher JVDG transcribed the interviews verbatim. Data were analyzed using a thematic approach proposed by Boeije and supported by NVivo (version 14; Lumivero) qualitative research software [30]. This approach consists of 2 phases: segmenting and reassembling. In the segmenting phase, JVDG reread the transcripts and inductively assigned codes to relevant text fragments. In vivo coding was applied to the first 7 interviews. During axial coding, these initial codes were grouped into broader categories, resulting in a preliminary codebook with broader codes, which was then used to code the remaining interviews. This phase was also carried out by JVDG. Before the reassembling phase, JVDG created a mind map to become familiar with the coded data. In the reassembling phase, the axial codes were interpreted and discussed with senior

XSL•FO
RenderX

researchers OH and TVH, leading to the development of conceptual themes and categories. An independent researcher with expertise in qualitative research reviewed the conceptual themes, whereupon JVDG established the final themes. Consensus on the final themes was reached among researchers OH, TVH, and JVDG. Representative quotes and descriptions of themes and categories were derived from the original Dutch data and translated into English.

Study Rigor

The study's credibility was enhanced through member checking and researcher triangulation. Participants received a summary of the key points from their interviews and were invited to provide feedback. The feedback received was incorporated into the data to ensure alignment with participants' perceptions. Researcher triangulation was achieved through weekly meetings between researchers OH, TVH, and JVDG to discuss and monitor the study's progress. Additionally, 2 external researchers—1 with expertise in patient-driven innovation and 1 in qualitative research—were consulted during various phases of the study. To enhance confirmability, a digital logbook containing observational, methodological, and analytical memos was maintained throughout the research process [31].

Ethical Considerations

The study adhered to the principles outlined in the Declaration of Helsinki [32], as well as the European [33] and Dutch codes of conduct [34]. Participants received verbal information about the research and were sent an information letter and ICF via email by the researcher JVDG. All participants signed the ICF prior to the start of the interview. Data confidentiality was ensured through pseudonymization. The study was reviewed and approved by the medical ethics review committee of the Erasmus Medical Center for a nonmedical scientific research application (MEC-2024 - 0019).

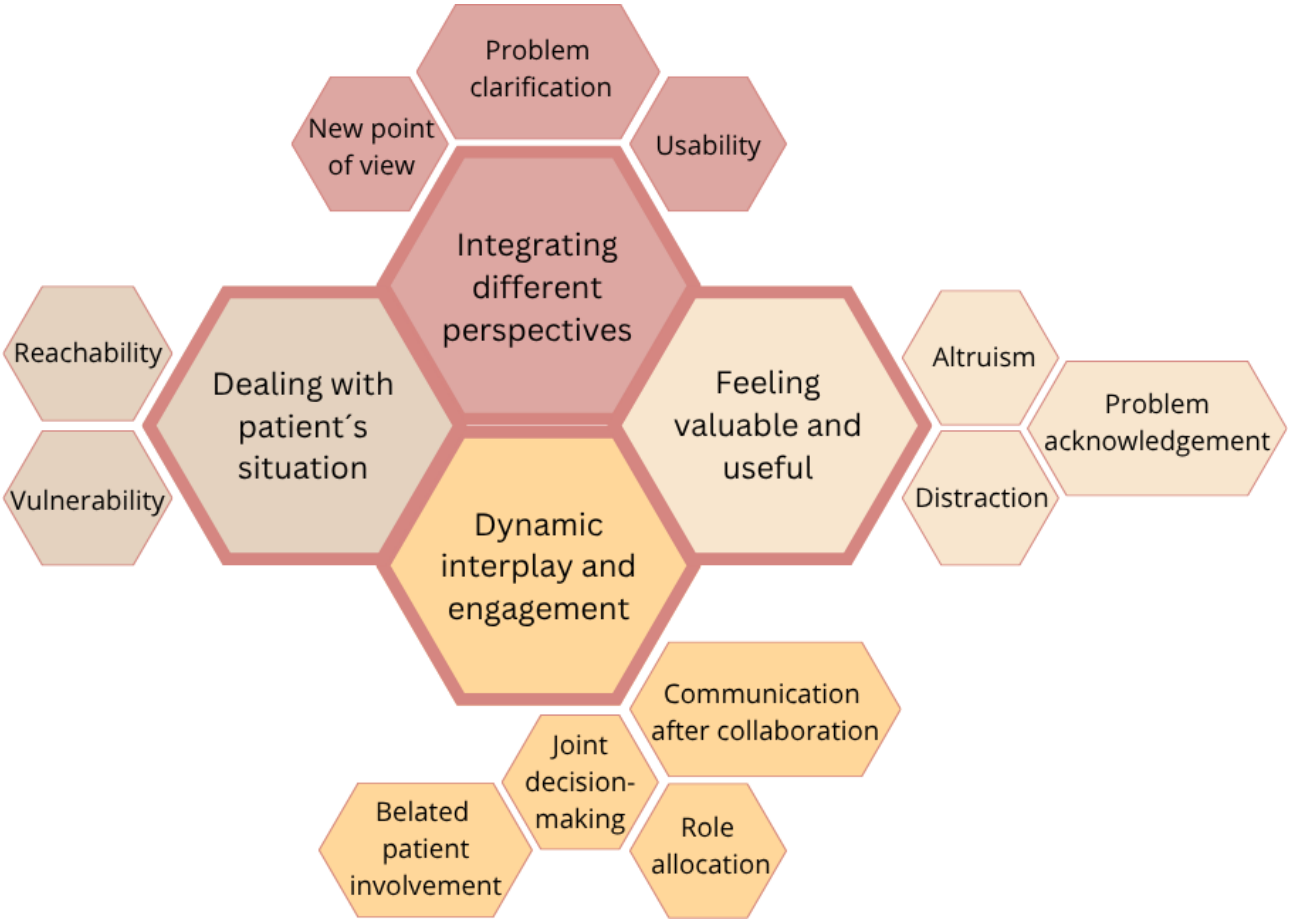
Results

Overview

In total, 12 individuals participated: 6 with the designer's perspective and 6 with the patient's perspective (Table 1). The patient perspective was represented by 2 patients, 2 parents, 1 staff member of the Children's Advisory Council who helped patients during the cocreation with the makerspace, and 1 nurse who cocreated with patients and the makerspace to develop an innovation to enhance patients' self-sufficiency in medication administration. All invited eligible individuals agreed to participate. Among these 12 participants, 4 designer-patient pairs were included. From the 8 cocreated innovations discussed in the interviews, 4 innovations were developed for children, 3 innovations for adults, and 1 innovation was primarily developed for a child's caregiver. Most of the participants were equally distributed between the age ranges of 18 to 35 and 36 to 50 years. All designers had more than 3 years of previous experience in innovation projects; patients mostly had none or up to 3 years of such experience.

Table . Demographics of participants (N=12).

Characteristics and categories	Participants, n (%)
Age range (years)	
18-35	5 (42)
36 - 50	5 (42)
51 - 65	1 (8)
>65	1 (8)
Previous experience with innovation (y)	
None	2 (17)
<0.5	0 (0)
0.5 - 1	1 (8)
1 - 3	2 (17)
>3	7 (58)
Perspective	
Industrial product designer	5 (42)
User experience designer	1 (8)
Parent	2 (17)
Patient	2 (17)
Staff member of Children's Advisory Council	1 (8)
Nurse	1 (8)



After 8 interviews, no new categories emerged, indicating data saturation. To confirm and assess the identified themes, 4 additional interviews were undertaken. The interviews lasted an average of 51 (SD 19) minutes, with durations ranging from 25 to 90 minutes, depending largely on the participant's level of involvement in the cocreation. Three interviews were

XSL•FO
RenderX

conducted online for convenience, while 9 interviews took place at the hospital. One interview included the patient's partner. Member-check feedback was obtained from 10 participants, all of whom agreed with the summary made by JVDG. Two minor corrections were made based on their feedback. Despite an email reminder, responses from 2 participants were not received.

The following themes emerged: dealing with the patient's situation, integrating different perspectives, feeling valuable and useful, and dynamic interplay and engagement (Figure 2).

Figure 2. Four themes (represented by the larger hexagons) and 12 associated subthemes regarding the experiences of designers and (carers of) patients cocreating in a hospital's makerspace.

Theme: Dealing With the Patient's Situation

The circumstances of patients differ significantly from the everyday experiences of healthy individuals. This theme explores the challenges and implications that these differences create for patients and designers during their collaboration.

Vulnerability Due to the Patient's Health

Participants noted that a patient's compromised health often limits their ability to engage fully in the innovation process, although they may have wanted otherwise. Illness brings competing concerns such as fatigue. Designers—particularly younger ones—are often aware of this vulnerability. For many, cocreation with patients is a new experience, and they may hesitate to impose an undue burden on patients. Some designers struggle with knowing what is appropriate to ask or expect from patients under these circumstances:

> *I was sometimes a bit ashamed to ask things, because I felt like the person would then literally have to think back to such a moment [traumatic experience] you know, just to answer my question.* [P3, user experience designer]

Reachability

Participants suggested that maintaining low-key contact and close involvement increases the patient's reachability. However, they also noted that a patient's reachability is often limited by their health circumstances. First, rapid changes in the patient's condition can lead to unexpected transfers to another ward or home. Designers found it challenging to reach a patient after discharge:

> *It was by chance that [child's name] was admitted, so I could just walk back and forth, but in the future, I would like to be more physically available. If someone says, "come and have a look," I would like to be able to do that, and now that's not possible.* [P12, parent]

Second, designers were hesitant to visit patients on their wards because they do not interact with patients on a daily basis, and extra effort was needed. This was perceived as a barrier. Once on the ward, some designers felt uncomfortable or rushed due to the ward's often hectic environment:

XSL•FO
RenderX

> *But that is just how the intensive care unit is. It is hectic. You don't know at what time someone will come to the bedside [of the patient]. So that was for me a challenge.* [P3, user experience designer]

Additionally, the makerspace is not yet well-known among patients. This lack of knowledge has made it difficult for a patient to access the makerspace. In many collaborations, intermediaries often facilitate contact between designers and patients:

> *Yeah well, I was lucky my nurse knew [industrial product designer 1], otherwise I would never have come up with it.* [P4, patient]

Patients emphasized that, for both parties, it simply comes down to asking. They value their autonomy in decision-making and felt encouraged to express whether or not they wished to participate in a cocreation.

One less experienced designer wondered why she had not collected the patient's contact information during their hospital stay, which would have allowed for continued collaboration after discharge.

Theme: Integrating Different Perspectives

This theme explores the value of incorporating multiple perspectives and the challenges that may arise as a result.

New Point of View

Incorporating multiple perspectives provides a range of viewpoints during the innovation project. Both designers and patients noted that differing perspectives can generate fresh insights into the problem or proposed solution. Both parties felt as though the other party had been given carte blanche:

> *Sometimes, you just have to give people carte blanche because you're already too involved. I had my own bag [tracheostomy tube emergency bag], so I was too much into that concept. You know; this is how we do it. So, I would just show that. But that is not helpful at all, because sometimes you have to start from scratch.* [P7, parent]

> *No, as blank as possible, without any prior knowledge that you just shout what is possible, what you think is possible. That's just beautiful [...]. And then someone else who knows more about it can say, well, this might be possible, and this might not be. I wish they did that more often, [...]. No idea is crazy enough, so to speak.* [P1, industrial product designer]

Problem Clarification and Usability

Designers emphasized the importance of the patient's perspective in clearly defining the problem. Participants also agreed that integrating multiple perspectives had a positive impact on the usability of the innovation in practice. Some noted that when an innovation is not adopted in practice, it is often because the needs of all stakeholders were not adequately identified:

> *And it turned out they [patients] did not like it at all. And then I looked back, and I thought, yes, I can understand that, because we didn't involve them at all in that initial new design. We did ask those parents; what do you prefer? What is important to you? What should come out of it for you? We actually completely forgot to include the patient.* [P6, staff member of Children's Advisory Council]

However, 1 designer pointed out that the inclusion of multiple perspectives, such as a project involving a patient, parent, and nurse, could also cause interference. The differing needs made it harder to clearly define the core problem, and the designer felt that the patient's needs were overshadowed:

> *And that is what I mean by those different perspectives: I get a lot of information but then I wonder, how is it from the child's point of view? It was not clear to me which pain points the child was really experiencing.* [P3, user experience designer]

Theme: Feeling Valuable and Useful

This theme captures how cocreation gave both designers and patients a sense of contributing to something valuable and useful.

Altruism

All participants expressed a strong motivation to contribute to the improvement of health care, even if they did not benefit directly from the outcomes. They desired to help solve a problem and do something for others:

> *I always like to participate in these kinds of experiments. To make people's lives more comfortable.* [P9, patient]

> *Well, someone who is sick, who has a problem and addresses this to ultimately help others sort of, with that approach, running such a project, I think is really great.* [P1, industrial product designer]

Distraction

For patients, participation also served as a distraction from their medical situation. It provided them with a sense of activity and usefulness, allowing them to contribute even in the midst of an unpleasant situation, "And then … yeah, I was bored to death anyway, so I thought yes let's do it" (P4, patient).

Problem Acknowledgment

Both designers and patients felt that the innovation process validated the underlying problem. They appreciated that it was taken seriously and actively addressed. This acknowledgment gave participants a sense that they did not have to simply accept problems or settle for inadequate solutions:

> *Once I had a parent standing in front of me, almost in tears, and she said something like: I think it is really wonderful that there are people who think about those small, seemingly insignificant things, but it makes life easier for such people.* [P10, industrial product designer]

XSL•FO
RenderX

Theme: Dynamic Interplay and Engagement

General Outline

This theme explores the depth of cocreation throughout the innovation process, with a focus on the interplay between designers and patients. The interviews revealed instances where the perceived level of cocreation did not align with the patient's actual involvement.

Participants highlighted that cocreation is highly contextual, varying depending on factors such as the stage of the innovation process and the patient's role. The level of patient involvement often depended on their personal interest, enthusiasm, or health condition:

> *Genuinely working together, yeah, it's possible, but it's difficult. And I think it really depends on the patient or depends on the setting and context.* [P2, industrial product designer]

Role Allocation

Some participants wondered if the cocreation could be considered truly collaborative, as patients were not fully involved throughout the entire design process. Designers often took a leading role, with patients only providing feedback on developed concepts:

> *It's constantly; you go and test something, you receive feedback, you go and redesign it, and you go and test it again.* [P11, industrial product designer]

One designer suggested that genuine cocreation would involve patients actively contributing ideas and helping to design prototypes—essentially taking on a co-designer role. However, the designer also questioned whether this expectation was realistic for patients. Many patients expressed that their level of involvement—whether throughout the entire process or within a single phase—felt appropriate. Contributing to just one part of the cocreation required less time and energy, yet still gave them a sense of satisfaction, particularly knowing that their input could benefit others:

> *If I had been in my full power, I might have done more exploring or for example thought what can we do with this, you know? [...] But now I had so much on my mind, I left it as it was. But I enjoyed it, though.* [P4, patient]

Belated Patient Involvement

Designers expressed concerns about burdening patients, which led them to consider involving patients only in a single phase of the design process. They also noted that excluding patients early on benefited their individual creative process, enabling them to freely explore multiple design options. Often, designers developed a physical prototype before involving patients, as they believed that patients provided more useful feedback on tangible products than on abstract ideas on paper:

> *Because if you start describing it [idea of concept of the innovation] then they might also have questions something like "yes but how about that?" So, seeing a model or something may lead also to other ideas.* [P11, industrial product designer]

Designers highlighted the risk of making unintentional assumptions during the process, which can impact the final design and limit the ability to make changes later. Two designers expressed that they would have preferred to involve the patient earlier in the process. Consequently, participants confirmed that valuable information related to the problem or solution could have been overlooked by excluding patients' perspectives in the early phases:

> *And then you have to take them along from the very beginning, not asking them to test it when you already have developed the [innovation], because that [innovation] might work, but the question is whether that is the best fitting innovation for those parents, because maybe there was something much better.* [P6, staff member of Children's Advisory Council]

Joint Decision-Making

Participants indicated that decisions were largely made collaboratively, which they perceived as pleasant and fostered a sense of equality. This approach facilitated open communication and contributed to a good atmosphere in the makerspace. Patients felt free to express their opinions about the design. While joint decision-making sometimes led to shared disappointment when a design fell short, all participants ultimately reflected positively on the cocreation and were satisfied with the final innovation.

> *It was always a very open conversation, and yeah, we, she was like the designer, and we were the ones presenting the problem, so to speak, but we could really meet each other halfway.* [P5, patient's perspective represented by nurse]

Communication After Collaboration

Participants highlighted the importance of letting patients know—as a sign of appreciation—how their feedback was incorporated. However, many patients said that they missed such communication and wondered how the innovation was further developed.

> *After that, I didn't hear how it ended, and I find that a shame, do you understand? So, then you think, well, he said maybe we'll apply it throughout the whole hospital during that treatment. It would be nice for those who in this case participated to know what happens next to it.* [P9, patient]

One patient discovered that the innovation had not been further developed, and they felt that the innovation was "just" a project that had been shelved. Several participants indeed noted that innovations are sometimes not further developed due to a lack of interest and funding.

Discussion

Principal Results

This study focused on the cocreation between designers and patients (or their carers), exploring their experiences throughout the innovation process. Four key themes were identified. The first theme, dealing with the patient's situation, highlighted

XSL•FO
RenderX

challenges related to patients' vulnerability and limited availability due to their condition. The second theme, integrating different perspectives, emphasized the value of incorporating diverse viewpoints, which helped clarify the problem. However, it also revealed that differing perspectives could complicate problem definition. The third theme, feeling useful and valuable, described how participation fostered a sense of meaningful contribution among patients, offering both a positive distraction and a sense of validation regarding their experienced problem.

The fourth theme, dynamic interplay and engagement, focused on the nature of the interactions within the cocreation. During the interviews and analysis, questions arose about how to distinguish genuine cocreation from surface-level involvement. Despite this, participants generally viewed each other as equal partners. Key aspects within this theme included role allocation, the extent of patient involvement, decision-making, and communication. While existing literature provides limited insights into patient-designer interaction within the cocreation process in hospital-based makerspaces, this study provides a better understanding from both perspectives.

Strengths and Limitations

A strength of this study was the high quality of the data collected using an interview guide based on the Sunnybrook team–based competencies in combination with the design thinking model. Additionally, the use of the constant comparison technique allowed for iterative adjustments to the interview guide, enabling interviews to more effectively address relevant topics. This approach facilitated deeper exploration and assessment of conceptual themes, ultimately leading to data saturation. The high response rate in the member check procedure confirmed that the data accurately reflected participants' experiences, thereby increasing the study's credibility. Another strength was the inclusion of designer-patient cocreation pairs across diverse innovation projects, each with varying levels of patient involvement. This diversity provided detailed insights into how different perspectives interpreted the same collaborative experience.

A limitation of this study is that it was conducted at a single hospital and with a relatively small population of eligible participants. However, for each cocreation between designers and patients within the makerspace, all eligible individuals were contacted. Both perspectives were ultimately represented by 6 participants. Literature suggests that data saturation in heterogeneous samples is typically reached between 9 and 16 interviews, depending on the sample characteristics [35]. We observed a consistent overlap in overarching categories after 8 interviews. Therefore, we consider our sample size to be appropriate for this study.

The patient perspective was represented by 2 patients and 4 individuals who were not patients themselves: 2 parents, a nurse, and a member of the children's advisory board. Because half of the cocreated innovations focused on children, some findings may be slightly oriented toward pediatric contexts. While these participants drew on their own experiences and their interpretations of patients' experiences during cocreation, it remains uncertain how their inclusion may have shaped the patient perspective described in this study. Certain overarching themes, such as dealing with the patient's situation, may initially appear misaligned with a strictly patient-focused view. However, emotional and physical vulnerability were also central to the parents' experiences and therefore remained relevant to our analysis.

Importantly, the nonpatient participants contributed substantial experiential knowledge based on their involvement in cocreation processes with patients and the makerspace. Given that our findings are consistent with existing literature from comparable settings, we consider these complementary perspectives as meaningful additions to the patient perspective rather than a distortion of it.

Another limitation is the potential for recall bias, as some projects took place several years ago. While fading memories may have influenced participants' perceptions, many reported that the interview process helped revive their recollections.

Comparison With Prior Work

Our study highlights how incorporating the patient's perspective can enhance the understanding of user needs, leading to better problem clarification and greater usability of innovations. These findings support previous research on patient involvement in service innovation, as well as literature emphasizing broader stakeholder engagement in health care [19,36-38]. However, our study also sheds light on the complexity of developing technical innovations that involve various end users, including hospitalized patients. Identifying and addressing the diverse needs of stakeholders—such as patients, nurses, infection prevention specialists, and manufacturers—while also complying with existing regulations poses a significant challenge.

Within the makerspace of this study, the average time between the start of development and the implementation of the innovation is 19 months, ranging from 6 to 48 months. This extended timeline often exceeds the duration of hospital stays for patients and is further complicated by the high turnover of patients, making it difficult for designers to reach and involve patients throughout the development process, as observed in our study. Compromised reachability due to these short admissions could explain the belated involvement of patients.

The vulnerability experienced by designers and patients is likewise seen in the literature, where patients' physical and mental conditions influence their preferred level of involvement [39,40]. In a qualitative study by Rowland et al [38] exploring the patient's perspective, vulnerability was identified as an essential element of the patient experience, contributing to a unique form of embodied knowledge. While participants in our study acknowledged the value of the patient perspective, this same vulnerability often led to hesitation and hindered involvement. This finding offers new insights into how patient vulnerability can impact cocreation and innovation development within a makerspace context. A mixed methods study on motives for involvement in service innovation found that patient engagement fostered feelings of accomplishment and was often driven by a desire to give back, as well as by social connection and enjoyment [41]. These motivations closely align with the theme of feeling valuable identified in our study.

XSL•FO
RenderX

A systematic review on service innovation highlighted the gap between the intention to involve patients and the practical challenges of doing so—particularly in joint decision-making processes [42]. The review emphasized that care providers require proper attitudes, skills, and a deeper understanding of patients to facilitate meaningful involvement. Our finding about the lack of communication with patients after the collaboration has not been explicitly reported in previous literature. However, a co-design framework for health care innovation includes a final step of revisiting co-design participants to share the outcomes of the project [23]. This step appears to have been missed by the patients in our study.

Delayed patient involvement, as observed in our study, limited the optimal use of patient contributions. Previous literature similarly indicates that stakeholder involvement often occurs primarily during the front-end prototyping phase, rather than during the earlier inspiration phase of design thinking or consistently across all phases of development [20,43,44]. A qualitative study identified 17 strategies for stakeholder involvement, 1 of which involved real-time modification of prototypes in collaboration with stakeholders [43]. However, this strategy was found to be underused, which aligns with our findings regarding limited patient participation across all development phases.

Implications for Practice

This study underscores the importance of involving patients and their carers in the development of health care innovations. Their unique perspectives are highly valuable, particularly for innovations related to patient care. The findings offer insights into how patients and designers collaborate in innovation development and provide practical guidance for hospital-based makerspaces seeking to strengthen cocreation with patients (Textbox 1). Makerspaces should actively evaluate their cocreations and ensure that cocreation experiences are systematically assessed through patient feedback.

While this study explored the makerspace's previous patient cocreations, it raises the question of how to increase the frequency of patient cocreation. Patients in our study were previously unaware of the existence of the makerspace. Therefore, makerspaces should research strategies to enhance their visibility and accessibility to patients. It is crucial for patients who experience troubling issues to know that a makerspace is available to help them find solutions. Additionally, makerspaces should strive to involve the patients' perspectives in a broader range of projects, beyond those directly related to patient-experienced issues. By doing so, innovations will be better aligned with patients' needs and experiences, ultimately leading to more effective and user-centered health care solutions.

Textbox 1. Practical tips for hospital-based makerspaces regarding cocreation with patients.

The tips are as follows:

- Let patients speak for themselves. Respect patient autonomy in decision-making. Do not hesitate to initiate contact out of concern it may burden the patient. Participation can evoke positive emotions.
- Involve patients early. Engage patients from the problem formulation phase, as they can offer valuable clarification. When their condition allows it, involve them throughout all development phases.
- Maintain communication after collaboration. Keep patients informed about the further development of the innovation. Continued communication reinforces their sense of involvement and appreciation.
- Gather ongoing feedback. Regularly collect feedback from patients on their experiences and suggestions. This helps to refine the cocreation process and ensures that future collaborations are more inclusive and effective.

Conclusions

This study explores the cocreation between designers and patients (or their carers) from both perspectives and offers valuable insights into the cocreation process of patient-initiated technical innovations within a hospital-based makerspace. While cocreation is widely perceived as valuable in innovation development, its success is influenced by the patient's individual situation and their level of involvement. To strengthen future cocreation, makerspaces may benefit from applying practical strategies to effectively involve patients.

Abstract

Background: South Asian individuals face a higher burden of long-term conditions while also experiencing more inequities in health care access and outcomes. Despite the potential of remote monitoring technologies to improve management of long-term conditions, South Asian individuals are less likely to engage with digital health interventions and are underrepresented in health research, partly due to language barriers.

Objective: This study explored the perspectives and needs regarding remote monitoring technologies of South Asian individuals living with a long-term condition in the United Kingdom who did not have English as their first language. We used Pakistanis as an example subgroup of South Asian individuals and rheumatoid arthritis and early inflammatory arthritis as example long-term conditions.

Methods: We conducted semistructured interviews and a focus group discussion with Pakistani adults diagnosed with rheumatoid or early inflammatory arthritis who did not have English as their first language. Audio-recordings were transcribed verbatim, deidentified, and analyzed thematically.

Results: Seventeen adults participated in this study (n=9, 53% in an individual interview and n=8, 47% in the focus group); none of them had previous experience of remote monitoring technologies. We identified three themes: (1) the perceived value and challenges of using remote monitoring technologies for disease self-management, (2) differences in perceived needs and capacity for using remote monitoring technologies between first- and later-generation immigrants related to social determinants, and (3) the role of community and family support in using remote monitoring technologies. Participants perceived remote monitoring technologies as useful, particularly where they were dissatisfied with current health care services. Language and the role of family and community members in supporting technology use were considered important factors, but needs in these areas varied between first-generation (migrated to the United Kingdom) and second- or third-generation immigrants (born in the United Kingdom to parents or grandparents who migrated to the United Kingdom). For first-generation immigrants, these factors intersected with other social and digital determinants, such as gender and literacy, resulting in additional requirements.

Conclusions: Addressing language and literacy barriers, alongside leveraging family and community support, will contribute to equitable remote monitoring technologies to facilitate self-managing long-term conditions among South Asian ethnic minority groups. Future efforts should focus on developing tailored, culturally responsive approaches, particularly for first-generation immigrants, to ensure remote monitoring technologies decrease rather than exacerbate existing ethnic health inequities.

KEYWORDS

patient-generated health data; remote monitoring; digital inclusion; South Asian individuals; ethnic health inequalities; language barriers

Introduction

South Asian individuals represent a substantial ethnic minority in many high-income countries, including the United Kingdom [1] and the United States [2]. In these settings, South Asian individuals experience a higher prevalence of long-term conditions [3-5] and related mortality [6,7] compared with their White counterparts. They are also more likely to live with multiple long-term conditions [8], but their needs often remain unmet [9,10]. These differences may partly be attributed to culturally influenced health and treatment beliefs and to language barriers that hinder understanding and engagement with treatment [11-14]. Delayed or limited access to health services further compounds poor experiences and health outcomes [13], as well as quality of life and work productivity [15].

Culture and language shape people's perceptions of and communication about health [16,17], as well as their interactions with health care services and subsequent outcomes [18]. For South Asian individuals, language proficiency is crucial to accessing health information and services. Those with limited formal education may need interpretation support [19], which is not always available due to a shortage of interpreters and logistic complexities [20]. Specific subgroups among South Asian individuals, such as older adults and immigrant women, may face additional challenges, including misalignment between their culturally influenced health beliefs and behaviors and how health services are offered [21]. Compounding these issues is the lack of cultural confidence and competence among health care professionals [22,23], which in turn can result in poor patient and health care provider communication and a lack of consideration of sociocultural factors in care planning. For instance, managing chronic pain effectively requires sensitivity to a patient's cultural context, yet such considerations are often overlooked, leading to suboptimal treatment decisions [24,25].

Remote monitoring technologies, such as symptom-tracking apps or connected home blood pressure monitors, have the potential to improve patient and health care provider communication when managing long-term conditions [26-28], for example, by providing visual summaries of changes in symptoms [29]. The UK National Health Service (NHS) Race and Health Observatory further recognized the potential of digital health technologies to address inequities in health service access and outcomes for ethnic minority populations [30]. However, the successful implementation of such technologies relies on patients' digital literacy skills [31] and meaningful, digitally enabled engagement between patients and health care providers [32]. These requirements may present particular challenges for South Asian communities, where language barriers and culturally inappropriate health practices may hinder uptake and sustained use. Applying digital equity frameworks [33,34] and engaging with South Asian communities during the early stages of technology development may help address these issues and contribute to digital health solutions that are equitable, inclusive, and culturally appropriate.

However, despite this growing attention to digital health technologies, South Asian individuals have lower use rates of digital health tools within the NHS [35] and remain underrepresented in related research [36,37]. This is likely due to intersecting factors at individual and system levels, resulting in language barriers, health beliefs, behaviors [38], and challenges in accessing digital health services and research [39]. These factors leave South Asian individuals' perspectives and needs regarding remote monitoring technologies largely unknown.

Therefore, this study aimed to explore the perspectives and needs regarding remote monitoring technologies among South Asian individuals in the United Kingdom living with a long-term condition, specifically those who do not speak English as their first language. We used Pakistanis as the largest example subgroup of South Asian individuals living in the United Kingdom and rheumatoid arthritis and early inflammatory arthritis as example long-term conditions.

Methods

We used a narrative study design as we wanted to focus on people's narrative accounts of their unique experiences and perceptions regarding various aspects of human interactions and culture [40]. We used the Consolidated Criteria for Reporting Qualitative Research (COREQ) checklist to report this study [41] (Checklist 1).

Ethical Considerations

The study received ethics approval from the UK Health Research Authority South Central - Berkshire B Research Ethics Committee (22/SC/0103). All participants provided written informed consent before taking part, ensuring they understood the purpose of the study, data confidentiality measures, and their right to withdraw from the study without impact on their care and treatment. All participants received compensation for their time. The collected data have been anonymized to safeguard participants' information. The study was conducted in accordance with the Declaration of Helsinki and its later amendments.

Study Context

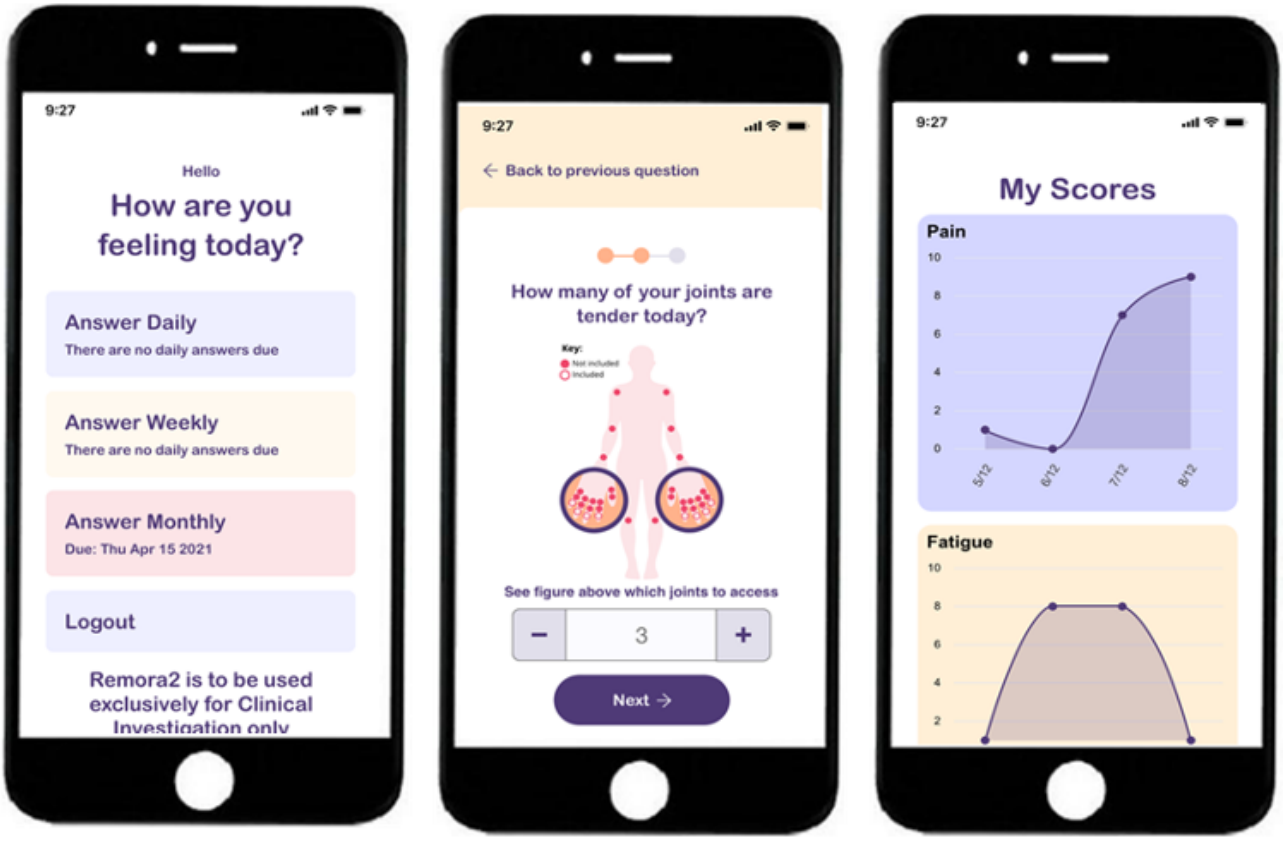
We used rheumatoid arthritis as the example long-term condition for our study because it is more prevalent among South Asian individuals [42]. They also face significant delays in being diagnosed with rheumatoid arthritis [43] and are less likely to receive treatment [9]. Similar to conditions such as asthma, heart failure, and inflammatory bowel disease, management of rheumatoid arthritis relies on patient reports of symptoms and flares. Many patients struggle to describe these accurately during their brief and infrequent outpatient consultations [44], which may lead to incomplete and inaccurate information, poor

XSL•FO
RenderX

treatment decisions, and ultimately worse outcomes [45,46]. This may be harder for people who do not have English as their first language. Remote monitoring technologies may help to address this by enabling all patients to track their symptoms at home using a smartphone app and share this symptom data with their health care team for discussion during consultations. As an example technology for this study, we used the Remote Monitoring of Rheumatoid Arthritis (REMORA) symptom-tracking smartphone app, which served as a prompt during interviews and focus groups. The app is currently being evaluated as part of a complex intervention in a randomized controlled trial [47].

Study Participants and Recruitment

We recruited participants using a purposive sampling method. People were eligible to take part if they were aged 18 years or above, did not have English as their first language, self-identified as Pakistani, had a diagnosis of rheumatoid arthritis or early inflammatory arthritis, and were able to give informed consent. We focused on Pakistanis as a South Asian subgroup because they form the largest ethnic minority in the United Kingdom [1], and we had 2 research team members from the same background: SMA, a male digital and public health researcher, and YM, a female qualitative health service researcher. Both had Urdu as their first language and had experience working with the Pakistani community in the United Kingdom. SMA and YM were mindful of their possible influence on the data collection, analysis, and interpretation, and they used reflexivity to bring insights, which were relevant for addressing the study objectives.



We identified and recruited potential participants via a rheumatology outpatient clinic and a community center for South Asian women in Greater Manchester. Local research nurses and a community center manager approached people to introduce the study, share or read the participant information sheet, and obtain consent to contact from those who were interested. One researcher (YM) contacted potential participants to determine whether they had any questions and were willing to participate, after which they were asked to provide written informed consent. Recruitment continued until data saturation was achieved, with no new ideas emerging from the interviews.

Data Collection and Analysis

We used a brief questionnaire to collect data on participants' age, gender, language proficiency, and their diagnosis. People were invited to participate in either a focus group or an individual interview, whichever they preferred. We conducted interviews and a focus group discussion with the help of topic guides (Multimedia Appendices 1 and 2), which were developed based on published literature [34,37,39,48] and input from patient representatives (KS and others). Topics included experiences of living with rheumatoid arthritis or early inflammatory arthritis, experiences of health care services, experiences of using digital technologies, views on symptom monitoring, and views on using digital health care technologies, including potential benefits or barriers. Previous studies have highlighted the importance of the wider context in which people manage their health care problems, including any social support and existing health care arrangements, when researching perspectives regarding implementation of new health care technologies [42]. Consequently, interviews and the focus group began with a discussion of this wider context before focusing on views about remote monitoring technologies. The topic guides provided a structure for the interviews and focus group discussion while leaving flexibility for participants to introduce topics that researchers had not considered. In addition to the topic guides, we used screenshots from the REMORA app as visual prompts to give participants an idea about what a remote monitoring technology could look like (Figure 1).

XSL•FO
RenderX

Figure 1. Screenshots of the Remote Monitoring of Rheumatoid Arthritis (REMORA) app, an example remote monitoring technology (Copyright University of Manchester).

Individual interviews were conducted in Urdu or in English, whichever language participants preferred. The focus group discussion was in English, as participants were bilingual and were comfortable sharing their thoughts in English. All data collection happened in a community setting familiar to participants, which facilitated a more comfortable and culturally sensitive interaction. All interviews and the focus group were audio-recorded and transcribed verbatim in the language in which they were conducted. The interviews lasted approximately 45 minutes, while the focus group discussion lasted approximately 90 minutes.

SMA and YM independently reviewed transcripts line by line and assigned codes using NVivo software (version 12; Lumivero) to manage the data. For interviews in Urdu, SMA and YM coded the Urdu transcripts and selected and translated relevant quotes into English through discussion. Selected and translated quotes were then discussed with the wider research team (CS, KS, SMA, SNvdV, and YM) to guide iterative coding, thematic analysis, quote selection, and interpretation. We also shared a summary of the findings with our patient representatives to sense-check our interpretations. Finally, SMA and YM double-checked translations of selected quotes used to illustrate themes in the manuscript.

Results

Overview of Participants

Table 1 shows the characteristics of the 17 participants, of whom 10 (59%) participated in an individual interview (9 in Urdu and 1 in English). Most were women (n=16, 94%), aged 60 years and above (n=11, 65%), migrated to the United Kingdom during their life (hereafter referred to as first-generation immigrants; n=15, 88%), bilingual (proficient in speaking and understanding English but with limited proficiency in written English language; n=16, 94%), and living with multiple long-term conditions (hypertension and diabetes were most common; n=11, 65%).

[a]Defined as having migrated to the United Kingdom during their life.

Perspectives and needs related to remote monitoring technologies were explored within a wider context of managing rheumatoid arthritis or early inflammatory arthritis and experiences of health care services. None of the participants had prior experience using any remote monitoring technology. We identified three main themes that reflected participants' views regarding remote monitoring technologies and were developed through an iterative process of analysis: (1) perceived value and challenges of using remote monitoring technologies for disease self-management, (2) differences in perceived needs and capacity for using remote monitoring technologies between first- and later-generation immigrants related to social determinants, and (3) the role of community and family support for using remote monitoring technologies. We described the themes in more detail in the following sections, illustrated with participants' quotes and characteristics (individual interviews only).

Perceived Value and Challenges of Using Remote Monitoring Technologies for Disease Self-Management

Participants perceived both challenges and value in using remote monitoring technologies for disease self-management. Particularly, their self-management practices or lay remedies and their experiences with health care services provided a relevant context for discussing the potential value of integrating remote monitoring technologies in their care.

The use of culturally influenced lay remedies was reflected strongly in people's health beliefs and behaviors regarding managing their condition. All participants mentioned the use of one or more lay remedies, ranging from consuming turmeric, garlic, vinegar, honey, ginger, and herbs to applying massaging oil and turmeric paste on painful sites. Participants also mentioned incorporating lifestyle modifications, such as exercise, yoga, and changes in diet (eg, consuming more vegetables) to manage their condition.

> *I use herbal products too...sometimes I ask someone to bring them from Pakistan or sometimes I get them from Birmingham. Consuming them makes me feel better.* [Female, aged 70 - 80 years, retired, first-generation immigrant]

> *My condition gets worse when I have flare ups...for that time...someone told me to apply black seed oil on my heels...I also add vicks to it...it feels better.* [Male, aged 50 - 60 years, working, first-generation immigrant]

Many participants reported unsatisfactory experiences with health care services, seemingly stemming from a long and difficult diagnostic process, a lack of treatment options being offered, delayed appointments with health care professionals, and limited consultation time. One of the participants said:

> *Firstly, you don't get an appointment...if you get it...then they are not interested in knowing about what has been happening with you.* [Female, aged 60 - 70 years, retired, first-generation immigrant]

They also shared their expectations about support between clinical consultations:

> *I think so between consultations there should be a person who can advise how to manage your pain and your arthritis. This can help a lot, because not everyone is alike.* [Female, aged 70-80 years, retired, first-generation immigrant]

Participants also mentioned how memory affected their day-to-day living and how this might have affected the quality of their consultations with clinicians. One participant described it as follows:

XSL•FO
RenderX

> *I go to my appointment myself...I leave home, and when I reach for my appointment, I forget what I am here for.* [Female, aged 50-60 years, working, first-generation immigrant]

Following these previous experiences, participants acknowledged the potential value of remote monitoring technologies in aiding patient and health care provider interaction, helping patients between consultations, scheduling appointments, and helping them remember and communicate important information about flares, their underlying causes, and their frequency during clinical consultations. One of the participants described how the use of remote monitoring technology could help in memorizing key information about their conditions:

> *[E]ven if I open that app and start using it, I may forget what I wanted to do...but then it would also refresh my mind. If you have already put some information in it then it won't go anywhere.* [Focus group participant]

Remote monitoring technologies could potentially benefit patients by capturing changes in their pain and guiding them in managing their conditions better, as described by one of the participants:

> *It [remote patient monitoring] can help you monitor your condition, if it is getting better or worse, and what are the underlying causes...and what are the alternatives...if your condition is getting better, then how can you improve it further and if it is getting worse then you can identify if a consultation or help is needed.* [Female, aged 60-70 years, retired, first-generation immigrant]

Recognizing the potential benefits of remote monitoring technologies, all participants expressed positive views about sharing their data with health care professionals. However, one of the participants raised concerns about data sharing:

> *Well...it depends where it [data] is going, where it's going to be used, or how far will it go...I don't know.* [Female, aged 70-80 years, retired, first-generation immigrant]

In addition, some older women expressed a lack of motivation for learning to use new digital tools. One woman aged >70 years, who opposed using remote monitoring technologies, shared her frustration regarding trying different tools or approaches for managing rheumatoid arthritis:

> *I have accepted now that this the way I am going to live my life...initially I was advised to maintain a diary, which I used to do. Now I have threw everything away...that I will not do anything now...I feel like I am fed up of all this.* [Female, aged 70-80 years, retired, first-generation immigrant]

When asked how barriers to accessing and using remote monitoring technologies among Pakistani people could be addressed, participants suggested some technology features such as in-app reminders to submit symptom scores, questions or instructions presented in translated and/or audiovisual formats, information explaining how to interpret symptom summary reports, and biometrics-enabled login instead of using passwords. Participants shared challenges or difficulties related to their experience of using technologies:

> *The password is the worst...when you have to make it and they say it's not right, do this, there's no capital. I hate passwords. I have to get my sons to do it.* [Focus group discussion]

Differences in Perceived Needs and Capacity for Using Remote Monitoring Technologies Between First- and Later-Generation Immigrants Related to Social Determinants

Participants suggested differences in needs and capacity for using remote monitoring technologies between first- and second- or third-generation (ie, those born in the United Kingdom to parents or grandparents who migrated to the United Kingdom during their lifetime) Pakistani immigrants and related this generational aspect to other social and digital determinants of health, such as gender. For example, one of the participants referred to gender norms and said:

> *Women are usually at home and are not exposed to technology, and in our culture, it's very common that women are least engaged with new technologies.* [Male, aged 50-60 years, working, first-generation immigrant]

Limited proficiency in English was mentioned by participants as a key potential barrier to using remote monitoring technologies, mainly for first-generation immigrants. Among these immigrants, participants suggested young immigrant women (ie, who moved to the United Kingdom at a young age) were a subgroup at greater risk of developing inequities because of their language barriers. For example, some young immigrant women can only communicate effectively in their local language (such as Punjabi or Pothwari) rather than in Urdu, the national language of Pakistan. One of the participants described it as:

> *The ladies group that I attend regularly [organized by local charities]...most of the group members don't know how to speak English...they sometimes find it hard to communicate in Urdu...these are the ladies who came to the UK for marriage when they were very young, and they typically lack good education and digital skills.* [Female, aged 60-70 years, retired, first-generation immigrant]

One of the participants suggested how language requirements could be addressed:

> *[Referring to the REMORA app] see the content of the app in English, which is a barrier. This should be translated into Urdu...may be in audio format. Certain words such as tiredness and others in the app can be best described through images or visuals.* [Male, aged 50-60 years, working, first-generation immigrant]

There were also different language requirements between first- and second-generation immigrants, suggesting that not every individual with a Pakistani background would require Urdu to access digital health tools and resources (ie, understanding written materials or content). For example, second-generation

XSL•FO
RenderX

immigrants can understand spoken Urdu but may not be able to read Urdu. Similarly, first-generation immigrants are proficient in spoken English but may struggle to read English. One of the participants described it as follows:

> *Having the app in English and Urdu languages will be helpful...our kids understand Urdu...but if you speak to them in Urdu, they feel shy in answering in Urdu, but they do understand it...they just not speak Urdu.* [Female, aged 60-70 years, retired, first-generation immigrant]

Participants considered second- or third-generation immigrants to be more educated and digitally skilled:

> *This second generation is very educated and intelligent. They are well settled and capable to do anything. They are capable to use digital health technologies too.* [Male, aged 50-60 years, working, first-generation immigrant]

Among second- or third-generation immigrants, participants also perceived an emerging need for digital health tools because Pakistani people are being diagnosed with rheumatoid arthritis or early inflammatory arthritis at younger ages. Acknowledging the hesitation among older adults, one of the participants highlighted the need for older adults or first-generation immigrants to use digital health tools for managing their health conditions:

> *...if you can't look after yourself who's going to look after the rest of the family? So, take the time out for yourself. I encourage other ladies to have a free computer lesson. It's a big help to them. But they are reluctant to go, they are scared to go.* [Focus group participant]

According to participants, most first- and second- or third-generation immigrants either lived together in the same household or remained in close contact to support each other in health and non–health-related matters. Related to this, participants identified older women living alone as an example of a subgroup at risk of inequities because of their living and social circumstances. One of the older women said:

> *There are women in their older age, who live alone, their husbands are dead, their kids are settled elsewhere, so normally they are left with their own challenging circumstances...I personally think that women of my [older] age are either not interesting in using digital health technologies or they don't have enough resources to support the use of these technologies.* [Female, aged 60-70 years, retired, first-generation immigrant]

Role of Community and Family Support for Using Remote Monitoring Technologies

Participants acknowledged family and communal values of helping each other, particularly older people, individuals living in challenging circumstances, and those with less education. For example, one of the participants said about older adults:

> *Older people normally would not be able to use these tools [remote monitoring technologies] on their smartphones. Unless there are community groups...just like the one I attend...where someone sits with them and explains and shows them.* [Male, aged 50-60 years, working, first-generation immigrant]

Similarly, participants described how some women got help from local community groups, where they received support for day-to-day living and managing health issues. In addition to community support, children and grandchildren could provide family support for their parents and grandparents to handle their day-to-day affairs and manage health issues. For example, they could find and share relevant health-related information or show them how to search for relevant information online themselves (eg, YouTube videos, which participants mentioned as a common source of information, often shared by their family or friends). One of the participants said:

> *I am not very educated...so kids can help us in recording important information in the app so that doctor could access that information. Otherwise, I would not be able to remember and communicate this information during consultation.* [Female, aged 50-60 years, working, first-generation immigrant]

Sometimes, help available from children and grandchildren was a reason for older adults to lose interest in learning new skills and tools that could otherwise enable them to manage their own conditions better without receiving help from their children. One of the participants said:

> *I am not interested in learning how to use the [remote patient monitoring] app, when all such needs are fulfilled at home by family members.* [Female, aged 60-70 years, retired, first-generation immigrant]

Finally, participants proposed different activities and resources that might be helpful for patients to improve their health and digital literacy, particularly regarding the use of remote monitoring technologies. For example, disease-specific awareness sessions are regularly conducted by local physicians in community settings. Participants proposed organizing similar sessions to promote the potential value of remote monitoring technologies and train people how to use them effectively. In addition to in-person sessions, participants also proposed audiovisual content to help enable them to use such technologies. Group exercise sessions were also suggested, as one of the participants described the difficulty they faced:

> *Say, a physiotherapist gave you exercise, then they say go and just do it. There is no follow-up, there is nothing. You are just left to your own devices. If there is something that people every so often kept on top of called you in, there was some groups or sessions, and it's like how you are doing, and has it worked or not worked?* [Female, aged 70-80 years, retired, first-generation immigrant]

Discussion

Principal Findings

This qualitative study explored perspectives and needs regarding the use of remote monitoring technologies for self-managing

XSL•FO
RenderX

long-term conditions among South Asian individuals living in the United Kingdom who did not speak English as their first language. Study participants were dissatisfied with health care services and perceived remote monitoring technologies as a potential solution to these issues. For example, they believed these technologies could help address memory problems, enrich patient and health care provider communication, and help them feel supported between consultations. However, some subgroups (such as older women living alone in challenging circumstances or young immigrant women with language barriers and poor educational backgrounds) were considered at greater risk of developing further inequities if remote monitoring technologies are introduced in care pathways. Moreover, first-generation immigrants were expected to face more inequities than later-generation immigrants because of differences in intersecting social and digital determinants. Participants highlighted how family and communal values within the South Asian community could be leveraged to guide the development of support for people using remote monitoring technologies, facilitated by audiovisual content and in-person awareness sessions.

Relation to Other Studies

Despite recognizing the perceived benefits of remote monitoring technologies, common authentication methods (eg, passwords), along with a lack of motivation to learn how to use these technologies, may create accessibility barriers [49], as reported by participants in our study. In addition to addressing these accessibility barriers, the provision of timely and personalized care may further promote sustained engagement with remote monitoring technologies [28].

Our study showed intergenerational differences in perspectives and needs regarding the use of remote monitoring technologies to support South Asian individuals in managing their condition. In keeping with Aldosari et al [39], our study highlighted that literacy levels and language requirements varied between first- and second-generation immigrants. This supports previous research advocating language proficiency as an important determinant for equitable access to and use of digital health technologies for South Asian individuals [39] and for ethnic minority groups more generally [50,51]. While technological capabilities to translate English content are improving, people with language barriers may still prefer face-to-face communication [38] and therefore remain reliant on available interpretation support via professional interpreters or informal carers [52]. In turn, this influences their trust in digital health research and services [37,53], making it crucial to explore and address language requirements to ensure equitable and inclusive digital health research and technologies.

We also found that the role of family and community members is important in supporting the use and adoption of remote monitoring technologies. Their role is increasingly being recognized in facilitating South Asian individuals' access to digital health tools and services [38,54] and building their skills and trust in using digital health technologies [55,56]. Particularly in the context of multigenerational households, living arrangements may improve digital literacy and health care access [57] and help navigate usability issues related to digital health technologies [58]. This dependence might not necessarily be perceived as negative, as in Asian cultures more broadly, interdependence tends to be valued (rooted in filial piety, a concept where social norms shape intergenerational relationships [59]). However, we also found that the availability of support from family carers (eg, children or grandchildren) could have a simultaneous negative impact on people's motivation to obtain digital skills. This aligns with findings from another study in South Asian individuals living with cardiometabolic diseases, suggesting that family members and South Asian community members acted as both positive and negative drivers for adopting healthier versions of cultural food [38]. Overall, this suggests that social context could be leveraged to enhance the adoption of remote monitoring technologies, but future research should further explore how family and community support moderate interdependent relationships and ultimately people's engagement with digitally enabled health care services.

Limitations

One of our eligibility criteria was that participants did not have English as their first language. Our aim was to recruit a sample at risk of experiencing language barriers when engaging with digital health technologies and research. Overall, in the United Kingdom, around 20% of people who do not have English as their main language report limited or no English language proficiency [60]. However, most participants in our study were able to speak English very well and did not consider language an important barrier for themselves. Although they highlighted the English language as a potential barrier for some other first-generation immigrant women, our sample did not allow in-depth exploration of perspectives from those with more limited English language proficiency.

Most study participants were recruited via a community-based organization that organized regular health-related activities (eg, awareness sessions and exercise sessions). This may partly explain why community support was identified as a potential enabler for using remote monitoring technologies. Patients recruited through other routes or less health-focused community-based organizations might have had different perspectives on the role of community-based resources in addressing ethnic health inequities.

Implications for Practice and Research

Researchers and technology developers should consider proficiency in reading and writing English or people's native language as an important determinant of health when designing equitable remote monitoring technologies for end users from South Asian ethnic minority groups. This should include exploring the language proficiency of end users' family members (eg, children or grandchildren) to examine if and how information should be offered to ensure it is accessible to multiple generations, enabling both the end user and their "supporters" to engage with digital health tools and resources. Requirements to involve family carers are also reflected in NHS England guidance on access to health services, including the implementation guidance on accessible information standards [61] and the framework for action on digital inclusion [62]. However, the literature provides limited specific examples of how language needs are addressed in practice. Therefore, future

XSL•FO
RenderX

research should examine how aspects of language requirements for digital health technologies can be effectively implemented, particularly within the context of multigenerational households. These explorations should form part of understanding people's wider social context and of proactively involving family carers in co-designing remote monitoring technologies, as has been done previously in the context of dementia [54] and diabetes [63]. While digital skills-building training, as well as educational and cognitive-behavioral programs, have been developed for carers to enhance their pain-related knowledge and self-efficacy, robust evidence of their effectiveness remains limited. Therefore, future research should focus on strengthening this evidence base [64,65]. Overall, involvement of carers will support the development of more equitable remote monitoring technologies that contribute to better health outcomes among South Asian ethnic minority groups.

Conclusions

Remote monitoring technologies have the potential to enhance care for South Asian individuals by addressing language barriers, cultural needs, and issues of trust. Language barriers often intersect with other social and digital determinants, such as age, educational attainment, and digital health literacy. This creates further obstacles, especially for first-generation South Asian immigrants, who may require additional support. In this context, the role of family carers and the wider community in supporting access to and use of remote monitoring technologies is particularly important. Researchers and technology developers must therefore consider the social and cultural environments in which people from South Asian minority backgrounds live to ensure that remote monitoring technologies are inclusive, accessible, and capable of addressing existing health inequities for those living with long-term conditions.

Acknowledgments

The authors would like to thank members of the public involvement group who guided the research. The authors would also like to thank Ms Humera Haqqani from Let's Talk, who supported participant recruitment and helped organize interviews in a community venue.

Funding

The Remote Monitoring of Rheumatoid Arthritis (REMORA) research program is funded by the National Institute for Health and Care Research (NIHR) with a contribution from Versus Arthritis, under NIHR's Programme Grants for Applied Research scheme (grant NIHR202030). The views expressed are those of the authors and not necessarily those of the NIHR, Versus Arthritis, or the Department of Health and Social Care.

Data Availability

Anonymized data will be made available by the corresponding author upon reasonable request.

Authors' Contributions

SNvdV, WGD, CS, and KS conceived the idea of this study. YM drafted topic guides and used them for collecting data. YM and SMA coded and analyzed textual data. SMA, YM, SNvdV, CS, and KS interpreted the data. SMA and YM contributed to the first draft and all authors reviewed and approved the final draft of the manuscript.

Abstract

Background: Population aging is associated with a rising number of people living with cognitive impairment (CI), straining traditional caregiving systems. More than 55 million individuals live with CI worldwide, while care delivery faces severe capacity constraints. China's rapid aging provides a context for examining the acceptance and use of digital assistive technologies (DATs) in CI care. Although DATs offer the potential to address this care gap, systematic evidence on acceptance and use remains limited.

Objective: This study examined caregivers' acceptance and use of DATs in CI care, applying the Technology Acceptance Model (TAM) framework to identify key facilitators and barriers shaping acceptance and effective technology integration in caregiving environments.

Methods: This qualitative study used semistructured interviews and thematic analysis to examine the use of DATs and identify facilitators and barriers shaping caregivers' acceptance of DATs. Purposive sampling recruited 15 primary caregivers of people with CI across varying decline stages. The study focused on caregivers of people with CI aged 60 years and older. Caregivers were selected as participants because they serve as the primary decision-makers and technology facilitators in CI care.

Results: In CI care, DATs served 5 primary functional domains. Caregivers identified perceived usefulness and ease of use as primary acceptance facilitators. Factors shaping acceptance emerged across 3 dimensions: technological design factors, user psychological factors, and external environmental factors.

Conclusions: The findings suggest that traditional TAM constructs may benefit from contextual adaptation. The acceptance of DATs is not merely an individual assessment of usefulness or ease of use but also a relational and socially mediated process shaped by emotional dependence, family attitudes, technology anxiety, and support systems. Technology may therefore need to evolve dynamically across different stages of cognitive decline, while human caregivers remain irreplaceable in providing emotional support, personalized judgment, and crisis management. Effective DAT integration requires coordinated efforts among relevant stakeholders.

digital assistive technology; cognitive impairment; Technology Acceptance Model; caregiver; older adults

Introduction

Background

China faces severe challenges from population aging, with the population aged 65 years and older exceeding 220 million, accounting for 15.6% of the total population by 2025 [1]. This demographic transformation has generated substantial demands for innovative care solutions, particularly as cases of cognitive impairment (CI) are growing alarmingly from 55 million globally in 2021 to an estimated 139 million by 2050, with China bearing the largest share worldwide [2]. China currently has approximately 9.83 million patients with Alzheimer disease, one of the most prevalent forms of CI, which imposes substantial medical costs and caregiving burdens [3].

Digital Assistive Technologies in Care for People With CI

In response, digital assistive technologies (DATs) have been increasingly promoted to support the care for people with CI. DATs refer to technology-based tools and systems that are designed to support individuals in maintaining functional ability, independence, and quality of life, particularly in the context of aging and disability [4]. In CI care, these technologies include cognitive training applications, wearable monitoring devices, smart home systems, and other digital solutions that support

XSL•FO
RenderX

daily living, safety, and health monitoring [5,6]. While some DATs require active user interaction, others operate passively through ambient sensing and background monitoring, highlighting the need to align technological solutions with users' cognitive capacities and care environments.

The Chinese government has incorporated CI care into national strategic planning and recent policies promoting smart health and older care models, including wearable devices, service robots, smart antiwandering terminals, medication and care reminder systems, and products for CI assessment and training [7]. Despite growing needs and technological development, a persistent gap remains between the potential of DATs and their effective use in everyday CI care. The usability and effectiveness of DATs are shaped by both technological design and practical deployment [8]. Usability refers to how well a technology enables users to achieve their goals, while effectiveness concerns the accuracy and completeness of that achievement [9]. However, these objective characteristics may not fully explain why some technologies are accepted in practice, while others are not accepted. A device may perform well by objective standards yet still be perceived as difficult to use or of limited value in a specific care context. Focusing solely on objective outcomes, therefore, risks overlooking the subjective factors that determine whether a technology is accepted. Accordingly, this study focuses on caregivers' perceived usefulness and perceived ease of use, rather than on objective measures of system performance.

Caregiving in People With CI

CI encompasses a spectrum of conditions affecting memory, attention, language, and executive function, ranging from mild to severe CI, and is associated with progressive loss of independence and increased reliance on caregivers [2]. Caregivers play a central role in mediating the use of DATs for older adults with CI, particularly when individuals experience diminished capacity to evaluate or communicate their preferences. As many older adults with moderate to severe cognitive decline may have difficulty articulating their needs, caregivers serve as key decision-makers, facilitators, and evaluators of technology use in real-world settings. Accordingly, this study examined both formal (trained professionals providing paid care) and informal (nonprofessional individuals, such as family members, relatives, or friends) caregivers to reflect the varied contexts in which DATs are introduced, integrated, and evaluated in CI care.

Theoretical Frameworks and Related Work

The Technology Acceptance Model (TAM) has been widely used to explain technology acceptance in health care settings [10,11]. TAM proposes that perceived usefulness and perceived ease of use are the primary determinants of users' behavioral intention to use a technology [12]. It has also been applied to studies of technology uptake in aged care, including mobile health services, wearables, and smart home systems [13].

However, TAM does not fully capture the complexity of CI care settings, where acceptance may also be shaped by personalized training, safety concerns, cultural relevance, disease progression, and digital inequality [14]. A further consideration is that technology use does not necessarily reflect acceptance. Caregivers may continue using a device out of obligation or lack of alternatives, even when they do not perceive it as useful or easy to use. Given that DATs in CI care have not yet been widely embedded in routine practice, understanding the factors shaping acceptance is especially important. This study adopts TAM as its primary theoretical framework, with the interview guide structured around its core constructs. The subsequent thematic analysis was conducted inductively, remaining open to themes beyond TAM's original scope. As technology continues to evolve, the factors shaping acceptance may also shift. The findings are therefore discussed through the lens of TAM and its extensions to explore whether the specific context of care for people with CI raises considerations not fully addressed by existing models.

Factors Shaping Technology Acceptance in CI Care

Existing research has identified multiple factors influencing technology acceptance among caregivers and older adults with CI. A systematic review mapping barriers to TAM domains found that most relate to behavioral intentions to use technology, including cost, privacy concerns, stigma, and fear of misuse [15]. Physical and cognitive factors also pose significant challenges, including cognitive decline, reduced physical functioning, and visual, auditory, and language impairments [13]. While prior research has examined caregivers' acceptance of DATs in the care of people with CI, factors beyond perceived usefulness and perceived ease of use have not been fully examined. This study therefore aims to explore other factors that may shape caregivers' acceptance of DATs.

Research Questions

To address these gaps, this study adopts a qualitative approach to explore caregivers' experiences with DATs in the care of people with CI. Specifically, it examines how caregivers use DATs in everyday care scenarios and identifies the factors influencing their acceptance and sustained use. The study is guided by 2 research questions (RQs):

- RQ1: How are DATs used in CI care settings?
- RQ2: What factors shape caregivers' acceptance of DATs?

Methods

Study Design and Participants

This qualitative study used semistructured interviews to explore caregivers' experiences with DATs in CI care among older adults aged 60 years and older. Caregivers were selected as the primary participants because they serve as the key decision-makers in technology acceptance and use in this context. As cognitive capacity varies across stages and types of CI, caregivers play a central role in evaluating, implementing, and sustaining the use of DATs in real-world care settings.

Purposive sampling was used with the following inclusion criteria: (1) age ≥18 years, (2) >1 year of experience caring for older people with CI, (3) used at least one DAT, (4) informal or formal caregiver, and (5) communication ability to clearly express care experiences. It should be noted that inclusion criterion (3) restricted participation to caregivers who had

XSL•FO
RenderX

already adopted at least one DAT; the experiences and views of caregivers who had not used any DAT were therefore not captured in this study.

Fifteen caregivers were recruited through online communities, offline activities, and institutional recommendations, including 11 informal and 4 formal caregivers. The mean age of the participants was 39.67 (SD 15.0; range 21-78) years (9 women and 6 men), and the mean duration of care was 4.3 (SD 4.0; range 1-16) years.

Data saturation was assessed after each interview by evaluating thematic redundancy, adequacy of data to address the RQs, and the overall coherence of the emerging thematic structure. Initial data saturation indicators emerged by the 10th interview, when core themes around technology acceptance factors began stabilizing. No new themes emerged after the 13th interview, and data collection concluded after the 15th interview. Participant characteristics, caregiving contexts, and types of DATs used are summarized in Table 1.

XSL•FO
RenderX

Table . Technology use among informal and formal caregivers in cognitive impairment (CI) care[a].

ID[b]	Gender	Age (y)	Relationship with older adult	Condition of older adult[c]	Duration of care	Technology used	Usage scenario
ICG1	Female	44	Mother-daughter	Severe CI	5 years	Social robot and smart home	Home-based
ICG2	Male	50	Father-son	Mild CI	3 years	GPS shoes and smartwatch	Home-based
ICG3	Male	25	Grandfather-grandson	Mild CI	2 years	Smartwatch	Home-based
ICG4	Female	50	Father-daughter	Severe CI	7 years	Social robot and GPS wristband	Home-based
ICG5	Female	23	Grandfather-granddaughter	Mild CI	1 year	Smart voice assistant	Home-based
ICG6	Male	44	Father-son	Severe CI	3 years	Smartwatch and online mini-program	Home-based
ICG7	Female	46	Father-daughter	Moderate CI	9 years	Social robot and tablet games	Home-based
ICG8	Male	24	Grandmother-grandson	Severe CI with aphasia	2 years	"Xiao Ai" smart assistant and smart mattress	Home-based
ICG9	Female	21	Grandfather-granddaughter	Moderate CI	3 years	Walking aid, smartwatch, and smart home	Home-based
ICG10	Male	78	Spouse	Moderate CI	16 years	Walking aid and smart home	Home-based
ICG11	Female	39	Mother-in-law and daughter-in-law	Severe CI	6 years	Walking aid and emergency alarm system	Home-based
FCG1	Female	44	/[d]	/	1.5 years	"Xiao Ai" smart assistant and smart mattress	Home-based
FCG2	Female	44	/	/	1 year	Smart mattress and senior landline phone	Institutional
FCG3	Male	40	/	/	4 years	Virtual reality (VR) video system	Institutional
FCG4	Female	23	/	/	1 year	Smart wristband and smart mattress	Institutional

[a]To facilitate the identification of participants' roles in the analysis, each respondent was assigned a unique identifier. Informal caregivers are labeled as ICG (informal caregiver), and formal caregivers as FCG (formal caregiver). No standardized cognitive assessment was conducted. Detailed descriptions of the digital assistive technology listed in this table are provided in Multimedia Appendix 1.

[b]The number following each label indicates the individual participant's ID.

[c]CI levels reported in this study reflect caregivers' descriptions informed by prior clinical diagnoses.

[d]Institutional caregivers who provide care to multiple older adults.

Data Collection and Analysis

Semistructured interviews lasting 40 to 60 minutes were conducted online and offline. The interview guide covered participants' background information, DAT use experience, perceived ease of use and usefulness, and factors influencing technology acceptance. TAM informed the interview guide by sensitizing the study to perceived usefulness and perceived ease of use, but it did not determine the full scope of questioning. The semistructured format allowed participants to introduce concerns, experiences, and interpretations beyond the initial TAM-informed prompts. All interviews were recorded and transcribed verbatim, forming approximately 100,000 Chinese words of textual data.

The subsequent thematic analysis was conducted inductively rather than deductively. Codes and themes were generated from participants' accounts following a systematic 6-step approach:

XSL•FO
RenderX

(1) familiarization with data through repeated reading of transcripts and immersion in the dataset; (2) initial code generation to systematically identify and extract key concepts and patterns across the entire dataset; (3) searching for themes by collating codes into potential overarching themes and gathering relevant coded data extracts; (4) reviewing themes through iterative refinement to ensure internal coherence and clear distinctions between themes; (5) naming and defining themes, with later contextualization in relation to the TAM constructs where appropriate; and (6) producing the final analysis report with compelling evidence and analytical narrative [16,17].

The transcribed interviews were read repeatedly by author (XS). Guided by the study aims, relevant data segments were identified and extracted from individual responses, and meaning units were developed with attention to their content and context. These meaning units were interpreted at a semantic level rather than at a latent level. Codes were produced using keywords that captured the essence of the meaning units. The coded meaning units were compared and grouped into categories. After reviewing and refining the categories, they were organized into themes named using short sentences. These themes were finally contextualized and classified according to TAM through a process involving all authors, with authors (HC and PAK) providing final verification and validation. Details of the coding table for data analysis are provided in Multimedia Appendix 2. Research quality was ensured through expert consultation, supervisor discussions, double-checking procedures, diverse participant selection, and regular review of the analysis.

Ethical Considerations

This nonmedical qualitative study was conducted in accordance with the Finnish National Board on Research Integrity (TENK) guidelines [18]. After the discussion with the Ethical Committee of Research at the University of Eastern Finland, no formal review board number was issued for this study. According to Finnish research ethics principles, interview-based human sciences research should follow the guidelines of TENK, including voluntary participation, informed consent, confidentiality, and protection of personal data. As this study involved qualitative interviews with caregivers rather than medical interventions or direct experimentation with older adults with CI, it would normally be assessed as nonmedical human sciences research under Finnish ethical review principles. Particular attention was nevertheless paid to the sensitive caregiving context, participants' emotional burden, and anonymization of all interview data. Participation was voluntary, informed consent was obtained prior to data collection, and confidentiality and anonymity were strictly maintained throughout the study. To acknowledge participants' time investment and valuable contributions, appropriate compensation was provided as an expression of gratitude for their participation. Strict confidentiality protocols were maintained throughout the study, with all personal information and sensitive data anonymized during data processing. Interview recordings were securely stored and deleted on completion of analysis, and all participants are referred to anonymously in research outputs to ensure privacy protection.

Results

Overview

This section presents the key findings in responding to the 2 RQs. The first part addresses how DATs are used in CI care settings (RQ1), highlighting 5 core functional domains. The second part examines factors shaping caregivers' acceptance of these technologies (RQ2), outlining both barriers and facilitators. These themes emerged from the thematic analysis of caregiver interviews.

It is important to note that the functional capabilities of a technology do not automatically translate into perceived benefits for users. A device may be designed to perform a specific function, yet caregivers may not experience it as useful or manageable in their particular care context. This gap between objective functionality and subjective perception is central to why this study focuses on caregivers' perceived usefulness and ease of use, rather than on what technologies are technically designed to do.

DAT Applications: From Daily Living to Cognitive Intervention

The following findings address RQ1 by examining how DATs are used in CI care settings. The analysis of caregiver interviews revealed that DATs serve 5 functional domains in CI care, with applications spanning safety support, emotional and social engagement, daily living assistance, health monitoring, and cognitive function support.

Safety Support Functions

Safety emerged as the primary concern for caregivers, with DATs showing significant value in this domain. Caregivers reported that smart home devices had an impact on safety and caregiver burden reduction and perceived that these technologies enabled individuals with CI to maintain greater independence.

> *My mother's condition is serious, and these technologies help a lot. The robot alerts me if she doesn't move for a while. I can also monitor her remotely on my phone, which makes me feel much more at ease.* [ICG1]

Caregivers described that safety technologies helped reduce the incidence of falls, wandering, and other safety incidents and reported that real-time monitoring enhanced their ability to respond quickly to emergencies.

> *My dad fell in the yard. The watch immediately sent an alarm to my phone, and I rushed over. Fortunately, it wasn't serious. At least I could know it in time…* [ICG2]

> *My father once got lost near the community, but the wristband gave an alarm. We checked the location and found him quickly. The function is very crucial.* [ICG4]

> *We installed smart lights that turn on when they sense movement, and the door locks notify us if Grandpa tries to go out.* [ICG9]

XSL•FO
RenderX

Emotional and Social Support Functions

Social robots are perceived as valuable tools for addressing emotional isolation and social disconnection among individuals with CI. These anthropomorphic devices provided consistent companionship through conversational interactions, entertainment content, and emotional regulation support. Caregivers noted significant reductions in patient agitation, anxiety, and behavioral disturbances when social robots were integrated into care routines.

> *At first, I was confused about the robot, but it has helped our family a lot. My mother now chats with it daily, greeting it every morning and even confiding in it. This relieved much of my stress and gave me more time for other tasks.* [ICG1]

The personalization capabilities of social robots were described as especially beneficial, with devices able to simulate familiar voices or faces, play preferred music, and engage in individualized conversations. Caregivers demonstrated perceived usefulness of DATs in reducing caregiver emotional burden while providing older adults with meaningful social experiences that resembled interactions with family members or friends.

> *Before using the robot, my father would wander looking for my deceased mother daily. The robot's programmed video tasks helped distract him, and now he no longer roams or leaves home. His smiles have even increased from 'chatting' with the robot.* [ICG4]

Caregivers also perceived social robots as supporting emotional stability and social interaction among care recipients while providing themselves with valuable respite and emotional support tools. Caregivers also reported that the continuous availability of these companions helped maintain social connections.

> *This robot is very important to my father. When he was depressed, it suggested playing his favorite music. After listening, he began chatting about the past and gradually recovered.* [ICG7]

Daily Living Assistance Functions

Caregivers reported that smart voice assistants reduced the demands of daily care coordination, particularly in managing medication schedules and appointment reminders. The voice-based interface was seen as especially well-suited to care recipients with declining cognitive abilities by participants, as it required minimal operational effort.

> *We use an intelligent voice assistant to set daily medication reminders. It's very convenient—I don't have to watch over Grandpa all the time. The assistant reminds him when to take which medicine, which is much better than constant supervision.* [ICG5]

> *Sometimes I forget what the medicine is for... the voice assistant tells us its functions, side effects. This saves us the trouble of reading instructions or asking doctors.*
>
> *[ICG5]*

The medication management capabilities of voice assistants extended beyond simple reminders to include drug information provision, dosage verification, and safety monitoring. According to caregivers, when patients or caregivers had questions about medication purposes, administration methods, or potential side effects, voice assistants could provide immediate, accurate information, reducing the risk of medication errors.

Health Monitoring Functions

Caregivers highlighted the reassurance provided by wearable devices and smart sensors through continuous monitoring of vital signs, including heart rate, blood pressure, and body temperature. The ability to receive real-time data and alerts was described as enhancing caregivers' confidence in managing health risks at a distance.

> *I bought a watch for my grandpa to monitor his heart rate. It connects to my phone, so I can know if his heart rate or blood pressure is abnormal.* [ICG3]

Caregivers also reported health monitoring technologies as tools that supported routine observation and early notification in institutional care settings. These devices were presented as assisting caregivers by generating alerts when unusual conditions were detected, which helped staff become aware of potential problems in a timelier way.

> *The smart mattress at the nursing home where I work monitors vital signs, such as when residents get up or remain immobile for long periods. It automatically alerts the responsible nurse in case of abnormalities.* [FCG3]

Cognitive Function Support

Cognitive training applications delivered through various digital platforms, including WeChat mini-programs (lightweight applications embedded within WeChat, a widely used instant messaging and social media platform in China), tablet-based cognitive games, and mobile-based apps, were perceived as showing promise in maintaining cognitive engagement among care recipients.

WeChat mini-programs allow users to access services, including cognitive games without installing separate software, offering convenient cognitive training, including memory exercises, attention training, and logic tasks.

> *My father plays a memory card matching game on WeChat daily. Though he sometimes forgets details, he enjoys it greatly. The group also has small games like arithmetic and riddles, which keep him engaged and prevent excessive daydreaming or sleep.* [ICG6]

Tablet-based cognitive games provided more comprehensive cognitive training through touchscreen interfaces and intuitive game mechanics. These applications were reported to address multiple cognitive domains, including memory, attention, problem-solving, and reasoning skills through engaging, gamified activities such as puzzles, spot-the-difference games, and simple mathematical problems by caregivers.

> *I downloaded a tablet game with puzzles and spot-the-difference for my dad. He plays it daily, which helps improve his reaction speed and concentration.* [ICG7]

XSL•FO
RenderX

Caregivers described the gamified format as helpful for sustaining care recipients' engagement and motivation. In their accounts, game elements such as challenges and progression systems made cognitive exercises feel more enjoyable and supported more regular participation.

> *Grandpa played a tablet game where he had to identify potential dangers like kitchen knives or falling objects. This helped enhance his risk judgment.* [ICG3]

According to caregivers, language-focused games appeared to support verbal communication and delay language decline, although these observations reflect caregiver perceptions rather than clinical assessments.

> *These games include language exercises such as word puzzles that delay language decline and improve vocabulary.* [ICG7]

Factors Influencing Technology Acceptance in CI Care

The following findings address RQ2 by examining the factors that shape caregivers' acceptance of DATs in CI care. These factors are organized into 3 categories: technology design, user psychology, and external environment, each of which encompasses both facilitators and barriers to acceptance.

Technology Design Factors

Design Usability and Operational Challenges

Participants identified operational complexity and user interface design as significant barriers to technology acceptance among individuals with CI and their caregivers. They reported that complex operational procedures and nonintuitive interfaces created difficulties for older adults with declining cognitive abilities, which could reduce willingness to use these technologies.

> *Smart home devices have many functions, but the operation is too complicated. My parents often forget which button to press and sometimes give up. Some functions expected to be automatic aren't used, so I must operate them manually, which takes more time.* [ICG1]

> *My dad struggles with the tablet. There are too many options, and he gets confused easily. He often presses the wrong buttons and ends up on unfamiliar pages with ads. He can only use it with my help.* [ICG2]

Participants further described a gap between their initial expectations and their actual experience of the technologies. Caregivers reported that they had expected these tools to reduce care burden and support care recipient autonomy, but technical limitations and inconsistent performance often limited these perceived benefits.

> *The smart assistant doesn't understand grandma's dialect well; she only speaks Teochew, and her Mandarin isn't standard.* [ICG8]

> *The positioning shoes sometimes fail to give timely alarms, which worries me.* [ICG2]

> *My grandfather often can't hear the voice assistant's medicine reminders clearly and sometimes just ignores repeated instructions.* [ICG3]

> *I thought the smartwatch would reduce my caregiving burden by reminding medicine and monitoring health, but unstable networks and inaccurate data made me spend more time managing it.* [ICG6]

> *I hoped the social robot could ease my dad's emotional issues so I wouldn't have to be with him constantly. But it often misunderstands him, and my daughter or I must stay nearby to help.* [ICG4]

> *The sensor light helps at night when my spouse gets up, but the camera isn't sensitive enough and sometimes misses parts of the room, which worries me.* [ICG10]

Taken together, participants' accounts suggested that perceived usefulness in the care of people with CI was shaped not only by a technology's intended functions but also by the extent to which it performed reliably and aligned with caregivers' expectations in everyday care practice.

Personalization and User-Specific Needs

Participants identified insufficient personalization and limited inclusive design as significant constraints on the perceived usefulness of DATs in the CI care. They reported that many smart devices followed a "one-size-fits-all" design and did not adequately respond to individual care needs, which could reduce willingness for sustained use.

> *Our robot can only customize one spouse image for my dad, which isn't enough. He used to have many friends. If we could add images of old friends or comrades, he'd be happier. We'd pay for better customization, but current options are very limited.* [ICG4]

> *I bought my dad a big tablet, but it has too many functions he can't use. He can't remember complex steps. Many functions are unnecessary for him. The design doesn't fit his needs.* [ICG7]

Although some devices provided simple customization options, these typically failed to fully meet the actual needs of care recipients and caregivers. Participants also expressed a need for more flexible customization across different stages of CI and noted that the absence of stage-appropriate functions limited the usefulness of existing devices in everyday care.

User Psychological Factors

Technology Anxiety and Psychological Adaptation

In the interviews, technology anxiety was presented as an important barrier to technology acceptance among both individuals with CI and their caregivers. Caregivers reported that unfamiliar technologies often gave rise to confusion and apprehension, which could reduce willingness to use these devices.

Caregivers' accounts suggested that technology anxiety became stronger when devices required abilities that people with CI could no longer easily manage. They described complex

XSL•FO
RenderX

technology as increasing psychological burden and sometimes leading care recipients to avoid or resist use. Repeated operational difficulties were also reported as weakening users' confidence and heightening uncertainty about their own ability to use the device. Caregivers further noted that they experienced similar pressure when device setup was complicated or when they had to repeatedly solve technical problems and explain unfamiliar functions during care.

> *Every time my grandfather tries to use the smartwatch, he gets nervous. He fears pressing wrong buttons or accidental payments. Even with repeated teaching, when alone, he dares not operate the device and prefers to give up.* [ICG9]

Caregiver Technology Burden and Support

Although DATs were reported to reduce caregiver burden and improve care efficiency, caregivers reported that learning new technologies alongside daily care work increased their workload, particularly when they also needed to manage maintenance and provide repeated support during use. Limited technical support was described as a further challenge. Several participants noted that device malfunctions often had to be handled independently, and some formal caregivers reported that they had received little training and mainly relied on trial and error.

> *My father can't use mini-programs independently. Whenever issues arise, I have to help him reset or troubleshoot. I've taught him repeatedly, but he can't remember, so I'm always the one managing it.* [ICG6]

> *My dad enjoys interacting with the robot, but it often fails to recognize his speech or responds incorrectly. I must stay with him to correct errors. When no one helps, he becomes anxious and frustrated, sometimes telling the robot to shut up. I worry he'll lose willingness to try.* [ICG4]

> *When equipment malfunctions, we resort to online guides or customer service, but problems often remain unresolved. Instead of reducing workload, these devices increase our burden.* [FCG2]

> *The smart mattresses at our nursing home need training, but it was brief and insufficient. When malfunctions occur, we rely on customer support or technicians, which is time-consuming. Sometimes the alerts misidentify patients, and fixing these issues is complex.* [FCG4]

External Environmental Factors

Family Attitudes and Cultural Values

Caregivers' accounts indicated that family member attitudes and support were important to the acceptance of DATs. They reported that encouragement or resistance from family members, as well as the presence or absence of emotional and practical support, could shape care recipients' acceptance of these technologies in everyday care.

Across interviews, some caregivers described family involvement as facilitating technology use. Support with selecting, purchasing, installing, and explaining devices was presented as helping reduce hesitation and making technologies easier to introduce into daily care.

> *I was hesitant at first because these high-tech products are expensive and unfamiliar. But my daughter was very supportive, helping with installation and teaching my dad step-by-step. Now, although my dad learns slowly, he can basically use the devices, and I feel more secure knowing my daughter is there to help.* [ICG7]

> *My daughter suggested installing smart home systems and helped me choose and set up lights and alarms. I was initially afraid of improper operation, but with her help, I gradually found the devices easy to use. Sometimes, they really save us a lot of trouble.* [ICG10]

Interview accounts also showed that family attitudes could constrain the introduction of DATs. Some caregivers reported that objections from relatives, concerns about cost, or discomfort with the idea of technology-mediated care limited their acceptance of such devices. In these accounts, hesitation was related not only to practical issues but also to concerns about whether technology-based care might be seen as inadequate, impersonal, or inconsistent with family responsibility.

> *I wanted to install a monitoring system to know if grandma is safe when I go out, but my parents opposed it. Grandma said, "What's the point? Treating me like a show?" She often gets angry and resents the nanny. Since grandma disliked it, I didn't argue and didn't buy the equipment.* [ICG8]

> *I wanted to buy my mother-in-law a talking robot, but my husband said it's too expensive and unnecessary...* [ICG11]

> *My mother feels that using robots makes her seem irresponsible or disrespectful to the elderly, who need human companionship more. Although these technologies might reduce burden, she feels uneasy.* [ICG9]

> *People here think elderly care should be done personally. When I mentioned smart devices to peers, many thought I was being lazy or irresponsible. I felt conflicted because the intention was to reduce burden, but it was seen negatively.* [ICG4]

Taken together, these accounts suggest that acceptance of DATs was shaped not only by practical considerations but also by family norms and cultural expectations surrounding care. For some caregivers, technology was viewed as potentially helpful, while for others, it raised concerns about responsibility, appropriateness, and the place of human care in family life.

Affordability and Sustained Use

Economic conditions were an important consideration in caregivers' acceptance and use of DATs. Several caregivers raised concerns about the cost of devices, particularly in families with limited financial resources where purchase, maintenance, and continued use could place a substantial burden on the household.

XSL•FO
RenderX

> *Some technologies like health monitors are excellent, but our family can't afford the high cost, especially for long-term use and maintenance.* [ICG2]
>
> *If prices were reasonable, with public resources or subsidies, I would consider buying more useful devices. Often the technology is good, but we can't afford it.* [ICG6]
>
> *I wanted to buy my mother-in-law a talking robot, but my husband thought it was too expensive and unnecessary. We rely on my income alone, so it's not affordable.* [ICG11]

Across interviews, caregivers indicated that they would be more willing to try or continue using DATs if costs were lower or if financial support, such as subsidies, were available. Some participants acknowledged the potential value of these technologies but described cost as a practical barrier to uptake and continued use. Ongoing expenses, including service fees and maintenance costs, were also mentioned as limiting sustained use in everyday care.

Discussion

Principal Findings

This study explored how DATs are used in care for people with CI and what factors shape caregivers' acceptance. The discussion first relates 4 identified themes to TAM-related models, including family attitudes, social support, technology anxiety, and emotional dependence. It then considers stage-specific care needs, the essential role of human caregivers, and coordinated support for DAT integration.

Technology Acceptance Beyond Established TAM Constructs

Overview

The findings of this study are broadly consistent with TAM's core constructs. Caregivers identified perceived usefulness and perceived ease of use still as central factors shaping their acceptance of DATs. However, the findings differentiate this study from conventional technology acceptance studies by showing how social, emotional, and care-contextual dimensions shape acceptance alongside perceived usefulness and perceived ease of use. Beyond TAM's core constructs, participants described 4 themes shaping their acceptance: family attitudes, social support, technology anxiety, and emotional dependence. Examined through the lens of TAM, TAM3, and Unified Theory of Acceptance and Use of Technology (UTAUT), the identified factors showed different degrees of correspondence with established constructs, although some factors point to dimensions of technology acceptance that existing models have not fully addressed in the care context for people with CI. These observations are offered tentatively, as they are grounded in a small qualitative sample and warrant further empirical investigation.

Family Attitudes

Family attitudes toward technology shaped DAT acceptance in care for people with CI by influencing both attitudes toward technology and the practical conditions for continued use. Sustained technology use is often less a matter of older adults' individual acceptance than of family members' decisions and ongoing involvement, particularly in China, where older adults often rely on family support. Family caregivers typically take responsibility for selecting, setting up, and maintaining technologies, as well as providing day-to-day guidance during use. Prior research on technology socialization highlights that adult children and other family members frequently act as key facilitators by embedding technologies into everyday family practices [19]. Evidence from China further shows that intergenerational support enhances perceived ease of use, perceived usefulness, and trust in digital health services [20]. These findings correspond in part to UTAUT's social influence construct because relatives' expectations shaped attitudes toward DATs [21]. It also relates to facilitating conditions because family members often provide practical support for use.

Social Support

Social support, particularly from social workers and community programs, enhances technology acceptance by providing training and psychological support during initial acceptance phases. The existence of social support enables some caregivers to receive timely assistance when they encounter difficulties, enhancing their confidence and persistence in the use of technology [20]. This corresponds to UTAUT's facilitating conditions construct, which highlights the importance of support structures for technology use [21] because community programs, social workers, and service providers shaped whether caregivers had the training, troubleshooting support, and reassurance needed to continue using DATs. In this study, such support was not limited to formal organizational or technical arrangements, but also included community-based and interpersonal forms of assistance.

Technology Anxiety

Technology anxiety, identified as a barrier to acceptance among both people with CI and caregivers, corresponds closely to the computer anxiety construct in TAM3, where anxiety is understood as shaping perceived ease of use [22]. In this study, this was reflected in caregivers' accounts that unfamiliar or cognitively demanding devices often created apprehension and reduced willingness to engage. Among people with CI, such anxiety was especially strong when repeated operational difficulties occurred, while among caregivers, it was linked to complex setup requirements and responsibility for troubleshooting.

Emotional Dependence

Emotional dependence was the theme least readily aligned with existing TAM or UTAUT constructs. Prior research on human-robot interaction has identified emotional connection as a factor shaping older adults' engagement with assistive technologies, alongside more functional considerations such as perceived usefulness and ease of use [23]. From a relational care and sociotechnical perspective, this finding suggests that DATs enter existing care relationships rather than being added simply as neutral tools. Their acceptance depended partly on whether caregivers and care recipients perceived them as fitting into routines of companionship, reassurance, and emotional

XSL•FO
RenderX

presence. Some caregivers remained hesitant about technology use when they felt that devices could not provide warmth or emotional presence. Others reported that when older adults developed emotional attachment to a device, they were sometimes more willing to engage with it. This theme therefore extends beyond traditional TAM constructs in a narrow functional sense. Devices became more acceptable when they gained emotional meaning within care routines but were resisted when perceived as unable to provide human warmth or relational presence.

Technology Needs Across Stages of Cognitive Decline

Caregivers Described Technology Needs as Evolving Alongside Cognitive Decline

Caregivers described care priorities and technology use as changing across stages of cognitive decline, ranging from cognitive support and memory assistance in mild stages to safety monitoring and passive sensing in later stages. Their accounts suggested 3 broad patterns. In mild stages, caregivers tended to prioritize independence and described using memory aids and cognitive training tools to support everyday functioning. In moderate stages, greater emphasis was placed on safety monitoring and personalized interaction, with social robots and monitoring systems described as more relevant in responding to behavioral change. In severe stages, caregivers referred more often to comprehensive monitoring and nonverbal forms of interaction in the context of high care dependency. These patterns appeared to vary across individuals and care settings. Taken together, the findings suggest that technologies for the care of people with CI may need to be flexible enough to respond to changing care needs across stages of decline.

Human Caregivers and Technology in Collaborative Care

Participants' accounts suggested that human caregivers remained essential in 3 aspects of care: emotional support, personalized judgment, and response to complex situations. Technology was not perceived as fully capable of meeting these needs, particularly when care involved unexpected circumstances. These accounts suggest that participants viewed DATs mainly as supportive tools, while human caregivers continued to be seen as central to care.

> *My mother feels that using robots makes her seem irresponsible or disrespectful to the elderly, who need human companionship more. Although these technologies might reduce burden, she feels uneasy.* [ICG9]

> *The smart mattress means I don't have to stay by the patient's side all the time, but when something more complex happens, you still need a person there to handle it.* [FCG2]

Implications for Coordinated Technology Integration in Care for People With CI

The findings suggest that effective integration of DATs in the care of people with CI may depend on coordinated support across multiple stakeholder groups [24]. Previous research has highlighted the role of clinicians in evaluating and responsibly introducing DATs in this context [25]. In this study, participants' accounts pointed to 3 areas of practical relevance. For technology developers, the findings highlight the importance of age-friendly interfaces and functions that can respond to changing care needs across stages of cognitive decline. For social workers, the findings suggest a role in supporting technology use through guidance, training, and emotional support during implementation. For policymakers, the findings point to the need to improve affordability and reduce structural barriers to access, including through financial support and appropriate regulation. Taken together, these implications suggest that DAT integration requires coordinated support across technology design, caregiver training, implementation support, and policy measures addressing affordability and access.

Limitations

This study acknowledges several limitations. First, the sample was relatively small, comprising 15 caregivers primarily from family care settings in China, which limits representativeness across diverse geographical and cultural contexts. More detailed sociodemographic characteristics, such as education level, socioeconomic background, and digital literacy, were not systematically examined, and these factors may influence technology acceptance. As inclusion criteria (3) required prior DAT use, the sample reflects the experiences of adopters only, and the views of caregivers who had not used any DAT are not captured. The diversity of the sample in terms of caregiver type, age, and technologies used also means that findings cannot be attributed to any specific caregiver group or device category.

The qualitative methodology, while providing rich insights into caregiver experiences, inherently carries subjective interpretation risks and lacks quantitative validation. Additionally, the study focuses on currently available technologies rather than emerging innovations such as AI-powered robots or VR/AR applications, which remain limited in practical implementation due to cost and accessibility barriers [24].

A further limitation concerns the source of the data, as this study captures caregiver perspectives rather than direct experiences of care recipients, who may face communication challenges that complicate assessment of their actual technology preferences. In addition, CI stages reported in Table 1 were based on caregivers' descriptions informed by prior clinical diagnoses, and no standardized cognitive assessments were conducted by this research. Future research should include larger, more diverse samples; use mixed method approaches, longitudinal designs to assess long-term technology adaptation, and develop innovative methods to capture the authentic experiences of care recipients themselves.

Conclusions

This study examined how DATs are used in care for people with CI and what factors shape caregivers' acceptance of these technologies. Caregivers described DATs as being used across 5 functional domains: safety support, emotional and social engagement, daily living assistance, health monitoring, and cognitive function support. Their accounts also showed that acceptance was shaped not only by perceived usefulness and perceived ease of use but also by family attitudes, social support,

XSL•FO
RenderX

technology anxiety, and emotional dependence. Technologies were described as more acceptable when they were reliable, easy to manage, and responsive to stage-specific needs. They were less acceptable when they increased caregiver burden, failed to match everyday care demands, or conflicted with family expectations and care values. DATs may be used in care, but acceptance still depends on perceived usefulness, ease of use, relational care, family attitudes, and support conditions. Overall, the findings suggest that DAT integration depends on relational, cultural, and social contexts rather than technical functionality alone. Across interviews, DATs were generally viewed as supportive tools within care, while human caregivers remained essential for emotional support, individualized judgment, and response to complex situations.

These findings have 3 practical implications. First, DAT design should prioritize simplicity, personalization, and flexibility across different stages of CI. Second, implementation should be accomplished by accessible training and sustained support for caregivers. Third, wider uptake is likely to depend on enabling family, community, and policy conditions. In summary, improving DAT integration in care for people with CI requires attention not only to what technologies are designed to achieve but also to how caregivers and recipients experience, assess, and sustain their use in everyday care. Effective DAT integration must be grounded in caregivers' perceptions and in the broader social and cultural contexts of technologies. Future research should further examine these dynamics in larger and more diverse samples.

Abstract

Background: Emotional disorders (EDs) are the most prevalent mental disorders worldwide. Health services face significant difficulties in attending to the high demand and applying evidence-based psychological treatments. Combining the transdiagnostic approach with the group and blended formats could help the accessibility of treatment for ED. It is important to assess the feasibility and acceptability of new interventions from a qualitative perspective.

Objective: This study aimed to explore the experiences and opinions of patients with ED who have received transdiagnostic cognitive behavioral therapy treatment in a group and blended format.

Methods: Two subsamples of participants were included: those who completed the intervention (n=18) and those who did not (n=4). The completers' subsample participated in focus groups, which were transcribed verbatim and subsequently analyzed using a consensus qualitative research methodology. The noncompleters subsample completed a brief online questionnaire. Key themes identified by 2 independent researchers were described and used as complementary to focus group findings. Results were reported following the COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines.

Results: After analyzing the focus group interviews using the consensus qualitative research method, 8 domains (or topic areas) were identified, namely experience with the online platform, configuration of the blended intervention, therapeutic content, experience with the group sessions via videoconference, role of the therapists, overall assessment of the blended treatment, elements that help maintain adherence, and suggestions for improvement. Overall, participants reported benefits from this type of intervention, expressed satisfaction with the treatment, and highlighted the perceived improvement and usefulness of what they learned. They also noted the good usability of the platform and the possibility of establishing a good therapeutic alliance in this format. Participants also pointed out unfavorable aspects and offered suggestions on possible areas for improvement. For noncompleters, various reasons for dropping out were identified: lack of treatment efficacy, intervention-related stress, difficulty in applying learned strategies, low involvement, lack of motivation, time constraints, or need for different types of help. Strategies to enhance adherence to treatment were also identified, such as changes in the format and configuration of the sessions, allowing more time to discuss individual problems or reducing the number of homework assignments.

Conclusions: These qualitative results support the feasibility, acceptability, and clinical utility of a blended group transdiagnostic intervention for the treatment of ED. This novel format could be a scalable and well-valued option within mental health services, although it can still be further optimized based on the results of this study.

Trial Registration: ClinicalTrials.gov NCT04008576; https://clinicaltrials.gov/study/NCT04008576

Introduction

Depressive, anxiety, and other related disorders, commonly known as emotional disorders (EDs) [1], are the most prevalent mental disorders worldwide [2]. In Spain, the cases of ED reach almost 17% of the general population, being the most frequently diagnosed psychological disorders in health care services [3] and generating a high economic burden [4].

In this regard, the National Health System (NHS) faces significant challenges in meeting the high demand for mental health care, with a limited number of psychology professionals [5]. While international recommendations suggest a caseload of approximately 86 patients per year per professional, psychologists in the Spanish NHS attend approximately 330 patients annually [6]. This contributes to delayed care, long waiting lists, and extended time between sessions, thereby hindering the implementation of evidence-based treatments (EBTs).

To address these limitations, alternative therapeutic approaches with a more dimensional perspective have been proposed. The transdiagnostic approach stands out among them. This approach focuses on intervening in common factors involved in the origin and maintenance of various psychological disorders [7], such as the various EDs [8], which could facilitate the implementation of EBT and the management of comorbidities [9].

In parallel, digital mental health interventions, particularly internet-based therapy, have emerged to improve treatment accessibility. Online cognitive behavioral therapy (CBT) has been shown to be effective for treating anxiety and depression [10], even when using a transdiagnostic approach to address ED [11]. However, some patients require more therapist contact and customized treatment [12,13]. Blended treatments, which combine elements of face-to-face and online therapy, have emerged as a promising alternative, leveraging the strengths of both approaches while reducing some of their barriers [14]. Additionally, the blended format has been effective in reducing symptoms of depression and anxiety [15-17].

Another alternative that can help to improve psychological care, especially in the NHS, is to carry out interventions in group format. This type of intervention has been shown to be as effective as individual therapy in treating ED [18,19] and also has advantages for patients, such as peer support and reducing stigma [20,21]. Furthermore, it is a more efficient option than individual therapy as it allows treating many individuals at once and reducing the burden of services [21,22].

Consequently, there is growing interest in combining transdiagnostic, blended, and group approaches into a single treatment protocol [23]. This integration could help more people with ED access EBT and allow a greater number of individuals with similar issues to be treated simultaneously. However, beyond effectiveness, it is crucial to evaluate the feasibility and acceptability of these innovative interventions from both quantitative and qualitative perspectives [24]. Qualitative research is a valuable method for collecting and analyzing nonnumerical data, enabling an in-depth exploration of individual experiences and providing detailed information about concepts and opinions [25].

There are some qualitative studies on blended interventions from the patients' [26,27] and the therapists' points of view [28,29]. However, literature in this area remains scarce, and, to our knowledge, no studies have reported the opinion of patients who have received a transdiagnostic CBT intervention for ED applied in a blended and group format.

This qualitative study is part of a broader feasibility trial (trial registration: NCT04008576) [23] and its main objective was to explore in depth the experiences and opinions of patients who received a transdiagnostic CBT intervention in blended and group formats for ED, in order to understand their degree of acceptance, satisfaction, and possible areas for improvement from their perspective. Quantitative results on feasibility, acceptability, and preliminary efficacy are reported elsewhere [30].

Methods

Participants

Participants were selected through convenience sampling from a community sample of patients who had received a blended transdiagnostic group intervention for EDs at the Emotional Disorders Clinic of Universitat Jaume I [30]. Patients were required to be 18 years or older; no upper age limit was imposed. The initial sample included both individuals who had received psychological treatment prior to the feasibility trial and participants who were receiving psychological therapy for the first time.

Patients began the same intervention but differed in their level of treatment adherence; 23 out of 34 participants (68%) completed the full intervention, and 11 out of 34 (32%) discontinued treatment [30]. Therefore, this study included 2 subsamples based on treatment completion status. This was done to explore the experiences of those who finished the intervention and those who dropped out.

The first subsample consisted of 18 patients (14 women and 4 men) who completed the full intervention protocol, with a mean age of 33.94 (SD 11.03; range 20 - 54) years. Sociodemographic and clinical characteristics of participants at the beginning of the treatment can be found in Table 1.

XSL•FO
RenderX

Table . Sociodemographic and clinical characteristics of subsample 1.

Code	Sex	Age	Marital status	Educational level	Main diagnosis	Comorbid diagnoses
P[a]1#FG[b]1	Female	23	In a relationship	HE[c]	MDD[d]	3 (PD[e], A[f], GAD[g])
P2#FG1	Female	54	Married	HE	GAD	0

[g]GAD: generalized anxiety disorder.

Treatment

The treatment in which all participants previously took part was a transdiagnostic CBT intervention designed to address ED, composed of 16 modules and lasting 24 weeks. It was delivered in a group and blended format, so that patients attended a total of 8 group sessions by videoconference (2 hours in duration), and, in the period between sessions (3 weeks), they worked on the therapeutic content through online modules on a web platform. In this platform, the recommendation was to advance at a rate of approximately one module per week, allowing participants to consolidate therapeutic content between sessions. During the intervention, 2 messages of support per week were sent to participants (an email and an SMS text messaging). These messages served as reminders and motivational prompts to encourage continued participation. Further details regarding the intervention structure and content can be found in the study protocol [23] and in the paper on quantitative results [30].

Procedures

The qualitative data collection procedures differed according to participants' treatment completion status. On the one hand, those who completed the treatment (n=23) were invited to participate in focus groups (in-depth group opinion interviews). This was done with the goal that interview participants had sufficient knowledge about the intervention and could provide more complete opinions on all the aspects explored. Invitations were made during the final treatment sessions and by email. Finally, a total of 18 participants accepted and took part in the interviews (subsample 1), while the remaining 5 were unable to attend.

A total of 4 focus groups were conducted, one per treatment group, each lasting approximately one hour. Meetings were held via videoconference between 2 and 5 weeks after the end of treatment. All interviews were recorded and subsequently transcribed verbatim for later analysis. No field notes were taken.

Each focus group was conducted by 2 psychologists from the research team. In total, 5 psychologists (4 women and one man) conducted the interviews; 3 of them PhD students (NJ-O, Macarena Paredes-Mealla, and Rosa Lorente-Català) and 2 were PhDs in psychology with previous experience in qualitative research (AD-G and Alberto González-Robles). All interviewers were also experienced clinicians and researchers in transdiagnostic and internet-based interventions. These psychologists were the therapists for the therapy groups in the feasibility study, so to ensure an unbiased procedure, they only interviewed those participants who had not previously been their patients (eg, Macarena Paredes-Mealla and Alberto González-Robles moderated an interview with participants whose therapy group had been led by AD-G and NJ-O). During the focus groups, there were no observers; only the 2 interviewers and the participants were present. Participants were informed that the aim of the study was to explore their opinions and experiences in order to improve the future implementation of the intervention.

Focus groups continued until all available participants from the previous study had been interviewed, corresponding to one group interview per therapy group. The research team determined that data saturation had been reached. According to Krueger and Casey [31], a commonly accepted rule of thumb is to plan 3 or 4 focus groups for a specific audience and, once they have been conducted, determine whether data saturation has been reached, that is, the point at which ideas begin to be repeated and no new information emerges. Furthermore, in the consensus qualitative research (CQR) methodology, it is recommended to include at least 8 - 15 participants to achieve data saturation [32,33].

On the other hand, participants who did not complete treatment (n=11) were invited via email to complete a brief open-ended online questionnaire aimed at exploring their reasons for dropping out. A total of 4 participants completed this questionnaire (subsample 2), while the remaining participants did not respond to the questionnaire nor to the email.

Interview Protocol

Following recommendations [31,33], a semistructured interview with 12 open-ended questions was developed to explore participants' perceptions and experiences in depth through focus group discussions. To that end, 2 doctoral students reviewed

XSL•FO
RenderX

the literature of qualitative studies on psychological interventions, including those using blended treatment formats. Afterward, each doctoral student independently designed a list of relevant interview questions, which were then shared and discussed collaboratively until consensus was reached. Finally, 2 senior researchers (AD-G; JB-L) and full professors reviewed the proposal of questions, and the final version was defined. An effort was made to reach a balance between obtaining the greatest amount of information possible and asking the fewest number of questions. The interview script can be found in Multimedia Appendix 1. Two questions that constituted the dropout questionnaire can be seen below in Table 3.

Table . Responses to the dropout questionnaire.

Participant	Responses	
	Question 1: Please write a comment indicating the reasons why you have discontinued the treatment.	Question 2: Please write a comment indicating any strategy that, in your opinion, could help to improve the treatment or enhance adherence to it.
D[a]1	"It hasn't helped me and it overwhelmed me more than it helped me."	"That it be individual or that it doesn't have so many mandatory tasks."
D2	"I wasn't fully committed, and since I thought this study was helpful in a more general way, I thought in-person therapy would be more effective for me."	"I think it would help if the sessions were in person, although that would mean the study could only be conducted with people from Castellón. Also, sometimes I didn't know how or at exactly what moments to apply the treatment, and I didn't know where to start."
D3	"I've gotten worse and I'm not able to do things on my own. My excessive lack of motivation and energy prevented me from studying and applying the tools I was given. That's why I decided I needed more specialized help, because I'm not able to follow through on my own."	"It could be improved by dedicating part of the group session to sharing problems that are currently worrying each person and talking about them a bit with everyone."
D4	"Lack of time to follow treatment guidelines."	"Well, I'm not sure, but maybe, personally, weekly in-person sessions would help me get more organized. With so many things going on in my daily life, I still had to access the platform, and by the time I realized it, 3 weeks had already passed."

[a]D: dropout.

Data Analysis

The CQR methodology [32,33], which is a structured and rigorous method for analyzing qualitative information, was used to analyze the focus group data. This methodology combines elements from constructionism and from postpositivism, and seeks to understand people's subjective reality while simultaneously reporting that reality as objectively as possible [33].

Two doctoral students trained in qualitative analysis acted as judges (NJ-O and AF-J), and 2 full professors with prior experience in qualitative research acted as auditors (AD-G and JB-L). All researchers involved in the analysis were women. One of the judges also served as an interviewer in the study.

First, the 2 judges independently identified the domains and then pooled them until a consensus was reached. The 2 auditors reviewed the proposed domains and again a consensus was reached between all of them. Subsequently, the judges independently identified and placed the core ideas from each interview into the corresponding domains and then shared them until a consensus was reached. Core ideas were also shared interview by interview with the auditors, and the necessary modifications were made until consensus was reached again. Finally, cross-analysis was carried out and the categories were established, following the same consensus procedure explained above. The information has been identified from the data (data-driven coding), although the domains partially correspond to the interview questions.

Following the suggestions of Hill et al [33], the frequency of each category was quantified to indicate its representativeness. Categories were labeled as "General" if they applied to all or all but one case (17 - 18 cases), as "Typical" if they applied to more than half of the cases (10 - 16 cases), as "Variant" if they applied to half or fewer of the cases (3 - 9 cases), and as "Rare" if they applied to only 1 or 2 cases.

The information available regarding the reasons for the dropping out of the participants who discontinued the intervention was very limited, so it was not considered appropriate to conduct a formal qualitative analysis based on an established methodology. Instead, this information was treated descriptively as complementary to the insights gathered in the focus groups. Nonetheless, the key themes identified independently by the 2 judges are briefly reported.

The COREQ (Consolidated Criteria for Reporting Qualitative Research; Checklist 1) [34] guideline was used to report the results.

XSL•FO

Ethical Considerations

The study received approval from the Ethics Committee of Universitat Jaume I (CD/40/2019) and all participants provided informed consent prior to participation. Participant data were handled in accordance with applicable data protection regulations. Privacy and confidentiality were ensured by anonymizing all data and storing them securely on password-protected institutional servers accessible only to the research team. No personally identifiable information is reported in the manuscript. Participants did not receive financial compensation for their participation in the study.

Results

Focus Group Results

A total of 8 domains and 47 categories were identified after analysis using the CQR method, 10 of which were categorized as "Typical," 31 as "Variant," and 6 as "Rare." The results obtained from the focus group interviews are shown in Table 4, which includes several illustrative core ideas according to the frequency of the category.

XSL•FO
RenderX

Table . Results from focus group interviews.

Domains and categories (frequency)	Illustrative core ideas
Experience with the online platform	
Overall positive perception; typical (10)	• P[a]4#FG[b]1 says he has had a good experience with the platform • P13#FG3 indicates that she likes the platform • P14#FG4 notes that the experience with the platform has been very positive for her and that it has been very good
Usability; variant (9)	• P9#FG2 highlights that the platform is very easy to use • P12#FG3 indicates that she found the platform to be quite simple, intuitive, and easy to use • P15#FG4 considers that it has been a simple and easy-to-use platform
Availability of resources and content; variant (7)	• P5#FG1 appreciates having a tool with all the contents, multimedia, tasks, and monitoring logs • P10#FG2 says that one of the advantages is being able to review all the resources once the treatment is over
Positive assessment of the tools offered; variant (6)	• P12#FG3 appreciates having PDF summaries at the end of the modules because it is like a “photograph” that helps her to review • P16#FG4 adds that being able to download the PDFs and have them at hand to implement the strategies has been a key point and that she was very pleased to be able to see the progress graphs
Utility; rare (2)	• P9#FG2 reports that the platform has been very useful to complement what was seen in the sessions
Difficulties; variant (7)	• P5#FG1 agrees with the disconnection of the platform during use and indicates annoyance at not being able to access the specific part of the module where she had reached • P8#FG2 mentioned that the “calendar” tool did not indicate the days she had accessed the platform
Configuration of the blended intervention	
Positive aspects (pace of progress, frequency and duration of sessions); typical (14)	• P1#FG1 says she feels it is a good pace to advance at one module per week and feels it works • P10#FG2 notes that if the duration of the sessions had been longer, they would have been tedious, and if they had been shorter, there would not have been enough time to deal with all the topics • P13#FG3 is satisfied with the timing, she thought it was good that the contents were explained in the sessions and then they had a 3-week period to work on them, she thinks it was adequate • P16#FG4 commented that she has found the length of the sessions and the spacing between them to be very good
Unfavorable aspects (demand, frequency and duration of sessions); typical (10)	• P3#FG1 said that the duration of the sessions was a bit long and tiring • P4#FG1 expresses that he felt that the waiting time until the next session was too long and that he would have liked them to be more frequent • P10#FG2 indicates that some modules were longer and required a little more time
Ambivalent opinion on the duration of the intervention; rare (2)	• P18#FG4 points out that it is a long therapy and it is possible to fall behind and lose the motivation to continue
Individual variables that modulate the adequacy of the configuration; variant (7)	• P8#FG2 explains that during the first modules she was a bit down in the dumps and found it hard to feel motivated to do them, although this did not pose a problem for her • P13#FG3 indicates that her problem has been her lack of time to keep up with the platform and complete the tasks due to her busy life
Therapeutic contents	

XSL•FO
RenderX

Domains and categories (frequency)	Illustrative core ideas
Suitability and richness of the contents; typical (14)	• P5#FG1 notes that there is a lot of information and many strategies that are useful • P6#FG1 says that he really liked the content and finds it very useful, and agrees that everyone should have access to this syllabus • P8#FG2 considers that the contents are very well explained and that it is a very complete program • P9#FG2 considers that the richness lies in the fact that different strategies are provided and you can choose the one that best suits you
Notable usefulness of the different therapeutic components; typical (11)	• P8#FG2 points out that the strategy that has helped her the most is cognitive flexibility • P12#FG3 says that some modules have helped her more than others, especially those that are “action-oriented,” such as mindfulness and those related to positive affect • P18#FG4 highlights the usefulness of mindfulness in his case and explains that he liked the exercises very much and noticed a difference when practicing them regularly
Difficulty in choosing strategies; rare (2)	• P4#FG1 agrees that he lacked clarity on when to use each strategy
Influence of the level of prior knowledge about the contents; variant (4)	• P4#FG1 mentions feeling overwhelmed by the amount of information due to his lack of prior knowledge
Experience with group sessions via videoconference	

XSL•FO
RenderX

Domains and categories (frequency)	Illustrative core ideas
Group bonding; typical (11)	• P6#FG1 mentions looking forward to the session time to talk to everyone • P15#FG4 considers that the exchange has helped them a lot to create synergies and that the group has also served as social support • P17#FG4 points out feeling comforted because her peers said things that she had been through or she could say things that they could also identify with, and highlights that she would recommend group therapy because you feel more understood and a bond is generated
Positive aspects of the group format; typical (11)	• P6#FG1 positively values being able to share with other people and that it helps to not feel lonely and strange • P7#FG2 mentions being able to share your problems with others as an advantage • P10#FG2 adds that an advantage of group therapy is learning a lot from the other participants, seeing how others deal with and manage their problems
Initial reluctance toward the group format; variant (7)	• P7#FG2 acknowledges that when group therapy was proposed to her, she did not like the idea because she had a previous experience in which she had not felt well • P15#FG4 notes that the first day he was very nervous and self-conscious, because he didn't know what to say and if he could open up so easily
Limitations of the group format; variant (3)	• P3#FG1 believes that the group format may limit the ability to share certain topics that could be shared privately
Relevant variables for the proper functioning of the group; variant (4)	• P2#FG1 believes that they were a very heterogeneous group in terms of problems and life stages, and that it would have been better to find people with greater homogeneity
Positive aspects of videoconferencing; variant (8)	• P3#FG1 appreciates the fact that the sessions were online since she would not have been able to attend in person due to the geographical distance • P9#FG2 is grateful that the sessions were held via videoconference because wherever you are, you can connect to the session
Limitations of videoconferencing; variant (7)	• P1#FG1 believes there may be connection problems and that this will determine the course of the session • P7#FG2 agrees on the difficulty in expressing what she really felt and thought if there was someone at home
Preference for individual format; variant (5)	• P2#FG1 expresses preference for individual treatment • P13#FG3 shares that she prefers individual therapy that, since everyone has their own story, she likes more individual therapy because of the way she wants to work on her problem
Preference for in-person format; variant (8)	• P14#FG4 mentions that it was difficult for her to speak via videoconference and that she would have preferred in-person format • P17#FG4 points out that she prefers face-to-face versus online sessions, but believes that this aspect has been managed quite well in the sessions and was not bad
Satisfaction with the sessions; variant (4)	• P9#FG2 mentions that she would always prefer the group format via videoconference and would recommend it that way because it worked very well for her, and also explains that online group therapy allows her to feel less exposed and invaded as well as to have freedom to intervene and to be able to be in a familiar environment during the sessions
Positive assessment of the dynamics followed in the sessions; rare (2)	• P15#FG4 notes that reviewing previous modules at the beginning of the sessions helped refresh and remember what had been seen previously and made it easier to solve doubts and stay up to date

XSL•FO
RenderX

Domains and categories (frequency)	Illustrative core ideas
Role of therapists	
Positive evaluation of the therapists (abilities, aptitudes, and availability); typical (12)	• P5#FG1 highlights that the therapists are wonderful, they have listened to them, explained to them, and emphasized when they had doubts • P7#FG2 agrees that the therapists are very understanding, and highlights that they always gave each one time to talk and encouraged them to share • P12#FG3 highlights that the therapists were always available when you asked them and responded fairly quickly and in detail • P18#FG4 describes the therapists as excellent people, emphasizes their warmth and their excellent organization and preparation, and is very grateful for the availability of them to help and answer questions
Importance of therapist support; variant (9)	• P5#FG1 considers the role of therapists to be fundamental; she believes that they provide the professional vision, help you to talk about certain topics, and make recommendations • P9#FG2 considers that without the therapists they could not have done it and highlights that their support was vital throughout the process • P11#FG3 believes that the support from the therapists has been good and that it always goes well; he explains that the therapists have been supportive for some things that they did not know or did not know how to interpret well
Establishment of a good therapeutic alliance; variant (9)	• P6#FG1 reported having felt a bond with the therapists • P10#FG2 agrees that the therapeutic alliance can be formed in the same way (as in face-to-face individual therapy) and considers that the commitment of the therapists to the patients and also of the patients to them and to the therapy has been noted • P17#FG4 mentions that they have had a very good alliance with the therapists
Greater difficulty in creating the bond; variant (3)	• P4#FG1 considers that in group it is more difficult to create a bond with the therapists, and that a different type of bond is created compared to individual therapy
Overall assessment of the blended treatment	

XSL•FO
RenderX

Domains and categories (frequency)	Illustrative core ideas
Perceived improvements and usefulness of learning; typical (15)	• P5#FG1 indicates that she has learned many things and has found new methods that work for her • P8#FG2 considers that she has changed a lot since the intervention and that it has helped her a lot, and adds that, although her life circumstances have not changed, she feels that her coping has improved tremendously • P9#FG2 indicates that at the beginning she did not expect to get so many results and explains that thanks to the intervention her anxiety has decreased and she has been able to learn to manage crises, understand them, and know what to do when they occur • P11#FG3 agrees that treatment has been useful to him, especially finding ways to deal with the problems that arise
Satisfaction with the treatment; variant (7)	• P1#FG1 considers that the intervention has satisfactorily fulfilled everything expected in 70 - 80% • P10#FG2 is very grateful and happy for the intervention received, she values her evolution very positively and emphasizes that most of her initial objectives have been met
Recommended treatment; variant (5)	• P7#FG2 notes that she would recommend this treatment to other people with emotional disorders • P12#FG3 mentions that she would recommend the intervention and would invite anyone with an emotional disorder to do it because she believes it is really useful
Advantages; typical (11)	• P11#FG3 considers that the combination of online content and sessions with the therapists has been very helpful and worth doing this way • P8#FG2 highlights the temporal flexibility that this format allows and adds the spatial flexibility as an advantage, in the sense of being able to do the intervention from any location, which allows it to continue despite inconveniences or unforeseen circumstances such as COVID • P18#FG4 adds that the main advantage he enjoyed was accessing the treatment from another country, explaining that otherwise he could not have done it and that it does not exist in his country, so for him it is a great advantage
Disadvantages; variant (9)	• P5#FG1 indicates that the treatment takes too long because you have to know all the strategies to know which one you can use in your case • P6#FG1 indicates that the treatment was more general and does not focus on what she believes her problem is • P10#FG2 believes that this intervention format, in comparison to traditional therapy, does not allow to delve into the why of the problems or to understand where they come from at the individual level
Elements that help to maintain adherence	

XSL•FO
RenderX

Domains and categories (frequency)	Illustrative core ideas
Therapist support; variant (8)	• P13#FG3 adds that the fact that 2 psychologists explain the topics helps to continue, she considers it as the main thing. A total of 2 psychologists explain the topics help to continue; she considers it as the main thing • P18#FG4 points out that what helped him not to drop out despite being behind was that the therapists continued to invite him to attend the sessions, which gave him confidence
Therapeutic resources and materials; variant (6)	• P13#FG3 mentions that the videos have helped her a lot to get motivated and continue with the treatment because she saw herself reflected in it • P17#FG4 indicates that in moments of overwhelm or low mood, having the decisional balance table visible helped her a lot to move forward
Having graphs that represent progress; variant (5)	• P1#FG1 highlights the progress graphs on the platform as motivating elements • P16#FG4 mentions that seeing her week-by-week progress on the platform's graphs helped motivate her to continue with the treatment
Having scheduled sessions; variant (5)	• P9#FG2 highlights that the schedule of having to meet every 3 weeks for the sessions is what helped her stay consistent with the tasks, keep going, and complete the treatment • P12#FG3 highlights the fact that there are established sessions as a motivating element that helps to keep going
Commitment to the group; variant (3)	• P6#FG1 indicates that her groupmates are one of the elements that helped her the most to continue with treatment
Perceived impact of the intervention; variant (3)	• P18#FG4 mentions that what motivated him the most was seeing that the tools were working, that watching the videos and applying the strategies really had an effect on his mood
Readiness to change; rare (2)	• P5#FG1 highlights the desire to change as a person and to find new ways of doing things as a motivating element
Having reminder messages; rare (1)	• P12#FG3 adds that the constant reminder messages, although subtle, have been very important for her in keeping going
Proposals for improvement	

XSL•FO
RenderX

Domains and categories (frequency)	Illustrative core ideas
Modifications to the platform; variant (6)	• P1#FG1 suggests that the platform could be more interactive and incorporate activities that allow decision-making to be put into practice • P16#FG4 notes that she has missed a forum or a similar tool to be able to use between sessions and try to make the group closer
Adjustments in the configuration (pace of progress, duration and periodicity of sessions); variant (5)	• P3#FG1 suggests that sessions of one or one and a half hours and weekly frequency would be more bearable • P11#FG3 notes that it would have been better if the time between sessions had been adapted according to the content to be worked on in the corresponding modules
Suggested changes regarding the sessions; variant (3)	• P1#FG1 proposes doing some of the group sessions in person
Greater individualization of the intervention; variant (4)	• P8#FG2 suggests having, from time to time, an individual space with the therapist for about 10 minutes to delve deeper into individual difficulties
Suggestions for improving adherence; variant (7)	• P3#FG1 suggests that individualized weekly follow-up, including by email, could help improve treatment adherence • P18#FG4 proposes leaving less space between sessions and doing them every 2 weeks to improve adherence for people who need more follow-up or who are a little disorganized

[a]P: participant.

[b]FG: focus group.

Experience With the Online Platform

This domain includes all experiences and opinions related to the online platform. It does not include what is clearly identified as proposals for improvement of the platform (included in the domain "proposals for improvement"). The categories found are described and exemplified below.

Overall Positive Perception (Typical)

Participants expressed an overall positive experience with the use of the platform. We can see an example in the following excerpt:

> *Let's see, for me the experience (with the platform) has also been very positive. And as my colleagues say, you had it there and you could go in and do it little by little. And the truth is that yes, it was very good. I liked it.* [Participant (P) 14#focus group (FG) 4]

Usability (Variant)

Participants highlighted the simplicity of the platform and its ease of use. An example of this is the following extract:

> *As for the use of the platform, I found it to be a fairly simple and intuitive platform, uh well, easy to use, also… all the different elements were quite clear, simple.* [P14#FG4]

Availability of Resources and Content (Variant)

Some participants highlighted having the contents accessible through the platform as positive.

> *I imagine in individualized therapy it won't work the same way, that it will be totally different, they won't give you… an application where you can read all the information, watch videos, do exercises, monitoring logs… so in that sense I think that… I liked it, it works well.* [P5#FG1]

Positive Assessment of the Tools Offered (Variant)

Some participants appreciated the different tools found on the platform (eg, videos, downloadable PDFs, review tool for revisiting completed modules, and progress graphs).

> *Eh, I'd add that for me a point that I really liked about the application is, eh, the section called "Weekly evolution" or something like that, the fact of physically seeing, that is, graphically seeing the evolution you've been having week by week. […] And besides, as P15#FG4 had said at the beginning, being able to download the PDFs later to have them at hand to be able to put them into practice in case you forget something or whatever, I also think that has been a key point.* [P16#FG4]

Utility (Rare)

Some participants referred to the usefulness of the platform from a clinical point of view. The following fragment can serve as an example:

> *And… I think it (the platform) has helped us a lot to complement everything that was discussed in each session.* [P9#FG2]

Difficulties (Variant)

Participants mentioned perceived technical difficulties or aspects that they would have liked to be another way. We can see an example below:

XSL•FO
RenderX

> *Eh, it's true that when you went a while without using it, it disconnected immediately, you had to re-enter the program and what really bothered me the most was that maybe I didn't have time to see the entire module and I only viewed maybe a couple of pages, and when I connected another day and re-entered, it wasn't saved where I had left off, you had to start the module again and look for where you had left off. For me, this is the inconvenience that has caused me the most discomfort, but otherwise, in general, very well.* [P5#FG1]

Configuration of the Blended Intervention

This domain includes all aspects related to the structure of the blended intervention and how its different components were combined or organized.

Positive Aspects (Typical)

Most participants identified positive aspects of the configuration regarding the pace of progress on the platform, the frequency of the sessions, and the duration of the sessions.

> *As for me, eh, I think the same as you. I thought they were good, the sessions were also quite good. If they had lasted longer, they would have been a bit tedious, and if they had been shorter, there would have been a lack of topics to address.* [P10#FG2]

Unfavorable Aspects (Typical)

Participants also identified unfavorable aspects of the configuration in relation to the demand of the pace of progress as well as the periodicity and duration of sessions.

> *It seemed like too much time to me. I would have liked a little more, closer together, but well, I understand that that's what we had, but for me the group sessions were what helped me the most, and I would have liked them to be more frequent, and the duration of 2 hours seemed fine to me.* [P4#FG1]

Ambivalent Opinion on the Duration of the Intervention (Rare)

Some participants expressed their opinion about the duration of the treatment. While one person pointed to the duration as a positive aspect, another person pointed to it as a more unfavorable aspect:

> *The fact that it has lasted so long, for so many months, I think it has helped us a lot, yes, it has not been short, you see your progress month after month.*
>
> *[P9#FG2]*
>
> *That can happen, you can fall behind because it's a long course, a long therapy, so you lose a little bit, you can also lose the motivation to keep going if you're too far behind.*
>
> *[P18#FG4]*

Individual Variables that Modulate the Adequacy of the Configuration (Variable)

Some participants also mentioned personal variables that may influence the appropriateness of the configuration in each case. The following excerpt is an example of this:

> *My problem is that lately I've had a very busy life, but just as I haven't been able to do my homework, I had to go to the physiotherapist and I haven't gone, so I'm not justifying, but well, for failing something, it has been my time.* [P12#FG3]

Therapeutic Contents

This section includes all the experiences and opinions regarding the treatment modules or therapeutic strategies, which were taught both in the group sessions and on the online platform. The categories found are described and exemplified below.

Suitability and Richness of the Contents (Typical)

Most participants emphasized the adequacy of the contents as well as the richness of the program. We can see an example in the following extract:

> *Personally, I thought the program was super complete, I really liked the fact that different tools and methodologies are provided because that way everyone chooses, tests, and at the end looks or explores what works best for him/her, and it is very well explained.* [P8#FG2]

Notable Usefulness of the Different Therapeutic Components (Typical)

Participants highlighted those activities, strategies, or therapeutic components that they had found most useful in their case.

> *Yes, in my case the same, mindfulness. I think, like everyone else, I really liked the exercises, I did the exercises as they came and yes, I noticed a difference. After about 3 or 4 days, I noticed a difference, and I think that if you do it constantly, it really helps you to relax. What other one? I also liked the cognitive flexibility one a lot, to see a fact from different perspectives, because one normally goes with the belief… that one already has programmed, right? The beliefs, distressing or anxious beliefs usually. So, trying to see it from different perspectives, that's very useful. Very useful. And the identification of maladaptive behaviors as well, that normally one acts automatically, right? Again, according to the anxious perspective that you have, and you don't realize that those behaviors are generating again the anxiety and the anxiousness, reinforcing the anxiety, the anxiousness. So those 3. I would highlight 3 very useful tools.* [P18#FG4]

Difficulty in Choosing Strategies (Rare)

Some participants mentioned difficulty in knowing when or in which situations to use each of the strategies. An example of this is the following intervention:

XSL•FO
RenderX

> *I haven't been able to grasp, understand everything and so on, and especially what P5#FG1 was saying, that I don't know when to use each thing, and that's what really… I fell short on, I missed that part I think, of knowing when to use each thing and so on.* [P4#FG1]

Influence of the Level of Prior Knowledge About the Contents (Variant)

Some participants indicated how their prior knowledge of the treatment contents influenced their evaluation. While some emphasized the importance of having some background, for others, having more prior knowledge made the contents seem somewhat repetitive:

> *What happened to me was that… it overwhelmed me a little. I think the information was very good and all, but the thing is that since I didn't have much (prior) knowledge, I suppose it overwhelmed me a little* [P4#FG1]

> *Eh, for me it was a bit the opposite, I informed myself a lot beforehand, so there were many things that felt very obvious or very repetitive to me. Well, I guess it depends on the person and their knowledge about the topic. And overall, well, yes, I obviously learned a lot of new things, and I also enjoyed that part… but yeah, in general, some of the information felt a bit boring because… I already knew it beforehand.* [P3#FG1]

Experience With Group Sessions via Videoconference

All experiences and opinions related to group sessions by videoconference are included here. Aspects related to the frequency and/or duration of the sessions, already included in the configuration domain, are not included in this section.

Group Bonding (Typical)

Participants reported a connection or bond with the group, which they identified as a source of support or understanding and acknowledged looking forward to the sessions to talk to everyone and share. The following excerpt is an example of this category:

> *It comforted me because sometimes my groupmates would say things that I had also gone through, or I could say things that they could identify with. So, I think it has been quite good and it has changed my perspective. And what's more, I would recommend it because you feel more understood and maybe there's a bond of mmm I don't know, there's a bond there.* [P17#FG4]

Positive Aspects of the Group Format (Typical)

Participants highlighted advantages or positive aspects of the group format, as exemplified in the following fragment:

> *I think you also learn a lot. I mean, I think there are things I wouldn't have learned if the others had not been there, because… everyone has their own experiences and their own way of dealing with things, and seeing how other people deal with the problem, even if it's not included in the modules, or whatever, also helps a lot, because you can try it that way or not, and the truth is that in an individual therapy you don't get that, that is, having other examples from real life, seeing a person who is doing it and living it, it helps a lot.* [P10#FG2]

Initial Reluctance Toward the Group Format (Variant)

Some participants admitted to being uncertain about the group format and expressed initial feelings of fear, strangeness, or nervousness about having to speak in front of other people.

> *At the beginning, before starting the group therapy, I was looking for individual therapy, but they recommended me 'there is this group that is going to be formed, I think you would be interested in joining, try it, you don't lose anything', obviously. And it's true that the first day I was very nervous, I was very self-conscious, like 'I don't know what to say, I don't know if I can open up so easily'. But in the end, you mention your problem, you see that another person comments on his/her problem, there are points in common, what I can say can help a person or what another person says can help me, and I believe that throughout the sessions it has also been seen that we were talking more and more, it was less difficult for us to start talking.* [P15#FG4]

Limitations of the Group Format (Variant)

A few participants also highlighted the possible limitations of the group format, as we can see in the following excerpt:

> *I haven't had experience of other types of therapy either, but I think that there are certain things that you might not be able to share in a group and that maybe in private you would be able to. I don't know. That's what I believe.* [P3#FG1]

Relevant Variables for the Proper Functioning of the Group (Variant)

Some participants mentioned some important factors that may influence the group therapy experience, such as how the particular group gets along, how homogeneous the group is, or how participative people are:

> *Well, I think that ehh I agree with everything my groupmates are saying, but I think that we were a very heterogeneous group. Ehh each one had a different problem, was in a different stage of life,… so… […] Maybe it would have been better to find groups of people among whom… people among whom there would have been a greater homogeneity, maybe.* [P2#FG1]

Positive Aspects of Videoconferencing (Variant)

Participants highlighted advantages or positive aspects of the videoconference, as exemplified in the following extract:

> *I really appreciated the fact that they are by videoconference, because each one has his/her own life rhythms and schedules, and no matter where you are in the world, you can connect 2 hours for the session.* [P9#FG2]

XSL•FO
RenderX

Limitations of Videoconferencing (Variant)

Participants also highlighted possible limitations of conducting the sessions via videoconference, as we can see in the following intervention:

> *The same as P8#FG2, that many times I have wanted to express what I felt, but like for example, I didn't know if my roommates were there, I couldn't say everything I really thought for fear of being heard.* [P7#FG2]

Preference for Individual Format (Variant)

Some participants expressed a preference for individual therapy, as can be seen in this case:

> *Well, I'm going to give my opinion first because I've gone through individual and group, and I think it is, I can be more objective. I prefer individual. I also like to have met mm the groupmates, but it's true that as everyone has their own story… I like it more individual. I do… but that doesn't mean group was bad for me, nooo, but I liked individual more, maybe because of the way I want to work on my problem.* [P13#FG3]

Preference for In-Person Format (Variant)

Some participants expressed a preference for the in situ format, as exemplified in the following excerpt:

> *Eh. I, like P15#FG4, was also looking for something individual, and they offered me this and I said I'm going to try it. And the truth is that it's good, but I would prefer face-to-face. […] In videoconference I have felt that it's more difficult for me to talk. The truth is that I have found it difficult to speak. Maybe it's personal. I don't know, it's because I'm like that, but the truth is that face-to-face would have been better.* [P14#FG4]

Satisfaction With the Sessions (Variant)

Some participants highlighted their satisfaction with the sessions received, as we can see in this fragment:

> *I would add the fact that I would always prefer to do it online and in group rather than face-to-face and individual because in the individual sessions I've done I feel very exposed, very invaded, like now is the moment and you have to talk, say everything, you have this schedule, everybody, you know? Doing it in a group online, things come up, right now I don't feel like talking, I listen to the other, you're in your space, in your home, you're not in a psychologist's office, it's different, I… I think I would always recommend doing it this way. It worked really well for me.* [P9#FG2]

Positive Assessment of the Dynamics Followed in the Sessions (Rare)

Some participants positively valued the dynamics followed in the development of the group sessions via videoconference, for example:

> *And also one thing we did in the sessions, which I imagine we'll discuss later, was that at the beginning of the session, for example, the beginning of session 2, we reviewed a little bit what we had seen in the previous modules, so that also helped you refresh and remember what you had seen, in case there was something you had missed or you had doubts about, that also helped you to keep up to date. […] It's also true that the dynamics within the sessions made everything quite, quite free-flowing and the feeling of tiredness wasn't so common.* [P15#FG4]

Role of Therapists

This domain encompasses all the experiences, assessments, and opinions regarding the role of the therapists in the intervention, including therapeutic support received, therapeutic alliance, etc. The identified categories are outlined and illustrated below.

Positive Evaluation of the Therapists (Typical)

Participants positively rated the therapists in terms of their abilities, their aptitudes, and the availability shown throughout the intervention.

> *Yes, apart from that, I totally agree with my groupmates, for example, they always gave each one of us our own time to talk, if for example at a certain moment we didn't have time to talk, they always told us, 'oh, how about you?', and I don't know, they are very understanding, really, we are very grateful that they have been there.* [P7#FG2]

Importance of Therapist Support (Variant)

Participants emphasized the importance of having therapeutic support, that is, the presence of the therapists. We can see an example in the following excerpt:

> *I think it's fundamental, I mean, the role of therapists in this case. They are the ones who open you up to talk about certain topics, who help you, who… advise you, who give you their point of view, who is the… the wise one, so to speak… So it's a fundamental part of it.* [P5#FG1]

Establishment of a Good Therapeutic Alliance (Variant)

Participants felt that a bond with therapists could be established in this format and reported having established a good therapeutic alliance.

> ***Interviewer:*** *Did you feel that this alliance was able to develop in the same way that perhaps you would have developed it face-to-face, though, in this online version?*
>
> ***P9#FG2:*** *I think so.*
>
> ***P10#FG2:*** *I also, I mean, even though they don't know absolutely everything about me and everything that has happened to me, I think I felt that commitment, didn't I? I mean, that commitment from them to us and also from us to them and to the treatment. So, yes.*

XSL•FO
RenderX

Greater Difficulty in Creating the Bond (Variant)

Some other participants felt that it was more difficult to create a therapeutic bond in group therapy than in individual therapy or that this bond is different. An example of this is the following intervention:

> *I also agree, it's another type of bond, no, I don't think it's the bond that… […] It's another type of bond and regarding the ease of creating it or not, I think it's more difficult in a group because there are many people, it's more risky eh with, with one person alone it's much easier, isn't it?, more risky, but well, if it works, it's also very good.* [P4#FG1]

Overall Assessment of the Blended Treatment

This section includes all experiences, opinions, and assessments regarding the intervention as a whole, including its impact or effects, its advantages and disadvantages, etc.

Perceived Improvements and Usefulness of Learning (Typical)

Most participants highlighted their improvement after the intervention as well as the usefulness of the learning achieved during the treatment in their lives, as exemplified below:

> *Ehh, in my case, I also agree with my groupmates, especially, let's see, I had enough knowledge, I think, ehh… to practice and all that, but I hadn't taken the time to do it, I mean, the theory was 'ok, very good,' but I had never taken the time, and it seemed to me that the treatment has been like an opening key to something that was already there, you know? Mm… especially the fact of continuing to practice, of saying 'jeez, it's fundamental…,' like going to the gym, right? to keep practicing and so on. It has helped me a lot to become aware that… that I need it, and… and I have also changed a lot from before having started it to now, it has helped me a lot. […] I would like to add that in my case the situation hasn't changed, I mean, there are some groupmates whose situation has changed and so on, but in my case it has not, that's why I'm happier in life, because the situation hasn't changed, but I've improved and I'm handling things much better.* [P8#FG2]

Satisfaction With the Treatment (Variant)

Some participants also emphasized their satisfaction and positive feelings toward the treatment received, as can be seen in the following case:

> *I feel that… you can't cure a problem, none, in a few online sessions and that you have to work and for that what they give you are tools to achieve it individually and then, in that, I think it has helped me a lot, I think they have given me many tools to know how to manage what happens to me, more than cure me, and also… ehh well, the importance of emotions and what happens to me in general I have also learned a lot and, and well, I think that 70-80% has satisfactorily fulfilled everything what, what I expected.* [P1#FG1]

Recommended Treatment (Variant)

Some participants went a step further and indicated that they would recommend the treatment to others with emotional problems.

> *It is true that it requires more work and more time, but I would recommend it. The truth is that it is quite useful, and I would invite anyone who has any emotional disorder to do this treatment because the truth is that it is really useful.* [P12#FG3]

Advantages (Typical)

Most participants mentioned advantages of this type of blended treatment, which combines group sessions delivered via videoconference with self-applied work through an online platform. The following excerpt is an example of an outstanding advantage:

> *Well, the advantages. Mmm. I think the convenience, as my groupmates mentioned, it's very easy to attend the sessions, very easy to access the platform, the course. […] Um, another thing. The main advantage that I enjoyed was having taken this course from another country. I wouldn't have been able to take it. I wouldn't have. I wouldn't have. It doesn't exist in Mexico. So, well, for me it's a great advantage.*' [P18#FG4]

Disadvantages (Variant)

Participants also mentioned disadvantages of this type of blended intervention, among them:

> *I think if I had been alone with one of them (therapists), I think it would have been, I would have focused more on, on my problems or I don't know… This was more, more general, a help, […] it has been very helpful, but […] it doesn't focus on what I think my problem is.* [P6#FG1]

Elements That Help to Maintain Adherence

This domain includes participants' opinions and experiences regarding the aspects of the intervention that helped them to stay motivated, continue progressing with the treatment, and promoting adherence to it.

Therapist Support (Variant)

Participants identified therapeutic support as a key factor that helped them maintain motivation and continue with treatment.

> ***Interviewer:*** *Did you notice any other aspects? Because it's a procedure that involves some work at home, then the sessions, eh, there's a lot of work there. Is there anything that's helped you stay motivated and keep going? What do you notice the most?*
>
> ***Interviewer:*** *From any of the aspects of the treatment.*
>
> ***P13#FG3:*** *Well, obviously everything helps. Having 2 psychologists explain the topic to be addressed, of course that helps. […] I think it's the main thing.*

XSL•FO
RenderX

Therapeutic Resources and Materials (Variant)

Participants identified therapeutic resources and materials, such as the modules, the videos, and the decisional balance table, as important factors for adherence.

> *Well, I was going to say that I, for example, haven't had the thought of quitting, not at all, but it's true that there was a time when I was really swamped with exams and many other things […] So it's true that in that moment of overwhelm, […] the table we made at the beginning of the pros and cons, I think it was, of starting treatment, of changing, and all that, helped me a lot. Well, for me, the table was, I mean, I made it to my liking, so I have it posted and that helps me a lot when I'm feeling more down or whatever, having seen it and saying, look, here's the reminder of this. Well, that's been very good for me.* [P17#FG4]

Having Graphs That Represent Progress (Variant)

Participants highlighted that being able to see their evolution reflected in the progress graphs of the platform was a motivation element for them. The following is an illustrative example of this category:

> *Seeing the progress graphically week by week is something that, at least for me, also helped motivate me to continue with the treatment.* [P16#FG4]

Having Scheduled Sessions (Variant)

Participants highlighted having established sessions as an element that helped them to continue with the treatment and do the homework tasks.

> *I think it has been the constancy, seeing each other, seeing each other every 3 weeks, I think it has been that, wait, today I don't feel like doing it, okay, tomorrow neither, but in 3 weeks these people are going to ask me what… 'what have you worked on?' you know? So, it's like a duty, like going to class, for me that has helped a lot. It was like I have to do my homework for college or my thesis or whatever, I have to do my psychology homework, I mean the psychologist, where I'm going, the treatment, because I started it and I have to finish it, and in 3 weeks I have to see them, so it's been like a constant and that's how it's been every month.* [P9#FG2]

Commitment to the Group (Variant)

Some participants also identified groupmates and commitment to the group as an element that helped them maintain motivation and not drop out of treatment, as we can see in the following case:

> ***Interviewer:*** *What elements of this treatment helped you to stay motivated, to stay connected, to keep moving forward in this treatment?*
>
> ***P6#FG1:*** *In my case, more than the modules and all that, the therapists and my groupmates the most.*

Perceived Impact of the Intervention (Variant)

Some participants highlighted that the perceived impact of the treatment, that is, noticing the effect it had on them or the progress they were making, helped them to continue with the intervention.

> *In my case, what motivated me the most, even though as I mentioned before, I was behind in the course, was to see that the tools worked. Knowing that the videos and applying the tools that were mentioned in them really showed an effect on my mood, at least in the short term, I mean, because we know that this problem is long, it's not a, you have to practice these tools in the long-term to notice a change, but a change was noticeable in the short-term, at least in the short-term. And that was quite motivating for me.* [P18#FG4]

Readiness to Change (Rare)

Some participants mentioned the readiness to change and commitment to oneself as a motivating element.

> *Also the motivation of wanting to change ehh yourself as a person, yourself… and knowing how to control yourself, knowing… well, to control! Okay, it's accepting your emotions and ways of facing the things that happen to you, well, for me to have the motivation to find new, new ways of doing things, that were not the ones I used to do previously.* [P5#FG1]

Having Reminder Messages (Rare)

One participant also noted how important the weekly motivational reminder messages they received were to her for continuing.

> *'Well, let's see, in my opinion the fact that there are established sessions and also the constant, constant online reminders, I mean, by email, which I think have been very important, although subtle, but for me they have been very important.* [P12#FG3]

Proposals for Improvement

This domain refers to any suggestion, proposal, or idea to improve the intervention in any way from the patients' point of view.

Modifications to the Platform (Variant)

Participants suggested some modifications to the platform, aimed at improving the current functionality or incorporating new tools. We can see an example in the following extract:

> *P1#FG1: Yeah, well, my, my idea is, it's also related to the platform, but I've also missed like the interaction, I mean, it was like just listening to the video, it would be interesting to do activities in umm like games… from the video and it explained to you Maria's situation, for example, Maria has anxiety and this. Like a kind of 'What would you do in this situation if you were Maria?' Because that also puts you a little bit in the role of what you're going through, although, although you don't necessarily*

XSL•FO
RenderX

have anxiety, but… something like more interactive with the platform that also helps you to understand a little bit the type of decisions, or if it's a good decision, that kind of thing, it would be interesting ehh that the platform itself motivates a little bit more and not just listening to a video.'

Adjustments in the Configuration (Variant)

Participants proposed some adjustments regarding the pace of progress on the platform and the duration and periodicity of sessions, as exemplified below:

> ***Interviewer:*** *Do you think that the duration of the group sessions that you had, 2 hours of online sessions every 3 weeks, is adequate? That is, 2 hours every 3 weeks, did you see it as adequate or how did you feel that temporality?*
>
> ***P11#FG3:*** *I think it's fine. To be there for 2 hours, ehh it's really like attending a therapy session or even a class.*
>
> ***Interviewer:*** *And what about it being every 3 weeks? Did you find that spaced out enough, too spaced out?*
>
> ***P11#FG3:*** *Mm maybe… it depends, it depends on the subject that we were doing… more time or less time would have been better.*

Suggested Changes Regarding the Sessions (Variant)

Some participants made suggestions about the sessions, proposing some additional sessions or that some of the sessions be held in person.

> *Even though it's online, I like it, but later, when we were doing about 2 or 3 sessions, I would also have liked it to be in-person format because well I actually miss in-person attendance, because I got used to it at the university and then when we went back to in-person, the difference was also noticeable, so, well, doing at least one or 2 in person I think it would also help a lot.* [P1#FG1]

Greater Individualization of the Intervention (Variant)

Some participants emphasized the importance of personalizing or individualizing the intervention further, as we can see in this case:

> ***P8#FG2:*** *Maybe what was missing… I don't know, a proposal also, like maybe 10 minutes, once in a while, not every week, obviously it cannot be done, to go deeper into the problem or more individual difficulties. You know? […] It's true that there were sessions when we were asked about the problems, 'how did you deal with them?' and each of us talked a little bit. But, yes, I was referring maybe to one more difficulty that you have, and you can't share with the group or whatever, no… maybe not frequently, but it would be good.*
>
> ***Interviewer:*** *It would be like a space for, an individual space with the therapist, right? To share the things that in the group are not…*
>
> ***P8#FG2:*** *Exactly.*

Suggestions for Improving Adherence (Variant)

Participants made proposals to improve adherence to treatment and reduce dropouts. This category includes proposals specifically linked to enhancing adherence, although some of them mention, for example, changes in the configuration or suggestions for greater individualization.

> ***Interviewer:*** *Great, okay. Emm can you think of any strategies that you can or we can recommend, we can include improving adherence, so that people can get to finish this treatment, prevent them from dropping out of therapy, that you want to suggest to us?*
>
> ***P3#FG1:*** *I don't know if it could be done, or if it would be useful, but maybe ehh as a kind of weekly follow-up by the, by the therapists, even if it's by email, asking you how the week went or… I don't know.*

Perspective of Dropouts

Participants who discontinued the intervention identified various reasons for dropping out. Participants mentioned treatment-related variables (lack of results, treatment-related stress, or difficulties applying the strategies), person-related variables (low involvement, lack of motivation and energy, or time constraints), and the need for other types of help (in-person or more specialized professional help). As strategies to improve adherence to the treatment, participants suggested adjustments in the format and configuration of the sessions (individual and in-person or weekly) and other aspects (less homework tasks and more time to discuss individual problems). Table 3 shows the literal responses to the dropout questionnaire.

Discussion

Principal Findings

The goal of this study was to explore in depth the experiences and opinions of patients who received a transdiagnostic CBT intervention for ED, delivered in a blended and group format, in order to understand their degree of acceptance and improve the future implementation of these types of interventions.

Overall, the results of this study indicate a general satisfaction with the transdiagnostic intervention, consistent with prior evidence on the feasibility and utility of blended psychological treatments [26,35]. Positive perceptions were observed across multiple dimensions, including the usability of the web platform, the perceived richness and relevance of the therapeutic contents, the added value of group format, and the perceived support provided by the therapists. Furthermore, participants generally reported perceived improvements following the intervention and emphasized the advantages of this blended format. Consequently, this intervention appears to be both feasible and well-accepted by patients for the treatment of ED. The results of this study also provide relevant information on specific measures that could be adopted in the future to further optimize treatment and minimize dropout rates.

Generally, participants reported an overall positive user experience with the platform, particularly regarding its intuitive design and the availability of multimedia materials and contents.

XSL•FO
RenderX

They also appreciated the different tools offered by the platform. These results are consistent with the previous feasibility and acceptability study in which the patients included in this study participated [30]. In the aforementioned study, adequate adherence to the platform and high-excellent usability according to the System Usability Scale [36,37] scores were observed. Previous studies on other treatment protocols administered through the same web platform also reported high usability scores [38,39]. In addition, these findings align with research suggesting that ease of use, clarity, usability, attractive appearance, and perceived utility are critical factors in the acceptance and engagement with digital mental health interventions [40,41]. Participants also identified some technical difficulties with the platform, such as progress within each module not being saved and disconnection of the platform after a period of inactivity that required them to log in again. However, this feature was intentionally implemented as a security measure to protect users' privacy if the platform was accidentally left open. A future challenge will be to maintain robust security standards that enable patients to use digital devices confidently and safely [42] without compromising usability and acceptability. Technical problems have also been reported in other studies of blended interventions [12,26,27], suggesting that the difficulties identified in this study are common in this field.

The mixed evaluations of pace of progress on the platform reflect a common challenge in online and group interventions: balancing standardization with individualization. While participants were generally satisfied and considered the weekly pace adequate, others wished for a more flexible rhythm, particularly for modules involving complex skills such as emotional avoidance or acceptance. Prior literature suggests that personalizing the configuration of blended treatments may enhance adherence and treatment benefits [43]. As the systematic review by Erbe [14] indicates, there is no single optimal ratio between face-to-face and online components in blended interventions; thus, patient-specific customization may be key. The length of the sessions was considered appropriate by most participants in focus groups, although a few felt they were slightly long. There were also differing opinions on session frequency; some found the timing adequate to work on the content of the modules, while others would have preferred more frequent sessions or less time between them. These findings are in line with the heterogeneity of session lengths reported in the literature. For example, Osma et al [44] implemented 2-hour unified protocol group sessions, while Schuster et al [45] noted that therapists were concerned that 90-minute weekly sessions did not allow enough time for discussion. This variability of configurations in the literature highlights the need to customize the specific combination of in-person and online elements, as well as the timing. This personalization of the intervention has been emphasized by Fernández-Álvarez et al [12] and Patel et al [13], especially within transdiagnostic frameworks where symptom profiles and levels of functional impairment can vary significantly. Although not asked directly, a couple of focus group participants talked about the duration of the treatment. While one participant felt that the duration had allowed them to track progress month by month, another participant believed that it could cause a loss of motivation. Interestingly, participants mentioned personal variables that had an impact on the optimal fit of the planned configuration. These insights suggest that individual factors, such as workload, time management challenges, or fluctuating symptoms, may impact the optimal engagement and highlight the value of adapting to the patient's life circumstances.

Participants highlighted the appropriateness and richness of the content. They valued the material positively, indicating that it is a very comprehensive program and suggesting that everyone should have access to the modules. They stated that the content was well explained and relevant to their issues. They also pointed out which content had been most useful for their specific cases. Mindfulness was the strategy mentioned by more participants, followed by activities belonging to the positive affect component—such as value-based behavioral activation or the identification of psychological strengths—and emotional avoidance and emotion-driven behavior modules. It may be thought that patients could be reluctant to adopt strategies like mindfulness, as avoidance is a common trait among people with ED [46]. Therefore, it is very important to note that participants responded positively to mindfulness and felt it was very helpful, as it was the strategy most frequently mentioned. They also highlighted the exposure component, cognitive flexibility, and relapse prevention as other useful strategies, providing a comprehensive overview of the entire program. Overall, these results align with previous quantitative findings. When participants were asked how useful each module was on a scale from 0 to 10, the average scores were 7 or higher for all modules [30]. Another important point from participants' feedback was the variability in prior knowledge and its impact during treatment. Some participants felt unsure about which strategies to use in specific situations, while others sometimes found the content repetitive due to their previous familiarity with similar material. Previous research emphasizes the need to tailor the complexity of therapeutic content to participants' prior knowledge and learning styles [47,48]. These findings suggest the value of preassessment tools to gauge prior familiarity with CBT concepts, which could help guide each patient's pacing or personalized use of modular content.

Regarding the group format, participants noted some limitations and expressed initial reluctance toward this approach. However, most participants recognized positive aspects, such as learning from others and feeling a bond with the group. This aligns with literature highlighting the therapeutic value of shared experiences, group cohesiveness, and peer learning among individuals with similar issues [20,49,50]. Numerous studies on the acceptability of transdiagnostic interventions report good acceptance and high treatment satisfaction, and this is held in a group setting [51,52]. In terms of videoconferencing, participants identified limitations like potential connection issues and challenges in finding a private space. However, they also highlighted several advantages, such as the convenience of joining sessions from anywhere and the fact that emotions surfaced in the same way through videoconferencing as in face-to-face therapy. These benefits and additional advantages of this form of psychotherapy have been noted in previous literature [49,53]. This research indicates that, in general, patients have a positive attitude toward videoconferencing as a

XSL•FO
RenderX

therapy option [54-56]. In line with this, some participants in this study reported satisfaction with the sessions and positively valued the dynamics of group interactions. However, despite these benefits, some participants expressed a personal preference for individual or in-person therapy. This preference was one of the recruitment challenges faced in the treatment feasibility study [30]. Previous literature has also reported that some individuals prefer in-person groups [49], and many patients with ED often favor individual face-to-face therapy [57]. Therefore, it is crucial to explore ways to make more acceptable those interventions that enhance the cost-benefit balance.

Most participants highlighted the qualities of the therapists and their availability, such as their explanations, their empathy and closeness, their expressiveness, or their response to doubts that arose, among other issues. Additionally, in general, participants emphasized the importance of the therapist's role, indicating that it was fundamental and that without therapists they could not have done it. Likewise, they reported having established a good alliance with the therapists in the same way as in classical psychotherapy. This is consistent with previous studies in which the importance of support from therapists was highlighted [12,13]. The establishment of a strong therapeutic alliance, even in an online group format, was reported by several participants, consistent with previous research demonstrating the feasibility of alliance building in digital contexts [58]. Furthermore, research shows that patients and therapists experience a good therapeutic alliance with videoconferencing therapy, comparable to that obtained with face-to-face therapy [55,59-61]. Studies on blended interventions also show that it is possible to establish a good therapeutic alliance between therapists and patients in this format [26,35].

Participants identified several general advantages of the blended intervention they received, notably temporal flexibility and, particularly, spatial flexibility, which allows treatment to be accessed from anywhere without the need to travel. Additionally, the combination of online modules and sessions was highlighted as a positive aspect, with both elements considered useful. These advantages have been noted in other studies of blended interventions. For instance, in the study by Etzelmueller et al [26], patients also emphasized the spatial flexibility and convenience of working from home, and they found the combination of online modules and synchronous video-based sessions to be beneficial. The main disadvantage identified by participants in focus groups was the more general nature of the treatment, which limits in-depth exploration of individual circumstances or specifics. This is related to the transdiagnostic nature of the intervention and likely its group format. Despite this, most participants reported perceived improvements and the usefulness of the skills learned in their daily lives, noting that they have discovered methods that work for them, that they can better cope with difficult situations or their own symptoms, or that they feel better overall. This is consistent with the preliminary efficacy found in our previous study [30], where significant reductions in anxious and depressive symptoms were obtained at posttreatment and follow-up compared to baseline, and where significant changes were found in other clinical measures, such as negative affect, neuroticism, emotion regulation, or quality of life. In other blended interventions mentioned above [26], patients also reported positive treatment effects. Focus group participants also expressed satisfaction with the intervention, and some even said they would recommend the treatment to others with ED. This is consistent with the quantitative satisfaction reported in our previous study, where patients showed high satisfaction with the treatment [30]. It is also in line with previous research, which generally shows positive opinions [26,27] and high satisfaction with blended interventions [16].

Regarding the domain related to elements that helped them maintain adherence, the most frequent category was therapeutic support, which once again highlights the importance of the therapist's presence. The existence of scheduled sessions and the commitment to groupmates were mentioned, which also appears to reinforce the importance of support and guidance from therapists as well as one of the advantages of the group format [20,21]. Other important points were the therapeutic materials themselves and the effects of the treatment on the patients, both in terms of their personal experience of improvement and the possibility to see their progress reflected in the platform's graphs. In addition, although less frequently mentioned, some participants described internal factors, such as readiness to change and self-commitment, pointing to the role of intrinsic motivation. Taken together, these findings suggest that successful adherence in blended formats likely results from a combination of external (therapist, structure, characteristics, and content of treatment) and internal resources (motivation and self-management), supporting recent models of digital intervention engagement [62]. Future adaptations might benefit from integrating dynamic feedback systems and tailored support strategies to further optimize adherence.

With regard to this, during focus groups, participants suggested incorporating some changes to the platform, such as a discussion forum or a greater degree of interactivity. They also proposed adapting the configuration to the specific modules to be worked on or making the sessions more frequent, or even some of them in person. In addition, they proposed a greater individualization of the intervention, suggesting creating brief individual spaces with the therapist or combining some individual sessions with the current intervention. They also made proposals to improve adherence to treatment, some of which were also related to more individualized follow-up or leaving less space between sessions. Thus, the importance for patients of the presence of the therapists throughout the intervention and the customization of treatment is once again evident.

Finally, participants who dropped out of treatment provided reasons for dropping out and suggested some strategies to improve treatment adherence. Although they did not complete the program, we considered it important to include their experiences to enrich understanding of the intervention's acceptability and identify potential barriers to engagement. Similar to what was found in previous studies [12], participants mentioned that the treatment was not working for them, that they had difficulty applying the strategies learned, or that they identified the need for other types of assistance, such as in-person or more specialized help. The relevance of addressing these aspects has been previously evidenced because noncompletion of tasks generates dissonance, may lead to

XSL•FO
RenderX

increased discouragement, and is related to treatment success [27]. Dropout participants proposed changes regarding the format and configuration of the sessions with the aim of improving adherence to treatment, suggesting that they could be individual, in-person, or held weekly. They also believed that having more time to discuss individual problems in sessions or having fewer homework assignments could help to increase adherence. It has been shown that patients who engage more with homework assignments in online CBT interventions achieve a greater reduction in anxiety and depression symptoms [63], so it would be important to assess patients' engagement in this regard to be able to implement preventive strategies. Several of the identified barriers and proposed suggestions for improvement coincide with aspects mentioned by participants in the focus groups, which reinforces the value of the findings obtained. Taken together, the importance of focusing on the personalization of treatment emerges.

Although this format may not be suitable for all individuals, the findings from the feasibility study [30], together with the qualitative results from this study, support the viability and acceptability of this blended intervention, which also appears to have clinical utility. Additionally, it may help to overcome some of the disadvantages of fully face-to-face and fully self-administered formats and may be a good resource to facilitate access to EBT for a broader population. This is particularly relevant in the context of public health systems such as the Spanish NHS, where there are long waiting lists and sessions occur infrequently. Therefore, a key recommendation for future research and clinical practice would be to explore which patient profiles and under what circumstances this type of blended intervention is most effective [43], as well as to identify cases where alternative formats may be more beneficial.

Limitations

This study has several limitations. One of them is that retrospective responses pose a methodological limitation due to possible recall bias. However, this is a common limitation in qualitative research and not specific to this study. Nonetheless, the focus groups were conducted shortly after the end of the intervention, which likely reduced the extent of this bias. An additional limitation is that 2 of the participants in the focus groups hardly spoke during the interview, resulting in very few ideas from them, which made it difficult to reach the "General" category. Another limitation is that very few participants who dropped out of treatment completed the dropout questionnaire, so formal qualitative analyses could not be conducted. Finally, it would be advisable for future studies to be conducted with people treated in other settings, such as the Spanish NHS, in order to increase the generalizability of the results.

Despite the aforementioned limitations, this study contributes to completing the established conclusions regarding the feasibility, acceptability, and preliminary efficacy of the intervention studied [30]. Furthermore, to our knowledge, it is the first qualitative study to explore the opinions of patients (completers and noncompleters) who have received a transdiagnostic intervention applied in group and blended formats, thus contributing to the development of this novel format.

Conclusions

This study reinforces the feasibility and acceptability of a blended transdiagnostic group treatment for ED. These qualitative findings provide valuable insight into patient experiences, perceived benefits, and areas for improvement while also offering guidance for future research and implementation. This study supports this innovative format as a potentially scalable, acceptable, and effective option within mental health services.

Acknowledgments

Thanks to Rosa Lorente-Català, Alberto González-Robles, and Macarena Paredes-Mealla for their collaboration in conducting the focus groups.

Abstract

Background: Alcohol use remains a major public health concern, and although preventive alcohol self-help interventions aim to support individuals in need of indicated prevention, they continue to face challenges related to low engagement and high attrition. Chatbots, also known as conversational agents (CAs), powered by artificial intelligence, may enhance engagement by offering personalized guidance and 24/7 availability. Yet, user perspectives on CAs in preventive alcohol self-help care remain largely unexplored.

Objective: This paper aimed to gain insight into the diverse factors shaping the adoption of CAs in preventive alcohol self-help by qualitatively exploring users' expectations and concerns, complemented by descriptive questionnaire data on perceived usefulness, intention to use, comfort, and trust.

Methods: This qualitative, exploratory study with a small purposive sample (N=12) included adults recruited from a Dutch digital alcohol self-help intervention and a client advisory board. Data were collected during an online focus group (n=8, 66.7%), 4 semistructured interviews (n=4, 33.3%), and a brief questionnaire administered to all participants in March 2025 and April 2025. The qualitative data were analyzed inductively using thematic analysis.

Results: Qualitative findings showed that participants appreciated the 24/7 availability, practical guidance, and nonjudgmental stance of CAs but doubted their capacity for genuine empathy and authenticity. Participants emphasized that the conversational tone was important: CAs should be supportive without being overly agreeable and should be confrontational once trust is established. Concerns about undue influence arose occasionally, while privacy was viewed by 1 (8.3%) participant as a major issue. Descriptive questionnaire results showed that 11 (92%) participants had prior experience with CAs, whereas only 6 (50%) had experience with digital health interventions. Most participants considered CAs potentially useful for reducing alcohol use, yet few expressed strong intentions to use one themselves. Comfort and trust ratings were largely neutral, reflecting a cautious but generally open attitude toward CA use.

Conclusions: CAs appear to hold promise as complementary tools for preventive alcohol self-help, although they are not perceived as replacements for human contact. Future design efforts should emphasize personalized interactions; an appropriate conversational tone, supportive yet not overly agreeable; and transparent communication about data use to enhance engagement and acceptance. The findings are descriptive and are not intended to be broadly generalizable.

(JMIR Hum Factors 2026;13:e86752) doi:10.2196/86752

KEYWORDS

conversational agents; preventive health care; self-help; alcohol use; qualitative study

Introduction

Although global alcohol consumption has declined since 2010, alcohol use remains a significant public health concern [1]. Alcohol use is associated with increased risks of physical illness, psychological distress, and adverse social outcomes [2]. Despite these consequences, globally only around 1 in 6 individuals with alcohol use disorder receives any form of treatment [3].

XSL•FO
RenderX

This treatment gap is driven by a range of factors, including limited availability of services, inadequate screening and referral procedures, and stigma surrounding alcohol-related problems [4].

In response to the limited availability of services, digital interventions have emerged as promising tools to increase access to care. These interventions, delivered via websites or mobile apps, can be used independently or alongside professional treatment. They are typically low-threshold, flexible in timing and location, and have shown small to moderate effects in reducing alcohol use and improving mental health outcomes [5,6]. There is growing recognition that digital interventions should not only target individuals with alcohol use disorders but also those engaging in risky drinking behavior. Preventive digital programs can reach this broader group early, potentially reducing harm before dependence develops [7,8].

Preventive digital interventions can vary in intensity, and a key distinction concerns the degree of guidance. Guided interventions—those that include contact with a therapist or coach—tend to show higher adherence than fully automated self-help formats [5,9,10]. This suggests that some form of personalized feedback or interaction is important for maintaining engagement. Conversational agents (CAs), also known as chatbots, offer a potential solution to deliver such guidance in a scalable way. A CA is an artificial intelligence (AI) system designed to engage users in natural, humanlike dialogue. Preliminary evidence suggests that CAs can enhance user satisfaction and engagement compared to unguided digital interventions and may even support reductions in depressive symptoms [11-13].

Although evidence for the effectiveness of CAs in digital mental health care is increasing, it is also important to understand users' perspectives on these technologies. A recent qualitative study with users of a CA for anxiety reported that participants valued its accessibility but expressed concerns about the agent's ability to demonstrate empathy and maintain privacy. Many participants also emphasized the need for human supervision [11]. A review highlighted that factors such as personalization, reliable responses, and ease of use are important for user engagement with these technologies [14]. Additionally, although some users remain skeptical about the role of CAs in providing health advice, they appear somewhat more open to using them as a supplement to mental health support [15]. Reviews further emphasize that personalization, reliability, and transparent communication are central to sustained engagement [14].

Although existing research provides important insights into the general use of CAs for mental health, much less is known about their potential role in alcohol-related prevention and self-help. Alcohol consumption involves distinct behavioral, social, and motivational dimensions that may influence how users perceive and interact with automated support. Understanding these perceptions is important for assessing whether CAs can effectively complement existing preventive self-help approaches and for identifying factors that may facilitate or hinder their adoption. This study therefore examines the experiences, expectations, and concerns of participants in a Dutch preventive alcohol self-help program and of members of a client advisory board, focusing on their perspectives on CAs in digital alcohol prevention and the reasons why they would or would not use such tools. Given the limited existing evidence, the study adopted an exploratory qualitative design without predefined hypotheses or preregistration, with the goal of generating inductive insights to inform the future development and evaluation of CAs in digital alcohol prevention interventions.

Methods

Study Design

This study used an exploratory qualitative design based on an online focus group, 4 semistructured interviews, and a brief questionnaire to gather contextual information. The focus group primarily generated interactive discussions around shared experiences and general expectations, while the individual interviews provided more nuanced and personal reflections, particularly regarding doubts about empathy, trust, and personal willingness to use CAs. The questionnaire was administered prior to the focus group and interviews to obtain participants' independent views on CAs, uninfluenced by group dynamics, and to serve as a basis for more in-depth exploration during the discussions. The questionnaire data were used descriptively and for contextual triangulation of the qualitative findings, rather than for inferential analysis. Given the small sample size, the quantitative results (eg, mean scores) should be interpreted with caution and are intended to provide indicative insights only.

Recruitment

The qualitative and quantitative components of the study included 12 participants recruited between March 2025 and April 2025 from a Dutch online self-help program for alcohol use and the client advisory board of a large mental health care institution (Arkin, the Netherlands). The self-help program consists of 6 evidence-based modules based on both motivational interviewing and cognitive behavioral therapy. Other intervention features include a support forum, a personal diary, and encouragement for users to log their daily substance use and craving in accordance with cognitive behavioral therapy principles.

Inclusion criteria were participation in Jellinek's digital self-help alcohol intervention, familiarity with the program, proficiency in Dutch, and willingness to participate in an online group discussion or interview. Due to the anonymous nature of the self-help program, participants' contact details were not initially available. However, individuals who expressed interest in participating in the study by responding to a forum message or clicking a banner within the self-help program were asked to provide their phone number or email address, enabling the researchers to provide more information and formally invite them to the focus group. A total of 24 participants provided contact details, all of whom were contacted multiple times to schedule participation. Of these, 2 (16.7%) participants did not speak Dutch, 6 (50%) were unable or unwilling to join an online group discussion or interview, and 7 (58.3%) did not respond to phone calls or emails. Ultimately, 8 (66.7%) participants from the self-help community joined the focus group. In addition to the focus group, 4 semistructured interviews were conducted. Three interviews were held with members of Arkin's client

XSL•FO
RenderX

advisory board, and 1 was conducted with another self-help user who did not want to join a group discussion but was willing to participate in an interview. Because of the limited number of participants (n=12, 100%), formal data saturation could not be established; however, recurring patterns and overlapping themes emerged across the focus group and interviews. This suggests a degree of thematic consistency, even if full saturation was not attained [16].

All participants completed a questionnaire prior to the focus group and interviews and received a €45 (€1=US $1.14 as of June 23, 2026) gift voucher as compensation.

Data Collection Procedures

Data were collected between March 2025 and April 2025 through 1 online focus group session (n=8, 66.7%) and 4 online semistructured interviews (n=4, 33.3%). The focus group followed a semistructured discussion format exploring attitudes toward the integration of a CA. The focus group lasted approximately 3 hours, although it was planned for 2.5 hours. The same thematic areas were addressed in the individual interviews, allowing deeper reflection and more personal nuance. The interviews lasted approximately 1.5 hours. The focus group was moderated by an independent researcher, a female psychotherapist (MSc) with prior experience in moderating focus groups. She had no relationship with any participants. She was independent because she did not have assumptions or personal interests related to the study, which was important to minimize the risk of leading questions or undue influence. The primary researcher (first author) was present during the focus group in a nonparticipatory role. She introduced herself as the researcher of this project, explained why an independent person moderated the focus group, and explained the rationale for conducting this research. The researcher was also present to address potential procedural questions from participants and to become familiar with the data. This allowed the researcher to gain a contextual understanding of the discussions, including tone and group dynamics, which may not be fully captured in written transcripts. The researcher also made field notes during the focus group and interviews.

Prior to the focus group and interviews, participants were asked to complete a short, researcher-developed questionnaire about their prior experiences with CAs and their perspectives on how these could be used in the self-help program. All participants were asked for what purposes they would use a CA after being given several examples of possible functions. They were invited to write down as many desired functions as they wished. The questionnaire also included several demographic items (Table 1). The questionnaire was pretested by researchers involved in the study prior to data collection to ensure that it functioned properly and that the wording was comprehensible for individuals with varying levels of language proficiency. Several questionnaire items were also discussed during the focus group and interviews to gain deeper insight into participants' responses and to stimulate group-level discussion (Checklist 1).

Table . Characteristics of participants (N=12).

Characteristics	Participants
Gender, n (%)	
Men	8 (66.7)
Women	4 (33.3)
Age (years), mean (SD)	61.1 (8.3)
Education level, n (%)	
Lower	3 (25.0)
Higher	9 (75.0)
Country of birth, n (%)

Yes	6 (50.0)
No	6 (50.0)
Previous experience with digital interventions[a], n (%)	
Yes	6 (50.0)
No	6 (50.0)

[a]Excludes the Jellinek digital alcohol self-help intervention.

Data Analysis

The qualitative data were analyzed using inductive thematic analysis [17,18]. This method was selected for its suitability for generating in-depth, exploratory insights into participants' experiences, perceptions, and attitudes regarding complex and potentially ambivalent topics such as AI in mental health care. In addition, the inductive approach enables researchers to maintain an open perspective toward the data. Alternative

XSL•FO
RenderX

qualitative approaches, including grounded theory, content analysis, and framework analysis, were considered in consultation with a qualitative data supervision group before thematic analysis was selected as the most appropriate method, given the exploratory aim of the study.

The focus group and interviews were audio-recorded and transcribed verbatim. Transcripts were anonymized prior to analysis and were not returned to participants. The focus group and interviews were conducted in Dutch, and the quotes were translated into English and checked by a native speaker for accuracy.

In the first phase, the primary researcher (first author) familiarized herself with the data by repeatedly reading the transcripts of the focus group and interviews. An initial phase of open, inductive coding was then conducted, in which segments of the data relevant to the research question were identified. Given the nature of focus group and interview data, nonrelevant conversational content was not coded. Codes were generated at a semantic level, staying close to participants' own words and meanings without imposing predefined categories.

After completion of the initial coding, codes were systematically compared and grouped based on similarities and patterns, resulting in the development of candidate themes. These themes were iteratively reviewed and refined in relation to both the coded extracts and the full dataset. The coding process and theme development were discussed with a second independent researcher (M Begeman). Discrepancies in interpretation were resolved through discussion until consensus was reached. A documentation process was maintained by documenting coding decisions, code definitions, and changes to the coding structure, supported by analytic memos and versioning within MAXQDA 2022 (VERBI Software GmbH). Participants did not provide feedback on the findings.

The questionnaire data were analyzed descriptively using means and SDs to provide contextual information about participants' familiarity with and attitudes toward CAs.

Ethical Considerations

All participants provided informed consent and received €45 as compensation for participating. The Medical Research Ethics Committees United determined that the study was not subject to the Dutch Medical Research Involving Human Subjects Act (Dutch: *wet medisch-wetenschappelijk onderzoek met mensen*) and granted approval (2024.1147). To minimize potential bias, the focus group was moderated by an independent facilitator who was not involved in the research project. The primary researcher has a background in clinical psychology and addiction research, with an interest in digital mental health. She was not involved in the development of the self-help program under study but is involved in planned future adaptations and improvements to the program. To minimize potential bias, the researcher adopted a nondirective role during the focus group, avoiding leading questions and allowing participants to freely express their perspectives.

Results

Participant Demographics

Participant characteristics are presented in Table 1. The sample consisted of 8 (66.6%) men and 4 (33.3%) women, with a mean age of 61.1 (SD 8.3) years. Previous research among users of the same self-help program has shown that the average age in this population is relatively high, at around 51 years [19]. Most participants had completed higher education, and half reported prior experience with digital interventions (excluding the Jellinek digital alcohol self-help intervention).

Qualitative Data

The thematic analysis of the focus group data identified 2 overarching themes related to the use of CAs: motivating factors that encouraged participants to consider CAs as supportive tools and hindering factors that limited their willingness to engage with such systems. Within each theme, several subthemes captured both functional and experiential dimensions of how participants envisioned interacting with CAs in the context of a self-help program to reduce or quit their alcohol use.

Many of the themes raised by self-help participants during the focus group were echoed in the interviews with members of the advisory board, indicating a high degree of consistency across the 2 participant groups.

Motivating Factors for CA Use

Immediate Support in Moments of Need

A central theme was the perceived value of CAs as a source of immediate support, particularly during moments of craving or relapse. Participants described situations in which traditional support options, such as friends, family, or health professionals, would be unavailable, noting that cravings often occur at night or during other moments of isolation. The promise of a tool that is available "anytime, anywhere" was repeatedly emphasized as a unique strength of CAs.

One participant explained the following:

> *When you wake up at 2:30 a.m. craving a drink, it would be great to have something right then.*

For several participants, this possibility filled a gap that existing services or peer support could not reliably address. Others stressed that even if the CA could not "solve" the craving, the act of engaging in dialogue might provide enough distraction or motivation to resist the urge.

Information Source

Participants also emphasized the value of CAs as a reliable and comprehensive source of information. Many described using tools such as ChatGPT (OpenAI) in their daily lives as a quick reference point, highlighting their utility for clarifying questions about health, lifestyle, or substance use.

One participant shared the following:

> *I use ChatGPT like Google now.*

Several saw this practical, informational function as more appealing than emotional support, which they preferred to seek

XSL•FO
RenderX

from human contacts. The CA's broad knowledge base was described as particularly useful for offering "unexpected angles" or "new ideas" that might not occur to the user.

One participant noted the following:

> *Sometimes it gives you ideas that make you think, wow. A little spooky, but interesting.*

Such input was considered helpful for self-reflection, even when participants did not act directly on the advice.

Positive Design and Interaction Characteristics

Beyond specific functions, participants valued certain interactional characteristics of CAs. Among these were reliability (ie, being always available and never tired) and a nonjudgmental tone. Several participants contrasted this with human helpers, who might express disappointment, irritation, or fatigue in response to relapse disclosures. By contrast, the CA was viewed as a safer and more consistent space for sharing sensitive information.

One participant stated the following:

> *It doesn't get angry with you or sigh when you've relapsed again.*

In terms of design, participants expressed divergent preferences.

Some preferred a minimalist, text-only interface, emphasizing simplicity and focus:

> *Give me just text. No human-like figure.*

Others felt that adding visual or customizable elements could make interactions more engaging, even playful:

> *I'd find it funny if you could create the character yourself. With a weird hat and glasses, so it feels like someone you know.*

This design flexibility was highlighted as a motivating factor because it could adapt to different user needs and preferences.

Hindering Factors for CA Use

Reluctance and Unfamiliarity

For several participants, reluctance to engage with CAs stemmed less from negative experiences and more from a lack of familiarity with the technology. The novelty of AI-based systems created hesitation, described by 1 participant as "cold feet." This sense of uncertainty was tied to limited exposure and the perception that AI was still a "black box" or unknown territory. Others indicated that although they were curious, they preferred to observe developments from a distance before adopting such tools themselves. This hesitation therefore reflected not outright rejection but rather a cautious, wait-and-see attitude.

Privacy and Security Concerns

Privacy did not emerge as a dominant barrier in this study. Most participants distinguished between highly sensitive information, such as financial or medical records, which they would never entrust to a CA, and less sensitive disclosures about drinking behavior, which they perceived as relatively harmless.

One participant explained the following:

> *Who cares whether I drink or not? If that information leaks, that doesn't bother me.*

However, this general downplaying of privacy did not mean that all concerns were absent.

One participant raised questions about where their data might end up, mentioning companies or countries with geopolitical associations:

> *Which cloud does it end up in? To Elon Musk? The Chinese? The Russians?*

These statements suggest that although privacy was not top of mind for everyone, uncertainties about data storage and control could still undermine trust if left unaddressed.

Lack of Human Empathy and Authenticity

One of the most frequently cited barriers was the perceived inability of CAs to replicate essential human qualities, particularly empathy. Several participants emphasized that emotional support during moments of vulnerability required a genuine human connection.

One participant stated the following:

> *When it comes to moral support, my experience is that it only works with people.*

The absence of warmth or emotional resonance limited the value participants attributed to CAs in deeply personal situations, such as feelings of shame. Moreover, some participants found the communication style of existing chatbots unconvincing. Responses were described as "too smooth" or overly scripted, lacking the imperfections and nuances of human dialogue.

Rather than offering comfort, this polished style sometimes reduced credibility:

> *I don't want a super smooth answer. I want something I can actually use.*

These reflections highlight a tension around tone: responses that are overly smooth or pleasing may come across as inauthentic, making the CA feel less trustworthy or connected to the user's real struggles.

Off-Putting Design and Potential Influence

Design elements were another source of hesitation. Although some participants appreciated the possibility of customizing avatars or visual interfaces, others described these features as deceptive.

The idea of interacting with a humanlike avatar provoked discomfort, with 1 participant remarking the following:

> *I'd feel betrayed if a fake person was sitting across from me.*

Concerns about undue influence underscored the importance of transparency regarding the capabilities and limitations of CAs. Some worried that users with limited digital literacy or critical thinking skills might overrely on the system or accept its advice uncritically. The risk of undue influence underscored the importance of transparency about the limits of what CAs can and cannot do.

XSL•FO
RenderX

Finally, trust was repeatedly described as something that could not be assumed but had to be earned. Participants suggested that credibility would need to be built gradually, through consistent and reliable interactions over time. Without this foundation, early negative experiences could quickly erode the willingness to use the CA.

Survey: Familiarity With and Opinions on CAs

Participants' knowledge of and experiences with AI and CAs are presented in Table 2. The desired functions of a CA are presented in Figure 1.

The most frequently desired functions were helping users find information, providing advice, and offering motivation when struggling or after a relapse.

On a 5-point scale, participants reported moderate knowledge of AI (mean 3.0, SD 1.2) and perceived the usefulness of CAs for reducing alcohol use as fairly high (mean 3.8, SD 1.1). Comfort and trust levels were largely neutral (mean 3.0, SD 1.2 and mean 2.8, SD 0.9, respectively), while willingness to use a CA was mixed (mean 3.3, SD 1.3).

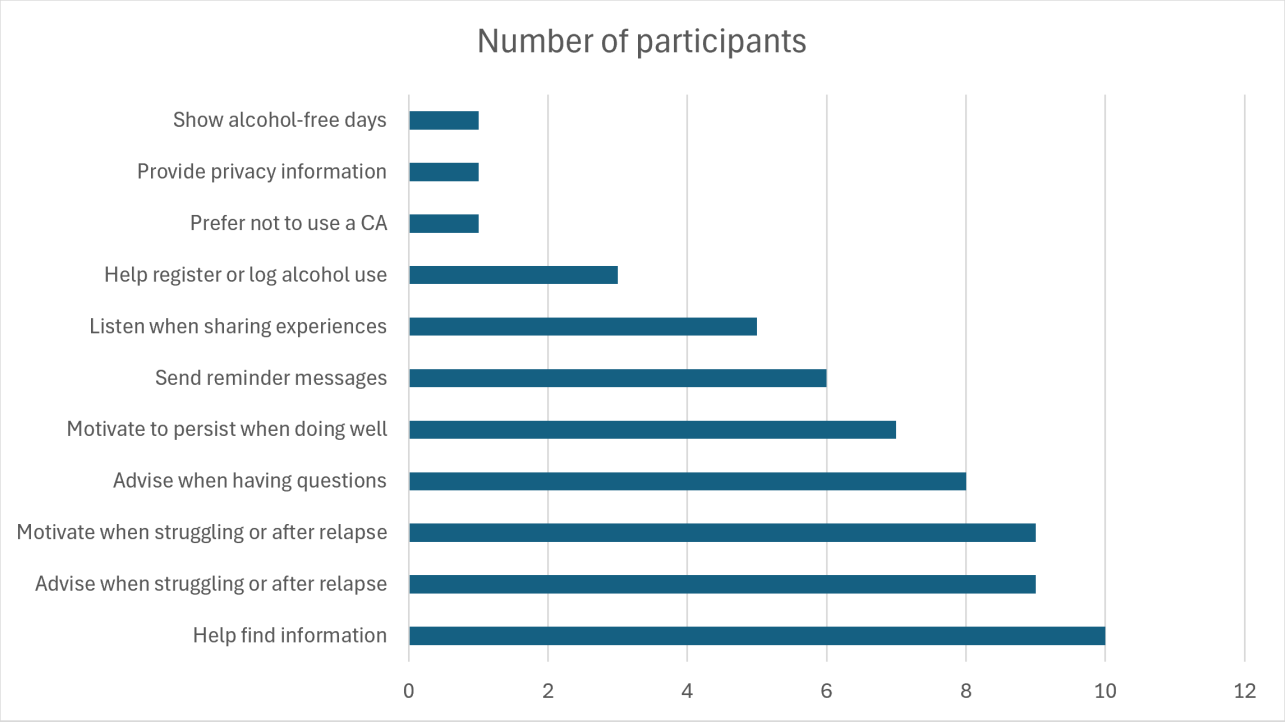

Table . Participants' knowledge of and experiences with conversational agents (CAs; N=12).

Items	Response scale (5-point)	Participants, mean (SD)
Knowledge of AI[a]	"Very low" to "very high"	3.0 (1.2)
Usefulness of AI for reducing alcohol use	"Not useful" to "very useful"	3.8 (1.1)
Willingness to use a CA	"Definitely not" to "definitely yes"	3.3 (1.3)
Comfort discussing alcohol use with a CA	"Very uncomfortable" to "very comfortable"	3.0 (1.2)
Trust in a CA ability to give good advice	"Very low" to "very high"	2.8 (0.9)
Satisfaction with chatbots[b]	"Very dissatisfied" to "very satisfied"	3.6 (0.8)

[a]AI: artificial intelligence.

[b]Only participants with prior chatbot experience answered this question (n=11).

Figure 1. Desired functions of a conversational agent (CA) for alcohol self-help among participants (N=12).

Discussion

Principal Findings

This qualitative study examined how users of a Dutch preventive alcohol self-help program and members of a client advisory board perceive the potential role of CAs in digital alcohol prevention. Across both qualitative and survey data, findings indicate a general perception of CAs as potentially useful, albeit accompanied by notable reservations regarding trust, authenticity, and willingness to adopt them.

Participants broadly valued the accessibility and functionality of CAs, particularly their around-the-clock support and practical guidance during moments of craving or relapse. They emphasized the appeal of an always-available, nonjudgmental companion that could offer both information and motivation without the social barriers often associated with human help.

XSL•FO
RenderX

These qualitative perceptions were supported by survey results showing relatively positive evaluations of usefulness for reducing alcohol use (mean 3.8, SD 1.1), suggesting that participants recognize the potential functional value of CAs in preventive contexts.

Despite the perceived usefulness, both datasets consistently indicated ambivalence regarding personal uptake. Although survey responses indicated only moderate willingness to use a CA themselves (mean 3.3, SD 1.3), participants in the focus group and interviews expressed ambivalence about empathy and authenticity. This tension suggests that perceived usefulness does not directly translate into intended use.

Concerns about empathy and authenticity were central in both methods. In interviews and focus groups, participants questioned whether CAs could provide meaningful emotional understanding or whether responses might feel too "scripted" or "pleasing," particularly in vulnerable situations. These concerns were also reflected in the survey data, with neutral trust ratings (mean 2.8, SD 0.9) and moderate comfort levels when discussing alcohol-related issues with a CA (mean 3.0, SD 1.2), indicating cautious attitudes toward relational aspects of CAs despite recognition of their functional benefits. Privacy concerns, in contrast, were mentioned less frequently and were generally not perceived as a major barrier.

Several factors that may facilitate engagement include trust, consistency, and flexibility in design. Participants viewed trust as something that must be earned gradually through reliable, transparent, and contextually appropriate interactions. The combination of practical functionality and emotional credibility appeared central to the willingness to use a CA in preventive care. Taken together, these findings provide a more nuanced picture of user perspectives on CAs in alcohol self-help: interest exists, but readiness to adopt CAs is conditional.

The study adds to existing knowledge by situating these insights specifically in a preventive context, where users are not seeking treatment but exploring support to maintain control over their drinking. This distinction helps explain the observed ambivalence, as CAs are perceived as promising complements rather than substitutes for human contact or established self-help methods.

Comparison With Prior Work

The finding that accessibility, neutrality, and broad knowledge are seen as major advantages aligns with prior digital mental health research [20,21]. Our results extend this work by showing that these qualities may be particularly relevant in preventive contexts, where individuals often hesitate to seek formal treatment because of stigma or low perceived need. In such cases, the neutrality of a CA may not be a limitation but rather a functional strength, lowering the threshold for disclosure and support.

Personalization emerged as a strong desire in our sample, ranging from tailored interaction styles to flexible interface design. This resonates with broader evidence that adaptive systems can foster engagement and adherence [22]. At the same time, personalization brings to the forefront a central tension in digital health: the more interventions are tailored to individuals, the more data collection is required. Prior research has shown that increased data demands can create privacy concerns and reduce trust [15]. Interestingly, most of our participants downplayed privacy as an obstacle in hypothetical discussions. This aligns with previous research on the self-help intervention, which showed limited concern for ethical aspects of applying machine learning to adapt the digital intervention [23].

This discrepancy points to a possible gap between imagined use and real-world adoption. Our survey data support this interpretation. Although most respondents described AI as useful for reducing alcohol use (5="very useful" and 3="quite useful"), only a minority expressed strong intentions to use a CA themselves (3="definitely yes"), with trust and comfort ratings largely neutral. These findings suggest that enthusiasm for CA functionalities in principle does not automatically translate into personal uptake.

Our findings also add nuance to debates about the emotional capacity of CAs. Previous studies have questioned whether they can provide empathy and called for human supervision [11]. Some participants in our study echoed these doubts, but others highlighted neutrality as preferable to human interaction, which can evoke feelings of disappointment or judgment. This suggests that the role of CAs may not be to replicate human warmth but to provide a complementary form of support in moments where neutrality is an advantage.

Finally, our results speak to the broader challenge of adherence in digital self-help programs. Dropout and inconsistent use remain persistent problems in unguided interventions [10]. The motivating factors identified by our participants—24×7 availability, nonjudgmental stance, and personalized feedback—mirror elements that prior research has associated with higher adherence in digital interventions, particularly studies showing that guidance and personalization increase completion rates [5,9,10,22].

Broader Implications and Ethical Considerations

The findings highlight both practical and ethical implications for the design and implementation of CAs in preventive alcohol self-help. From a design perspective, participants expressed diverse preferences regarding visual appearance and interaction style. Some favored a simple, text-based interface, while others appreciated the idea of a more humanlike avatar or personalized appearance. However, across these differences, participants consistently emphasized that the *tone of* communication mattered most. The CA should respond in an empathetic, respectful, and nonjudgmental way, without becoming overly pleasing or superficial. Participants valued honesty and even confrontation when appropriate, but only once trust had been established. This suggests that CAs in this context should be capable of adjusting their interactional style over time, matching their tone and feedback to the user's stage of engagement and level of trust.

Beyond design, and building on participants' emphasis on 24×7 availability and low-threshold access, CAs may serve as complements to existing self-help or prevention programs by offering immediate support during moments when human help is unavailable. Integrating such systems into alcohol prevention

XSL•FO
RenderX

and broader eHealth strategies could potentially increase accessibility, although this remains to be tested in practice. At the same time, the very features that make CAs attractive, such as their constant availability and responsiveness, may also introduce new ethical challenges. Participants' concerns about undue influence and the lack of genuine empathy suggest that CAs are not merely neutral tools but may function as moral technologies that shape decision-making and redistribute responsibility within care relationships. For example, when users rely on a CA for advice during moments of vulnerability, questions arise regarding who holds responsibility for the outcomes of such interactions—whether this lies with the user, the developers, or the system itself.

Limitations

Several limitations should be acknowledged. The sample was small, relatively homogeneous, and skewed toward older, higher-educated participants, which limits generalizability. However, previous research among users of the same self-help program has shown that the average age in this population is approximately 51 years [19], suggesting that the sample is broadly consistent with the program's user base. Another limitation concerns recruitment. Because participants were informed that the study involved discussing AI-based tools, it is possible that the sample included individuals who were more interested in or open to technological innovations in health care than the average self-help user. This may have resulted in a group with relatively well-developed or positive opinions about CAs, potentially limiting the range of perspectives represented.

Finally, although recurring patterns and overlapping themes were observed across the focus group and interviews, formal data saturation could not be confirmed because of the limited number of participants. Future studies with a larger and more diverse sample could build on these findings to further explore differences in user expectations, trust development, and CA design preferences.

Future Directions

Future research should replicate this study in larger and more diverse samples to verify whether these findings hold across different populations and drinking profiles and to achieve stronger data saturation. Observational and experimental studies involving actual interaction with CAs would allow researchers to examine how trust, comfort, and engagement evolve over time. Directly observing user-CA exchanges, for example, within existing preventive self-help platforms, could provide valuable behavioral data and reveal when and how users disengage.

It would also be valuable to explore how specific design features, such as text-only vs avatar-based interfaces and conversational tone, affect engagement. Finally, longitudinal research could clarify whether CAs can meaningfully support adherence and sustained behavior change over time, beyond initial curiosity or short-term use.

Conclusions

This study shows that users see potential for CAs in preventive alcohol self-help, mainly because of their constant availability, practical guidance, and neutral stance. However, CAs are not perceived as replacements for human contact. Moreover, enthusiasm in principle does not automatically translate into willingness to use such tools, as doubts about empathy, authenticity, and trust remain. CAs should therefore be viewed as complementary support within broader self-help systems. Future design efforts should emphasize personalized design; an appropriate conversational tone, supportive yet not overly agreeable; and transparent communication about data use to enhance engagement and acceptance. Their future value will depend on design, user involvement, and real-world evaluation to strengthen trust and engagement.

Acknowledgments

The authors thank all participants for their valuable contributions to the focus group and interviews. The authors are especially grateful to the chair of the focus group for her guidance and support during the discussions. The authors declare the use of generative artificial intelligence (GenAI) tools during the research and manuscript preparation process. According to the GenAI Disclosure Taxonomy (2025), the following tasks were delegated to GenAI tools under full human supervision: proofreading, editing, and translation. The GenAI tools used were ChatGPT (version 4.5; OpenAI) and DeepL (DeepL SE). The authors take full responsibility for the final content of the manuscript. GenAI tools are not listed as authors and bear no responsibility for the final outcomes. DeepL was used to translate text into scientific English. As English is not the authors' native language, portions of the manuscript were initially drafted in Dutch and subsequently translated using DeepL. The authors reviewed all translated content for accuracy and fidelity to the original meaning.

In addition, selected portions of the Introduction and Discussion sections were proofread and edited using suggestions generated by ChatGPT-4.5 to improve readability.

Abstract

Background: Video-algorithmic patient monitoring (VAPM) combines remote, noncontact sensors and algorithmic analysis and is increasingly trialed in acute psychiatric and other care settings. While promoted for improving safety and reducing risk, it raises ethical concerns regarding safety, privacy and surveillance. Little is known about how those encountering VAPM in mental health care contexts anticipate its use and potential impacts, including where it has not yet been implemented.

Objective: This study aimed to explore the views of patients or mental health consumers, specialized mental health nurses and nurse academics, hospital managers, and technology vendors regarding the appropriateness and anticipated implications of VAPM in mental health inpatient care.

Methods: This qualitative study identified key stakeholders in Australia via networking techniques for participation in a deliberative workshop. A deliberative workshop was held, and the workshop discussion was audio-recorded, transcribed, and thematically analyzed, consistent with methods in health technology research, which enable exploration of different viewpoints, including convergences and divergences across stakeholder groups.

Results: In total, 16 stakeholders participated, exploring themes concerning (1) contestation over the rationale for VAPM in mental health settings, (2) VAPM reshaping care and relationships, (3) perceived harms of VAPM, (4) perceived observational support for safety and reduced disruption, (5) serious privacy implications of VAPM, (6) the need for appropriate governance, and (7) the potential for VAPM to transform, not augment, service delivery. General views differed across groups. Patients or service users expressed concerns about privacy, coercion, and the potential to intensify stigma. Mental health nurses were cautious but interested in possible benefits for safety and suicide prevention. Hospital managers and technology vendors largely emphasized safety gains.

Conclusions: The findings suggest that the anticipated risks of VAPM are primarily experienced subjectively, as infringements on privacy, dignity, and trust, while purported benefits remain largely untested and unquantified. From a utilitarian perspective, direct comparison is therefore difficult—the risks are set out in the anticipated experiences of those with lived experience, and the benefits remain hypothetical. From this view, robust, independent evidence of real-world outcomes is required. Yet, for some participants, the very premise of such calculation was rejected, with privacy, dignity, and trust regarded as nonnegotiable, rather than items for trade-off. If VAPM is to be pursued at all, it should proceed only with extreme caution, with transparent evidence of outcomes, and with meaningful participation from those whose lives and care are most directly impacted.

Introduction

Technology used to monitor and surveil is proliferating in many areas of contemporary life. However, there are not always opportunities for people to consider the implications, personally and socially, for monitoring and surveillance in specific settings.

This paper refers to "video-algorithmic patient monitoring" (VAPM) to describe a form of monitoring that incorporates remote sensors, video technology, and algorithmic analysis. This technology is being trialed in varied health and social care settings, including mental health inpatient wards. VAPM involves video cameras or other sensors, artificial intelligence (AI) software, and an interface for nurses and other mental health practitioners to make remote, noncontact clinical observations and data collection about patients in hospital environments [1]. Other descriptors include "vision-based patient monitoring and management" and "passive remote monitoring technology" [2,3].

We conceptualize this monitoring arrangement as a "sociotechnical system" insofar as it is a "system involving the interaction of hard systems and human beings, in ways that either cannot be separated or are thought to be inappropriate to separate" [4,5]. This framing offers a way to analyze the dynamic interaction of people and technology, rather than narrowly focusing on the technology itself.

Traditional patient monitoring in hospitals involves in-person checks by health care professionals or simple alerts provided by clinical technology that tracks certain vital signs (eg, a pulse oximeter). VAPM is an iteration of these monitoring techniques. Proponents advocate for their use to improve upon in-person monitoring, including traditional forms of vital sign monitoring, and to reduce disruption for patients. Others have raised concerns that these technologies pose a threat to service user safety, privacy and dignity [6,7].

In mental health inpatient settings, VAPM involves patients' bedrooms being fitted with sensors [1], typically designed to focus on a person's pulse, breathing rate, and movement. Signals are detected remotely and continuously, based on physiological phenomena such as the chest rising and falling or the use of photoplethysmography (a simple optical technique that uses light to measure blood volume changes in peripheral circulation). Unlike vital sign monitoring, which is used extensively in health care settings, VAPM entails remote monitoring that does not rely on sensors attached to a person's body (on-body sensors). Attempts are underway to use such data as alerts to reduce self-harm, assault, and suicide in mental health wards [8].

At the time of data collection (December 2021), there was limited research on the impacts and use of VAPM [1,2]. Although several studies emerged since this time [9-13], empirical studies into VAPM remain limited. A systematic review of surveillance-based technology initiatives in inpatient and acute mental health settings [14] identified 9 studies that covered VAPM (the systematic review authors used the term "Vision-Based Patient Monitoring and Management" [14]), all from the United Kingdom; all were rated as "low quality," except one, which was rated "high quality" [3]. In total, 8 of the 9 studies also reported conflicts of interest, with the high-quality study being the only paper by Dewa et al [3], which did not report any conflicts of interest [14]. As we will discuss, the post-2021 studies—which are UK-centered—are broadly consistent with participants' anticipation that VAPM might reduce disturbance from in-person observations and improve efficiency (particularly overnight), with potential flow-on safety and cost implications [8-11,14]. However, participants also anticipated that these benefits would remain contestable and difficult to justify without clear evidence and strong governance, and that concern is reinforced by the still-limited and often conflicted UK evidence base [14].

The stated aims of VAPM include reducing disturbance to patients by making observations less intrusive, which may have several flow-on benefits to people's health and recovery [1], improving efficiency with night-time safety and reducing reliance on intensive monitoring, which may lead to reduced costs [10], improved quality and safety in care [10,11], reduction in incidents of assaults, and reductions in the associated involuntary tranquilization of patients and service users [13].

Ethical and legal concerns have arisen in the United Kingdom, with several complaints about the technology being reportedly made by rights organizations, nurses, and patient groups on the basis that VAPM raises privacy concerns, is objectionable, and is potentially harmful to patients [6,15]. In at least 1 National Health Service (NHS) Trust, complaints reportedly led to a cessation of VAPM [16]. These concerns suggest that even if further studies confirmed benefits to patients' sleep or other areas, such as reduced self-harm or suicide, such findings would have to be considered alongside other social, ethical, and legal implications of the technology. The legal implications of VAPM, for example, are not well understood [17].

This paper reports the findings of a qualitative exploratory study, via a workshop with key stakeholders which asks about the anticipated implications of VAPM in mental health inpatient settings. The study occurred in Australia, where VAPM is not widespread but has been applied in aged care settings [18] and seems likely to be trialed in mental health care settings [19]. The study aims to consider not just the practical and clinical implications of VAPM, but also the social, ethical, and legal issues, situating VAPM within broader debates about surveillance technologies in health care and their effects on privacy, consent, trust, and so on. This paper also draws on recent scholarship on new technologies of automation, such as AI ethics and algorithmic accountability, to analyze how VAPM may impact governance, decision-making, and trust in inpatient mental health care. We use these perspectives to assess the implications of data-driven monitoring for matters such as privacy, agency, and relationships of care.

Methods

Overview

We adopted a deliberative workshop format to elicit multistakeholder perspectives on the use of VAPM in mental health inpatient settings. Methods such as citizens' juries, co-design workshops, and deliberative panels are increasingly

XSL•FO
RenderX

used in health technology and medicolegal research to qualitatively explore ethical, legal, and social implications of new technologies [20,21]. They enable structured engagement with complex dynamics and trade-offs concerning issues of privacy and safety and are supported by recent empirical examples demonstrating their value in AI health care deliberation and digital tool development [22,23].

An online workshop was held in December 2021 with 16 participants and the 6 study authors, as well as an additional research assistant and an independent facilitator. The authors worked with an independent facilitator with expertise in group process design to develop an online workshop that was interactive and would provide participants with the opportunity to engage with evidence, deliberate, and respond both in verbal and written formats.

Recruitment

Using networking techniques, each coauthor identified 4 individuals who were invited to the workshop in a process of purposive sampling, informed by criteria concerning participants' appropriateness, capacity, and willingness to participate [24]. We aimed to recruit participants from 5 broad groups: consumers, nurses and nurse academics, health care managers, technology vendors, and ethico-legal and psychology academics. Invitations were sent directly to participants via email. As academics, practitioners, and advocates who research extensively in the field, we drew on our networks, as well as "cold-calling" potential participants to meet recruitment targets.

Participants

The 16 participants included 3 mental health consumers, 7 specialized mental health nurses (employed across direct care and academic and policy roles), 2 managers of acute mental health care services, 2 patient monitoring technology vendors, 1 legal academic, and 1 public health academic who specializes in inpatient hospital settings. The research team included a consumer academic, a legal academic, a computing academic who specializes in digital mental health, 2 mental health nurse academic researchers, and a health informatician.

Given that patients are most directly impacted by VAPM, the authors prioritized the recruitment of mental health "consumers," a term used in Australia to refer to someone who has used or continues to use mental health care services. ("Patient" is sometimes used throughout this paper, acknowledging that involuntary patients in mental health inpatient settings do not choose to be there in the sense conveyed by "consumer.") We sought a diversity of consumer perspectives on the topic of VAPM [25], but only 3 were able to attend the workshop, all of whom had served in representative and advocacy roles that required them to understand and articulate the views of diverse consumers. This latter experience enabled them to engage with both the governance and policy dimensions of VAPM and to consider VAPM based on their personal experience of inpatient mental health settings. A total of 7 consumers were invited to participate, all of whom expressed interest, but only 3 of whom were able to make the scheduled workshop.

We also prioritized the recruitment of nurses, given the implications of VAPM for care work. Psychiatrists and health service managers were invited, as they would be expected to make resourcing and care design decisions and interact with VAPM in mental health inpatient settings. Two vendors of VAPM who worked in a private technology company were invited, given technology vendors are involved in the creation, sale, and implementation of these technology types. Several scholars of health law and ethics were invited, but did not reply or could not attend, except for 1 legal academic.

The participants have been coded according to their stakeholder group, which is presented in Table 1.

Ethical Considerations

This study received ethics approval from the University of Melbourne Ethics Committee (reference: 2021-22674-23512-4). All participants provided written and verbal informed consent before participating in the workshop. Participants were informed about the purpose of the study, the nature of their participation, and the intended use of their contributions, including publication of anonymized findings. Participation was voluntary, and participants could decline to answer questions or withdraw from the study prior to publication. To protect participant privacy and confidentiality, all contributions were anonymized, and participants are identified only by participant codes and broad stakeholder groups in the paper. No identifying information is reported. Participants were offered an Aus $50 (US $34.50) honorarium to participate if they were not able to otherwise attend in a professional capacity.

Reflexivity and Researcher Positionality

All authors approached VAPM without settled views and with an exploratory orientation. One author (the legal academic) had previously written about the ethico-legal issues raised by VAPM [17], and the consumer academic's interest in the topic started with experience serving on a health service advisory group that had been asked to share views on VAPM. Reflexivity was addressed through ongoing team discussion, with attention throughout to separating normative concerns about VAPM from faithfully reporting participant accounts. Throughout the analysis, we aimed to let the data guide theme development, while acknowledging that researchers' standpoints shape interpretation and therefore warrant explicit disclosure rather than being glossed over.

Data Collection

The 3-hour workshop was moderated by an independent facilitator, with breakout discussions in small groups facilitated by the 6 authors. The workshop first entailed a plenary session in which members of the research team summarized existing empirical research on the use of the monitoring systems in acute psychiatric settings. Participants were provided information before the workshop, which included a summary of the literature on VAPM. Participants were separated into small groups and asked to share their views. Each group comprised a diverse range of participants (rather than being separated into cohort groups).

The small group discussions were an adapted form of focus group, a method offering rich descriptions by relevant actors of a phenomenon and the context in which it operates [26]. Breakout discussions were facilitated with the aim of offering a neutral, semistructured approach. Facilitators sought to guide the discussion to remain focused on the workshop prompts while refraining from evaluative commentary on the merits of particular viewpoints.

The audio recording of all workshop group discussions was transcribed for analysis. In total, 5.5 hours of audio-recorded data were generated.

Analysis

Analysis proceeded using thematic content analysis to capture broader group-level themes across the data [27], and a descriptive phenomenological method to frame and analyze the subjective, experiential accounts from workshop participants (particularly if they shared personal narratives, which occurred with some consumers and mental health nurses). Descriptive phenomenology takes an interpretivist stance, well-suited to practice-oriented research that seeks to record and understand

XSL•FO
RenderX

participants' lived experience of a phenomenon while suspending researcher assumptions [28].

Four of the coauthors (SD, BH, TK, PG) used a blended approach of inductive and abductive coding [29] to code the workshop transcripts. This was done in person (not using coding software), using printed transcripts, and codes were written on sticky notes before being grouped into themes on a physical whiteboard. Each transcript was read by at least 2 researchers to ensure coding consistency. The research team met to compare interpretations, discuss points of divergence, and refine the developing thematic structure.

Differences in coding were resolved through discussion and consensus. Consistent with a reflexive thematic analysis approach, we did not calculate a formal statistical measure of intercoder reliability. Rather than seeking statistical reproducibility, our aim was analytic rigor through collaborative scrutiny, reflexive dialogue, and iterative theme development.

Quotes were selected to exemplify themes. Participants did not review findings before publication.

We did not aim to achieve thematic saturation in the sense of exhaustively capturing all possible views on VAPM. Rather, the purpose of the workshop was exploratory, designed to elicit and compare the reasoning, concerns, and anticipated benefits articulated by key stakeholder groups and to identify points of convergence and contestation relevant to decisions about VAPM, including whether it ought to be used, and if so, how it should be governed. In qualitative approaches aimed at interpretive thematic analysis and exploratory issue-mapping, "saturation" can be a poor fit where the aim is to illuminate key tensions and meaning-making rather than to enumerate all views [30].

Results

The analysis led to the development of 7 themes, some of which included subthemes. In Table S1 in Multimedia Appendix 1, we provide illustrative quotes for the cross-cutting theme and each major theme and subtheme to convey the findings overall, before summarizing each.

Contestation Over the Rationale for VAPM in Mental Health Settings

A recurring thread across the findings was contestation over the rationale for using VAPM in acute psychiatric settings and its unique implications in the mental health care context. A fundamental tension appeared in the discussion between the utilitarian ambition for enhanced safety and efficiency (often driven by administrators and technology vendors) and what might be described as a relational ethics of care approach, which prioritizes the ethical imperative to protect human dignity, privacy, and the relational essence of care (strongly advocated by consumers and many nurse and academic participants).

A utilitarian account of the technology considers its potential as a versatile tool that provides an "additional layer" of monitoring and "visibility" (Participant 10) in scenarios where continuous human observation is not feasible. From this view, the technology has the capacity, principally, to enhance patient safety, reduce physical disruptions, and provide valuable operational support to clinical staff. Those sympathetic to this view highlighted its potential utility in proactively identifying disturbed sleep patterns, detecting medical emergencies, and enhancing safety measures against potential harm from other consumers or staff—and thus viewed it as potentially amenable to ethical and high-quality care. From this view, VAPM can support and extend the reach of clinical care, particularly when direct physical presence is limited.

However, most participants focused on the potential negative effects of VAPM. Some—particularly the consumers—expressed profound concerns that it represents a dehumanizing, intrusive, and potentially harmful form of surveillance that undermines the core principles of high-quality, contemporary mental health care. Key aspects of this account include invasion of privacy, exacerbation of distress, erosion of trust and therapeutic relationship, potential for misuse and lack of agency, and complacency and deskilling of staff. Consumer participants with this view expressed a profound rejection of the technology in patient bedrooms.

These 2 broad accounts seemed to be underpinned by differing accounts of the ways in which the mental health care context was seen as unique compared to other areas of medicine. Most participants, particularly consumers and nurses, queried whether a tool primarily designed for physiological monitoring would align with the distinct needs and expectations of mental health care, where therapeutic engagement and trust are paramount. For example, one consumer said:

> *There's no electronic monitoring that will tell you that my hope was just crushed [...] The only way you can know that we're thinking and feeling that is to talk with us and listen to us.* [Participant 2]

A nurse (Participant 4) felt the proposal aligns with an "overly restrictive non-therapeutic program" and moves away from "strengths-based consumer-led models of care."

In contrast, a hospital manager (Participant 15) raised a comparison with general intensive care units, noting that in physical hospital care settings, staff "don't blink an eye" at monitoring physiological data. He added, "[a]s a rule, we've never had that facility in our ICU settings" within mental health, implicitly suggesting that the disparity in technological monitoring between the 2 creates a disparity in the safety and quality of care. Here, mental health care was viewed as different because it did not have parity of care with general health, which VAPM could help remedy.

All participants acknowledged the potential for coercion in public psychiatric hospital units, with several participants noting that this technology will have unique implications, given that patients or consumers are already significantly disempowered and monitored in (often locked) mental health care contexts.

VAPM Will Reshape Care and Relationships

Overview

An overarching theme among participants was the impact of VAPM on care and the people who give and receive it. Most participants expressed a concern with the potentially

XSL•FO
RenderX

dehumanizing impact of monitoring and surveilling people's bodies for "signs" and movements, instead of asking people about their distress or checking on them face-to-face. The extent to which VAPM was indeed viewed in this way varied in three ways, between (1) those who felt certain it was dehumanizing, (2) those who felt it potentially dehumanized but that more detail was required alongside consideration of potential benefits, and (3) those who felt it was a potentially exciting opportunity to transform care, and indeed to "rehumanize" care by freeing up care professionals' time for more valuable face-to-face care.

VAPM May Dehumanize Care Depending on How It Is Used

Participants raised competing concerns about whether VAPM would support or undermine care.

In total, 3 participants expressly described VAPM as "dehumanising" (Participant 2, Participant 4, and Participant 13). One participant said it felt "grotesque" and "the complete opposite direction that we should be heading for good care" (Participant 2). Such accounts conveyed not only fear of misuse but also anger at the idea that replacing observation with surveillance contradicts the relational ethos of mental health practice. Participants also worried that remote viewing could reduce therapeutic contact and intensify privacy intrusion; during in-person monitoring, a patient could at least know when they are being observed, unlike remote continuous monitoring.

Concerns extended beyond consumers to staff. One nurse warned that VAPM may be "dehumanising for the person you're serving, but also the workforce" (Participant 4), moving practice away from strengths-based and consumer-led approaches. For these participants, the possibility that biometric monitoring could detect crises did not outweigh the loss of direct contact, trust, and the complex facets of human care.

VAPM Could Humanize Care by Creating More Time for It

Some participants suggested that VAPM could actually create conditions for more humanized care. By automating routine and time-consuming observation tasks, the technology was seen as potentially freeing staff to focus on therapeutic interaction. A nurse academic explained that much of the current workload "is really not about actually caring for the person," but if monitoring was managed by technology, staff could "use our time and resources to actually support the person in a more therapeutic way" (Participant 14). This was echoed in specific clinical contexts, such as eating disorder units, where constant physical checks can be disruptive; VAPM was imagined as a way to reduce unnecessary physical intrusion while still safeguarding health.

Others envisioned VAPM as a "backup" safety mechanism that might enable staff to spend more time present on the ward. A hospital manager (Participant 3) linked this possibility to wider efforts to design units that keep staff "out there with the consumers" rather than tied to nursing stations. In this framing, the technology could reduce the burden of repetitive checks while fostering closer interaction, more group activity, and ultimately safer environments by reducing suicides (discussed in the VAPM as Observational Support for Safety and Reduced Disruption section). These perspectives framed VAPM not as a substitute for relational care, but as a tool that might support and expand it, if used judiciously.

Consent to Being Monitored

Some participants proposed that VAPM could be made more acceptable—and thus more "humanizing"—through a clear consent process, giving patients the choice to opt in or out depending on their needs. A nursing academic (Participant 12) suggested that for some, the technology might be preferable to the disruption of in-person checks during the night, allowing people to choose "what's going to be better for me." In this framing, VAPM could be a tool of choice, reducing intrusive physical monitoring and supporting therapeutic rest where it aligned with a consumer's comfort and sense of safety.

Yet, these proposals for consent were met with significant skepticism and distrust by some. Consumers worried that promises of choice would not be honored in practice: one participant doubted whether the system would truly be switched off if they declined and feared it could be misused by staff, undermining any sense of agency (Participant 2). Others warned that systemic pressures, such as staff shortages, could lead to VAPM becoming a default, regardless of individual wishes (Participant 11 and Participant 4).

Contestation also arose over whether consent requirements should differ from current observation practices, with a vendor questioning why AI monitoring should need explicit permission when in-person night checks do not (Participant 10). Nurses responded that, unlike a glance through the door, VAPM automatically records physiological data, which in other contexts would require active consent for a patient with capacity (Participant 12). For one nurse academic, the idea that VAPM should be installed so there was "no way of avoiding it," and that this could be presented as a "selling point" was described as "very disturbing" (Participant 9). Taken together, these perspectives highlight potential issues with relying on consent as a bridge to acceptability in inpatient settings, where structural constraints and fears of surveillance may undermine aspirations for genuine choice. The distinct privacy implications of VAPM (including 'privacy of place' and 'privacy of data') are addressed in the section "VAPM Has Serious Privacy Implications."

Perceived Harms of VAPM

There was broad agreement that VAPM could cause harm, though participants differed on the extent of this harm and how it compared to potential benefits. Consumer participants, along with several nurses, voiced the strongest reservations. For some, the concern was visceral: Participant 5, a public health academic who specializes in researching inpatient settings, described her "gut" as:

> *really uncomfortable ... if I was in that position, I wouldn't like it. I wouldn't like the experience of having a video camera in a place where I was sleeping.*

Nurses also expressed apprehension, with Participant 4 warning of "human rights and ethical considerations and safety," a theme echoed by others.

XSL•FO
RenderX

Several participants argued that VAPM could in fact undermine, rather than enhance, safety. One consumer explained:

> *I'd be trying to hit it with the chair, put water on it to anything I could to damage it because I'd be I'd feel really unsafe from it. The more distressed I was, the more I'd feel like that.* [Participant 2]

She added that surveillance might not stop self-harm, but simply shift it elsewhere: "if there's monitoring in the bedroom, then I'd self-injure on the toilet, you know." A nurse (Participant 13) cautioned that the technology could encourage "complacency" among staff, reducing engagement on the assumption that safety was assured. One of the vendors (Participant 1) acknowledged the same risk, noting that staff might fall into a "false sense of security" and miss critical issues.

Participants also highlighted the possibility of secondary and longer-term harms. Participant 7, a consumer, warned, "If I went into a ward that had these in every single bedroom, I'd probably flip lid." Both consumers and nurses suggested that VAPM could "exacerbate paranoia" (Participant 7), "play into ... someone's mental state" (Participant 1, technology vendor), or worsen anxiety. The technology was also described by two participants as potentially retraumatizing (Participant 12 and Participant 13), particularly for people with experiences of domestic violence in which surveillance had been used as a tool of abuse. Others raised concerns that awareness of such monitoring might deter people from seeking help in services where VAPM is in place. Some participants thus framed privacy intrusion as a harm in itself and a source of distress and mistrust. Detailed privacy implications (privacy of place and privacy of data) are addressed in theme "VAPM has serious privacy implications."

VAPM as Observational Support for Safety and Reduced Disruption

Participants who saw potential benefits framed VAPM as a way to support observation in two related ways: (1) risk detection or prevention and (2) less disruptive routine checks, especially overnight. Comments included that the monitoring offers an "exciting opportunity if it's used well" (Participant 14), provides an "opportunity to augment our care" and "prevent deaths" (Participant 15), and helps provide "continuous monitoring ... [and] constant data feeding back" (Participant 13).

Preventing Rare but Severe Adverse Events

Some participants argued that VAPM could add an extra layer of visibility to help detect and prevent rare but serious events, including suicide, sexual assault, or medical deterioration. Participant 15 (hospital manager) stated that although rare, deaths in hospitals "do occur frequently enough" and said his "primary concern is always the safety of the consumers or patients":

> *some of our patients unfortunately pass away in the middle of the night ... And of course, the other issue is the suicide risk, in the night. So the extent that this technology may help us manage prevent deaths, I think that's an important consideration.*

Participant 13 (nurse) highlighted the importance of mitigating interpersonal risks, particularly for vulnerable consumers, stressing the need for "sexual safety" and "being able to ensure that there's not a person entering another person's bedroom. I feel like that would offer significant reassurance to particularly our female consumers."

Physical health monitoring was seen as potentially beneficial when predicting, preventing, or responding to someone having a physical medical episode (eg, a stroke, fall, or asthma attack) or attempting suicide. Participant 15 (hospital manager) explicitly mentioned preventing deaths from issues like respiratory depression and managing suicide risk at night as key concerns occupying his mind, stating that "[a]s a clinician, this is what makes me deeply uncomfortable and I think this is an opportunity to augment our care."

Reducing Disruption From Routine Observation

Others focused on using VAPM to reduce sleep disruption and intrusive checks while still supporting physical monitoring. Participant 16 (nurse academic) noted that consumers frequently comment about the "very untherapeutic environment that nighttime [routine observations of every consumer] have on people and that disruption to sleep" and invasion of privacy, suggesting that the technology could offer "some positive aspects to that." Participant 13 (nurse) said that "lack of overnight disruption would be great, too." Participant 12 (nurse) agreed and described current night checks as "terrible," recalling that staff "always feel really bad" about waking patients up and shining a torch on them.

VAPM Has Serious Privacy Implications

Most participants raised concerns about intrusions on privacy. Participants distinguished between privacy of place—bedrooms and other intimate spaces—and privacy of data—the capture, storage, access, and potential secondary uses of video and physiological information.

Privacy of Place: VAPM Reshaping Privacy in Intimate Spaces

It is accepted that patients within inpatient mental health settings are subject to significant observation, even to the extent that observation is the primary objective of some hospital admissions. However, participants viewed VAPM as enabling observation of a different nature and scale, with heightened risks of intrusion and misinterpretation.

A participant warned that VAPM could intrude on "a personal moment" (Participant 8, nurse) and "a private intimate moment" (Participant 9, consumer), such as masturbation or other personal activities. Without control over when monitoring occurs, observation becomes constant and intrusive, and misinterpretation of what is seen could negatively affect the care someone receives.

Participant 15 (hospital manager) suggested that privacy and confidentiality risks could be mitigated by limiting the visual detail available to staff, for example, by displaying only a "pixelated body form" (sometimes referred to as a "point cloud") rather than a live video feed or detailed image of a person

XSL•FO
RenderX

"sleeping or going to the toilet or whatever and doing something private."

Privacy of Data: Handling, Retention, and Secondary Use

Concerns about data handling, storage, accessibility, and the eventual use of the generated consumer data were widely discussed among participants, demonstrating apprehension closely related to privacy and surveillance. Consumers expressed fears about how information could be retained and later misused, with one saying "[W]e hear lots of examples of from consumers of incidences from 10, 15 years ago being brought up now ... that affects their treatment now" (Participant 8) and querying whether that might occur with data collected by VAPM. Others questioned whether routine physiological data collected through VAPM would become part of a person's permanent medical record, with implications for how future admissions or treatments might be judged.

Nurses and consumers raised uncertainties about where and how the data would be used and stored, including whether it could be subpoenaed or whether it might be used in staff performance management, likening the situation to "police walking around with our cameras on" (Participant 9). Beyond immediate clinical settings, participants worried about the commodification of data, even in deidentified form. As one consumer academic put it, such datasets could be sold or repurposed to create behavioral profiles, with the risk of reinforcing surveillance and targeting of certain groups (Participant 11). Together, whether these perceptions were correct or not, these sentiments reflect concerns about how data generated by VAPM may pose risks not only for individual privacy but also for equity, trust, and the long-term integrity of mental health care.

VAPM Requires Appropriate Governance

Procedures and Guidelines to Support Use of VAPM

Most participants emphasized the importance of carefully developed guidance and rules on use, should a VAPM trial proceed. A nursing academic described the need for "strict guidelines necessary on how it supplements care rather than replacing care," which "would need to be really clear [as to] the expectations on staff on how it was to be used appropriately" (Participant 16). Concerns were also raised about responsibility in the event of a critical incident. A consumer (Participant 11), who had a legal background, noted that good "regulation and governance" must be in place, as these new technologies "stretch the existing structures that we have" and may even create liability under legal obligations that require a certain standard of care (evaluating the accuracy of this claim is outside the scope of this paper). A hospital manager described the need for a "fairly robust procedural implementation process to make sure that people's concerns were addressed" (Participant 15).

Legal and clinical participants worried that because the technology is proprietary, its inner workings would remain opaque, preventing proper scrutiny or challenge. Participant 6 (lawyer) noted that descriptions of the technology seem to be "always really vague." She questioned the nature of the AI and algorithm behind VAPM, stating that the inner workings of privately developed technologies more generally, which are sold to health services, are:

> *not explained because it's proprietary. Someone owns it and so on, which then makes it even harder to kind of scrutinise, let alone to kind of challenge if something goes wrong.*

Liability was thus not only understood in terms of potential harm in individual cases, but also as matters of organizational governance and responsibility: managing sensitive data appropriately, ensuring adherence to staff protocols, establishing private sector accountability mechanisms, and safeguarding the human rights of vulnerable consumers. Participants also questioned who would authorize the technology, how it would fit within established models of care, and whether it would support or displace existing clinical practice. No clear answers emerged, but several participants emphasized that such technologies should ultimately support, rather than replace, the work of health care professionals.

Safeguards in the Adoption of VAPM

Participants who supported trialing VAPM generally agreed on the need for safeguards. Proposed safeguards included clear guidelines for use, technological modifications to protect privacy, meaningful consent processes, and, in Australian jurisdictions with human rights legislation, ensuring that VAPM is "assessed [as to] it's human rights compliance" (Participant 11). Several agreed that additional "pilot" studies would be needed to test claims being made about the technology. One nurse raised the point that she would want to learn from "a mental health unit that's using it, [in which] people have responded, [and in which] their experiences are positive" (Participant 4).

Is VAPM a Technological Solution to the Wrong Problem?

One consumer described VAPM as:

> *a solution to problems that shouldn't have existed to begin with. That's kind of, I think where I'm sitting, we're providing solutions to problems that just shouldn't be problems.* [Participant 7]

She elaborated by stating:

> *Oh, you won't be getting a light shone in your eyes every 15 minutes. That's that sounds amazing—but can't we just stop doing it anyway?*

This encapsulated a critique of the plan to rely on technology to fix issues that stem from what they view as poor clinical practice or systemic failures. Another consumer, who was trained as a nurse, noted that nurses do not need to shine a torch in someone's eyes; she was taught to "shine the torch on the roof of the ceiling and you get an ambient light that that gives you enough to actually read obs, but not disturb the patient" (Participant 8). This concern relates to the earlier point, raised by consumer participants, that VAPM bypasses the need for genuine, therapeutic human interaction, which is the foundational element of mental health care.

XSL•FO
RenderX

Confusion Over the Specifics of VAPM

Most participants identified several aspects of VAPM that they felt were unclear, and several questions they would want answered before forming a view of the technology and its likely impact on the service system in which it would be used.

Because the workshop was held in a national context where VAPM had not been used, participants were not assessing a single, fully specified VAPM system. Limited technical detail about system configuration, performance (eg, false alarms), data flows, access controls, data retention, and workflow integration influenced how participants responded. Given the speculative nature of the discussion, participants had to reason from general principles, such as privacy and dignity, and draw analogies with other care contexts, such as in-person monitoring. At the same time, this uncertainty was itself salient to participants and contributed to the strong emphasis on transparency, independent evaluation, and governance safeguards as prerequisites for any trial or adoption.

Participant 6 worried that if the training datasets for the AI were biased (intentionally or unintentionally), the technology might be "more accurate for some people" than others (eg, men more than women), information which staff would not know because the workings are proprietary. Participant 3, the hospital manager whose service was considering this technology, stated that a key goal of their planned pilot was to determine if the technology was actually "going to be able to deliver what it can from an alerting perspective"—a matter which was unknown. Participant 9 (nurse academic) suggested that evidence would be needed to determine whether VAPM kept nurses "in the nurses station more and [on] the floor less," and questioned whether monitoring would be restricted to nighttime use or applied more broadly. Participant 7 (consumer) questioned if it would be used only for a "couple of beds" or for the "whole ward."

For most participants, therefore, views on the appropriateness of the technology in acute psychiatric care hinged on unresolved questions about the empirical basis for the technology, its scope and functionality, and questions about how it would be governed, such as what procedures were in place to protect patient privacy and prevent misuse.

VAPM Has the Potential to Transform Not Just Augment Service Delivery

The potential service transformation created by the use of this sociotechnical system was another theme in the workshop, which the researchers subdivided into 3 themes: function creep, cost minimization and corporatization, and confusion about unresolved evidentiary and governance matters.

Risk of VAPM Function Creep

Some participants worried that the monitoring scope would quickly expand from passive overnight checks in some rooms to encompass day shifts, hallways, and potentially all consumer and patient rooms, eroding privacy and human interaction. Participant 8 (consumer) described a "slippery slope" in which allowing VAPM in some rooms today would mean "eventually they'll just be in every room," to the point "we stop having any interaction, any sort of relational space between clinical staff and the consumers." A hospital manager (Participant 15) described the reality of function creep in health systems generally: "[t]he way systems work, the way organisations work, these things just happen without people thinking about it properly and putting the correct controls in place."

VAPM as a Form of Cost Minimization and Privatization

A recurring fear by some participants was that VAPM would be used as a cost-cutting measure rather than a tool to improve care, with some participants concerned that it would justify a push for nurses to take on larger numbers of patients or consumers. Some participants worried that, in a risk-averse system with finance as a major driver, the technology might provide what a public health researcher described as "just... an excuse to reduce staff numbers to actually do things that will undermine the system improving, not actually support improvements" (Participant 5). A nursing academic (Participant 14) who supported its use in certain circumstances, similarly cautioned that it could be "used as an excuse to reduce the nursing resource and also that human interaction between nurses and consumers." A broader concern was raised by Participant 11 about the role of the private technology sector in the development of health care technologies used in public health settings.

Discussion

Principal Findings

This study used a workshop with a range of key stakeholders to explore the potential implications of VAPM in acute psychiatric settings. The findings provide key insights into the impact VAPM might have, primarily for patients or consumers and nurses.

VAPM raised issues that sit within broader debates about surveillance technologies in health care, which are often justified in terms of safety and efficiency but raise concerns about consent, privacy, data governance, and the impact of monitoring on trust and therapeutic relationships [31]. Our findings reflect these tensions in a mental health inpatient context, highlighting how anticipated benefits are entangled with concerns about intrusion, misuse, and the conditions required for legitimate and acceptable use.

Participants who saw potential benefits emphasized patient safety and care efficiency, but these were framed tentatively and with caution, as potential benefits. Some tension emerged between groups: hospital managers and technologists broadly supported its testing and development; nurses and consumers varied somewhat but generally viewed VAPM negatively, with some qualifications. Most consumer participants were of the view that VAPM should be rejected, following its characterization as a form of intrusive surveillance that dehumanized patients and those who were supposed to care for them (for a similar viewpoint in the literature, see Powell et al [7]). Some participants, particularly nurses, saw potential use in specific circumstances and only if there was compelling empirical evidence to support its use, and ideally with patient consent. Most consumer and nursing participants articulated

XSL•FO
RenderX

the view that the technology risked undermining nursing practice by replacing nursing functions and limiting the ability of nurses to develop therapeutic relationships. Across groups, the lack of robust pilot studies was a recurring concern, leaving many participants hesitant to endorse the technology, while its strongest critics rejected the premise of its use altogether.

These findings could be used to argue that these technologies should not be adopted due to the risks they pose to the privacy and dignity of patients. Alternatively, they could also be used to inform the design and implementation of these technologies to ensure that the sociotechnical system of VAPMs contributes not only to clinical and management outcomes but also to dignity, experience, and privacy outcomes for patients.

Regarding therapeutic interaction, participants were clear that VAPM should not replace human care. Nurses acknowledged the value of reducing intrusive overnight checks but emphasized that fewer face-to-face interactions might also limit opportunities for rapport and engagement. Although some were cautiously open to exploring alternatives that would minimize sleep disruption, nurses and consumers wanted clarity about how the technology would be used, how privacy would be safeguarded, and how such matters would be communicated to patients. Participants alluded to the cost minimization objective seeming to butt up against claims that VAPM would be an adjunct to—rather than replacement of—face-to-face care, echoing the observation of Griffiths et al [14] that "it is unclear how this adjunctive role is envisioned alongside the stated aim of cost reduction." These concerns were often expressed by participants who explicitly or tacitly seemed to acknowledge that consumers and frontline staff are rarely the ultimate decision-makers in mental health hospitals.

In relation to privacy, VAPM was described as potentially less invasive if used in ways that reduce human intrusion and rely on abstracted physiological data rather than live video streams. From this view, VAPM could enhance care without reproducing the direct visual surveillance of closed-circuit television. However, participants cautioned that whether or not video feeds were actively viewed might matter little to patients, whose perceptions or experience of constant monitoring would still be experienced as intrusive.

Consent was a further complication, and our findings highlight challenges to individual autonomy, particularly within the coercive context of involuntary inpatient care. Some participants' skepticism about opt-out arrangements and the fear that monitoring would continue regardless of refusal suggests that consent is, at best, a partial safeguard for VAPM in these settings. Consent processes may improve acceptability for some (particularly where monitoring is time-limited and genuinely optional), but they cannot be relied on as the primary ethical justification for deployment.

While some argued for an opt-in process, others noted that in mental health inpatient settings, where involuntary psychiatric intervention is common [32], it is unclear whether genuine consent for VAPM will be possible in some cases or legally required. Legal status does not map neatly onto decision-making capacity, which may fluctuate, but the conditions of admission, power imbalance, and role of risk-aversion in services could make refusal difficult in practice. Furthermore, opting out may not necessarily be respected or even feasible in a resource-constrained system. Gooding and Clifford [17] have even queried (tentatively) whether VAPM in mental health inpatient settings would conform with current law in some Australian jurisdictions, particularly if video is used. In the United Kingdom, the nongovernment organization Rethink Mental Illness argues that in addition to being required to meet medical-device regulatory requirements, VAPM should be conceptualized as "a form of restrictive practice that breaches people's rights, with potential short and longer-term effects on people" [33]. These considerations also suggest that VAPM may (inadvertently) facilitate algorithmic paternalism [34], where algorithmic risk-management overrides a patient's agency or autonomy under the guise of safety. An individual's lack of agency over data captured from their most private moments, such as sleep or personal activities, may represent a fundamental breach of dignity that cannot be solved by a simple opt-in or opt-out checkbox. These concerns suggest that consent is, at best, a partial safeguard for VAPM in these settings. Consent processes may improve acceptability for some (particularly where monitoring is time-limited and genuinely optional), but they cannot be relied on as the primary ethical justification for deployment.

Uncertainty on matters of regulation and governance among the participants suggested that considerable planning and oversight would be needed before monitoring systems were trialed or adopted. Participants seemed to stress (and we agree) that any plans for implementation must go beyond minimum legal requirements to include consideration of social or ethical acceptance and perceived benefit among those most affected. On a related note, VAPM illustrates the insufficiency of perceived usefulness and perceived ease of use, the 2 pillars of the original technology acceptance model, which is used to explain whether, how, and why users adopt or reject a new technology [35]. Technology acceptance, particularly in health care, is not just about individual perceptions of usefulness and ease of use, but also about trust, perceived risk, and the social context in which the technology is introduced.

Again, such perspectives on implementation diverged along stakeholder lines. Consumers and nurses, whose daily experiences would be most directly affected, tended to be skeptical or resistant. They saw risks to therapeutic relationships and to their sense of agency and privacy. Technology vendors, by contrast, sought to promote their products by identifying problems to solve, and managers focused on organizational priorities rather than the details of nursing practice. Such contrasts highlight the importance of recognizing not only official intentions for new technologies but also the way they are interpreted and taken up.

On this latter point, there is some evidence from research on electronic health records that perceptions strongly shape adoption, where early concerns by stakeholders with electronic health records continued to influence professional practice long after implementation [36]. Management and technology providers may communicate their intention for a technology, but it is the users' interpretation of the technology that plays a key role in how it is used and whether it is used as planned or

XSL•FO
RenderX

not. Here, "users" are ostensibly nurses and other health practitioners at the ward level and could potentially extend to patients or consumers, though "users" seem an unsatisfactory description of this group. (On this latter point, Boetto [37] raises concerns in social care contexts that "end users" of AI are often envisaged as policymakers, managers, and practitioners, but not the service users who will ultimately experience its impacts and are best placed to identify risks and benefits.) Regardless, early perceptions such as those identified in this study can help us understand how end users and those affected will use and engage with the technology if implemented.

The theory of contextual integrity [38] may offer a useful lens for these concerns. Privacy, on this view, is defined by the appropriate flow of information within a specific context. What is appropriate is defined by context-specific information norms. Information norms that guide appropriate information flow can be mapped using the 5 parameters of actors (sender, receiver, and subject), information type, and transmission principle (which are constraints on information flow, such as consent). VAPM challenges established norms across several of these parameters by enabling more extensive data collection (eg, continuous rather than occasional checks), involving more actors (beyond the nurse at the door), and removing established principles of reciprocity and warning (patients can no longer see or hear when they are being observed). These shifts raise questions about whether such information flows are justified by reference to contextual values and whether less intrusive alternatives might achieve the same ends. Nissenbaum [39] suggests that, even where new technologies breach existing information norms, consideration should be given to whether the new information flows introduced by the technology serve the interests of different stakeholders, and whether they align with the ethical and political values of the specific context. Such an evaluation may result in breaches of existing information flows being viewed as justified. In mental health care, this question of alignment is especially difficult because ethical and political values are contested, particularly in inpatient settings involving involuntary psychiatric intervention, where competing views persist about whether risk and safety management should take precedence over the choices and rights of service users.

Applying contextual integrity also points toward possible design modifications. For instance, proactive notifications could alert patients when monitoring is active, or monitoring could be restricted to times when patients are asleep, thereby reducing unnecessary intrusion. Patients might also be given access to the data collected, for example, via a display screen. Such features potentially mitigate some of the privacy concerns raised in this study and afford patients a degree of control.

The erosion of digital trust [40] identified by participants is linked to the violation of contextual integrity. Trust in a mental health setting is built on the expectation that information remains within the boundaries of the clinician-patient relationship. VAPM challenges these established norms by involving new, often invisible actors, such as third-party technology vendors and data analysts. This in turn raises concerns about function creep and the commodification of patient data, that data collected for safety monitoring might eventually be used for purposes such as staff performance management or sold to create behavioral profiles. Establishing digital trust in VAPM, therefore, requires more than technical accuracy; it demands algorithmic accountability and transparent data stewardship that ensures information flows remain aligned with the ethical values of the psychiatric context.

Finally, there remains the question of how VAPM affects mental health itself. Paranoia and persecutory beliefs are common among people admitted to mental health inpatient settings [41], with evidence suggesting more than 70% of patients at first-episode psychosis experiencing some form of persecutory delusion [42]. Early evidence suggests that surveillance technologies may heighten such fears for some patients who have reported concerns that devices could "emit damaging rays" or "control them" [9], notwithstanding the potential benefits noted earlier. Future research is needed to assess whether purported benefits outweigh the potential negative psychological impacts of VAPM in these contexts.

Implications for Policy and Practice

The findings of this study raise serious issues for future research, policy, and practice, which we summarize in Textbox 1.

Textbox 1. Recommended steps for hospital managers, policymakers, and so on.

- Start with an appraisal decision, not implementation: use structured deliberative processes (like this workshop) to decide whether video-algorithmic patient monitoring is appropriate in particular inpatient mental health settings.
- Define the "nonnegotiables" up front: identify minimum requirements relating to dignity, privacy, trust, and therapeutic relationships that must be met before video-algorithmic patient monitoring can be considered.
- Specify the proposed system and use-case before any decision: clarify what is being deployed (video vs abstracted data, alerting functions, where or when used, and who can access) so stakeholders are not evaluating an undefined intervention.
- Require independent evidence as a precondition: treat claims about safety, efficiency, and cost as provisional unless supported by independent, publicly available evaluation.
- Assess consent feasibility in involuntary contexts: determine whether meaningful consent or opt-out is possible in practice; if not, treat this as a major barrier requiring a higher threshold of justification.
- If proceeding, set governance first: establish binding rules on purpose limitation, oversight and accountability, transparency, data handling or retention, auditability, and safeguards against misuse and function creep, with meaningful consumer participation.

We elaborate on 3 points here.

First, given the contested and still limited evidence base, the findings support the need for independent, coproduced research

XSL•FO
RenderX

that examines both the effects of VAPM and the conditions under which it might be regarded as legitimate and acceptable. Participants consistently questioned whether claimed benefits would be realized in practice, or whether they would be offset by risks to privacy, dignity, and therapeutic relationships. Independent, high-quality research that centers lived experience perspectives alongside frontline staff perspectives is therefore critical for informing any decision to proceed. Where VAPM is already in use, such evaluations should examine uptake across contexts, impacts on professional practice and ward culture, and the experiences of patients or consumers and staff. If a trial is contemplated, it should be treated as a research activity with transparent protocols and publicly reported outcomes, rather than a step toward routine adoption.

Second, participants made clear that decisions cannot be made about an ill-defined intervention. To reduce confusion and enable informed appraisal, any proposal to use VAPM should be accompanied by a clear description of the system and use-case: whether monitoring relies on video or abstracted data; when and where it is active (eg, selected beds vs whole wards and night-time vs broader use); measurable outcomes (eg, reducing false alerts, patient safety metrics, trust levels, incident reduction, and staff time spent with patients); who can access what information; and how data are stored, retained, and governed.

Processes for avoiding concerns about conflicts of interest must be clear [43]. On this latter point, one of the post-2021 studies reporting reduced self-harm following implementation was subsequently retracted [43]. While the retraction relates to an omitted conflict-of-interest declaration rather than an adjudicated finding of data error, it nonetheless highlights fragility in the VAPM evidence base and reinforces the importance of transparent disclosure and independent evaluation. As such, a transparent evaluation plan should be put in place to determine the accuracy of the technology and its impact on staff behavior, with results made public before any wider roll-out. By providing this clarity to all key groups, services can directly address the questions raised by staff, managers, and consumers in this study.

Finally, if VAPM is to be pursued, we would suggest that governance is established before implementation and should be guided by clear and collaboratively developed standards. Participants' concerns point to the need for standards on purpose limitation, oversight and accountability, consent and choice (including how these operate in involuntary settings), auditability, and safeguards against function creep and secondary uses (including performance management). Policymakers and hospital administrators may wish to draw on participatory governance and co-design models used in digital mental health, including standing lived-experience advisory groups, coproduced implementation planning, and deliberative panels used to set acceptable data practices and safeguards [44-46]. Examples include Australia's National Digital Mental Health Standards, which includes a "Consumer Partnership Principle" requiring service-user partnership across the planning, design, delivery, measurement, review, and evaluation of services [44], which can be adopted through practices like sustained lived-experience advisory groups that shape design and implementation over time [47].

Strengths and Limitations

The strength of this study included the relatively diverse sample. This mix of participants—consumers, mental health nurses, health managers, and technology vendors—increased the diversity of views and minimized the risk of a single perspective dominating. Another strength was the coproduction process whereby the workshop was coplanned, co-designed, and coproduced with traditional academics and a consumer academic. This study appears to be the only empirical study on VAPM in mental health settings with consumer academic leadership and which provided for consumers to be equally important contributors to understanding the social, ethical, and legal implications of the technology. Finally, it could be considered a strength that this is an independent academic study with no vested interests, unlike most studies in the field (for an overview, see Griffiths et al [14]).

One limitation, regarding diverse consumer perspectives, is that we recruited only 3 consumers. Recruitment was constrained primarily by scheduling. Although additional consumers were invited to participate, they were not available at the workshop time. The 3 consumer participants had extensive experience in consumer advocacy roles, which may be associated with higher confidence in formal deliberation, greater familiarity with service systems and rights-based discourse, and an ability to articulate concerns in more conceptual terms than may be the case for others. Accordingly, the findings should not be treated as representative of the broader service user population, and the consumer accounts should be read as informed perspectives rather than a cross-section of typical inpatient views. However, our aim was exploratory: to elicit and compare stakeholder reasoning about the acceptability and implications of VAPM. On that basis, the consumer contributions were substantively valuable, foregrounding how privacy, coercion, dignity, and trust may be experienced and reasoned about in relation to VAPM. We do not claim statistical generalizability; instead, the findings offer analytic insights and issues for governance and practice that should be tested in future research with larger and more diverse consumer samples.

Purposive sampling was used, which supported a somewhat diverse sample but left the potential to amplify the authors' biases, given the sample was effectively determined by author networks. Author positions may have influenced the framing of questions and interpretation. To mitigate this, we used reflexive practices across the study (including explicit efforts to set aside normative claims and a commitment to grounding themes in participants' accounts and illustrative quotations). Nonetheless, positionality cannot be eliminated in qualitative research; hence, we have sought to make it transparent so readers can assess how the team's perspectives may have shaped the analysis. The potential to amplify bias is somewhat offset by the consistency of the study aims (an exploratory study of viewpoints among people most likely to be impacted by the introduction of a technology), criteria (participants belonging to the main groups impacted), and epistemological basis of the research (valuing the qualitative input of those most affected in generating knowledge).

XSL•FO
RenderX

Response bias is a limitation. In this mixed-stakeholder deliberative workshop, participants may have tempered comments due to social desirability, professional norms around safety, or the presence of managers (in the case of nurses) or vendors. We mitigated this through independent moderation, neutral semistructured facilitation, and options for anonymous reporting, but some more critical or personal views may nonetheless be understated.

A further limitation is the time lag between data collection (December 2021) and publication. In the intervening period, the VAPM landscape—particularly in the United Kingdom—has evolved, with additional service evaluations and reviews published and wider use reported in some NHS mental health settings. There has also been increased public scrutiny and organized opposition, alongside policy attention, including an NHS-commissioned evidence review and work toward national guidance on vision-based monitoring. These developments mean that some issues raised in our workshop (eg, potential efficiency gains overnight) can now be compared against a larger, albeit still limited, evidence base, while other concerns (privacy, consent, dignity, and trust) remain live and contested in implementation debates.

As such, the study was somewhat hampered by the lack of empirical research at the time of the workshops, which had evaluated VAPM on its own terms, meaning that claims about its appropriateness could not be contrasted with claims about efficacy. Nor could we invite people who had encountered VAPM in the mental health care context, whether as patients, nurses, or hospital managers, given that it has not been trialed in Australian mental health inpatient settings to our knowledge, making the discussion largely hypothetical without the benefit of a specific VAPM definition or configuration for these inpatient settings. On the other hand, what this study suggests is that before technical development or empirical testing even takes place, the perspectives—if not leadership—of consumers and those working in mental health settings on the proposal should be sought.

Nevertheless, the workshop provided a valuable forum for persons likely to be impacted by VAPM to voice their views. There is value in deliberative input in the early stages of technology adoption or experimentation, particularly sociotechnical systems like VAPM. Our approach potentially offers a template for health services and researchers seeking to test views on proposed technologies, including for the purposes of risk mitigation, social acceptance, and safety.

Conclusions and Future Research

This study highlights the considerable uncertainty surrounding the anticipated use of VAPM in mental health inpatient settings. Currently, anticipated risks are primarily articulated as subjective, as potential interference with privacy, dignity, and trust, while the claimed benefits lack robust and independent evaluation. Ethical and practical concerns voiced by consumers and frontline staff suggest that wide adoption would be premature, and some accounts that tend toward an ethics of care approach rejected the entire premise of VAPM. Any future trials must clearly define the technology's purpose and mechanisms and be independently evaluated against not only safety and efficiency claims but also impacts on dignity, privacy, and therapeutic relationships. If VAPM is trialed, the findings of this study could inform both the technology configuration and model of care in which it is implemented. Crucially, research must be coproduced with those most directly affected—both staff and consumers, but particularly the latter, we would argue—to ensure that the technology serves the people it is intended to benefit.

Acknowledgments

The authors wish to thank the participants who took their time to be a part of this research. The authors would also like to thank Rusty Benson for his assistance as the independent facilitator who hosted the workshop.

Funding

This work was funded through a grant from the Centre for AI and Digital Ethics, University of Melbourne. PG acknowledges support for his contribution from the Australian Research Council (DE200100483).

Conflicts of Interest

None declared.

Abstract

Background: The risk of rehospitalization in patients with heart failure (HF) has initiated various efforts to prevent and simultaneously improve quality of life. Self-monitoring at home is one option, and technology is increasingly being used for this purpose.

Objective: This pilot study aimed to evaluate the feasibility and preliminary effects of a digital home monitoring intervention on patient-reported outcomes and 30-day readmissions among patients with HF in Indonesia.

Methods: A mixed methods pilot study was conducted, combining qualitative system development and quantitative evaluation. Patients were assigned to an intervention group (digital monitoring) or control group (standard care). Readmission rates were compared using chi-square tests and odds ratios. Changes in Kansas City Cardiomyopathy Questionnaire scores were analyzed using linear mixed-effects models.

Results: A total of 60 patients were included (n=30, 50% in the intervention group; n=30, 50% in the control group). Readmission occurred in 20% (6/30) of patients in the intervention group and 43.3% (13/30) of patients in the control group (odds ratio 0.33, 95% CI 0.10 - 1.09; *P*=.10). Linear mixed-effects analysis showed greater improvement in Kansas City Cardiomyopathy Questionnaire overall summary score in the intervention group (*P*=.02). Improvements were observed in the physical limitation, symptom frequency, symptom burden, quality of life, and social limitation domains. During follow-up, 3.3% (1/30) of the patients in the intervention group died of non–HF-related causes, and 10% (3/30) of the patients in the control group died due to HF.

Conclusions: This pilot study suggests that digital home monitoring is feasible and associated with improvements in patient-reported outcomes, with a potential signal toward reduced readmission. Larger studies are needed to confirm effectiveness.

KEYWORDS

heart failure; digital health; remote monitoring; Kansas City Cardiomyopathy Questionnaire; pilot study

Introduction

Heart failure (HF) is associated with high morbidity, mortality, and frequent hospital readmissions [1]. It affects over 20 million people worldwide, with a 5-year mortality rate of 60% to 70% [2]. It is a major public health problem, particularly among older adults, with a prevalence of 1% to 2% in low-income countries [3]. Reducing readmissions remains a key priority in HF management [4,5]. Digital health interventions, including home monitoring systems, have been increasingly used to support postdischarge management [6,7]. These systems enable early detection of symptom deterioration and may improve patient self-management. However, most evidence comes from high-income settings, with limited data from resource-limited

XSL•FO
RenderX

environments such as Indonesia [8,9]. This study aimed to evaluate the feasibility of a digital home monitoring intervention and explore preliminary effects on patient-reported outcomes and readmissions in a real-world Indonesian setting.

In many health care settings, postdischarge monitoring of patients with HF still relies on periodic outpatient visits and manual patient reporting [10]. This approach limits the ability of health care providers to detect early clinical deterioration. Consequently, innovative strategies are needed to support continuous monitoring and improve patient engagement in self-management [11,12].

Digital health technologies, particularly mobile health apps, have emerged as promising tools to support chronic disease management. Mobile-based monitoring systems enable patients to record symptoms, physiological parameters, and medication adherence while allowing health care providers to review patient-reported data remotely. Several studies have suggested that remote monitoring may improve patient engagement, facilitate early detection of clinical deterioration, and potentially reduce hospital readmissions [13]. However, the implementation of digital monitoring systems in real-world clinical settings remains challenging, particularly in terms of patient adherence, usability, and integration into existing health care workflows.

In Indonesia, the use of mobile-based monitoring apps for HF management is still limited. Understanding feasibility and patient adherence to such systems is essential before larger-scale implementation can be considered [14]. Therefore, this study developed a mobile-based monitoring app called FineHeart to support home monitoring and communication between patients with HF and health care providers.

This study aimed to evaluate the feasibility, patient adherence, and preliminary clinical outcomes associated with the use of the FineHeart mobile app among patients with HF following hospital discharge.

Methods

Study Design

This was a mixed methods pilot study consisting of qualitative needs assessment and system development combined with quantitative evaluation of feasibility and preliminary outcomes. This study was conducted from January 1, 2024, to November 30, 2024, at the National Cardiovascular Center (NCVC) Harapan Kita, Jakarta, Indonesia.

Participants and Setting

A qualitative needs assessment was conducted through interviews with hospital staff and document studies at the NCVC Harapan Kita. For the quantitative study, patients diagnosed with HF were recruited from a clinical setting. Eligibility criteria were applied consistently across groups. Participants were assigned to intervention or control groups based on predefined operational criteria (nonrandomized allocation). Baseline differences between groups were assessed and are acknowledged as potential confounders.

Intervention

The digital home monitoring system, named FineHeart, included daily symptom reporting, automated alerts for clinical deterioration, and remote clinician monitoring. The detailed system architecture and workflow are outlined in Multimedia Appendices 1 and 2, respectively. The development of the prototype was also based on the results of previous research using a machine learning method that developed a prediction model for HF readmissions at the same site implemented in a prototype mobile app [15].

Data Collection

The user acceptance test (UAT) was administered to both health workers and patients. The quantitative study involved posthospitalization patients with an I50 primary diagnosis code (*International Classification of Diseases, 10th Revision*). In the intervention group, participants filled out the Kansas City Cardiomyopathy Questionnaire (KCCQ) and were instructed on the use of the app prototype. A prototype link was given to patients and their families or caregivers, equipped with user-friendly instruments (digital sphygmomanometers, digital body scales, and digital oximeters), and were trained on how to use them. Patients filled out the app prototype daily for 30 days according to the parameters requested and could be monitored online by hospital nurses. If signs required a clinical response, indicated by the presence of green, yellow, and red notifications on the app, patients were followed up on by nurses or cardiologists. Readmission data were obtained from hospital records and verified during follow-up from patient reports. Readmission was defined as all-cause hospitalization within 30 days after index discharge. We used the 23 official and licensed items from the KCCQ from Outcomes Instruments, LLC, which has been translated into Indonesian and tested for reliability and validity, focusing on 4 domains that are closely related to public health: quality of life, self-efficacy, social limitation, and overall summary score [16,17]. Scores were obtained at baseline and 30 days. Missing outcome data were primarily due to incomplete reporting, loss to follow-up, or death during the study period. Adherence was defined as the proportion of days during which patients completed the required daily monitoring entries. After 30 days, participants were asked to re–fill out the KCCQ. In the control group, participants filled out the KCCQ before discharge and 30 days after discharge. No monitoring was carried out at home; only the follow-up schedule at the hospital was followed as usual.

Data Analysis

Qualitative data were analyzed using thematic analysis [18]. Coding was performed iteratively, and themes were derived through consensus among the researchers. For statistical analysis, baseline characteristics were summarized descriptively. Readmission rates were compared using chi-square tests, and odds ratios (ORs) with 95% CIs were calculated. Changes in KCCQ scores were analyzed using linear mixed-effects models that included all available data without imputation. Due to the pilot nature and limited sample size, multivariable adjustment was not performed to avoid overfitting. A P value below .05 was considered statistically significant.

XSL•FO

Ethical Considerations

Ethics approval was granted by the Research and Community Service Ethics Committee, Faculty of Public Health, Universitas Indonesia (Ket-718/UN2.F10.D11/PPM.00.02/2024), and by the institutional review board of the NCVC Harapan Kita (DP.04.03/KEP003/EC001/2024). All participants provided written informed consent.

Results

Qualitative Results

A total of 3 cardiologists and 7 nurses participated in the qualitative portion of this study. This qualitative analysis identified 7 major themes reflecting the needs of health care professionals regarding the development of a home-based monitoring system for patients with HF. They can be grouped into 3 overarching domains: digital transformation needs, service delivery optimization, and organizational readiness. The findings indicated that existing care was reactive rather than proactive, fragmented rather than integrated, and manual rather than digital. These limitations contributed to delayed detection of patient deterioration and inefficiencies in care delivery.

Participant Allocation

Patients who met the eligibility criteria were consecutively recruited during the study period (nonrandomized). A total of 60 patients with HF were enrolled in the study, of whom 30 (50%) were assigned to the intervention group using the FineHeart mobile app, whereas 30 (50%) were assigned to the control group receiving standard care.

During the 30-day follow-up period, 13.3% (4/30) of the patients in the intervention group and 20% (6/30) of the patients in the control group did not complete the quality of life assessment. Therefore, data from 86.7% (26/30) of the patients in the intervention group and 80% (24/30) of the patients in the control group were included in the final KCCQ analysis.

Baseline Characteristics

The baseline demographic and clinical characteristics of the participants in the quantitative portion of this study are shown in Table 1. Baseline differences were observed between groups in several variables, including educational level and clinical characteristics. Overall, the intervention and control groups showed comparable baseline characteristics in terms of age, gender distribution, and HF diagnosis. However, minor variations were observed in several clinical variables, which should be considered when interpreting the study findings.

[f]NYHA: New York Heart Association.
[g]LVEF: left ventricular ejection fraction.
[h]HFrEF: HF with reduced ejection fraction.
[i]HFmEF: HF with midrange ejection fraction.
[j]HFpEF: HF with preserved ejection fraction.

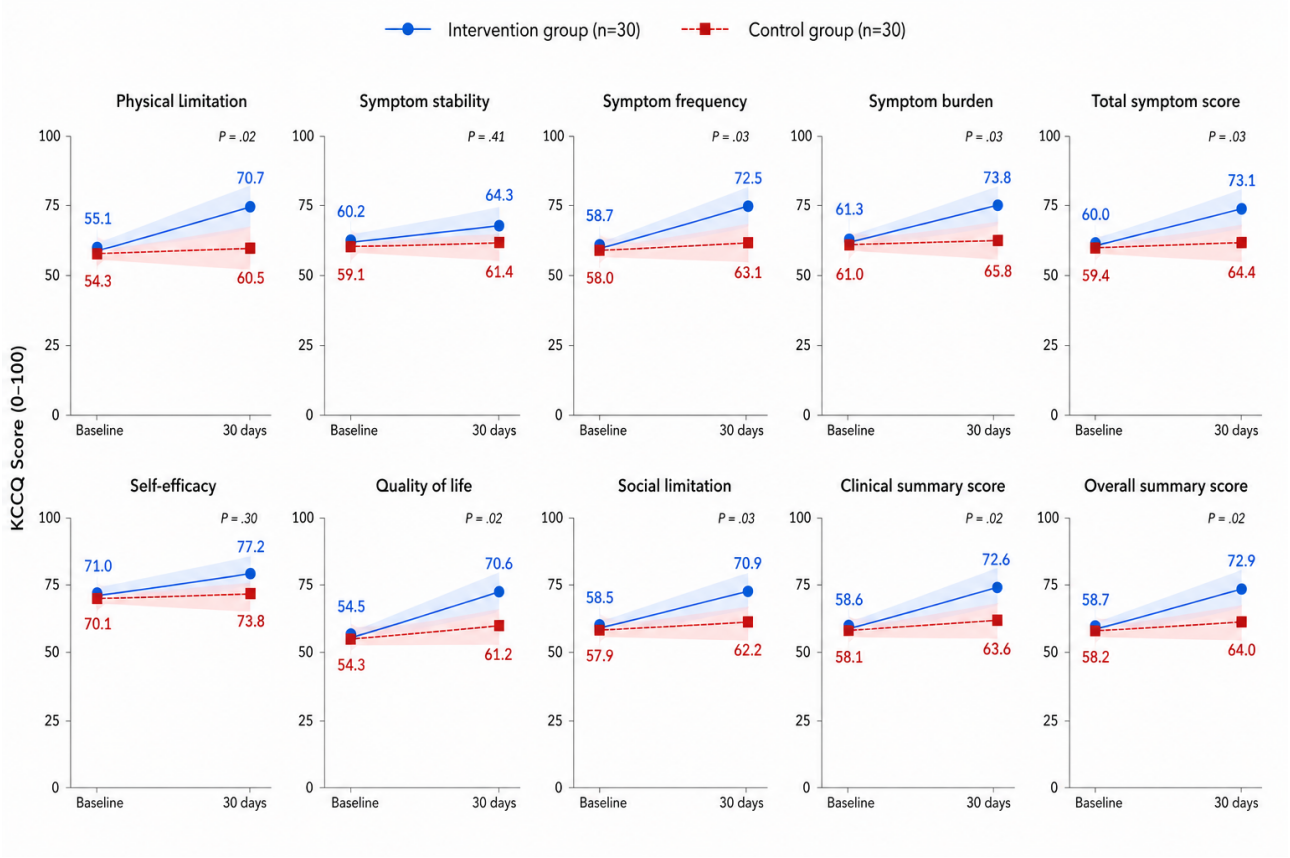
Patient Adherence to the FineHeart App

Among patients assigned to the intervention group, adherence to the FineHeart app varied. Most participants were able to use the app regularly during the monitoring period, although several patients (4/30, 13.3%) demonstrated lower adherence due to difficulties in operating the app or limited caregiver support.

Readmission Outcome

At 30 days, readmission occurred in 20% (6/30) of the patients in the intervention group, which was lower than the 43.3% (13/30) in the control group. This difference was not statistically significant (*P*=.10), but the OR suggested lower odds of readmission in the intervention group (OR 0.33, 95% CI 0.10 - 1.09).

KCCQ Outcomes



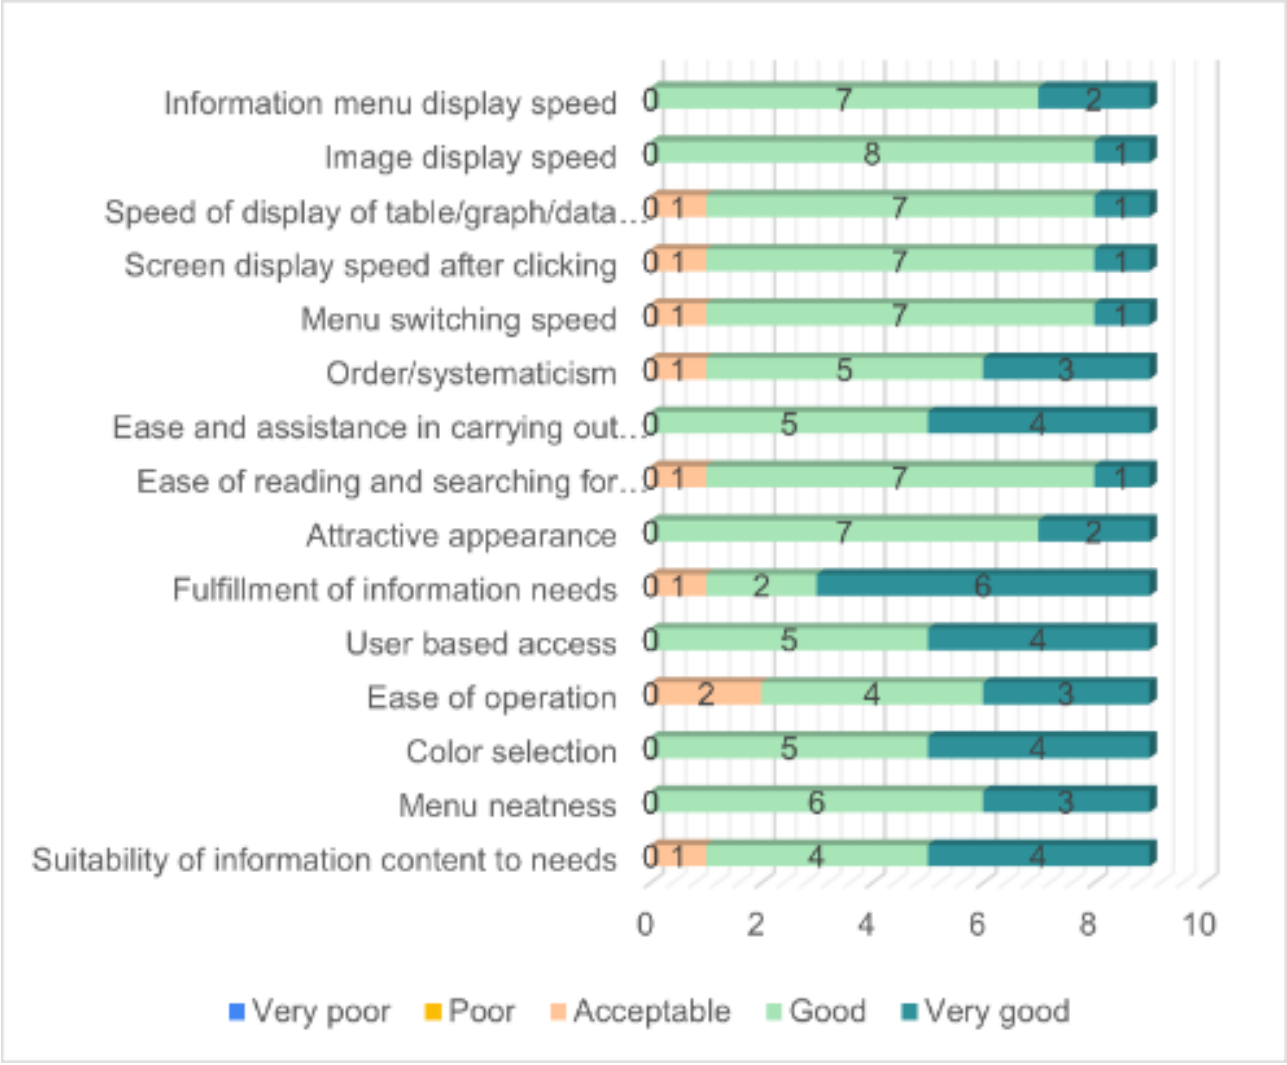
Linear mixed-effects analysis demonstrated a significant time-by-group interaction for overall summary score (*P*=.02), indicating greater improvement in the intervention group (Table 2). Improvements were observed in physical limitation, symptom frequency, symptom burden, quality of life, and social limitation. These changes exceeded clinically meaningful thresholds (>5 points). No significant differences were observed for symptom stability and self-efficacy (Figure 1).

XSL•FO
RenderX

Table . Changes in Kansas City Cardiomyopathy Questionnaire scores (linear mixed-effects model).

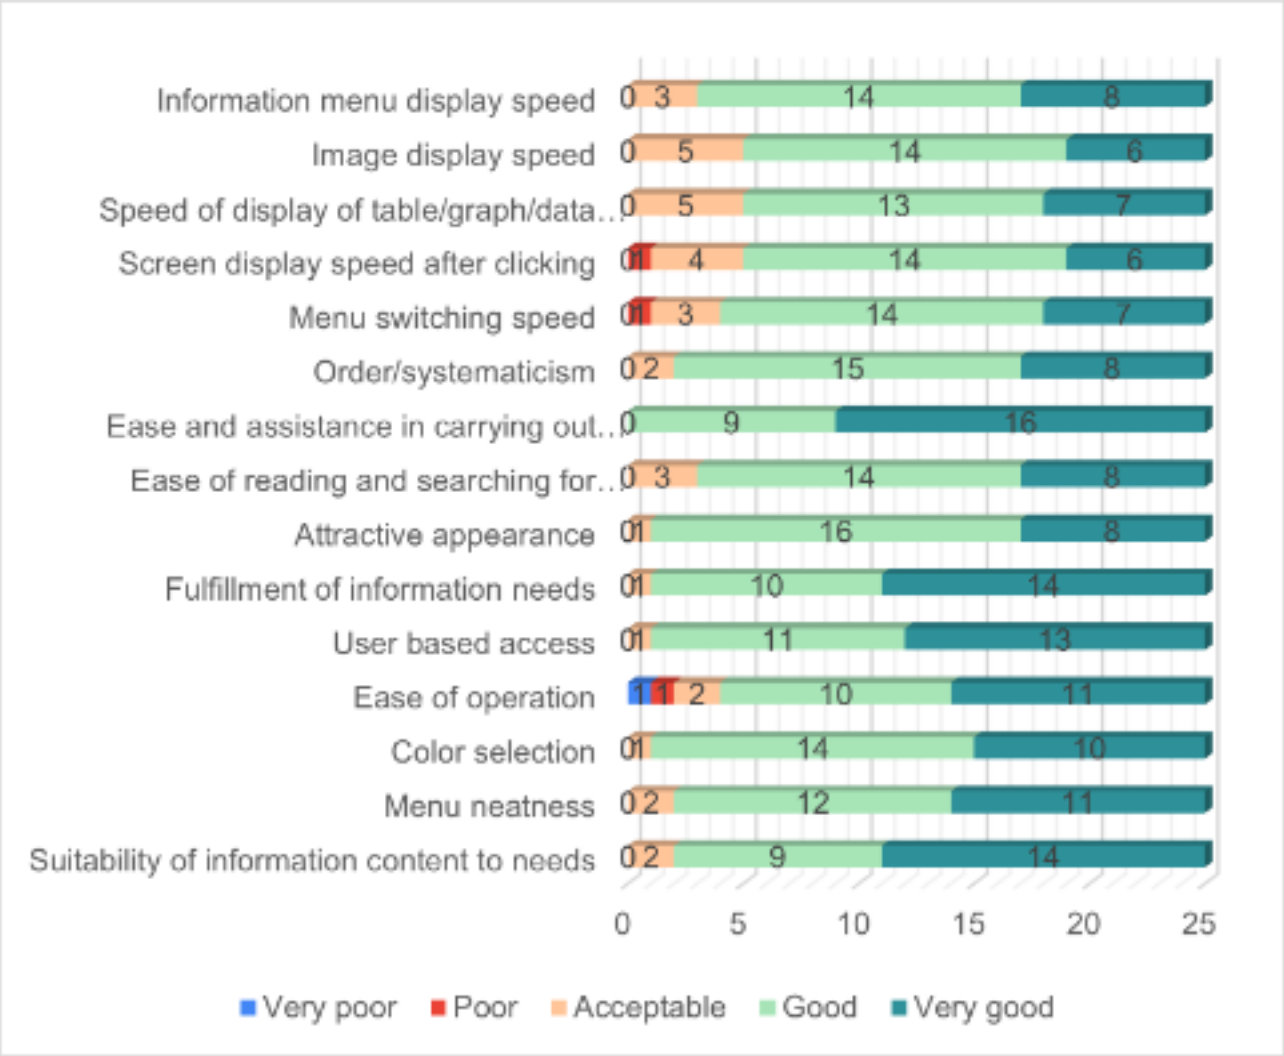
Domain	Change in the intervention group	Change in the control group	Interaction *P* value
Physical limitation	+15.6	+6.2	.02
Symptom stability	+4.1	+2.3	.41
Symptom frequency	+13.8	+5.1	.03
Symptom burden	+12.5	+4.8	.03
Total symptom score	+13.1	+5.0	.03
Self-efficacy	+6.2	+3.7	.30
Quality of life	+16.1	+6.9	.02
Social limitation	+12.4	+4.3	.03
Clinical summary	+14.0	+5.5	.02
Overall summary	+14.2	+5.8	.02

Figure 1. Improvement in Kansas City Cardiomyopathy Questionnaire scores from baseline to 30 days: intervention vs control group. Values shown are estimated marginal means from linear mixed-effects models with fixed effects for time, group, and time × group interaction and a random intercept for participant. Shaded areas represent 95% CIs. Higher scores indicate better health status. *P* values represent the time × group interaction.



User Acceptance Test

The UAT results among 9 health workers showed that the app prototype was complete and could be used by health care workers and patients at home. The results of the UAT among 25 patients with HF showed that patient acceptance of the FineHeart app prototype was predominantly either good or very good (Figures 2 and 3).



XSL•FO
RenderX

Figure 2. User acceptance test (UAT) results in health workers. Most of the 9 health workers who took part in the UAT provided good and very good ratings in all parameters.

XSL•FO
RenderX

Figure 3. User acceptance test (UAT) results in patients with heart failure. Most of the patients who took part in the UAT (90% on average) provided good and very good ratings in all parameters.

Missing Data and Mortality

During the 30-day follow-up, some KCCQ data were missing due to incomplete reporting or loss to follow-up. In addition, 3.3% (1/30) of the patients in the intervention group died of non–HF-related causes, and 10% (3/30) of the patients in the control group died due to HF.

Discussion

Principal Findings

This pilot study evaluated the feasibility of a digital home monitoring intervention for patients with HF in a resource-limited setting [19]. The findings suggested that the intervention was feasible to be implemented and associated with improvements in patient-reported outcomes, as reflected by significant changes in several KCCQ domains. In addition, a lower proportion of 30-day readmissions was observed in the intervention group than in the control group, although this difference did not reach statistical significance.

Importantly, the improvement in KCCQ overall and domain-specific scores indicated a positive effect on health-related quality of life [20]. These improvements were most pronounced in the physical limitation, symptom frequency, symptom burden, quality of life, and social limitation domains, suggesting that the intervention may support both symptom management and functional status. The observed improvements in KCCQ scores were clinically meaningful as changes exceeding 5 points are generally considered relevant for patients with HF [17]. The magnitude of change observed in this study suggests that patients in the intervention group experienced perceptible benefits in their daily functioning and symptom burden.

In contrast, while the readmission rate was lower in the intervention group (6/30, 20% vs 13/30, 43.3%), the difference was not statistically significant. This might be due to the limited sample size and the pilot nature of this study, which was not powered to detect differences in clinical outcomes.

Taken together, these findings should be interpreted as preliminary signals rather than definitive evidence of effectiveness. The results were hypothesis generating and provided a rationale for larger, adequately powered studies.

An important observation in this study was the difference in mortality between groups [21]. During the follow-up period, 10% (3/30) of the patients in the control group died due to HF,

XSL•FO
RenderX

whereas 3.3% (1/30) of the patients in the intervention group died from a non–HF-related cause. This imbalance might reflect differences in baseline clinical stability or disease severity. The higher rate of HF-related mortality in the control group might also partially explain the lower KCCQ scores and higher readmission rates observed in that group. Patients with more advanced diseases or greater instability are more likely to experience worse symptoms, reduced quality of life, and increased health care use.

The findings of this study were broadly consistent with those of previous research on digital and telemonitoring interventions in HF, which have demonstrated variable effects on clinical outcomes but more consistent improvements in patient-reported measures. Several studies have suggested that digital monitoring may enhance early detection of symptom deterioration, improve adherence, and support self-management [13,22]. However, the impact on readmission has been heterogeneous across studies, likely reflecting differences in intervention design, patient populations, health care systems, and implementation strategies [23].

Study Limitations and Future Research

This study had several limitations that should be considered when interpreting the findings.

First, the study involved a relatively small sample size and was conducted at a single center. As this was a pilot study, the sample size was intended to explore feasibility and preliminary outcomes rather than provide definitive evidence of effectiveness.

Second, this study used a quasi-experimental design without randomization. Although efforts were made to ensure comparability between groups, baseline differences may still have influenced the observed results.

Third, the duration of follow-up was limited to 30 days following hospital discharge. While this period allowed for initial evaluation of patient adherence and early outcomes, longer follow-up periods are necessary to better assess the long-term impact of digital monitoring on hospital readmission and quality of life.

Fourth, not all eligible patients were familiar with smartphone technology, and some declined participation due to concerns about using digital devices. This might limit the generalizability of the findings to populations with lower digital literacy.

Future studies should include larger multicenter cohorts and randomized study designs to better evaluate the clinical effectiveness of mobile-based monitoring systems. In addition, further research should explore strategies to improve patient engagement, the usability of digital platforms, and the integration of remote monitoring systems into routine clinical workflows.

Conclusions

This pilot study evaluated the feasibility and preliminary outcomes of the FineHeart mobile-based monitoring app for patients with HF following hospital discharge. The findings suggested that the app is feasible for supporting patient self-monitoring and engagement in postdischarge care. Patients who used the app showed favorable trends in several quality of life domains and demonstrated varying levels of adherence to digital monitoring. Although this study was not designed to establish definitive clinical effectiveness, the results provide preliminary signals that mobile-based monitoring may support patient self-management and potentially contribute to improved clinical outcomes. Larger studies are needed to confirm effectiveness.

Acknowledgments

The authors want to thank all the participants and the heart failure team of the National Cardiovascular Center Harapan Kita that were involved in this study for the facilities, data, and assistance provided. The authors declare the use of generative AI (GenAI) in the research and writing process. Abstract

Background: Online medical consultation (OMC) services have gained considerable attention as an integral component of telemedicine. Recently, AI has been increasingly integrated into OMC platforms, facilitating more efficient consultations and clinical decision-making. AI-driven OMC services can provide preliminary triage, medication guidance, and diagnostics for multiple medical conditions. Despite the availability and potential benefits of AI-driven OMC services, public acceptance and willingness to pay (WTP) for these services remain low.

Objective: This study aimed to identify perceived barriers, facilitators, expectations, and factors shaping public acceptance of and stated WTP for AI-driven OMC services.

Methods: We conducted semistructured qualitative interviews with patients, caregivers, and health care professionals to explore barriers, facilitators, expectations, and factors shaping public acceptance of and stated WTP for AI-driven OMC services. The study was informed by the theories of perceived risk and perceived benefit, which guided the development of the interview guide. All interviews were audio-recorded and transcribed verbatim. Data were analyzed using NVivo (version 15; Lumivero) with deductive thematic analysis guided by these theories. Coding was conducted independently and cross-checked by 2 researchers to ensure credibility and consistency.

Results: Thematic analysis of 20 in-depth interviews identified 2 main themes and 11 subthemes. Perceived risks and perceived benefits emerged as 2 key perspectives influencing participants' acceptance and WTP. Psychological, governance, social, functional, health, and financial risks reduced acceptance, whereas convenience, diversity, reliability, efficiency, and educational benefits promoted it. Participants' self-reported WTP ranged from RMB 0 to RMB 200 (US $0-$27.28; RMB 1=US $0.1364 as of January 15, 2025), with participants who had prior experience with OMC generally reporting higher values than those without prior OMC experience.

Conclusions: This study identified facilitators and barriers influencing public acceptance of and WTP for AI-driven OMC services using theoretical constructs. Our findings offer valuable insights into the development and refinement of AI-driven OMC services, enabling more targeted pricing strategies and tailored services that address public preferences and concerns, as well as supporting the development of standardized regulatory governance for digital medical consultation platforms.

Introduction

Telemedicine is the delivery of health care services in which distance is a critical factor and health care professionals use information and communication technologies to exchange valid information for the diagnosis, treatment, and prevention of diseases and injuries, as well as for research, evaluation, and education [1]. Online medical consultation (OMC) is an important element of telemedicine and has become increasingly popular over the past few years, especially since the COVID-19 pandemic [2]. Recently, the use of AI in health care has grown rapidly, particularly in the field of telemedicine. Integrating AI into telemedicine has transformed a wide array of medical practices, from diagnostics to medical consultation [3]. The integration of AI into OMC services enables real-time data analysis and decision support, thereby facilitating remote consultations with greater efficiency and accuracy [4]. AI-driven OMC services have been demonstrated to be an effective means of addressing consultations for various medical conditions, such as surgery [5], cancer [6], emergency care [7], psychiatry [8], and cardiovascular diseases [9].

Despite the availability and potential benefits of AI-driven OMC services, their uptake among the public remains low [10]. This gap in adoption highlights the need to understand the multifaceted factors influencing their use [11,12]. Previous studies have predominantly focused on facilitators and barriers associated with OMC services without AI integration. For example, multiple factors have been identified as facilitators of OMC services, including cost savings, reduced waiting and travel times, ease of use, familiarity with the system, trust in technology, family involvement, and patient age [11]. Several factors have also been identified as barriers to OMC services, including slow internet speed, poor audio or video quality, limited internet access, weak signal coverage, difficulty expressing emotions, lack of body language, and user resistance [11]. However, evidence regarding public perceptions of acceptance and willingness to pay (WTP) for AI-driven OMC services remains limited. Although the integration of AI into telemedicine can reshape OMC services, promoting adoption requires addressing both the perceived benefits and risks of these services from users' perspectives.

The theory of perceived risk suggests that consumers perceive risk due to uncertainty and potentially undesirable consequences associated with paying for or using services [13,14]. It has been widely applied in previous studies to explore public perceptions of health care services, such as mobile health (mHealth) technologies [15], e-consultation services [16], online pharmacy platforms [17], and AI-enabled health care apps [18]. Meanwhile, the theory of perceived benefit emphasizes consumers' beliefs about the extent to which they will gain positive outcomes from using a specific service [19]. Perceived benefits tend to enhance the intention to use and are associated with health care consumers' greater willingness to accept the vulnerability (ie, service uncertainty and potential negative consequences) resulting from such uncertainty [13,20]. Understanding perceived risks and benefits is crucial for designing health care services that meet consumer expectations, especially in the context of the rapid development of digital health services and AI technologies. Therefore, the theories of perceived risk and perceived benefit can serve as useful frameworks to evaluate the willingness to accept and pay for AI-driven OMC services.

This study used a qualitative approach informed by the theories of perceived risk and perceived benefit to identify perceived barriers, facilitators, expectations, and factors shaping public acceptance of and stated WTP for AI-driven OMC services. By doing so, it seeks to shed light on the development and refinement of AI-driven OMC services, including targeted pricing strategies and tailored service designs to address patient needs.

Methods

Ethical Considerations

This study was approved by the Ethics Committee of Peking University Third Hospital (approval number M20241044). All participants provided informed consent prior to participation. All information collected during the study was treated as strictly confidential. Interview data were anonymized before analysis and stored in NVivo (version 15; Lumivero) on secure, password-protected institutional servers, with access restricted to authorized members of the research team.

Study Design

In this study, AI-driven OMC services refer to OMC services in which AI technologies are used to support medication-related information provision, preliminary guidance, triage, or decision support. These services may include fully automated AI responses as well as AI-assisted models involving review by health care professionals. As this remains an emerging service model, the study explored participants' perceptions of this broader service category rather than evaluating a single standardized platform. This study adopted a descriptive qualitative research design to comprehensively explore the factors influencing patients' acceptance of and WTP for AI-driven OMC services. In-depth semistructured interviews were conducted to collect detailed information from participants.

Setting and Participants

Purposive sampling was used to recruit participants with diverse characteristics, including sex, age, geographic location, identity characteristics, prior OMC experience, and educational level. The research team approached potential participants from different cities in China through clinical, professional, and personal networks. Some participants also referred other eligible individuals to the research team. Recruitment continued until the sample included patients, caregivers, and health care professionals with varied backgrounds and experiences related to OMC services.

Eligible participants were individuals aged 18 years or older who were able to provide informed consent and participate in a Chinese-language interview. Patients, caregivers, and health care professionals were included to capture diverse perspectives on the factors influencing acceptance of and WTP for AI-driven OMC services. Participants were excluded if they were unable

XSL•FO
RenderX

to provide informed consent, unable to complete the interview, or unwilling to be audio-recorded.

In-depth semistructured interviews were conducted in Chinese either face-to-face or remotely via telephone in a quiet and private setting between December 2024 and January 2025. The sample size was determined based on data saturation, with interviews discontinued when no new information emerged [21].

Data Collection

Before the interviews, participants were informed of the study's purpose and provided written informed consent. Each interview lasted for 30-45 minutes and was audio-recorded with AI-assisted real-time transcription using a speech-to-text device. All transcripts were checked against the original audio recordings and verified against the recordings within 24 hours to ensure transcription accuracy. All interviews were led by QC, while SD served as the note-taker. Both researchers had backgrounds in pharmacy and qualitative research and were familiarized with the interview guide before data collection. A semistructured interview outline designed based on relevant literature and participant characteristics [22] was pilot tested with 3 volunteers and refined before the formal interviews. The outline consisted of 5 primary questions and was detailed in Textbox 1. Participants were not shown a standardized platform, workflow, use case, or pricing scenario before the interviews. Instead, the interviews used open-ended questions to explore participants' perceptions, concerns, expectations, and WTP regarding AI-driven OMC services as a broad and emerging service model. Interviews began with open-ended prompts (eg, "what" and "how") to elicit detailed responses, followed by probing questions for deeper exploration of emerging themes [23,24]. Plain and accessible language was used to encourage open communication. SD documented contextual information to complement the audio-recorded data, including facial expressions and body language in face-to-face interviews and tone, pauses, and emotional reactions in telephone interviews. Participants could withdraw at any time or refuse to answer any question.

Textbox 1. Semistructured interview outline questions for participants.

This semistructured interview outline was developed based on the research objectives and core research questions. Relevant interview questions are listed below:

1. Could you briefly share your personal information, including your age, place of residence, family situation, health condition, and internet proficiency?
2. Have you ever used any online medical consultation (OMC) service, particularly one driven by AI technologies? If yes, when would you choose to use such a service? If not, why?
3. How do you feel about AI-driven OMC services? What are their strengths, weaknesses, and key aspects you care about?
4. Would you be willing to use or pay for such services, and what factors might encourage or discourage your willingness to use or pay for them?
5. What are your expectations for AI-driven OMC services, and what areas do you think could be improved or optimized in the future?

Data Coding and Analysis

The data analysis process was conducted concurrently with data collection, and further sampling decisions and interview questions were guided by the findings of the ongoing data analysis [24]. Interviews were conducted until ongoing coding indicated that no new codes or subthemes relevant to the study objectives emerged [21].

Transcripts were sequentially numbered and imported into NVivo (version 15) for coding. To minimize potential bias and enhance the credibility and consistency of the analysis, 2 researchers independently coded and analyzed the data, followed by cross-checking and discussion to resolve discrepancies. An initial codebook was developed through comparison of independently generated codes and was refined iteratively during the analysis.

The analysis followed Clarke and Braun's 6-phase thematic analysis approach [25,26]. First, 2 researchers (SD and QC) independently read the transcripts to become familiar with the data. Second, each researcher independently generated initial codes across the dataset, focusing on participants' perceptions of AI-driven OMC services without applying a fixed coding template. Third, the researchers independently organized related codes into preliminary themes. Initial coding remained open to concepts emerging from the data, while the theories of perceived risk and perceived benefit were used as a sensitizing framework to support theme organization and interpretation. Although the final themes were organized under the broad dimensions of perceived risk and perceived benefit, the subthemes were not predefined by these theories. Instead, they were developed and named by the research team based on recurring patterns in participants' responses. The 2 sets of codes and preliminary themes were then compared. Differences in coding interpretations, theme boundaries, and theme names were discussed until consensus was reached. Where uncertainty remained, coding and thematic decisions were discussed with the wider research team. Analytic notes were used to document coding decisions, emerging interpretations, and points requiring further discussion. Fourth, the agreed themes were reviewed and refined to ensure internal consistency and clear boundaries. Fifth, the themes and subthemes were refined and named based on the coded data within the broader risk-benefit framework. Finally, the results of the analysis were compiled and presented in a structured report to support the interpretation of WTP and service acceptance.

The final set of codes, themes, and subthemes was jointly reviewed and confirmed by all team members. Representative quotations were selected from the Chinese transcripts to illustrate each theme, translated into English by bilingual

XSL•FO
RenderX

researchers, and checked against the original text to preserve participants' intended meanings.

Results

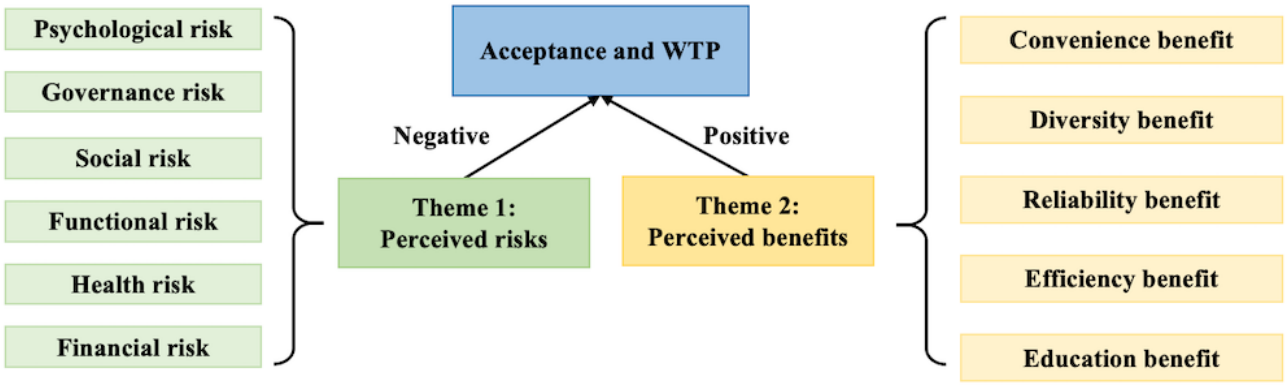
Participant Characteristics

A total of 20 participants were included in this study, comprising 5 male and 15 female participants, aged 22-68 years. Of the 20 interviews, 8 were conducted face-to-face and 12 were conducted remotely via telephone. The sample comprised 15 patients, 3 caregivers, and 2 health care professionals. In terms of geographic distribution, 11 participants lived in urban areas and 9 in rural areas. Regarding educational background, 5 participants held a master's degree or higher, 9 held a bachelor's degree, and 6 had completed high school education or below. Detailed participant characteristics are shown in Table 1.

Table . Characteristics of study participants. An OMC[a] experience refers to participants' prior experience with OMC services and does not necessarily indicate prior experience with AI-driven consultation services.

Participant number	Sex	Age (years)	Residence	Identity characteristics	Prior online medical consultation experience	Educational Level
1	Male	41	Urban	Patient	Yes	Master's degree or above
2	Female	36	Urban	Patient	Yes	Master's degree or above
3	Male	41	Urban	Caregiver	Yes	Master's degree or above
4	Female	35	Urban	Patient	Yes	Bachelor's degree
5	Female	22	Rural	Patient	No	Bachelor's degree
6	Female	41	Urban	Caregiver	Yes	Bachelor's degree
7	Female	39	Urban	Patient	Yes	Master's degree or above
8	Female	34	Urban	Health professional (pharmacist)	No	Bachelor's degree
9	Female	35	Rural	Patient	No	Bachelor's degree
10	Female	50	Urban	Patient	No	High school or below
11	Male	24	Rural	Patient	No	Bachelor's degree
12	Male	30	Rural area	Patient	Yes	Master's degree or above
13	Female	22	Rural	Patient	No	Bachelor's degree
14	Female	22	Urban	Patient	Yes	Bachelor's degree
15	Female	62	Rural	Patient	No	High school or below
16	Male	54	Rural	Health professional (doctor)	Yes	Secondary education, vocational education, or below
17	Female	68	Rural	Patient	No	High school or below
18	Female	25	Urban	Caregiver	Yes	Bachelor's degree
19	Female	22	Urban	Patient	No	Bachelor's degree
20	Female	53	Rural	Patient	No	High school or below

[a]OMC: online medical consultation.



Thematic Analysis Outcomes

Generated Themes: an Overview

Thematic analysis of 20 in-depth interviews identified 2 main themes and 11 subthemes, revealing the multifaceted factors influencing public acceptance and WTP for AI-driven OMC services (Figure 1). Representative participant quotations for themes, subthemes, and WTP are shown in Table 2. These findings reflect the underlying psychological mechanisms and decision-making processes in participants' evaluations of perceived risks and benefits.

XSL•FO

Table . The themes, subthemes, WTP[a], and participant quotations.

Themes, subthemes, and WTP	Quotations
Theme 1: perceived risks	
Subtheme 1: psychological risk	• "I think the process of AI-driven service was complicated for me, so I didn't use it." (Participant 17; patient without prior OMC[b] experience) • "I'm not really familiar with it yet, and I haven't had the chance to try it myself, so I don't really get how it works. But I guess once I get the hang of it, it might feel a lot easier. I hope the government could promote it more, maybe even have some kind of volunteers or people who can go around teaching how to use it. That would be great, right?" (Participant 20; patient without prior OMC experience) • "I don't really know what AI is. I'm getting on a bit, and I don't fancy trying out new things like that, so I probably won't be using it in the future." (Participant 15; patient without prior OMC experience)
Subtheme 2: governance risk	• "Yeah, I mean, although I haven't used these platforms myself, but I am concerned about the privacy." (Participant 5; patient without prior OMC experience) • "In the future, when AI becomes widely used, how can we ensure that it is not manipulated by certain individuals to create false information? In terms of medical treatment, certain safety assurances need to be provided, particularly in regulatory oversight and control." (Participant 16; service-participant doctor) • "Emm, it's not an official platform backed by the government right now. So, sometimes I'm not feeling confident about it." (Participant 3; service-experienced caregiver) • "If we're consulting at a physical place, when there's a problem, we can quickly identify the person and seek compensation. But for online consultation based on AI, we can't seek accountability." (Participant 11; patient without prior OMC experience)
Subtheme 3: social risk	• "With AI consultations, we are talking to a robot, not a real person. There's no face-to-face interaction, which makes it feel less natural. Unlike a doctor..., the AI-driven platform relies only on what you type in, so it might miss important details." (Participant 12; service-experienced patient) • "I feel like, since the AI cannot do a face-to-face consultation, the responses can sometimes be more conservative. This may be because it lacks direct observation and relies solely on the information I provide." (Participant 1; service-experienced patient)
Subtheme 4: functional risk	• "Also, since the consulting service provided by AI is just a computer program answering questions, it doesn't have the authority to prescribe medicine or order tests." (Participant 4; service-experienced patient) • "Health care professionals will ask about lots of different things when they're diagnosing, like your medical history..., AI might not be quite as good at handling these individual details." (Participant 12; service-experienced patient) • "AI lacks extensive clinical experience, and unlike doctors..., AI tends to rigidly follow standard guidelines." (Participant 18; service-experienced caregiver) • "Online consultations aren't linked to offline medical records, making it hard to review and consolidate information." (Participant 14; service-experienced patient) • "AI still needs training. It might not be well-developed enough to respond like health care professionals." (Participant 7; service-experienced patient) • "Sometimes the system crashed or the internet connection is unstable. It just keeps loading, or the conversation gets wiped out completely. It's really frustrating when that happens." (Participant 7; service-experienced patient)

XSL•FO
RenderX

Themes, subthemes, and WTP	Quotations
Subtheme 5: financial risk	• "What worries me is, if the AI gets it wrong or misses something important, I'll have to go see a doctor anyway. So I'd be paying twice, first for the AI, then for an actual consultation." (Participant 3; service-experienced caregiver) • "Even if the AI gives some medication advice, I still need a doctor for a prescription. So in the end, I'm paying for both, and that's just extra hassle and cost." (Participant 4; service-experienced patient)
Subtheme 6: health risk	• "The service should be available the whole day because you don't know when you might need to ask for advice. In extremely urgent situations, delayed responses can lead to severe outcomes." (Participant 10; patient without prior OMC experience) • "um, sometimes there might even be misunderstandings, you know, there's a risk of things going off track." (Participant 7; patient without prior OMC experience) • "Sometimes, AI doesn't get it right, ...the information and references aren't always accurate. If you don't double-check, you might end up trusting something that's not actually true." (Participant 18; service-experienced caregiver)
Theme 2: Perceived Benefits	

XSL•FO
RenderX

Themes, subthemes, and WTP	Quotations
Subtheme 7: convenience benefit	• "If I can get an appointment, I'd definitely go offline, but often there are no slots available. So, I use online consultations a lot. It's really accessible." (Participant 4; service-experienced patient) • "AI can handle many users at the same time. People can ask it questions anytime, and it gives us a quick response. It is more flexible" (Participant 11; patient without prior OMC experience) • "In rural or remote areas, people may not conveniently go to big cities or top hospitals for consultations. But through this way, they can get medical guidance effectively, and even without having to leave their homes." (Participant 16; doctor without prior OMC experience) • "...But for some small issues that I'm unsure about or I have a general understanding of my condition but encounter further questions or uncertainties later, I think these can easily be addressed through online consultations conducted by AI." (Participant 1; service-experienced patient)
Subtheme 8: diversity benefit	• "Personally, I'm not very fond of oral communication. For text-based consultations, it's easier for me to explain things. I prefer offline interactions with doctors to avoid any potential awkwardness." (Participant 12; service-experienced patient) • "A nice thing about online consultation is I can choose different consultation ways according to my needs. And there's no limit on how many messages you can send." (Participant 2; service-experienced patient) • "For example, if I feel that I have a mental illness and choose to take medication, I will go to the Internet for consultation, because I do not want to let others know." (Participant 9; patient without prior OMC experience)
Subtheme 9: reliability benefit	• "Theoretically speaking, if it's powerful enough, I think it might integrate information from different sources and give more comprehensive advice. In an ideal scenario, it might even be more professional because its memory and storage capacity could be stronger compared to humans. Also, it can retrieve information faster in some ways, so yeah, that's what I think." (Participant 18; service-experienced caregiver) • "If AI can supplement the answers from health care professionals it would be more comprehensive and reliable." (Participant 1; service-experienced patient) • "I'd trust AI more if a doctor reviewed its recommendations before they were given to patients, ensuring accuracy and safety." (Participant 19; patient without prior OMC experience)
Subtheme 10: efficiency benefit	• "AI consultations save time because I can quickly get basic medical information without waiting for a doctor to explain everything. Plus, it's free, so there's no cost at all." (Participant 6; service-experienced caregiver) • "Sometimes, I don't have time to visit a doctor in person, so using AI is much more convenient. It's free or at least much cheaper than online consultations with real doctors." (Participant 2; service-experienced patient) • "I can describe my symptoms to AI, and it helps me figure out which department I should visit. That way, I don't waste time wondering where to go when I actually need to see a doctor." (Participant 14; service-experienced patient)
Subtheme 11: education benefit	

XSL•FO
RenderX

Themes, subthemes, and WTP	Quotations
	• "If patients first use AI to get some initial information about their medication or health concerns, they can communicate more clearly and confidently with pharmacists. This often helps us give them more accurate and effective treatment." (P8; pharmacist without prior OMC experience) • "Health care professionals might not always be familiar with every medication, especially if it's outside their specialty area. In such cases, AI can really help by providing more detailed information." (P16; service-experienced doctor) • "I can first check with the AI, get some background knowledge, and this helps me discuss things better with the doctor later. Also, by using AI, I get to learn more about medication use, drug interactions, and overall health education." (P14; service-experienced patient)
WTP	• "To be honest, I just believe AI consultations should be free. It's not like there's an actual doctor involved. It's just pulling stuff from the internet, so why should we pay for that?" (Participant 11; patient without prior OMC experience) • "If it's just an AI spitting out answers, I wouldn't pay for it. But if there's a proper doctor checking things and making sure the advice is right, then yeah, that's different. That's worth paying for. I'd be willing to pay up to US $30 for that." (Participant 12; service-experienced patient) • "Maybe they could do it in levels—basic AI stuff for free, but if you want a real person to review it, then you pay a bit. At least that way, people can decide what they need." (Participant 18; service-experienced caregiver)

[a]WTP: willingness to pay.

[b]OMC: online medical consultation.

Theme 1: Perceived Risks

Subtheme 1 (Psychological Risk): Unfamiliarity and Skepticism Toward the Services

Many participants without prior OMC experience were skeptical about the reliability of online and AI-driven services and tended to prefer in-person interactions with doctors or pharmacists. Some expressed unfamiliarity with AI-driven medical consultation services, leading to apprehension and reluctance to use the platform. One participant had never heard of AI being used for medical consultations and showed little interest in adopting such technology. Additionally, several participants without prior OMC experience found the AI system difficult to navigate and often required assistance from others to access the service. Their hesitation was further reinforced by a lack of prior experience with similar digital health care platforms. Without adequate information, they found it difficult to recognize the potential benefits of AI-driven consultations. Training provided by health care professionals through video tutorials or user manuals could help them feel more confident in using the service.

Subtheme 2 (Governance Risk): Data Privacy, Security, and Institutional Accountability

Quite a few participants voiced worries over inadequate governance of AI-driven OMC platforms, covering 2 core dimensions, namely data privacy and protection and institutional accountability. Many feared that their confidential medical and personal data might be disclosed to unauthorized third parties, which would erode their trust in digital consultation services. More importantly, participants raised prominent governance loopholes regarding regulatory supervision and liability clarification. Some noted that current AI consultation platforms are not operated by nationally certified authorities, making it unclear where to file complaints or seek redress in cases of inaccurate advice or service failures. The lack of defined responsibility and regulatory oversight left them hesitant to rely on AI-driven consultations. Many participants indicated that they would only consider using and paying for such services if robust data protection measures and transparent mechanisms for complaint handling and accountability were established. Some noted that current AI consultation platforms are not operated by nationally certified authorities, making it unclear where to file complaints or seek redress in cases of inaccurate advice or service failures. The lack of defined responsibility and regulatory oversight left them hesitant to rely on AI-driven consultations. Many participants indicated that they would only consider using and paying for such services if robust data protection measures and transparent mechanisms for complaint handling and accountability were established.

Subtheme 3 (Social Risk): Limited Interpersonal Interaction and Communication Quality

Participants pointed out that one of the shortcomings of AI-driven OMC services was the lack of face-to-face interaction. Without body language or eye contact, they felt uneasy and found it difficult to convey complex information. Some also criticized the overly cautious nature of AI responses, which often suggested possibilities such as "might have" or "could be" instead of giving clear conclusions, leaving users uncertain. The quality of advice also depended on the completeness of the

XSL•FO
RenderX

information provided. When users lacked medical knowledge, struggled to describe symptoms, or had no test results, responses became vague and less useful.

Subtheme 4 (Functional Risk): Limited Clinical, Technical, and Usability Functionality of Platforms

Service-experienced participants indicated that current AI-driven consultation platforms still have functional limitations. Although these systems can analyze user inputs, provide basic drug information, and suggest possible treatment options, they cannot prescribe medications, request laboratory tests, or perform full medical evaluations. Patients must still consult health care professionals for accurate diagnoses, prescriptions, and examinations to ensure safe and effective care. Many participants also noted that AI performs poorly in handling highly individualized medical problems because it lacks clinical experience. It cannot independently access biomarkers or imaging data and depends entirely on user-provided information, which restricts its capacity to offer personalized advice. In addition to these clinical limitations, participants also raised usability-related concerns, including poor network connections, system errors, software glitches, and difficulty navigating the platform. These issues reduced their confidence in the stability and reliability of AI-driven OMC services. As these technologies are still at an early stage, some participants expressed concerns about technical stability, incomplete data integration, and limited accuracy due to insufficient real-world validation.

Subtheme 5 (Financial Risk): Uncertain Pricing and Potential Additional Health Care Costs

Participants expressed concerns that if AI-generated recommendations were inaccurate or incomplete, they might spend more on unnecessary treatments or follow-up consultations with health care professionals. Additionally, since AI lacks the authority to prescribe medications, users still need to consult doctors for prescriptions and laboratory tests, incurring further costs. These financial uncertainties made participants hesitant to invest in AI-driven consultation services, highlighting the need for clear pricing structures and transparent value propositions to justify any associated fees.

Subtheme 6 (Health Risk): Potential Health Harm From Delayed or Inaccurate Advice

Several participants mentioned that some AI-driven consultation services were embedded in company-developed platforms operating within fixed service hours. Although AI was always technically available, responses were sometimes constrained by platform schedules, leading to concerns about the ability to address urgent medical problems during the night. Some participants felt that delayed professional feedback, due to restricted hours or limited consultant availability, might increase health risks. Others expressed worries about the accuracy of AI-generated recommendations. Service-experienced users noted that communication during online consultations was less smooth than in face-to-face settings, which sometimes led to misunderstandings between patients and health care professionals. A few participants further reported that AI occasionally produced incorrect information or cited nonexistent references, creating a false sense of reliability.

Theme 2: Perceived Benefits

Subtheme 1 (Convenience Benefit): Accessible and Flexible Services

Participants highlighted accessibility as a major factor promoting the use of AI-driven OMC services. Those living in rural or underserved areas described these platforms as a convenient alternative for obtaining medical information and guidance, helping them overcome geographical barriers. Participants from larger cities also recognized the convenience of AI-driven consultations compared with traditional health care visits. Many appreciated the flexibility to seek medical advice at times that suited their schedules, often from home or other comfortable locations. Several participants mentioned that AI-driven consultations were useful for addressing minor health issues or follow-up questions after outpatient visits.

Subtheme 2 (Diversity Benefit): Multiple Consultation Formats and Language Options

By offering diverse communication methods and language options, AI-driven online consultation services foster a more inclusive health care experience. Participants indicated that they could choose between voice, text, or video formats according to their preferences. These communication options were also considered advantageous for discussing sensitive health topics, such as mental health, as they offered greater privacy and reduced the discomfort associated with face-to-face communication. In particular, some participants who were more introverted preferred text-based consultations because they found them less stressful than speaking directly with health care providers. Additionally, multilingual support further enhanced inclusivity, enabling users from different linguistic or dialect-speaking backgrounds to seek medical advice without language barriers.

Subtheme 3 (Reliability Benefit): Comprehensive Medical Information via Data Integration

Most participants regarded AI-driven medical consultation services as relatively reliable due to their ability to process large volumes of data and integrate multiple information sources. Unlike human consultations, these systems can rapidly analyze clinical guidelines, drug information, and statistical data to provide evidence-based recommendations. Several participants emphasized that AI's capacity to efficiently retrieve and cross-reference information could enable more comprehensive advice. Furthermore, several participants suggested that integrating AI-generated insights with human consultations could provide more comprehensive and trustworthy guidance, as it supplements health care professionals' responses with additional information. Others believed that implementing a system in which AI-generated recommendations undergo human review before being delivered to patients would further enhance reliability, accuracy, and patient safety.

Subtheme 4 (Efficiency Benefit): Reduced Health Care Costs and Time

Most participants highlighted the cost-effectiveness and time-saving advantages of AI-driven medical consultation services. Unlike traditional online consultations, which can be

XSL•FO
RenderX

expensive, AI services are either free or substantially more affordable, making them a cost-efficient option. They also help save time by providing quick access to basic medical information, reducing the need for lengthy explanations from health care professionals. Additionally, some participants noted that AI can assist in identifying potential health issues and recommending appropriate specialist departments, thereby streamlining the process before in-person visits.

Subtheme 5 (Education Benefit): Improved Health and Medication Literacy

Most participants emphasized that AI-driven medical consultation services play an important role in improving patient education and medical literacy. Participants found that AI's ability to clearly explain medication indications, dosage instructions, mechanisms of action, potential drug interactions, and relevant medical concepts helped them better understand their treatment plans. This enhanced their readiness for face-to-face consultations and facilitated communication with health care providers. AI-driven consultations were perceived as effective tools for empowering patients, promoting informed decision-making, and increasing confidence in managing their medications and health conditions.

WTP

The majority of participants assumed that AI-driven services should be free. Some believed that AI-driven online consultation services could be priced according to their level of human involvement. For example, fully automated AI-driven services that rely solely on algorithmic responses were expected to remain free or low-cost, as they primarily aggregate publicly available medical information. In contrast, AI-assisted services involving health care professionals could be charged, as expert validation and personalized advice make a paid model more justifiable. A tiered pricing model could balance accessibility and quality, offering free basic AI consultations while charging for expert-reviewed recommendations. Participants who preferred traditional offline consultations reported lower WTP, whereas those satisfied with prior OMC experiences showed higher WTP for such services. In summary, participants reported WTP values ranging from RMB 0 to RMB 200 (US $0-$27.28; RMB 1=US $0.1364 as of January 15, 2025), with some indicating a higher WTP for services reviewed or validated by senior professionals or tertiary hospitals.

Discussion

Principal Findings

This qualitative study explored perceived barriers, facilitators, expectations, and factors shaping public acceptance of and stated WTP for AI-driven OMC services. Through in-depth interviews with 20 participants from diverse backgrounds, perceived risks and perceived benefits were identified as 2 key dimensions influencing participants' acceptance and WTP for these services. Regarding perceived risks, psychological, governance, social, functional, health, and financial risks were found to negatively affect acceptance, serving as potential barriers that may discourage engagement with AI-driven OMC services. For perceived benefits, convenience, diversity, reliability, efficiency, and educational benefits emerged as key motivating factors encouraging acceptance. Participants reported WTP values ranging from RMB 0 to RMB 200 (US $0-$27.28; RMB 1=US $0.1364 as of January 15, 2025), with participants' views appearing to vary by their prior OMC experience and understanding of the service model. These findings provide valuable insights for the development and optimization of AI-driven OMC services, supporting targeted pricing strategies and personalized service design that address public preferences and concerns.

The theory of perceived risk provides a valuable framework for interpreting participants' hesitancy toward AI-driven OMC services [27]. As novel health care technologies often face initial resistance due to unfamiliarity [28], psychological risk was reflected in participants' lack of familiarity with AI-driven platforms, leading to skepticism about reliability and a preference for face-to-face interactions. The preference for in-person consultations reflects not only technological hesitancy but also established expectations regarding health care delivery models [29]. Governance risks emerged as major concerns, with participants expressing fears of data leakage and inadequate regulatory oversight. These findings align with previous studies that highlighted concerns about ethical dilemmas, unclear regulations, and data privacy in health care–related AI applications [30,31]. Lack of transparency remains a prevalent issue across most existing AI technologies [32]. Social risk was evident in participants' discomfort with non–face-to-face communication, which they felt hindered the expression of complex health information. Deficiencies in empathetic responses and human-centered care make AI interactions less acceptable to some users [33]. Functional risks were associated with both clinical and technical limitations of the platforms, including the inability to prescribe medications, conduct tests, or deliver highly personalized advice, which reduced the perceived value of the service. Beyond clinical functionality, usability appears to be an important factor shaping trust and acceptance, as technical stability, ease of navigation, and platform reliability influence whether users feel confident relying on AI-driven OMC services. AI-driven consultations were considered more reliable for managing straightforward tasks and therefore more acceptable [34], although technical failures may compromise reliability and erode trust among health care professionals [32,35]. Health risks centered on urgent care availability and potential misinformation, while financial risks reflected uncertainty about whether AI-driven services would ultimately reduce or increase health care costs. These multifaceted risks collectively present substantial barriers to the adoption of and WTP for AI-driven OMC services, particularly among participants without prior OMC experience.

Perceived benefits emerged as key motivating factors for WTP for AI-driven OMC services. Importantly, these benefits refer to participants' perceived benefits rather than demonstrated performance of the AI-driven OMC model, as this study did not evaluate a standardized platform or clinically validate the accuracy, safety, or reliability of medication advice. OMC may extend health care to marginalized populations through remote consultations, monitoring, and technology-assisted diagnosis [36], and AI is expected to provide more real-time predictions

XSL•FO
RenderX

of patient outcomes in the future [37]. AI has expanded access to integrated health care by enhancing provider communication, facilitating interactions, and serving as a knowledge hub [38,39]. Such flexibility aligns with increasing consumer demand for on-demand health care [40,41]. Service diversity, including multiple communication modes and language support, created a more inclusive health care experience appealing to diverse user preferences and communication styles. Reliability was attributed to AI's ability to process and integrate large datasets [42], although hybrid models with human oversight were considered more trustworthy. While user-friendly AI platforms are essential for implementation, integrating them into existing health care systems remains challenging and often requires substantial changes to established operational workflows [43]. Potential cost-effectiveness was perceived as another benefit, with participants expecting time or cost savings compared with traditional consultations. Moreover, participants perceived educational value in these services, particularly for improving medication knowledge, preparing for subsequent consultations, and supporting communication with health care professionals. However, whether these perceived benefits translate into improved clinical outcomes requires further evaluation.

Regarding WTP, our findings reveal that participants' WTP was shaped by how they understood the service model and the level of human involvement. Many participants believed that fully automated AI-driven OMC services should be free or low-cost, whereas services involving review by health care professionals were considered more acceptable as paid services. These findings align with the broader digital health literature showing that WTP is highly context-dependent and varies by service modality, user characteristics, and the perceived value of the service. A systematic review of eHealth WTP studies identified substantial heterogeneity across studies: one-time WTP ranging from US $0.88 to US $191.84 and monthly WTP ranging from US $5.25 to US $45.64, with WTP differing by population characteristics and delivery modality [44]. Another study of primary care web portals similarly suggested that patients may be willing to pay modest fees for online services that offer direct practical value, such as physician messaging, medical record access, and medication refills [45]. More recent evidence from health apps in Hong Kong also showed that WTP was associated with prior app experience and perceived benefit, while unwillingness to pay was commonly linked to expectations that such services should be free, distrust, and limited awareness of benefits [46]. In line with previous studies, our participants appeared to attach value less to AI involvement itself than to clinically meaningful service attributes, particularly professional oversight, trustworthiness, convenience, and affordability. Since WTP was elicited through open-ended qualitative questions and participants discussed different service models, including AI-only and professionally reviewed services, this range should be interpreted as exploratory evidence of perceived value rather than as a pricing estimate. As highlighted by a previous study on cost-aware frameworks, health care AI development expenses—including data acquisition, computational resources, and developer labor—are frequently underestimated in conventional cost assessments [47]. Rather than supporting a specific payment model, our findings suggest that future payment models for AI-driven OMC services need to balance affordability, perceived value, professional oversight, and equitable access. The strategic design of AI payment models is therefore crucial to enhance WTP while optimizing financial efficiency and ensuring equitable access across populations [48]. In the future, insurance companies or health networks may leverage reimbursement policies and out-of-pocket costs to influence or restrict patients' provider choices as part of cost-effectiveness–based payment strategies [49]. Prior OMC experience may have shaped how some participants described service value and payment conditions; however, this study did not formally compare WTP across experience groups. The experience-related observations, which refer to prior OMC experience with or without the involvement of AI, should be interpreted as exploratory and hypothesis-generating rather than as evidence of subgroup differences in WTP. Some participants with prior OMC experience provided more concrete descriptions of payment conditions, whereas participants without such experience more often expressed uncertainty or expected AI-only services to be free. Variations in preferred service models may also reflect personal characteristics, prior digital health experiences, perceived needs, and expectations [50]. These findings suggest that trial periods or freemium models may be worth further exploration to build initial trust, although future quantitative or experimental studies using standardized service descriptions and payment scenarios are needed before drawing conclusions about pricing models.

Implications

By identifying participants' perceived barriers, facilitators, expectations, and payment considerations, our findings provide user-centered implications for the design, implementation, and future evaluation of AI-driven OMC services. This study used a qualitative approach, informed by the theories of perceived risk and perceived benefit, to identify perceived barriers, facilitators, expectations, and factors shaping public acceptance of and stated WTP for AI-driven OMC services. These findings suggest that service design may need to consider not only technical performance but also usability, trust, privacy protection, professional oversight, and affordability from the user perspective. For policymakers, establishing clear regulatory frameworks for AI-driven OMC services could help address privacy concerns and build public trust. Regulations should balance innovation with consumer protection. For telemedicine developers, our results highlight the importance of intuitive, user-friendly interfaces to overcome psychological barriers associated with unfamiliarity. Integrating AI-generated recommendations with human oversight could mitigate concerns about accuracy, personalization, and accountability. From a payment perspective, tiered service models that distinguish between basic AI-only support and professionally reviewed services may be worth further exploration, although future quantitative studies are needed to evaluate WTP and pricing models more precisely.

Limitations

Several limitations should be considered when interpreting our findings. First, the sample size of 20 participants, while appropriate for qualitative research, limits the transferability of the results to broader populations and settings. Although

XSL•FO
RenderX

patients, caregivers, and health care professionals were included to capture different stakeholder perspectives, the small numbers of caregivers and health care professionals limited the ability to compare views across groups or determine whether saturation was achieved within each stakeholder group. Therefore, subgroup-related findings should be interpreted as exploratory rather than representative of each stakeholder group.

Second, the study was conducted during a period when AI-driven OMC services were in the early stages of adoption in China, suggesting that perceptions may evolve as these services become more mainstream. Third, the focus on stated rather than revealed WTP may not fully capture actual payment behaviors in real-world settings. In addition, WTP was explored through open-ended qualitative questions rather than a formal contingent valuation approach, and participants were not asked to evaluate one standardized service model or payment scenario. Therefore, the reported WTP values should be interpreted as exploratory observations of perceived value rather than pricing estimates. Participants' descriptions of AI as efficient, comprehensive, or reliable reflected perceived or expected attributes rather than empirically tested properties of a specific AI-driven OMC platform. Future studies should evaluate the clinical accuracy, safety, and reliability of AI-generated medical advice under standardized service scenarios. Fourth, because the interviews were conducted in Chinese and selected quotations were translated into English for reporting, some linguistic nuances may have been affected during translation, although translated quotations were checked against the original transcripts to preserve participants' intended meanings. Although some findings may be relevant to countries with similar health care contexts, such as uneven medical resource distribution, growing telemedicine use, and early-stage AI integration, transferability should be considered cautiously. Health care financing, regulation, pharmacist roles, and public trust in AI may differ across settings. Future research should address these limitations through larger quantitative studies, cross-cultural comparisons, and experimental designs measuring actual payment behaviors rather than stated intentions.

Conclusion

Through semistructured in-depth interviews with 20 participants from diverse backgrounds, perceived risks (psychological, governance, social, functional, health, and financial risks) and perceived benefits (convenience, diversity, reliability, efficiency, and educational benefits) were identified as 2 key dimensions associated with participants' acceptance and WTP for AI-driven OMC services. These findings provide exploratory insights into participants' concerns, perceived value, and expectations, which may inform future service design and further research on payment models for AI-driven OMC services.

Acknowledgments

We would like to thank all the researchers who participated in this study and the respondents who took part in the survey.

Disclosure of Delegation to Generative AI (GenAI)

The authors declare the use of GenAI in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to GenAI tools under full human supervision: Proofreading and editing

The GenAI tool used was: ChatGPT-5.6 Sol.

Responsibility for the final manuscript lies entirely with the authors.

GenAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Declaration submitted by: Qiushi Cai

Funding

This research was funded by the National Natural Science Foundation of China [grant number: 72304009].

Data Availability

Due to the sensitive nature of qualitative interview data and privacy considerations, the datasets generated and analyzed during the current study are not publicly available. Deidentified data may be provided by the corresponding author upon reasonable request and with approval from the Ethics Committee of Peking University Third Hospital (Approval No. M20241044).

Abstract

Background: Digital well-being support tools can offer adolescents tailored interventions embedded in their digital environments. However, there is a lack of high-quality, evidence-based digital interventions specifically designed for young people's well-being needs. Wellby is a mobile app and wearable device cocreated with Irish secondary school students to support stress management and overall well-being.

Objective: This study aimed to evaluate the acceptability and usability of the Wellby system using the technology acceptance model, focusing on ease of use, perceived usefulness, and behavioral intention among Irish secondary school students.

Methods: A mixed methods acceptability and usability study was conducted with Irish secondary school students (n=43) across 3 schools: 2 mainstream secondary schools and 1 Youthreach center for early school leavers. Students accessed the Wellby mobile app for 8 weeks and received the custom wearable device for the final 4 weeks (April-May 2024). Wellby included mood tracking, to-do lists, educational resources, text-based health coaching, and heart rate variability biofeedback with guided breathing exercises. Acceptability and usability were evaluated using the user version of the Mobile App Rating Scale (uMARS), structured focus groups, and app engagement analytics. Secondary measures included baseline well-being questionnaires (Perceived Stress Scale, Pittsburgh Sleep Quality Index, and EPOCH Measure of Adolescent Well-Being).

Results: Among survey respondents (n=29), uMARS subscale scores were high: information quality (mean 4.2/5.0), functionality (4.1/5.0), and aesthetics (4.1/5.0). The perceived impact subscale showed the highest scores for well-being awareness (3.8/5.0) and help-seeking intention (3.9/5.0). Of survey respondents who participated in prior co-design sessions, 88% (21/24) and 83% (20/24) felt the wearable and app, respectively, aligned with their co-design feedback. App engagement more than doubled following the introduction of the wearable and revealed that the wearable tab was most accessed (643/1688, 38% of interactions), followed by the home (430/1688, 25%), resources (338/1688, 20%), and coaching (277/1688, 16%) tabs. Focus group feedback highlighted the mood tracker as the most valued feature and identified technical improvements, including better battery life, enhanced Bluetooth connectivity, and more personalization options.

Conclusions: This study demonstrates that cocreated digital well-being tools can achieve high acceptability and usability with Irish secondary school students. Applying the technology acceptance model effectively captured student experience through mixed methods feedback. Students particularly valued self-tracking and personalization features over coaching or educational features. These findings highlight the importance of aligning digital technologies with adolescents' needs and preferences, such as features that encourage increased autonomy and identity formation. Future iterations of Wellby should address the technical limitations while continuing the involvement of students to adapt to their developmental needs and maintain high acceptability.

Introduction

Background

Digital tools present novel pathways to enhance the health and well-being of young people, particularly given the ubiquity of digital technology in many adolescents' lives [1]. Mobile apps offer scalable and accessible routes for adolescents to avail themselves of educational tools and interventions that address their well-being needs [2]. These can facilitate healthy lifestyle habits during the formative period of adolescence, which can encourage positive health later in life and reduce the burden of preventable noncommunicable diseases [3,4]. Additionally, connected technologies can augment the well-being support capabilities of mobile apps, such as wearable devices, which are increasingly used for tracking activities, health behaviors, and continuous physiological data [5]. While mobile apps include affordances that show promise in supporting adolescent well-being, there is limited research into adolescent-specific digital tools [6,7]. Given the potential for these tools to provide crucial support for young people, there is a need to further investigate and develop digital tools that are specifically designed to consider the health and well-being needs of this age group [2,8]. Because social, environmental, and demographic factors significantly impact adolescent health outcomes [9,10], understanding local contexts and cultures is critical for designing tailored interventions for specific cohorts of adolescents [7,11]. Several studies have demonstrated the importance of adopting adolescent-centered designs to promote intervention acceptability, usability, and effectiveness [12-15].

Co-Design and Participatory Approaches

Participatory design practices are well documented throughout history [16], and there are several modern frameworks for engaging participants in the cocreation of new interventions with young people [17,18]. Radical participatory design is one framework for any population that stresses the need to shift power from researchers or designers to the participants throughout each phase of the intervention creation process [16]. While many design processes involve users only after a prototype has been developed, co-design and cocreation offer a more inclusive approach by positioning participants as equal partners throughout the entire process [19]. The term co-design tends to focus solely on the technology development process, while cocreation includes broader involvement of participants such as during planning and implementation phases [19]. This collaborative approach is particularly important when designing for adolescents, as their unique contexts and preferences require specialized consideration.

When developing digital tools for this age group, it is also essential to acknowledge the risks of these technologies so that potential privacy and safety concerns are considered in the design. Digital tools present several potential risks, including concerns about data privacy, inappropriate content exposure, overuse or dependence, algorithmic bias, and insufficient safeguarding mechanisms [20,21]. Specifically, an increased reliance on mobile apps, particularly social media, has been associated with increased anxiety and depression among young people [22,23]. Often, these apps implement addictive features, aiming to maximize people's time on the platform, which can be particularly harmful for adolescents [24]. Participatory engagement and acceptability testing can help to mitigate these risks by centering the experiences, input, and impact on the people who will use these technologies.

Current Gaps in Adolescent Digital Health

Despite the potential of digital tools to improve adolescent health [1,6,7], there remains a gap in evidence-based digital interventions focused on supporting adolescent well-being. A review of over 1000 mobile apps available for wellness and stress management found that only 2% were supported by scientific research papers, while 4% of the apps focused on either young adults or youth [25]. Similarly, reviews of mobile apps targeting adolescents have found a need for more rigorous evaluation and the incorporation of co-design processes to promote relevant and engaging interventions for young people [6,26]. Among platforms co-designed with young people, many focus on chronic disease management or clinical mental health conditions rather than stress or overall well-being [17].

In response to the lack of adolescent-specific and evidence-based interventions, researchers have increasingly called for more rigorous evaluation of these tools to better understand their effectiveness, safety, and long-term impact on adolescent well-being [7,27,28]. Fields such as positive technology have emerged to focus on the minimization of risk while maximizing features that promote healthy and meaningful engagement with technology [29]. Additionally, participatory design processes can help to mitigate risks by fostering trust between adolescents, caregivers, and researchers or developers, while also ensuring alignment with the adolescents' goals and preferences [30].

Related Acceptability and Usability Studies

The assessment of acceptability and usability can help inform the iterative development of technology [31] and enhance the impact on participants' well-being [32]. This can be measured in several ways, including quantitative assessments using validated instruments, engagement patterns captured through analytics, and qualitative feedback on people's experience with technology. Inal et al [31] conducted a systematic review of usability evaluations for mobile mental health technologies, analyzing 42 studies across various populations. In this review, they found that data were most often collected through questionnaires, field studies, and interviews, with user reception and people's perception of the intervention being the main outcomes of focus. Notably, only 3 of the 42 included studies incorporated participatory design in the development of the technologies that were tested. Another systematic review by Creaser et al [33] synthesized results from 33 studies on the acceptability of wearable activity trackers for promoting physical activity in youth. This found that wearables increased motivation in young people to be more physically active, despite technical difficulties and novelty effects of wearables use.

A similar study investigated the app engagement, usability, and satisfaction of adolescents, aged 13 - 20 years, interacting with the BeMe app, focused on supporting adolescent mental health [34]. The BeMe app included content based on cognitive behavioral therapy, interactive activities, text-based coaching,

XSL•FO
RenderX

and links to clinical services. The majority of participants in this study engaged with the content, mood ratings, and skill training activities on the app, and greater participant engagement was associated with increased app satisfaction. Another study assessed the usability and acceptability of Fitbits for Australian adolescents aged 13 - 14 years during a 6-week period [35]. The adolescents in this study found the Fitbit easy to use and useful for monitoring physical activity, with barriers including comfort, design issues, and lack of activity-specific feedback. Additionally, Martin et al [36] outlined the co-design of a mobile app to promote a healthy lifestyle in European adolescents aged 13 - 16 years. Based on the co-design process, a series of recommendations were established for the mobile app including personalization features, accessible language and design, and comprehensive app tutorials. Finally, Swahn et al [37] summarized feedback from female adolescent participants using a wearable in an urban setting in Uganda. Despite general positive feedback from participants, they also shared concerns about comfort, surveillance, and data privacy, and strong reactions from community members. Although these studies focus on adolescent feedback on digital well-being tools, most evaluate either mobile apps or wearable devices in isolation.

Furthermore, few studies employ theoretical frameworks to systematically assess the acceptability and usability of these tools. The technology acceptance model (TAM) was chosen for this study as it offers a simple yet effective and adaptable framework for acceptability that has been applied in diverse contexts, such as education [38]. Other common frameworks include the unified theory of acceptance and use of technology (UTAUT) [39] and the theoretical framework of acceptability (TFA) [40]. The UTAUT is based on several frameworks, including the TAM, and outlines 4 key factors and modifiers that influence intention and usage, while the TFA was established for health-related interventions and includes prospective, concurrent, and retrospective components of acceptability. The TAM offers several advantages for this study. It presents a robust measure with previous application in similar adolescent and educational contexts [38,41], enabling comparison to related work and promoting reproducibility and adaptability of this method for future studies.

Aim and Hypothesis

This paper outlines student evaluations of the acceptability and usability of Wellby, a cocreated mobile app and wearable, to help to iteratively develop this intervention for student well-being. The acceptability and usability testing detailed in this paper helps to maintain alignment with students' needs and promote beneficial technology usage. The mixed methods approach of this study is transferable to other cocreated interventions, and students offer feedback that can be used to enhance digital tools more generally to support adolescent-specific well-being needs.

The aim of this study is to assess the acceptability and usability of the Wellby mobile app and wearable as part of a cocreation process with Irish secondary school students. The primary outcomes are ease of use, perceived usefulness, and behavioral intention of Wellby, which are measured using the TAM framework both quantitatively and qualitatively [42]. Secondary outcomes are students' stress, sleep, and overall well-being, measured by baseline questionnaires and demographic information to further contextualize the results. Wellby has been created through an iterative cocreation process with students (aged 15 - 19 years) at 4 Irish secondary schools to address students' well-being needs through a mobile app and wearable that offer educational resources, heart rate variability (HRV) tracking, and text-based coaching. Based on participatory design principles, we hypothesize that the cocreation process will lead to a system that aligns with students' well-being goals and demonstrates high acceptability and usability among students. This study was conducted across 3 of the 4 Irish secondary schools that were involved in the co-design process. Acceptability and usability feedback was gathered to adapt the next version of Wellby to provide relevant stress and well-being management tools for students.

Methods

Overview

This mixed methods acceptability and usability study evaluated Wellby over 8 weeks with Irish secondary school students (n=43) based on the TAM [42].

Ethical Considerations

Ethical approval for this study was obtained through the Research Ethics Committee at the Royal College of Surgeons in Ireland (ID 202403004). Informed consent was obtained from students' parents and/or legal guardians, with written assent provided by adolescents. This study was registered with ClinicalTrials.gov (NCT06294210). Participant data were pseudonymized, and qualitative feedback was assessed for identifiable information to preserve participant privacy. No compensations or incentives were provided to participants besides the potential benefits of the intervention itself.

Participants

Students from 3 schools participated in this study. Two of the schools were mainstream schools, while one school was a Youthreach center. Youthreach is an alternative coeducational program with locations around Ireland, providing specialized education for early mainstream school leavers [43]. The participants at the mainstream schools (schools A and B) were in their 5th year, aged 16 - 17 years. School A is a coeducational school in County Wexford, and school B is an all-female school in County Kildare. The survey participants at Youthreach (school C), in County Dublin, were in their first or second year of the program, aged 15 - 19 years. Eighty-eight percent of student participants were also involved in previous co-design sessions (Table 1). In usability studies, a baseline of 5 - 10 participants is recommended by Macefield [44]. This target number was reached for each school in this study to ensure representative feedback since these schools previously showed slight differences in well-being needs [45].

Wellby Mobile App and Wearable Description

The co-designed Wellby mobile app was published on the iOS Apple Store and the Google Play Store for students to access. The app was developed by JL, with educational well-being and HRV content curated by JM, PD, and JL. The mobile app includes four tabs (Figure 1): (1) a home tab with student-requested tools, including an optional daily quote, mood check-in and tracker, a clickable calendar with daily to-do lists, and settings where customizable app colors can be chosen; (2) an educational resource tab with evidence-based articles, infographics, and videos on topics requested by students, including stress management, sleep, digital well-being, and time management; (3) a wearable tab that facilitates connection to the Wellby wearable device and offers options to start new recordings, see past recordings, learn about HRV, and engage in breath work; and (4) a health coaching tab that offers optional text-based messaging with certified health coaches around student-requested well-being focus areas. Two certified health coaches were recruited through the Centre for Positive Health Sciences at the Royal College of Surgeons in Ireland (RCSI) and were vetted by RCSI and the participating schools. In future implementations, coaches could be school counselors, health and well-being staff, or community health workers.

The Wellby wearable is a wrist-worn device that includes a photoplethysmography sensor for tracking heart activity, a rechargeable battery, a Bluetooth connection module, and a light indicator of battery and connection status (Figure 2). This device was designed and assembled by engineering researchers based at RCSI (JL and SJ). Developing a custom device in this study allowed for increased adaptability and customizability of the intervention based on student input throughout the iterative cocreation process. It also enhanced data control, analysis, and security, enabling intentional and transparent data collection and processing. Students indicated in the co-design that the appearance of the device was important to them. Therefore, they were able to request the color of the nylon case, strap design, and strap material for the wearable in this study.

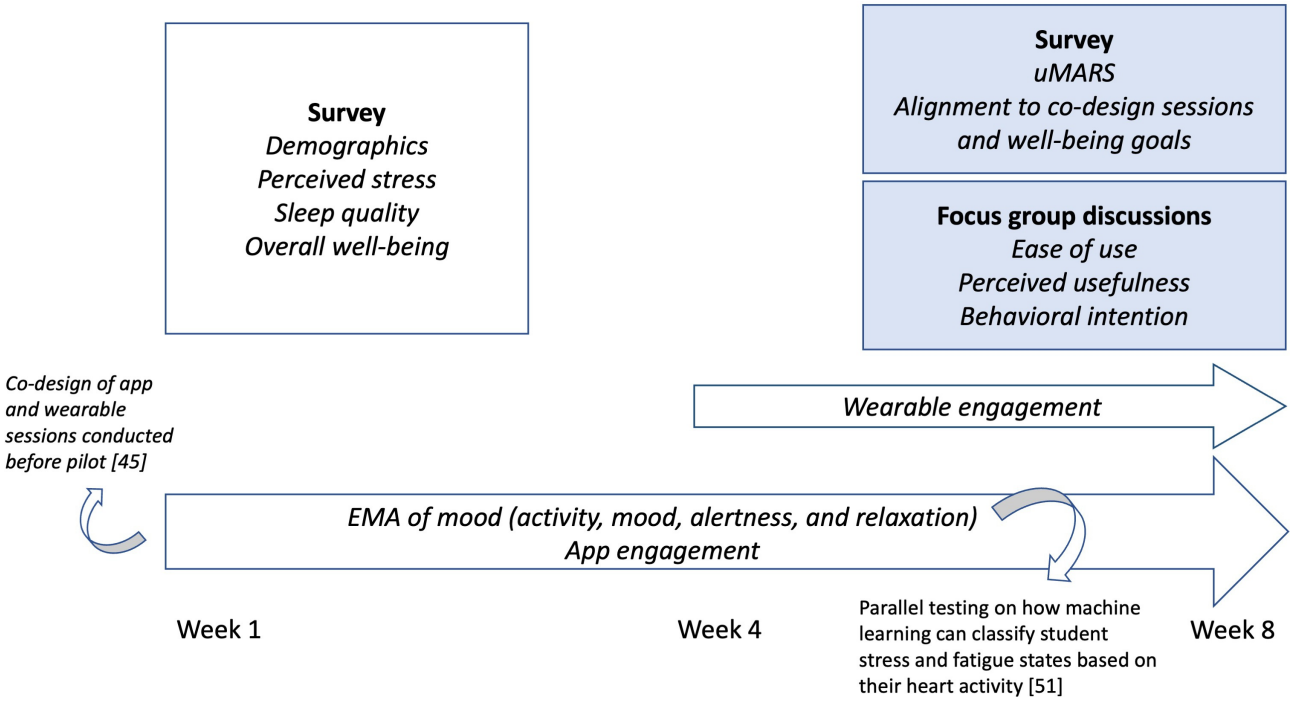
Study Design

In this study, students tested Wellby for 8 weeks (April-May 2024). The primary outcome measure of acceptability and usability was assessed using the user version of the Mobile App Rating Scale (uMARS) [46], survey questions, qualitative feedback from follow-up focus group discussions, and app engagement measured throughout the study. As secondary outcome measures, well-being questionnaires were collected at

XSL•FO
RenderX

baseline. Perceived stress, sleep quality, and overall well-being were measured using the 10-item Perceived Stress Scale (PSS) [47], the Pittsburgh Sleep Quality Index (PSQI) [48], and the EPOCH (engagement, perseverance, optimism, connectedness, and happiness) Measure of Adolescent Well-Being [49], respectively. Well-being questionnaires were only collected at baseline because of students' limited availability and increased pressure during the final weeks of their school year. We prioritized collecting the primary outcomes for this acceptability and usability study, which was designed to inform a follow-up longitudinal efficacy study with repeated well-being measures. Additional students were recruited at schools A and B who completed the well-being questionnaires without testing Wellby. This group was recruited to compare the well-being of students with and without access to Wellby for potential future efficacy studies on the impact of Wellby on student well-being. No additional students were recruited at school C because all students were involved in testing Wellby.

Students first had access to the Wellby mobile app alone for 4 weeks before receiving the connected wrist-worn HRV monitor for the final 4 weeks of the study. This allowed for the investigation of the acceptability and usability of the mobile app alone and in combination with the wearable device. Four weeks represents a common duration of acceptability studies of wearables for adolescents [33]. The phased approach aligns with the iterative development of cocreated tools [36] and enabled comparison between the intervention components. Students were encouraged to use Wellby as much as they found useful throughout the study period. The uMARS and hour-long focus group sessions were completed at the end of the 8-week study.



Positive design provided the framework to develop the Wellby system [29], and Radical Participatory Design [16] provided the methodological guidelines to promote continuous collaboration with students throughout the cocreation process. As outlined in a previous work [45], students were involved in a needs assessment and co-design sessions to shape the focus and design of Wellby.

Through the study protocol and cocreation approach, we aimed to reduce the potential risks that are presented by digital tools, such as privacy concerns, overuse, and fixation on negative data [20,50]. Data were encrypted in Google Firebase, and access was reserved to approved data controllers (JL and PD). We established an incident reporting protocol for in-app coaches to notify researchers of messages indicating potential violence or harm to students. During participant onboarding, we demonstrated the capabilities of the technology in person and provided multiple avenues for the students to raise questions or concerns during the study, such as through their teacher or an in-app feedback form. To avoid fixation on negative data, evidence-based text and diagrams were provided in the biofeedback tab about the meaning of HRV metrics, and signal quality metrics were included for each recording to enhance transparency about the reliability of the HRV data.

Additionally, students were encouraged to complete ecological momentary assessments (EMAs) throughout the study and wearable recordings during the final 4 weeks. The EMAs included questions about the student's current activity, mood (represented as an emoji), and alertness and relaxation level on a scale from 1 to 5. The focus on alertness and relaxation was connected to sleep and stress, previously identified as being the well-being priorities of this cohort [45]. Check-in reminders to engage with the app and complete the EMAs were sent at 3 random times during the school week, provided students had enabled notifications. A separate and parallel study was conducted based on the EMAs and wearable recordings from the testing of Wellby. The objective of this parallel study was to understand how machine learning could potentially be used to classify student stress and fatigue states based on their HRV metrics [51]. Figure 3 illustrates the data collection methods and timepoints throughout this study.

XSL•FO
RenderX

Figure 3. Wellby data collection methods outline of the 8-week study, including pre- and postintervention surveys, continuous data collection, focus group discussions, and connected research papers [45,51]. EMA: ecological momentary assessment; uMARS: user version of the Mobile App Rating Scale.

Questionnaire Measures

The postintervention survey included questions about the study's alignment with students' well-being goals and the uMARS questionnaire, providing quantitative data associated with the primary outcome of this study. The uMARS includes 5 subscales and has previously demonstrated an overall internal consistency (Cronbach α) of 0.90 [46]. Similarly, from the responses in our study, the uMARS resulted in good internal consistency (α=0.89). The first 4 subscales of the uMARS focused on engagement, functionality, aesthetics, and information quality, grouped into the "ease of use" of Wellby. The final subscale of the uMARS focused on the perceived impact on awareness, knowledge, attitudes, intention to change, help seeking, and behavior change based on the use of Wellby. Each subscale included questions with responses ranked on a scale from 1 to 5, with 1 being the lowest and 5 being the highest score.

The baseline well-being questionnaires, including the PSS, PSQI, and EPOCH, have been validated for adolescent populations where they demonstrated internal consistencies (Cronbach α) of 0.62, 0.72, and 0.88, respectively [52-54]. Our study demonstrated comparable internal consistency for the PSS (α=0.78), PSQI (α=0.74), and EPOCH (α=0.89). The overall scores for these questionnaires range from 0 to 40 for the PSS, 0 - 21 for the PSQI, and 0 - 25 for the EPOCH questionnaire, where higher scores indicate greater stress, lower sleep quality, and greater well-being, respectively.

Data Analysis

To analyze the uMARS results, the first 4 subscales were grouped to evaluate the ease of use of Wellby, while the fifth subscale was used to evaluate the behavioral intention and perceived usefulness in supporting student well-being. Survey questions about the alignment of Wellby with the outcomes of previous co-design sessions and students' well-being goals were summarized using descriptive statistics.

Qualitative feedback from the focus group discussions was analyzed by two researchers (JL and EB) using reflexive thematic analysis based on Braun and Clarke's approach [55]. The identified themes were then grouped into ease of use, perceived usefulness, and behavioral intention based on the TAM [42]. Pen profiles were constructed to illustrate these groupings and provide example quotations associated with each subtheme along with an indication of the number of mentions [56]. Focus group participants included students who were able to attend the in-person, postintervention meeting. These took place during the final weeks of the school year. Demographic information of focus group participants was not available for analysis as this was only collected in the onboarding survey.

App engagement was recorded on Google Firebase, which saved data to indicate the app tabs and features that the students interacted with throughout the study. The engagement data and well-being metrics were summarized across each school using descriptive statistics.

Results

Student Well-Being Assessments

The well-being questionnaires administered as part of the onboarding survey are summarized based on demographic categories in Table 1. Notably, the results demonstrate a higher perceived stress for students at school B, the all-female school, and for female participants overall. Similarly, perceived sleep quality was lowest at school B and for female students. The EPOCH assessment of overall adolescent well-being indicated the highest well-being in students at school A and in male students (Table 2).

White/other European (n=7)	17.7 (3.5)	6.6 (2.9)	16.3 (4.1)
White African (n=1)	19 (N/A)	8 (N/A)	15.3 (N/A)
White Irish (n=30)	20.2 (6.1)	7.5 (3.0)	16.0 (3.0)
Total (N=43)	20.4 (6.3)	8.0 (3.4)	15.8 (3.5)

[a]EPOCH: engagement, perseverance, optimism, connectedness, and happiness.

[b]N/A: not available.

Because of the notable gender differences in the well-being questionnaires and the potential confounding effect of the all-female school, results were analyzed by gender within each school. To increase sample size and generalizability, data from the comparison group (who did not test Wellby) were combined with the intervention group for this gender-based analysis.

Only data from female and male students are presented in Table 3 because these groups had sample sizes that enabled the use of the Mann-Whitney *U* tests for schools A and C to compare results from female and male students. School B was excluded from statistical testing due to the absence of male participants. For school A, Mann-Whitney *U* tests revealed no significant gender differences for PSS scores (U=79.5, P=.90, r=0.031), PSQI scores (U=77.5, P=.82, r=0.051), or EPOCH total scores (U=77.5, P=.82, r=0.051). At school C, a significant gender difference was found for PSS scores, with females reporting higher stress than males (U=0, P=.007, r=0.770). While effect sizes suggested greater sleep quality in males, no significant differences were found for PSQI scores (U=6, P=.08, r=0.514) or EPOCH scores (U=9, P=.19, r=0.385).

Students' well-being goals set at the beginning of the study included elements of lifestyle medicine (daily activity, eating well, relationships, sleep, and stress management) and digital well-being, identified by students as relevant well-being needs in the previous co-design sessions. Sleep and stress management were the most chosen categories for the total student selections (Table S1 in Multimedia Appendix 1). Daily activity and eating well were also frequently chosen, particularly at schools A and C.

Survey Data

Survey Overview

At the end of the 8-week study, students (n=29) completed the postintervention survey, aligning with the final weeks of their school year, which may have contributed to the 67% (29/43) response rate.

Ease of Use

On the first 4 uMARS subscales, the mean of the total scores was 4.1 (SD 0.7). School B had the highest average score for each subscale, 4.0 (SD 0.9) for engagement and 4.4 for functionality (SD 0.3), aesthetics (SD 0.8), and information quality (SD 0.7), compared to the other schools. Based on the student responses grouped across all schools, information quality had the highest overall score of 4.2 (SD 0.6), while engagement had the lowest overall score of 3.8 (SD 0.7). The functionality, aesthetic, and information quality subscales all reported average scores greater than 4.0 for the grouped responses (Table 4).

Table . The uMARS[a] "ease of use" subscale scores by school site[b].

uMARS subscale	School A (n=6)	School B (n=7)	School C (n=16)	Total (n=29)
Engagement	4.0 (0.7)	4.0 (0.9)	3.7 (0.7)	3.8 (0.7)
Functionality	4.3 (0.4)	4.4 (0.3)	3.9 (0.6)	4.1 (0.6)
Aesthetic	3.8 (0.9)	4.4 (0.8)	4.2 (0.8)	4.1 (0.8)
Information quality	4.2 (0.4)	4.4 (0.7)	4.2 (0.7)	4.2 (0.6)

[a]uMARS: user version of the Mobile App Rating Scale.

[b]Data are presented as mean (SD).

Perceived Usefulness and Behavioral Intention

On the final uMARS subscale, the perceived usefulness of Wellby was indicated by the highest scores of 3.9 (0.8) and 3.8 (1.0) for increased help seeking and well-being awareness, respectively (Table 5). Regarding behavioral intention, uMARS results indicated moderate levels of intention to change (mean 3.7, SD 1.0) and anticipated behavior change (mean 3.6, SD 1.2) because of Wellby.

Of the student respondents who indicated prior participation in the co-design sessions for Wellby (n=24), 88% (21/24) and 83% (20/24) felt that the wearable and the app, respectively, aligned "extremely well" or "somewhat well" with their feedback from co-design sessions. Remaining responses indicated students felt "neutral" about the alignment of Wellby with the co-design session outcomes. Responses from all students, including those not involved in the co-design sessions, indicated that a majority (22/29, 76%) felt Wellby aligned "extremely well" or "somewhat well" with their well-being needs (Table S2 in Multimedia Appendix 1).

XSL•FO
RenderX

Table . The uMARS[a] perceived impact scores at each school site[b].

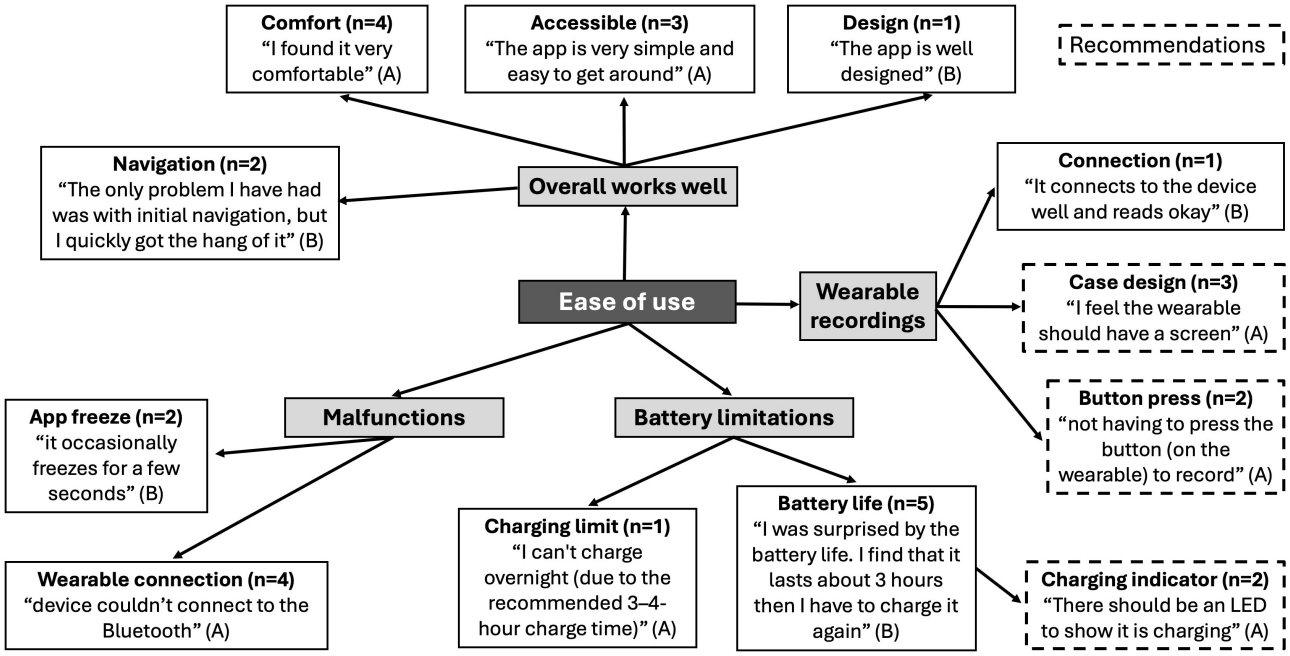
uMARS perceived impact questions	School A (n=6)	School B (n=7)	School C (n=16)	Total (n=29)
Awareness: Wellby has increased my awareness of the importance of addressing aspects of my well-being	3.5 (1.0)	3.9 (1.3)	3.9 (0.8)	3.8 (1.0)
Knowledge: Wellby has increased my understanding of my well-being	3.2 (1.0)	3.6 (1.1)	3.8 (0.9)	3.6 (1.0)
Attitudes: Wellby has changed my attitudes toward improving my well-being	3.2 (1.6)	3.6 (1.1)	3.9 (0.9)	3.7 (1.1)
Intention to change: Wellby has increased my motivation to address certain aspects of my well-being	3.7 (0.8)	3.6 (1.5)	3.9 (0.9)	3.7 (1.0)
Help seeking: Wellby would encourage me to seek further well-being support (if I needed it)	4.2 (0.8)	3.6 (0.8)	3.9 (0.8)	3.9 (0.8)
Behavior change: Use of Wellby will increase aspects of my well-being	3.0 (0.9)	3.9 (1.3)	3.6 (1.2)	3.6 (1.2)

[a]uMARS: user version of the Mobile App Rating Scale.

[b]Data are presented as mean (SD).

Focus Group Feedback

Focus Group Overview



Structured focus groups were conducted in person at the end of the intervention with students at school A (n=6) and school B (n=5). Due to time constraints at school C, less structured feedback from students was gathered, which is summarized under the “ease of use” section. Themes from the discussion were grouped based on TAM categories, and subthemes are detailed using the number of mentions for each theme, a student quotation, and a school indicator for each quote.

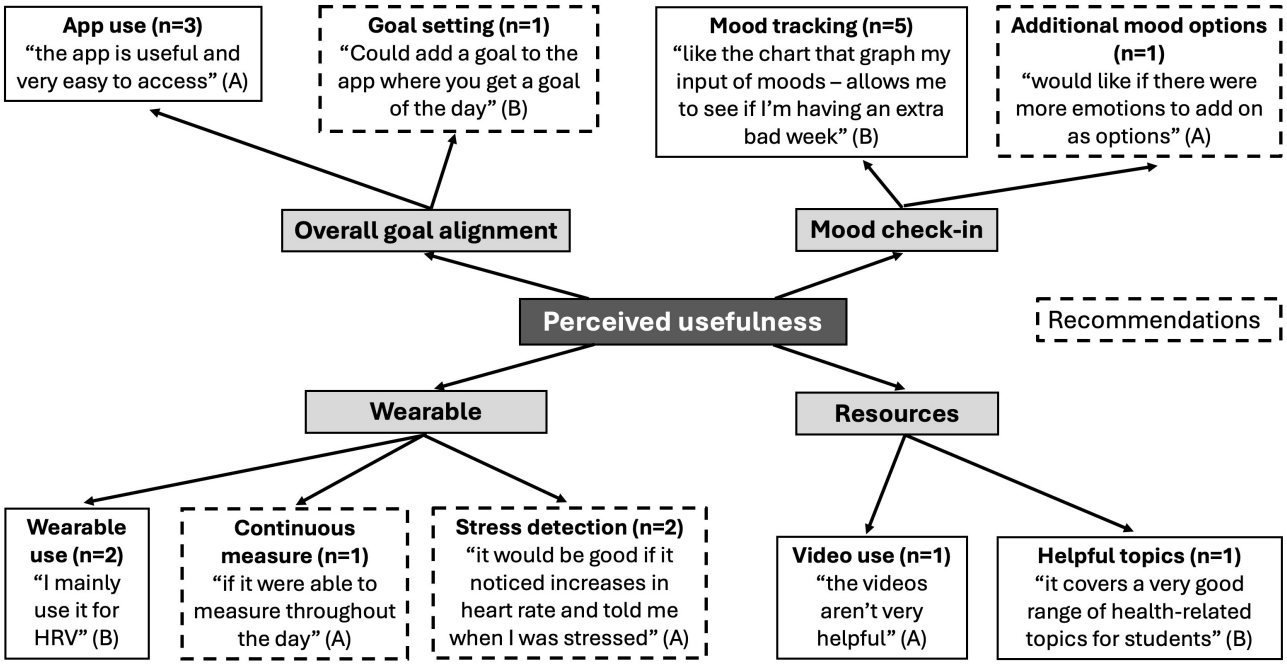
Ease of Use

There was an overall positive response to the ease of use of Wellby, with many students noting that the wearable was comfortable and that the app was “easy to get around” (school A) (Figure 4). Some students noted that it took time to initially understand the app navigation. While one student noted that the app “connects to the device well” (school B), others (n=4) noted challenges with Bluetooth connection, particularly on the Android version of the mobile app. Other limitations included occasional app freezing and battery life. Several students noted that the battery life was not long enough (n=5), and one student specified that they would like to charge it overnight but were unable to due to the recommended 3 - 4 hour charging time. Students also recommended ways to improve the ease of use of Wellby by including a light indicator for different charging stages on the wearable and making it possible to start a heart activity recording without having to press the button on the wearable. Additionally, some students (n=3) noted that they would like something on the face of the wearable, such as a screen or clock. Feedback from school C indicated that students didn’t see the wearable as socially acceptable with their school’s fashion norms. They recommended changes including making the device rounder, having a shiny or metallic material, and including more color options.

XSL•FO
RenderX

Figure 4. Student focus group feedback on the "ease of use" of Wellby grouped into major themes. The subthemes include the frequency (n), an example quote, and the school associated with each student quote (represented by A, B, or C). Subthemes that were recommendations from students are indicated with dashed borders.

Perceived Usefulness



Students indicated an overall alignment of Wellby with their well-being goals (Figure 5). One student recommended adding a feature to the app to specify and track student goals. The most mentioned app feature was the mood tracker, one student sharing that it "allows [them] to see if [they're] having an extra bad week" (school B) and another that they "like the check-in feature" and "spend ages looking through the emojis to choose [their] mood" (school B). To further enhance the mood check-in, a student recommended adding more options to this feature so that they can input more details about their current moods.

Students had mixed opinions about the usefulness of app resources, with one student noting that they "cover a very good range of health-related topics for students" (school B), while another noted that the video resources "aren't very helpful" (school A).

Students also noted feedback about the wearable, one describing that they mainly use Wellby to track their HRV. They also noted that they would like for the wearable to be able to monitor their heart activity continuously throughout the day and notify them of potential increases in stress levels.

XSL•FO
RenderX

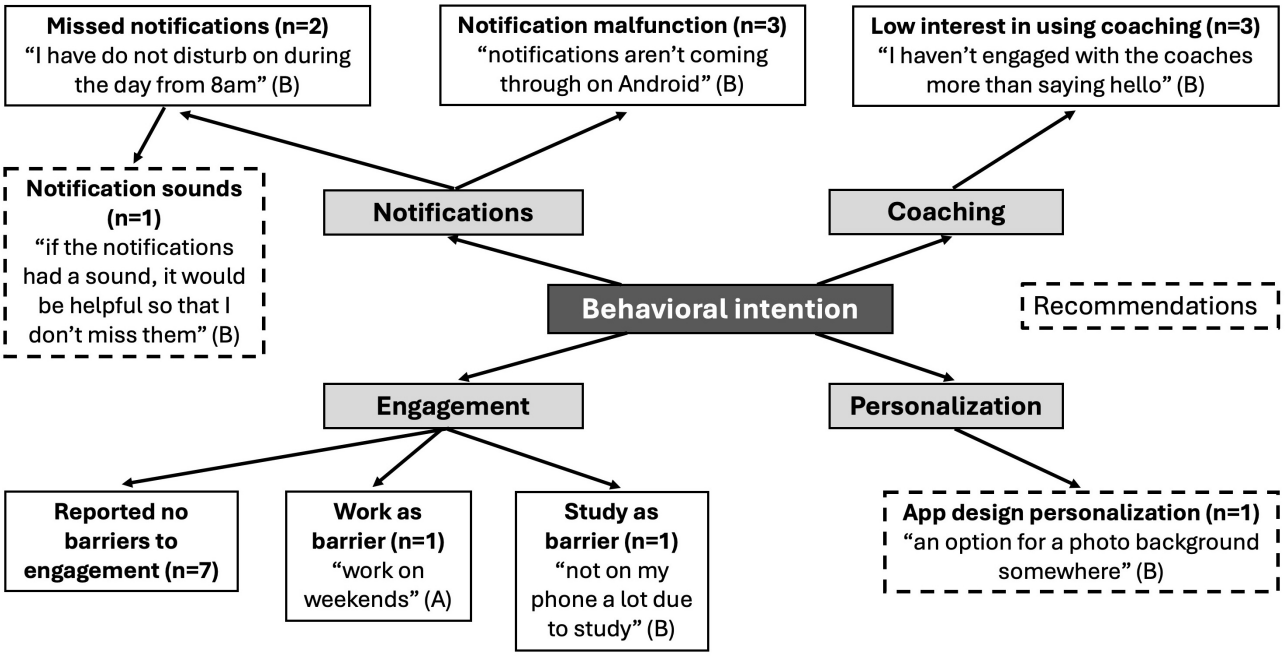


Figure 5. Student focus group feedback on the "perceived usefulness" of Wellby grouped into major themes. The subthemes include the frequency (n), an example quote, and the school associated with each student quote (represented by A, B, or C). Subthemes that were recommendations from students are indicated with dashed borders.

Behavioral Intention

Student feedback from the focus group also included barriers and facilitators of students' engagement with Wellby. Several students (n=3) noted that they had little interest in messaging the health coach provided through the app (Figure 6). Other students missed notifications due to focus features on their phones or malfunctions on Android. One student recommended adding sounds to notifications so that they remember to engage with the app. When asked if there were external factors preventing them from using Wellby, one student indicated that they had work on the weekends, another noted their focus on studying, while most (n=7) indicated no external barriers to engagement. Students also commented on the benefits of personalizing Wellby, such as the app background color or wearable strap material. One student recommended enhanced personalization through choosing custom background images for the app.

Figure 6. Student focus group feedback on the "behavioral intention" of Wellby grouped into major themes. The subthemes include the frequency (n), an example quote, and the school associated with each student quote (represented by A, B, or C). Subthemes that were recommendations from students are indicated with dashed borders.

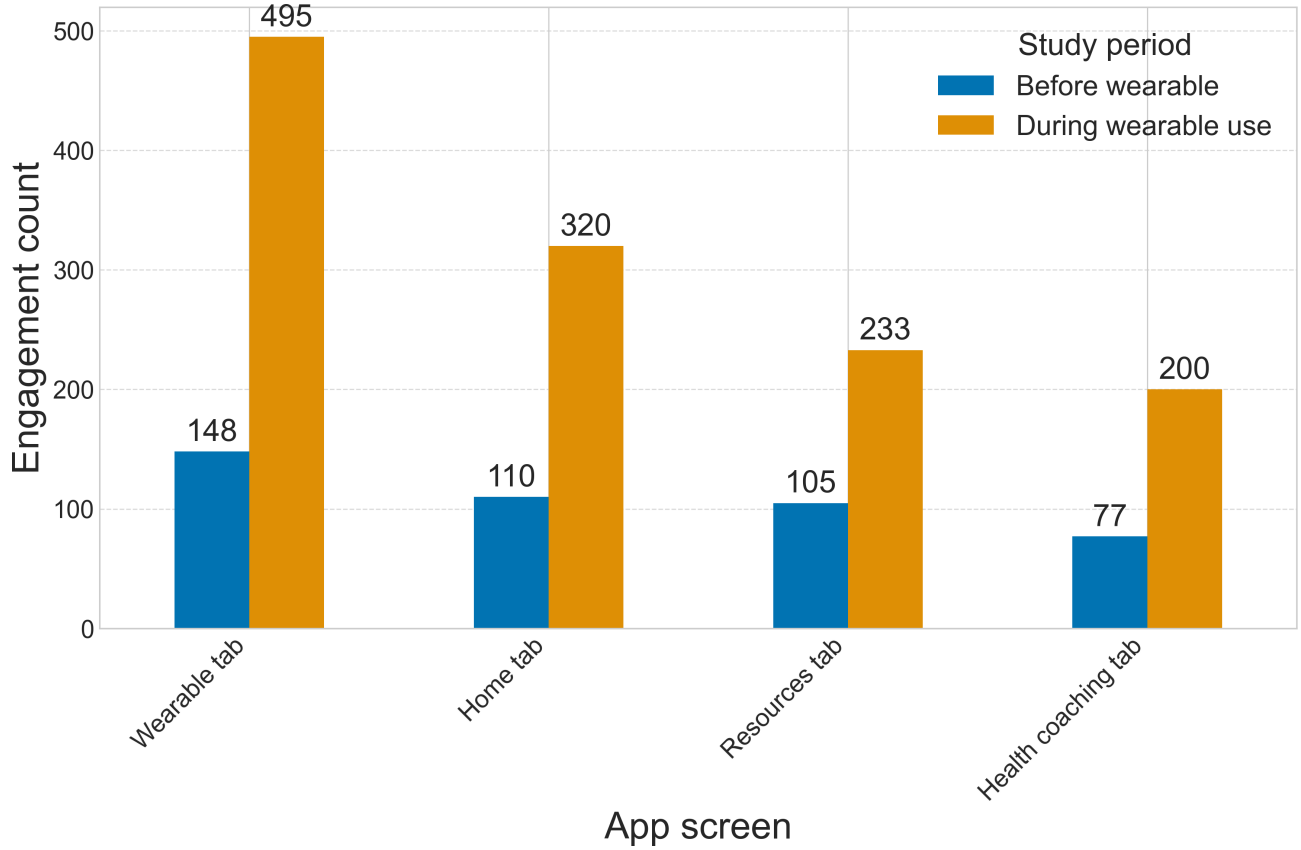
RenderX

Wellby Engagement Metrics

App engagement data throughout the 8 weeks was summarized based on the total engagement with the 4 app tabs, separated by school, and the overall engagement with each app feature. The wearable tab had the highest engagement, followed by the home tab, resource tab, and coaching tab, for each school. Engagement was highest at schools A and C, which had 5 more students involved in the testing than school B (Figure 7). The app features that allowed students to customize the background color on the app had the highest engagement, with 417 total clicks throughout the study period. The following 4 features with the most engagement included completing mood check-ins, viewing specific resource topics, recording HRV, and viewing HRV summary (Table S3 in Multimedia Appendix 1).



Since students had access to the mobile app alone for the first 4 weeks of the study before being given wearables, the engagement was analyzed during both time periods. Student engagement with each app tab increased substantially, ranging from 123 to 347 additional interactions per tab, during the final 4 weeks of the study when they had access to the wearable device (Figure 8). The wearable tab included access to HRV data summaries, a wearable connection to begin a new recording, information on interpreting HRV, and a customizable breath pacer.

XSL•FO
RenderX

Figure 8. Student engagement counts with the Wellby app tabs during the first 4 weeks of the study (before wearable access) compared to the final 4 weeks (when students had access to the wearable device).

Discussion

Principal Findings

This mixed methods acceptability and usability study demonstrated the successful alignment of the co-designed Wellby intervention with the needs and preferences of Irish secondary school students. Additionally, secondary baseline well-being measures captured student well-being needs.

The identification of stress and sleep as the most selected well-being goals aligned with the baseline questionnaire results that indicated high stress and low sleep quality in student participants. The mean overall PSS score (mean 20.4, SD 6.3) was substantially higher than scores reported from a similar cohort in Greece (mean 12.6, SD 8.1) [57], while the mean overall PSQI score (mean 8.0, SD 3.4) was above the 6.0 cutoff for poor sleep in young adults [58]. Additionally, the results of the well-being questionnaires varied across demographics and schools, with the highest perceived stress and lowest sleep quality in female students and at the all-female school. This is consistent with stress-related gender differences identified in similar studies of adolescents using digital health tools [59]. Our findings highlight the context-specific well-being needs that exist both between and within different school environments, echoing the results of the needs assessment and co-design phase of Wellby [45]. The gender differences observed from the well-being questionnaires at school C may indicate that the needs of Youthreach students when they join the program differ between genders. Future research could further examine the well-being and acceptability differences among demographics, including potential gender-specific differences, and how personalized features can enhance the adaptability of digital tools to meet a range of student needs.

The high uMARS scores and strong alignment with students' goals likely reflect Wellby's close adherence to student input during co-design. The overall average score for the first 4 subscales in the uMARS (mean 4.1, SD 0.7) is comparable to the uMARS evaluations of the highest rated available mental health apps (mean 4.1 - 4.3) assessed in a review by Ko and Woo [60], compared to those with the lowest ratings (mean 2.9 - 3.3) out of the 41 eligible apps reviewed on the same 4 subscales. The results also revealed that the alignment of Wellby with students' goals was higher for those in the co-design sessions (21/24, 88%) compared to students overall (22/29, 76%). Additionally, students shared recommendations for adjusting the wearable appearance to match their style and for additional features, such as goal tracking. These requested improvements to Wellby may explain why the alignment responses were not higher. Overall, these findings add to existing evidence on the effectiveness of participatory design processes in producing tools that are appropriate and acceptable for adolescents [17].

Barriers to engagement that emerged in the focus groups included technical challenges and environmental constraints such as schoolwork and nonacademic commitments. While technological issues are common barriers in mobile health research, there is a need to more thoroughly examine the system-level influences on students' engagement with digital well-being tools [61]. Researchers might investigate these by

XSL•FO
RenderX

working with students' guardians, teachers, and school staff members to gain a wider perspective on the implications and considerations for implementing digital well-being supports in an educational context. Together they could explore how to integrate these tools into schools' existing support pathways for students such as through school counselors, physical education, or health teachers. The financing for these supports could be allocated through governmental budgets for school well-being resources, which schools can then allocate to the most appropriate resources for their students. For example, the national health service in Ireland provides free digital cognitive behavioral therapy through various referral pathways, and Harty et al [62] demonstrated how this enables digital well-being support tools to be distributed at scale.

The recurring themes related to challenges with the study technology also have important implications for participant engagement. Technological barriers noted by students, such as the short battery life of the wearable and Android compatibility errors, likely reduced sustained engagement. This was underscored by the engagement subscale having the lowest "ease of use" score on the uMARS. Several feedback items from students were also recommendations for features that could increase the interactivity and student interest in Wellby, such as goal trackers, updates to the mood tracking and wearable feedback, and increased options for personalization.

Students additionally expressed their enjoyment in customizing the wearable case and strap, potentially increasing feelings of ownership and trust. While this study aimed to foster collaboration with students, there are several ethical considerations when working with adolescents [30], and technical issues can reduce trust in these types of digital interventions [63]. Notably, previous research demonstrated that trust in technology is a crucial driver of acceptability, particularly for adolescents [64]. Therefore, potential technical issues should be identified early, for example, through short-term tests with students before longer interventions. Future research could further investigate how to promote trust among participants through selected features and collaborative approaches to these interventions.

Student engagement patterns with Wellby indicated that app color personalization, mood check-ins, viewing educational resources, and HRV recordings were the most common features used during this study. This agrees with qualitative feedback indicating that students were most interested in personalized features, the mood check-in, and the wearable component of Wellby. Despite conflicting opinions on the usefulness of the in-app resources in focus groups, the information quality achieved the highest score (mean 4.2, SD 0.6) out of the uMARS subscales. Along with students' frequent engagement with the educational resources, this high uMARS score suggests that several students found the evidence-based well-being content to be relevant and beneficial to them.

After students received wearable devices at the study midpoint, engagement increased across all Wellby app tabs. Although technical challenges with the wearable were reported in focus group discussions, students emphasized their interest in the wearable and in features for future iterations. The engagement increases following wearable implementation, alongside qualitative feedback and moderate uMARS scores for intention to change and behavior change, suggests that the devices were a main driver of student engagement and demonstrate the potential of this tool to encourage behavior change in adolescents. Rather than providing an additional mobile app alone, wearables offer a tangible representation and reminder of students' commitment to enhancing their well-being. Wearable devices may provide valuable tools to catalyze student behavior change and the establishment of habits that can support them as they grow older, particularly by providing a device that can bridge the digital and physical sides of many adolescents' experiences.

Student engagement patterns and feedback also indicated students' overall interest in self-tracking by recording their heart activity and mood over time. This suggests that adolescents may prefer self-directed wellness approaches over guided interventions like coaching or prescriptive content, potentially connecting to their developmental needs for greater autonomy and identity formation. As self-tracking tools become more widely accessible and used, there is a need to provide targeted and mindful technologies that offer tools for adolescents' inclination toward self-exploration while avoiding the potential for excessive self-monitoring or overreliance on digital tools [65].

Students provided recommendations for the iterative development of Wellby, including increased stress-tracking features, mood-tracking options, and customizable features. This aligns with a main recommendation from a similar co-design study of European adolescents that emphasized the importance of a personalized interface [36]. Social acceptability is another important consideration for this cohort, which emerged in this study, and must be considered for adolescent-centered technologies, particularly wearable technologies that are highly visible. Understanding the psychosocial impacts of technologies can be aided using scales such as the Wearable Acceptability Scale, which offer ways to measure the social acceptability of wearables [66]. Mindful feature design and evaluation helped students to gain an increased sense of ownership and autonomy when using the Wellby system, aligning with the overall goal of cocreating Wellby with students.

Limitations

One limitation of this study is the short duration. A longer study with follow-up assessments could identify any novelty effects associated with the introduction of a wearable device and capture sustained engagement and actions resulting from students' behavioral intention beyond 8 weeks. Additionally, the custom wearable device experienced technical difficulties, including battery limitations, Bluetooth connectivity issues, and Android-specific bugs, which may have influenced students' perceptions of acceptability. These highlight the challenge of developing custom technologies for adolescents and managing students' expectations. The sample size, while meeting recommended guidelines for usability studies, was relatively small with 43 participants across 3 schools, limiting the generalizability of findings to broader adolescent populations

XSL•FO
RenderX

and the analysis of subgroup differences. The postintervention survey response rate of 67% (29/43) and the small focus group sizes should also be considered when interpreting findings, as this may introduce response bias toward students who were more engaged with the study. Future studies should consider timing intervention endpoints when students are more likely to engage by collaborating with school staff to avoid busy academic periods.

The substantial overlap of students involved in both the co-design sessions and intervention testing (38/43, 88% of participants) presents another potential limitation and methodological consideration. This overlap may have introduced familiarity bias due to students' prior interest and knowledge in the intervention, which could have inflated the acceptability scores. However, this also enabled assessment of participatory fidelity by gathering feedback on whether the intervention reflected students' input from the co-design session and revealed higher alignment of Wellby with the well-being goals of this cohort compared to students not involved in co-design sessions. When designing future interventions that include participatory design methods, researchers should consider the impacts of prior participatory engagement on the intervention outcomes. Involving the same participants throughout may be appropriate for cocreation studies focused on iterative design and fidelity [67]. However, for studies focused on the generalizability of intervention efficacy and usability, researchers could consider separating participants into cohorts based on prior engagement to control for familiarity bias and enable comparison of acceptability and usability outcomes between these groups.

Future studies should aim to capture a diverse adolescent population by recruiting from different geographic and socioeconomic areas. For example, in Ireland, this could include schools identified by the Delivering Equality of Opportunity in Schools program in both rural and urban areas. Additionally, researchers should collect comprehensive demographic data, such as socioeconomic indicators, to contextualize the outcomes and promote generalizability and reproducibility of their findings. Finally, as this study was conducted in the Irish secondary school context, the findings may not be directly transferable to other cultural or educational environments without consideration of local contexts and adolescent well-being needs.

Conclusions

This acceptability and usability study provides evidence that co-designed digital well-being tools can achieve high levels of user acceptance among Irish secondary school students when developed through participatory processes. The strong alignment between Wellby and students' well-being goals, as shown by both quantitative uMARS scores and qualitative feedback, supports the value of involving adolescents as equal partners throughout the design and evaluation process. Students particularly valued self-tracking features including mood tracking and HRV monitoring features, while they engaged less with educational resources and text-based coaching. This was underscored by the considerable increases in app engagement following the introduction of the wearable. This reflects the importance of creating adolescent-centered tools that consider developmental needs such as increased autonomy and identity formation in this age group. Despite some technical limitations, the TAM framework effectively captured students' experiences and highlighted the importance of ease of use, perceived usefulness, and behavioral intention in capturing the acceptance and usability of digital health interventions.

As adolescents increasingly avail themselves of technologies to aid in self-expression, identity formation, and habit building, these technologies become intertwined with their well-being journeys. Consequently, the design choices and features offered by these technologies influence the ability of adolescents to pursue their unique well-being goals and navigate challenges throughout adolescence. Participatory engagement of relevant stakeholders, well-being–informed design, and iterative testing can help to ensure that new technologies provide adolescents with appropriate support. In exploring the acceptability and usability of Wellby, this study highlighted the value that young people have for personalizable and aesthetic technology, features for self-exploration, and the ability to develop a sense of ownership and autonomy through these tools.

The presented findings provide insights for developers and researchers working to create adolescent-centered digital well-being tools. In addition to actionable student insights for Wellby and similar technologies, this mixed methods study contributes to the growing evidence base supporting participatory design methodologies in creating relevant technologies that can help adolescents to thrive.

Acknowledgments

The authors would like to acknowledge the students for their valuable time and contributions, which have been instrumental in shaping this research project. Additionally, the teachers (Anne Smyth, Elaine Brady, Brendan Boner, Marie O'Grady, Christine Hughes, Colm Feighery, Liam McCotter, Luke Coyne Curry, and Eimear O'Rourke) at each participating school contributed a substantial amount of work to coordinate these research activities, providing their insights and frequently communicating with the students.

Funding

This research was funded as part of a PhD scholarship partnership between the U.S. Fulbright Program and the Royal College of Surgeons in Ireland (RCSI; to JL) and the RCSI Strategic Academic Recruitment Start-Up Lectureship fund (to CC) to support PhD scholarship (to SJ).

Abstract

Background: The COVID-19 pandemic accelerated the adoption of virtual psychotherapy, making videoconferencing a vital tool for maintaining continuity of care. While virtual sessions offer flexibility and accessibility, concern has also been raised about the impact of virtual care on therapeutic relationships, a sense of community, and the ability to support clients with higher levels of clinical need.

Objective: This study sought to examine how mediums of care (ie, virtual vs in-person) impact the therapeutic experience for clients and providers in critical domains such as community, clinical presentation, and clinicians' use of clinical skills. The following themes were evaluated: (1) How therapeutic relationships and community dynamics differ across virtual and in-person mediums of mental health care? (2) How acuity and diagnosis influence the perception of effectiveness and safety of these mediums?

Methods: This study is a grounded theory design. Participants were intensive outpatient mental health clients and clinicians. Participants were interviewed in focus groups of either 6 - 8 clinicians or clients, assessing for important themes (ie, attendance, engagement, and therapeutic alliance) across the 2 modes of care (ie, virtual vs in-person). A total of 6 structured focus groups were conducted. Thematic analysis was conducted to analyze the transcripts until theoretical saturation was achieved.

Results: Results highlighted the nuanced differences in client and clinician perceptions of relational dynamics and effectiveness of care in virtual versus in-person mental health care. This study revealed, the perspectives of the client and clinician, that in-person treatment fosters more engagement and interpersonal connection (ie, therapeutic alliance and peer-to-peer) than virtual settings. Additionally, in-person care better supports the ability to exercise important clinical skills, especially for highly acuity clients with complex diagnoses.

Conclusions: The results of this study outline how the medium of care (ie, virtual vs in-person) impacts therapeutic experience from the perspective of both client and clinician. It is understood that critical domains such as community, interpersonal relationships, and clinicians' use of clinical skills are affected by the medium of care, and key factors such as clinical presentation (ie, acuity and diagnosis) must be accounted for when choosing a particular mode of care for a client.

KEYWORDS

face-to-face; online group psychotherapy; online treatment; qualitative methods; therapeutic relationship; video-delivered psychotherapy; acuity; diagnosis; community

Introduction

Virtual psychotherapy appointments saw an increase during the COVID-19 pandemic, helping to maintain continuity of care without violating social guidelines [1]. Years after the pandemic, virtual psychotherapy is still relevant for many populations, including those in rural areas, of marginalized communities, and with demanding careers, offering flexibility, convenience, and access to care for clients and providers [2,3]. In-home therapy sessions have increased, and some clients experience greater openness and relaxation in therapy, allowing for deeper conversations about their mental health struggles [4]. However, virtual sessions also present additional challenges to therapy, such as disrupting the ability to read body language and pick up on nonverbal cues. For individuals who struggle with activities of daily living (ADLs), a therapist may not be able to thoroughly assess whether a client has showered or brushed their teeth, due to the lack of physical presence [5]. Other

XSL•FO
RenderX

challenges to virtual therapy include concerns about establishing strong therapeutic relationships via online mediums, as well as the ability to care for clients with higher clinical acuity, as these clients may need a more involved approach [6-8].

In therapy, human connection (ie, therapeutic alliance and community-building) is crucial to positive mental health outcomes (ie, depression, anxiety, stress, and suicidal ideation and attempts) [9,10]. Therapeutic alliance is a foundation of psychotherapy, representing the trust and effort maintained by both parties to increase mental well-being [11]. The link between therapeutic alliance and positive outcomes is critical, where the therapeutic relationship acts as a mediator of change in mental health outcomes [12]. Research has also consistently demonstrated the importance of having strong relationships with others, reporting that a sense of community and higher levels of social support are positively correlated with reduced mental health symptoms and improved well-being [10,13]. Social relationships both within and outside treatment spaces are a critical part of the therapeutic process, and the changed nature of relationships over virtual mediums raises new questions into the quality of online relationships, and whether these online relationships may have an impact on mental health outcomes.

Research conducted during and since the COVID-19 pandemic highlights differing perspectives on the nature of virtual relationships in therapeutic settings. Some research has shown that clients are able to create a strong connection in virtual mental health care settings, with reports of no change in the quality of therapeutic relationship [1,14,15]. However, systematic reviews and meta-analyses following the COVID-19 pandemic suggest that teletherapy may hinder therapeutic alliance, as it has been shown to foster a weaker therapeutic alliance when compared to face-to-face settings [16,17]. Other research reports therapists' perceptions of virtual mediums as less effective due to the barrier of a screen and reduced authenticity when providing care [6,18]. The varied responses call for further research on differences between the perceived quality of in-person and virtual therapeutic relationships.

Virtual mediums may also impact a therapist's ability to appropriately treat high acuity clients. In virtual settings, therapists have reported a decreased ability to practice clinical skills and respond in crisis or emergency, which is especially important for high acuity clients, as they need more robust care [8,19]. Research has also shown that clients with higher baseline symptom severity demonstrate greater mental health outcomes as well as shorter length of stay in face-to-face versus remote treatment settings, suggesting that there may be a potential benefit to in-person care for high acuity clients [7,19].

While existing literature emphasizes the importance of in-person connection for therapeutic quality, there is a gap in existing literature on how clinicians and clients perceive key therapeutic factors, such as client acuity, diagnosis, and engagement, within virtual versus in-person treatment contexts. Notably, much of the existing teletherapy literature focuses on symptom outcomes or therapeutic alliance broadly, with limited qualitative examination of how clinicians and clients jointly experience acuity, safety, and clinical skill use across care modalities, particularly in higher acuity settings. This study explored how mediums of care (ie, virtual vs in-person) impact the therapeutic experience for young adult clients and providers in an intensive outpatient mental health setting across critical domains such as community, clinical presentation, and clinicians' use of clinical skills. Given there are benefits and drawbacks across virtual and in-person mediums of care, this paper explored 2 main themes from the perspective of clinicians and their clients. The research questions evaluated the ways in which therapeutic relationships and community dynamics differ across virtual and in-person mediums of mental health care and how acuity and diagnosis influence the perception of effectiveness and safety of these mediums.

Methods

Study Design

This study uses a grounded theory design, a qualitative research method aimed at developing a theory based on the data collected [20]. Initially, grounded theory methods were used to arrange and code the data, allowing the development of tentative categories. Reflexive thematic analysis, rooted in constructivist principles, then facilitated the identification and analysis of patterns across the data [20]. Through iterative coding and constant comparison, grounded theory methods helped in refining these patterns into themes, ultimately leading to an explanatory framework that elucidates the relationships among identified themes. The present researchers sought to develop a theory directly based on the data collected to understand the participants' experiences. The research questions were as follows: How do therapeutic relationships and community dynamics differ across virtual and in-person care? How does acuity of mental health diagnoses influence these perceptions?

Participants

Participants included clinical staff (ie, those with social work degrees, professional counseling degrees, nursing degrees, Master of Arts degrees, mental health counseling degrees, alcohol and substance use degrees, and dietetic degrees) and clients seeking intensive outpatient mental health treatment in New York, NY, and Washington, DC. The study included 32 individuals (14 clients and 18 clinical staff members) broken into 6 homogenous groups, 3 of which were client groups and 3 of which were staff groups.

Groups did not exceed 4 to 6 individuals, and this was intentional to provide ample opportunity for engagement of each respondent in the groups. During the focus groups, the client respondents were in 1 of 2 locations: home or a mental health treatment center. However, all clinicians were on site at the treatment program for focus group interviews.

Client demographics, including age, race or ethnicity, and gender identity, and clinical credentials for staff were consistent with those previously reported in Cerrito et al [5]. From the point of view of the analyses conducted, the distribution of the sociodemographic factors remains important, as the sample was predominantly White (n=12, N=14, 86%), and majority were cisgender male and female (n=11, N=14, 79%), with a smaller

XSL•FO
RenderX

portion identifying as transgender nonbinary (n=3, N=14, 21%), which may limit generalizability.

Ethical Considerations

This study is approved by the institutional review board at Yale School of Medicine (IRB #2000032626). Clinical staff and clients who had sought intensive outpatient mental health treatment since the pandemic provided insight about their experience through qualitative focus groups. All participants provided informed consent prior to participation. Data were deidentified and stored securely to protect participant privacy and confidentiality. No financial compensation was provided for participation.

Data Collection

This research followed the methodology outlined in Cerrito et al [5]. Recruitment occurred via an email invitation outlining the study's aims, the voluntary nature of participation, and the opportunity to contribute to advancing understanding of mediums of mental health care. Data collection occurred between March 20 and April 3, 2023, with participation invitations sent via email to staff and clients. Inclusion criteria were as follows: (1) at least 18 years of age, (2) are a client previously admitted to The Dorm or are a provider employed by The Dorm, and (3) able to read and understand the consent form. Exclusion criteria included the following: (1) are unfit to complete the survey due to medical or psychological constraints and (2) require a legally authorized representative.

In qualitative research, the social context of the participants' lives, time, place, and biography are important [21]. Client participant perspectives were interpreted within a shared social and clinical context, including engagement in intensive outpatient mental health care during the pre- and postpandemic period, while clinical staff participants had experience delivering both in-person and virtual treatment modalities. This was also the subject of attention both during the interview and the analytical process.

The invitation to participate in this study was sent out in emails that included detailed descriptions of the subject of the study, its course, and the purpose of the data being solely for scientific purposes. All the respondents gave informed verbal consent to participate in the study at the start of the focus groups. To minimize interviewer preconceptions, focus groups were conducted by a qualitative researcher trained in neutral, open-ended interviewing techniques that use nonleading prompts. These prompts were consistent with Braun and Clarke's reflexive thematic analysis approach, which emphasizes reflexivity, openness to participant meaning, and minimizing assumptions [22].

The first part of the interview guide was related to attendance and engagement in the 2 modes of care, and the second portion began to explore detailed topics, referring to a list of auxiliary questions, which had a semistructured form. To obtain the best quality of data possible, the researcher asked detailed questions about experiences and reflections related to engagement, friendships, rapport-building, trust, honesty, communication, and the benefits of virtual versus in-person. The questions were open and nonleading, and follow-up items were prewritten to ensure comprehensive dialogue, for example, "Tell me about attendance in virtual care settings."

During the interview, all respondents were consistently encouraged to share their experiences as openly and honestly as possible. The interviewer used nonjudgmental language and flexible pacing to ensure that all respondents had a chance to contribute. Much effort was made to create optimal comfort and safety in the space for this purpose.

Data Analysis

Throughout the data analysis process, the interpretative perspectives of clients and clinical staff were prioritized, consistent with grounded theory methodological assumptions. The analysis began with grounded theory techniques like open coding and constant comparison, which helped in the initial organization of the data [23]. Reflexive thematic analysis was then used to further analyze and report patterns, guided by Braun and Clarke's 6-phase framework [21]. This structured approach included familiarization with data, generating initial codes, and identifying themes [21,22]. Constant comparison was used to refine these themes into conceptual categories, contributing to the development of theoretical insights into the impacts of different care mediums [21]. For instance, themes such as client engagement, friendship, and rapport were identified as central to the sense of community. Through constant comparison, these themes were linked to broader constructs like therapeutic alliance and community dynamics, leading to theoretical insights into the differential effects of virtual and in-person care on these constructs.

The authors remained open to the depth of the transcripts and were responsive to emerging insights throughout the analytic process. The stages of this research study were adapted from Braun and Clarke's 6-phase thematic analysis framework, which include familiarization with data, generating initial codes, searching for themes, reviewing themes, and defining and naming themes, and the final phase 6, writing the report [22].

Thematic analysis in this study went in the following stages.

- Stage 1: All 3 transcripts were reviewed by each of the 3 authors (BC, AC, and AF) to uncover central codes that repeated throughout the 6 transcripts across clients and clinical staff.
- Stage 2: Codes were selected and would be used as the basis for coding in the next stage.
- Stage 3: Line-by-line coding was conducted, using the previously identified codes from stage 2 to guide reading and identifying analytically important text in the dialogue.
- Stage 4: Theoretical coding occurred, where all codes were considered collectively to generate conceptual categories (ie, themes).

Results

Overview

The in-depth qualitative focus group interviews were recorded on Zoom (Zoom Video Communications) and lasted up to 1 hour. As a result of the 6 focus group interviews (3 client groups and 3 staff groups of 4 to 8 individuals per group),

XSL•FO
RenderX

Zoom-recorded audio material of 4 hours 40 minutes was obtained, which was then subjected to transcription. Groups were labeled (ie, client groups 1, 2, and 3; clinician groups 1, 2, and 3) solely for organizational purposes and do not reflect hierarchy or analytic distinctions. The 6 interviews, 3 from clients and 3 from clinical staff, were rich in depth and content. Following iterative engagement with the data, it was identified that saturation was reached once no new themes emerged, and there was no need to conduct repeat interviews. Iterative engagement consisted of repeated transcript review, reflexive memoing, and ongoing refinement of themes as analysis progressed, in line with Braun and Clarke's reflexive thematic analysis [22]. Saturation was achieved when the data no longer yielded new insights or properties relevant to the emerging theoretical categories, and all core themes were fully developed and defined conceptually [22].

The identified codes that emerged were considered of greatest analytical importance due to their salience across interviews and relevance to the research questions. Analytic priority was given to codes that captured meaningful clinical patterns, rather than just those that appeared most frequently. The identified codes were as follows: client engagement, friendship, rapport, acuity, ADLs, client diagnosis, and use of clinical skills. These codes created 3 themes: community (client engagement, friendship, and rapport), clinical presentation (acuity, ADLs, and client diagnosis), and use of clinical skills.

Theme 1: Community

Overview

The theme of community reflects the depth of connection fostered in in-person versus virtual mediums of mental health care. Across client and clinician groups, participants noted that while virtual formats provided continuity and flexibility, they also introduced barriers to interpersonal relating and opportunities for spontaneous interaction, all of which were described as essential to a sense of therapeutic community. For example, one clinician said:

> *We've gotten to our ideal ... in person, no mask. We can see it all, and we have 100% of the information available to us in that moment ... it's ... just—was the last barrier down in terms of like physical body language and stuff.* [Staff group 1]

In this theme, community is explored thoroughly to fully saturate the concept through 3 subthemes: client engagement, friendship, and rapport. This section will explore how virtual care can serve as a valuable supplement to treatment, and where it may lack the relational qualities that contribute to the community, connection, and accountability of which in-person care naturally provides.

Client Engagement

Client engagement captured participants' observations about attention, presence, and participation, particularly in group settings. Many described virtual sessions as easier to get distracted from or tune out of, especially when cameras were off or notifications were popping up on the client's screen. If notifications are not manually turned off, it is understood that notifications may be distracting or cause the desire to "impulsively" check notifications instead of focusing on the session. Clinicians added that it is harder to address this lack of engagement when on Zoom (Textbox 1).

Textbox 1. Lack of engagement.

"It's a lot easier to be distracted. Just by being in a different space, you have different things around you that can go off. Your phone can go off. If you're on your computer, unless you make a conscious decision to turn off your notifications, you're getting notifications. Versus if you're in a group, it's like you just put your phone away and if it buzzes you feel awkward because it's buzzing and someone is talking ... And it's more of a conscious decision to not be distracted on a computer screen than it is to be in group" [Client group 3].

"I found that in virtual sessions, while they're still useful, there's inevitably going to be implicit distractions. Even if you're not explicitly trying to surf the web, you see your notifications everywhere. There's a top clock in the corner of your screen. And impulsively sometimes I feel like I just click my email, and I go back but I think that takes away from the interpersonal experience and it allows me to talk about things at a superficial level where maybe the therapist wouldn't notice" [Client group 1].

"I think that on Zoom or virtually, it's harder to address engagement or lack of engagement, so that's ... where it becomes a little different because ... it's very easy for someone to shut off their video even though we ask them not to. But it's hard for us to sort of pull them back out, whereas in person, it's a lot easier to ask them a question and look them in the eye ... and sort of feel ... the group pressure or groupthink process to get them involved. But ... I think engagement is a little bit less on—virtually 'cause it is easy to just sort of check out, look at other things" [Staff group 2].

Conversely, in-person groups were described as more immersive, often due to innate social pressure in being physically seen, subtle nonverbal cues, or eye contact that naturally invite participation, learning, and connection.

> *When you're in breakout rooms on Zoom, one, you're probably in a room alone because you're on Zoom, so you yearn for that social connection and you do that by talking about other things whereas in-person, you have time after group to talk about other things. I'm ... more focused on the subject matter of therapy with in-person groups.* [Client group 1]

> *I think it is largely more effective to be in person like everyone else has said too, but to have the flexibility and option can be nice and maybe encourage more participation if someone doesn't feel like, "Oh, I have to be in person no matter what even if X, Y, Z comes up."* [Staff group 1]

Friendship

Friendship highlighted the organic ways that peer relationships tend to form before and after in-person sessions, like "water-cooler" talk. Participants emphasized that between-group sessions is where true connection and trust were built, a dynamic

XSL•FO
RenderX

not easily replicated over Zoom, where interaction typically ends the moment the session does. For example:

> *Definitely, proximity is huge in making friends and making connections with others. I've always found the people that I'm closest with are the people that I find myself in really close proximity with and being really close involves having a shared space like [peer] said. That's a very helpful factor in making strong connections with others.* [Client group 3]

> *I mean, we have the clubhouse here and ... even if it's not anything super clinical, like the ability after group to like all go down to the clubhouse, play ping-pong, play pool, go get some lunch. That definitely wasn't happening virtually, and so I think it was definitely probably a lot harder for the clients to kinda connect with one another over Zoom, especially if they didn't already know each other.* [Staff group 1]

Rapport

Rapport focused on the alliance between clients and clinicians. While some participants described ways in which virtual care could support connection, such as learning clues about someone based on the way they decorate their home environment, many felt that unspoken exchanges and small talk were more organically cultivated in person. Additionally, a client shared that connection and community in person greatly reduced insecurities, leading to better engagement in treatment (Textbox 2).

Textbox 2. Nonverbal communication and connection.

"... let's say we're doin' like an online DBT or somethin' like that and we're going through stuff. It was more of giving someone support with what they said instead of something like—it seemed very clinical. It didn't seem organic" [Staff group 1].

"If I've heard somebody say something that I resonate with on a Zoom call, for example, I'll make a point to ... reflect on that ... and really giving them a verbal hint that I'm understanding what they're saying and nodding my head. Versus in-person, it's easier to see body language and better response than virtually whereas you would verbally need to say it instead of in-person cues" [Client group 3].

"... being able to relate to people on a personal level and getting details about them that I would not otherwise know profoundly reduced my insecurities. When I came here, I was really insecure about the fact that I was a student on a leave of absence and I talked to people and they're like, yeah, I'm also on a leave. And I'm sure maybe that would have came up but there's just details and stuff you learn about people that you just wouldn't know otherwise. And I think that's really important in building a foundation so when you get to groups [where] you're comfortable sharing, you feel better about your treatment" [Client group 1].

Some emphasized that the absence of shared physical space could subtly disrupt the therapeutic experience, due to rapport being lost. The concern is that this makes it harder to build trust and emotional connection. Some examples include:

> *I think that there's also the ability to pick up on ... body language and cues ... we'll have clients who are anxious. Like their leg is bouncing or they're fidgeting, and there's things that you can pick up that you can't pick up on virtually. And I also think having a space separate from their home and where they are allows for a different level of openness, and I think it can be hard to kind of really jump into the rapport-building in the same way virtually ...* [Staff group 1]

> *The disconnect comes from a place of personal experience with picking up on body language. And really connecting with others has a lot, for me, to do with experiencing others in their fullest sense and gaining a full experience of what others are saying versus on Zoom when we're virtual and there's not a full opportunity to gain the full experience with interacting with others. And granted, I'm definitely an extrovert, so I gain energy from being with others.* [Client group 3]

Theme 2: Clinical Presentation

Overview

Researchers also looked at clinical presentation, particularly as it relates to how a client shows up diagnostically (ie, how their symptoms are manifesting within the context of individual and group sessions and in virtual and in-person spaces). Clinical presentation was explored through 3 codes: client acuity, ADLs, and client diagnosis.

Acuity

When exploring client diagnostic acuity, openness, and engagement in individual and group therapy sessions across both mediums of care were discussed. Some staff felt that for clients in early recovery or in more of an acute psychiatric state, virtual sessions made it easier for clients to avoid addressing therapeutic issues head-on and even potentially engage in harmful behaviors behind the screen. Similarly, it was sometimes more difficult for clinicians to pick up on these behaviors virtually, decreasing the effectiveness of the therapeutic process. For example:

> *If they're in ... an environment that typically reinforces substance use or unhealthy behaviors ... I have heard stories about clients who were drinking ... alcohol out of a water bottle during sessions, and those sort of behaviors are obviously more difficult to do in an in-person setting. I think the high-acuity substance use also like takes a big hit when it's virtual as opposed to in person.* [Staff group 1]

> *Yeah, I think similarly with eating disorders as well, any with high acuity, very similar to substance use ...* [Staff group 1]

While some clinicians believed that in-person sessions were more effective for clients who needed higher levels of care and more oversight due to the severity of their symptoms, other clinicians also noted that virtual sessions could be a good option for those who are more stable (ie, in a maintenance stage of

XSL•FO
RenderX

treatment, able to cope more effectively, and need less clinical oversight). For example:

> *... if a client was then going back to college and ... wanting to be part of [mental health treatment] at like [outpatient level] it makes it a lot more accessible for them to be at [mental health treatment] if it's virtual if their university is far away, but if a client were to come straight from [residential treatment program] or a hospital setting, whatever it is ... we would probably like ... to work with them more in person to get that important work done and then—until they maybe are a little bit more stabilized. Then we can kind of transfer it over to virtual.* [Staff group 1]

> *I think that in-person therapy is absolutely imperative, especially with groups. But I can see the functionality and use of Zoom therapy as a useful supplement or tool for busy young adults.* [Client group 1]

Activities of Daily Living

ADLs explored a client's ability to take care of their mental, physical, and emotional needs. Some clinicians felt that it was more difficult to pick up on how a client was taking care of their hygiene or physical health during virtual sessions, whereas in person, there may be more obvious signs if a person did not take good care of themselves (ie, whether a person showered, shaved, and took their medication).

> *Even things like your ADLs. You can just walk past a client and smell whether or not this person took a shower or whatever. You could just see in a snapshot if they had a long night or whatever the situation is just walking around the place, seeing how they either get somethin' to eat, how they socialize with other people.* [Staff group 1]

> *I think some of the thought disorders. I think without having certain clients come in person, there are certain hygiene factors that you ... you don't know ... like when I have a client ... I can see other than just facial hair or their hair if there is—see or smell if there's different hygiene. It tells me like more about if they're taking their medication, how are they in their living, are they likely leaving their apartment at all or not, things like that.* [Staff group 1]

Clients and staff felt that virtual sessions enabled clients to engage in avoidant behaviors, such as not needing to engage in ADLs like getting out of bed, getting dressed, showering, or taking medication. This avoidant behavior sometimes even made it difficult for clients to transition into things like jobs or other settings that were not virtual.

> *You don't have to get dressed, put shoes on, go outside, take the train, all that stuff, think about transit time.* [Client group 1]

> *... being at an intensive like IOP level of care, kind of like what [therapist]'s—, like the getting up and getting to a place is part of the treatment. It's—a lot of people who haven't been leaving their house or haven't—whether it's anxiety based, depression based, executive functioning ... I think even just getting up and getting dressed and the basic kind of behavioral activation things that that help with mood and anxiety are taken away in a virtual setting.* [Staff group 1]

Client Diagnosis

When looking at diagnosis, researchers explored whether there were certain mental health diagnoses that were easier or harder to treat in a virtual session. Specifically, clinicians felt that virtual care was less effective for disorders like depression, agoraphobia, or social anxiety, where avoidance is prevalent, as it allowed clients to continue to stay in their homes and hide behind a screen, instead of addressing the issue more directly.

> *I feel like it's harder virtually to treat anyone. But I'm thinking of specifically people who like to avoid ... things, so maybe that's because of anxiety or depression. But a lot of clients here wanna avoid, and I've had lots of clients who were like, "Can we meet virtual?" because they wanna avoid taking transportation, they wanna void coming to [mental health treatment] ... but part of doing those things is like facing your anxiety head on, so by keeping things virtual for some people, that keeps them in their avoidance zone.* [Staff group 2]

> *Social anxiety. Anxiety in general. For some people, part of the therapeutic process is leaving their place to go to another office, and that obviously takes out a big part of it. I had a client who would say like, "Oh, I can't make it in today. I'm gonna be virtual," when they were hybrid, and they definitely used it as avoidance. I think that with clients who one of their goals is to be in like a more public space and interacting, virtual therapy like takes out a huge chunk of that. And I think that ... anxious and socially anxious conditions ... like virtual really is incompatible with it.* [Staff group 1]

Clinicians also felt that mental health conditions such as attention-deficit/hyperactivity disorder or thought disorders were often times more difficult to treat due to the amount of stimuli in the background and the potential for distractions.

> *What comes to mind is folks with executive functioning disorders, attention deficit disorder, and folks with psychotic disorders are distractible from their own internal stimuli and don't seem to do well with virtual.* [Staff group 2]

> *I feel like Attention Deficit Hyperactivity Disorder (ADHD), too, is another one because ... instead of you being in like a curated environment, you can be wherever. You can like walk around and someone might be in the other room, or ... there's just so ... much room for more distractions.* [Staff group 1]

Some clinicians also believe that eating disorders and substance use disorders are more difficult to treat virtually due to the lack of oversight in a virtual space. Specifically, due to the secretive nature and maladaptive behaviors of both disorders, it is harder

XSL•FO
RenderX

to assess whether clients are using substances, purging, or even eating their meals through a screen (Textbox 3).

Textbox 3. Visibility and accountability.

"I've also had a couple clients with like body image issues who didn't like to see their face on screen, and they'd hide behind like ... a ... photograph of a dog and just like would not engage and ... it was kind of disruptive in the group. I understood where they were coming from, but it was hard to find a workaround for that" [Staff group 1].

"I think it's impossible to do a truly beneficial EDO meal group virtually as opposed to in person just because of the amount of ED behaviors that would even be an option for the clients. Like I can imagine that like just having that sort of opportunity to engage in these behaviors would be either tempting or distressing to those in the group.I think that ... a successful virtual [eating disorders] meal group would be next to impossible" [Staff group 1].

"I think being in person and like seeing someone walk and sit down and being with them face to face is really helpful when you're dealing with folks who use substances. So there's just ... an added ... ability to, I think, go unnoticed and for folks to evade detection or toxicologies or any sort ... anything that will like get them found out. I think that's probably similar with eating disorders. We've seen people just completely refuse to like show how much they've eaten, or they just deny that they like went to the restroom right after eating" [Staff group 3].

There were some disorders, however, where clinicians and clients both thought that virtual sessions or groups could be appropriate and helpful depending on things like client age and the content of the therapy group, sometimes making it easier for clients to use coping skills in a comfortable space after an intense group.

> *My adolescent client ... we can do really, really good work, but due to her anxiety, like she is able to do makeup and like work on her hair and stuff like in session, which ... it also feels like very age appropriate, and I know she gets like super fidgety with her anxiety.* [Staff group 3]

> *... in terms of groups that are entirely virtual, the participation does depend group to group but there have been times where especially at trauma groups it's helpful to be virtual. I think there's less of a sense of vulnerability and I realize ... the goal is to be comfortable with vulnerability. But especially early on in treatment being in trauma groups ... it was helpful because I could sit on my bed and I could do my little things that help me calm down and I didn't feel like everyone was seeing me even though I was on camera, so in that way it was a lot more helpful.* [Client group 2]

Theme 3: Use of Clinical Skills

Finally, researchers looked at the use of their clinical skills and how the medium of care (ie, virtual vs in-person) impacts this, if at all, within the context of individual and group sessions. Use of clinical skills was both the theme and code for this category, with particular topics coming up around the importance of engagement, rapport building, and body language being a cornerstone for using clinical skills.

For example, engaging clients is a skillset that clinicians highlighted as difficult when comparing virtual and in-person therapeutic spaces. Clinicians reported that client engagement skills are negatively impacted in virtual spaces:

> *It was a deep, deep challenge to have the clients reflect until you ... found that sweet spot ... But if it was left up to, "Okay, you guys, what did you wanna talk about?" dead silent. And then working through just the different personalities ... so I didn't know where my leverage was with them or what I could use to engage them.* [Client group 3]

Fostering therapeutic alliance and rapport is another clinical skill that appeared in the transcripts when discussing the use of virtual versus in-person therapeutic spaces. Clinicians found that rapport building was easier in person. For example:

> *A big way I develop rapport is through humor, and I found that it's harder to be humorous or to exude my type of humor on Zoom 'cause just you get less ... bodily feedback and body language confirmation, so it can make me proceed a little bit more shyly on Zoom ... it's definitely about ... making sure to take that time and not like speed through something just because you have their attention and you're face to face with them.* [Staff group 2]

Clients and clinicians also noted that picking up on body language cues, an important domain of identifying signs and symptoms of mental health concerns, is more challenging in a virtual space. Being able to only see one's head prevents the clinician from accessing important nonverbal cues (ie, tapping fingers and legs shaking; Textbox 4).

XSL•FO
RenderX

Textbox 4. Challenges in a virtual space.

"I think it's just as difficult for [clinicians] to understand and realize my mannerisms ... I have a very difficult time, so I think anybody else would have a difficult time as well" [Client group 3].

"... all you can see is the square of their head. You can't see what they're doing with their legs, with their hands, who's on each side of them. It's not a real representation of therapy" [Staff group 2].

"I was trained as a psychoanalyst and group psychotherapist so seeing and lookin' at people's body language or a facial expression ... You have to really do a extra tune-in to someone that's virtual to see because again if it's just chest and above, you're not seein' other things. Is their leg movin' rapidly? Are they tappin' their fingers? Just you can't see as much as if they were in person, so it does take a shift in the way you read the room or read all group members, so there is that limitation there" [Staff group 2].

Finally, eye movement desensitization and reprocessing (EMDR) was mentioned multiple times as a modality that clinicians felt strongly about being conducted in person. The below quote summarizes the consensus:

> *I personally would prefer Eye Movement Desensitization and Reprocessing (EMDR) in person ... because it is so intense and because so much stuff can come up for a client, it's important to have a safety zone of being in an office with a clinician. And you really, really need to be able to read your clients during EMDR.* [Staff group 2]

Discussion

Principal Findings

While virtual care is acknowledged by the study participants as a valuable tool for maintaining treatment continuity, particularly in the face of logistical barriers (ie, distance, scheduling, school, or work), participants repeatedly emphasized the relational and clinical limitations innate to virtual platforms. This study uncovers, from the perspective of client and clinician focus groups, that in-person treatment is more supportive and fosters engagement in treatment, interpersonal connection (ie, therapeutic alliance and peer-to-peer), and the ability to exercise clinical skills than virtual settings.

Clinicians reported that their ability to use essential clinical skills (ie, engaging clients, fostering therapeutic alliance, and reading body language) is hindered in virtual settings. Certain modalities, such as EMDR, were considered more effective in person due to the emotional intensity they evoke and the importance of clinicians closely monitoring clients for safety in this type of therapeutic modality. While existing literature supports the feasibility of EMDR in virtual settings, there is a need for more robust methodological research to examine efficacy [22]. This study supports in-person treatment as the ideal medium for complex modalities, such as EMDR, and high acuity cases of all diagnoses, given the emotional and relational nuance that is missing when treatment is conducted online.

In examining how therapeutic relationships and community dynamics differ across virtual and in-person care, it was found that loss of connection occurs when therapy switches to a virtual format. Clients described distractibility and a reduction in therapeutic and peer-to-peer accountability when in virtual groups. Body language, nonverbal communications, and water-cooler conversations between sessions were some of the factors that were reported as being essential for therapeutic alliance and peer connection; yet, these were also reported to mainly occur in an in-person setting. Participants' reports made clear that there are qualities of in-person care that help build rapport and foster therapeutic alliance, naturally, in a way that only virtual settings can forcibly achieve. Existing literature supports the finding that virtual mental health treatment limits access to nonverbal cues, body language, and the type of connection that is central to therapeutic and peer alliance [5,17,24].

Acuity of mental health diagnoses also strongly influenced participant perceptions of the medium of care. When discussing clinical presentation, clinicians and clients admitted to the absence of and difficulty in noticing subtle cues (eg, smell and fidgeting) that are essential for picking up on signs and symptoms of mental health concerns. For this reason, in-person care was reported as a necessity for clients with higher acuity mental health concerns and complex diagnoses, such as active eating, substance use, or thought disorders.

Implications

This study extends previous work that examines the benefits and drawbacks of virtual mental health care [5]. The ability to connect, be present, and experience therapeutic alliance as well as support, particularly for young adults, is understood to be most effective when in person. While each setting offers distinct advantages, participants emphasized that clients with higher clinical acuity and complex diagnoses experience more effective support, safety, and peer-to-peer as well as therapist-to-client connection when in person. Certain diagnoses may need more support and the added element of in-person monitoring for safety, due to the complexity and/or acuity of one's mental health condition. These findings underscore the importance of accounting for therapeutic and diagnostic factors when deciding the medium of care, as this can offer an effective framework for optimizing client engagement and experience.

Limitations

The following limitations are consistent with Cerrito et al [5]. In summary, these include the following: (1) the analyzed group is not representative of the broader populations of mental health providers and young adults seeking mental health treatment, and future research should examine these hypotheses in a larger, more diverse population. (2) Considering factors that qualify a client for virtual versus in-person care is warranted in future research, as we understand that these results represent a specific group of individuals at a particular point in history (ie, post–COVID-19 pandemic), from large urban settings (ie, New York, NY, and Washington, DC), and social contexts (ie, predominantly high socioeconomic status). (3) Due to the

XSL•FO
RenderX

necessary exclusion criteria, the sample may not fully represent all vulnerable populations. Individuals were excluded if they were unable to complete the survey due to medical or psychological limitations or if participation required a legally authorized representative.

Conclusions

The results of this study outline how the medium of care (ie, virtual vs in- person) impacts therapeutic experience from the perspective of both client and clinician. It is understood that critical domains such as community, interpersonal relationships, and clinicians' use of clinical skills are affected by the medium of care, and key factors such as clinical presentation (ie, acuity and diagnosis) must be accounted for when choosing a particular mode of care for a client.

Abstract

Background: Artificial intelligence (AI)–driven clinical decision support (CDS) tools offer promising solutions for health care delivery by optimizing resource allocation, detecting deterioration, and enabling early interventions. However, adoption remains limited due to insufficient validation and a lack of transparency and trust. Explainable AI (XAI) seeks to improve user understanding of AI outputs; however, how clinicians interpret and integrate these explanations into their decision-making remains underexplored. Furthermore, discrepancies in explanations, known as the "disagreement problem," can undermine trust and, at worst, lead to poor clinical decisions.

Objective: This study examines clinicians' perspectives on the role and value of explainability in AI-driven CDS tools within Australian critical care settings and the impact of discrepancies in AI-generated explanations on clinical decision-making.

Methods: Qualitative data were collected using semistructured interviews with 14 clinical experts, incorporating scenario-based exercises, and were analyzed using inductive thematic analysis.

Results: Clinicians valued explainability, particularly in complex or unfamiliar situations, when explanations were clear, plausible, and actionable. Trust and perceived usefulness extended beyond explanation quality, encompassing factors such as system accuracy, alignment with clinicians' reasoning, workflow integration, and perceived reliability. Discrepancies in explanations generated by different XAI methods were not a major concern, provided that the AI-generated predictive alerts were accurate.

Conclusions: This study provides design recommendations for developing trustworthy, user-centric CDS tools that incorporate XAI. Findings highlight that explainability is critical for establishing initial trust in AI-driven tools by supporting perceived usefulness, but its importance diminishes over time and with user expertise and familiarity, as learned usefulness takes precedence. Recommendations highlight the importance of aligning the design and implementation of AI tools with clinicians' needs to enhance trust, mitigate risks, and promote successful adoption for improved patient outcomes.

KEYWORDS

artificial intelligence; explainable artificial intelligence; explainable AI; disagreement in XAI; clinical decision support; qualitative research; human factors

Introduction

Artificial intelligence (AI)–driven clinical decision support (CDS) systems are emerging as powerful tools in health care, leveraging large-scale medical data to identify patterns and generate insights that help clinicians deliver more informed and effective care [1-3]. Beyond supporting clinical decision-making, these systems have the potential to optimize resource allocation and streamline workflows by processing large volumes of electronic health data and deploying scalable, cost-effective algorithms that enhance efficiency while minimizing additional resource burdens [4-8]. Furthermore, CDS tools can detect subtle patterns of deterioration and offer predictive insights to help clinicians intervene earlier [9,10]. However, despite the promise of AI in health care, these tools have not been widely adopted for several reasons. One

XSL•FO
RenderX

significant barrier is the lack of real-world testing and validation [11-13]. While early evidence suggests that AI-driven tools hold promise beyond controlled academic settings, their effectiveness in dynamic, real-world clinical environments remains underexplored, and further research is needed to understand the factors influencing their adoption, including patient heterogeneity, system integration, and workflow compatibility [13,14].

Recent research on deployed decision support tools also highlights the lack of human factors consideration as a key driver behind their limited adoption in clinical settings [1,15-19]. This includes a lack of attention to how clinicians interact with technology, usability issues, and how well the tool fits into existing workflows [1,16-19]. Another major concern is the lack of explainability and transparency in many AI-driven CDS tools [20,21]. Clinicians are understandably hesitant to rely on tools they do not fully understand, especially in high-stakes environments such as hospitals [2,22]. When an AI-driven CDS system provides a recommendation or prediction, it is crucial for health care providers to understand the reasoning behind it. Without clear and understandable explanations, there is a risk that clinicians will not trust the tools, regardless of their accuracy [23].

Without adequate transparency, there is also a risk that clinicians may overrely on these tools, potentially leading to harmful outcomes [24-27]. This trust gap between health care providers and AI-driven CDS tools is a significant obstacle to widespread adoption [2,28]. Effective implementation of AI-driven CDS systems requires careful trust calibration, ensuring that clinicians develop an appropriate level of trust aligned with the system's real-world performance, to support safe and effective use in practice [27,29].

To support trust calibration of AI-driven CDS tools, explainable AI (XAI) methods have been designed to provide transparency by not only presenting the predictions but also revealing the underlying rationales that drive those predictions [27,30-33]. By allowing medical professionals to see the logic behind the AI's decision, XAI aims to bridge the gap between the complex algorithms used in machine learning and the human need for clarity and accountability in clinical practice. For tasks such as classification and regression, post hoc explanation methods are increasingly being used to shed light on the behavior of complex models after training [15,34,35]. Rather than altering the model, these methods aim to reveal how it makes decisions by producing clinically informative approximations or visual representations. However, recent findings in responsible AI have highlighted significant challenges in creating robust, user-centric, and context-sensitive explanations that can be trusted and easily comprehended [36,37].

While much of the existing literature has focused on the technical reliability or consistency of XAI methods, less attention has been paid to how clinicians interpret, evaluate, and use these explanations in practice. Understanding these human-centered aspects of explainability is critical for ensuring that AI-driven CDS tools support, rather than disrupt, clinical workflows and reasoning. One key challenge is that post hoc explanations generated by models can be overly sensitive to small input changes or offer convincing justifications for incorrect predictions [26,38]. Research has shown that when these explanations are presented alongside model outputs, they can unintentionally foster increased trust in the model, even if that trust is not justified, and lead to potentially harmful decisions [33,39-41]. Another challenge is the "disagreement problem," which refers to discrepancies among state-of-the-art methods in the explanations they provide, as revealed by recent research [37,42-46].

The disagreement issue arises when different XAI techniques produce conflicting explanations, even when applied to the same input and underlying model prediction. While several studies have shown that AI-generated explanations can increase clinicians' likelihood of accepting recommendations from CDS tools [1,47-50], they often rely on the implicit assumption that a correct model prediction is accompanied by a valid explanation. Previous studies have examined the impact of incorrect explanations on users when the AI's prediction is correct [51]. However, they often overlook the fact that different XAI methods can produce conflicting explanations for the same prediction. Moreover, recent research has shown that such explanations can inflate users' trust in the model even when that trust is not warranted [26,33,39,40]. Despite these concerns, little is known about how clinicians understand and respond to such discrepancies. This gap not only limits our understanding of explanation reliability in high-stakes settings but also complicates the task of selecting appropriate XAI methods for use in CDS tools.

Building on these insights, this study explores clinicians' perspectives on the role and value of explainability in AI-driven CDS tools, focusing on how explanations are interpreted, trusted, and incorporated into clinical decision-making through qualitative interviews with clinical experts. It also explores how discrepancies between different explanation methods affect clinical judgments through a scenario-based approach. Additionally, we seek to identify key considerations for effectively integrating explainability into AI-driven CDS tools. Our study is focused on Australian health care settings, where there is a growing need for exploration of AI-driven CDS tools [52]; yet, limited empirical evidence exists regarding their acceptance and impact in real-world clinical practice. This study seeks to contribute to this area by exploring 3 key research questions (RQs) listed below:

- RQ1: How does explainability influence clinicians' use, trust, and perceived usefulness of AI-driven CDS tools?
- RQ2: How do clinicians interpret and respond when different explainability methods provide differing explanation factors, despite the AI prediction being correct?
- RQ3: What key design considerations can support the trustworthy and user-centric integration of AI-driven CDS tools with explainability as a key component?

Methods

Study Design

Semistructured interviews were conducted with clinical experts to explore their views on XAI and the discrepancies observed

XSL•FO
RenderX

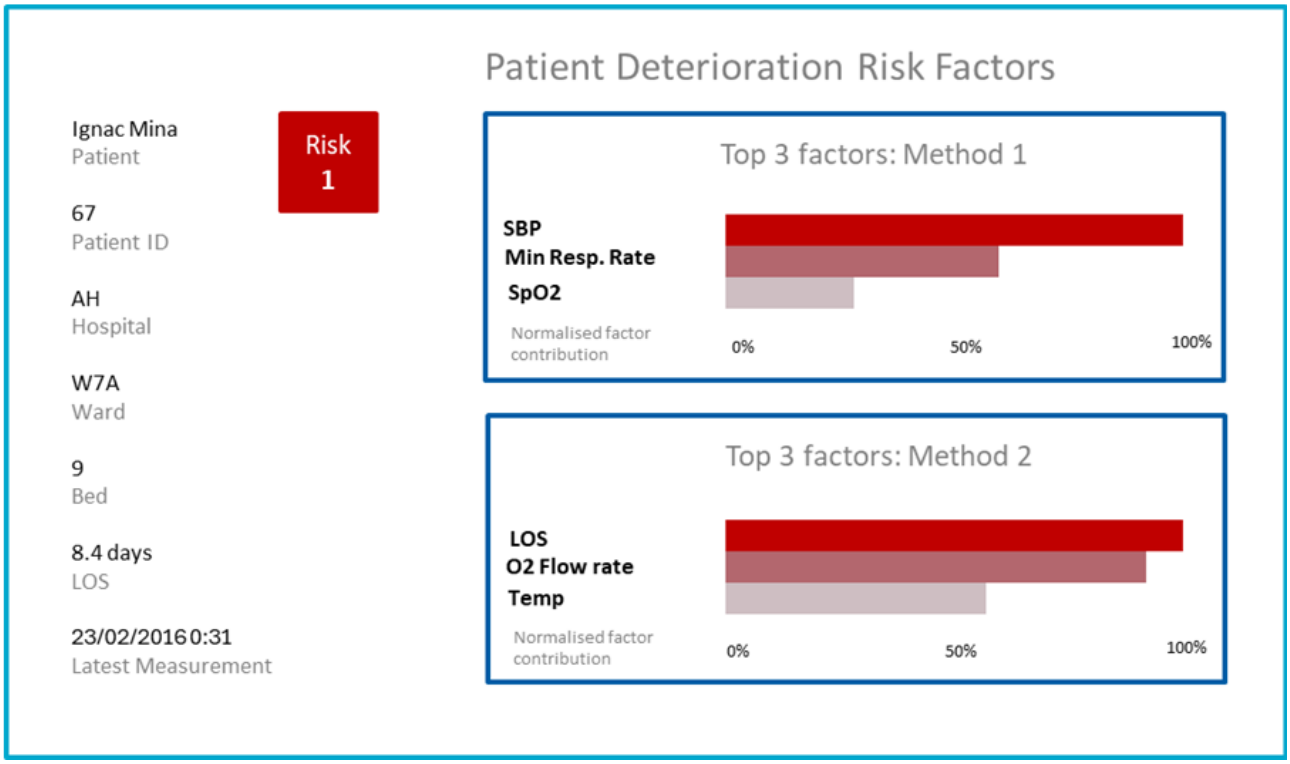
between different XAI methods. During the interviews, participants were given a scenario-based exercise using an AI-based predictive CDS tool to assess how discrepancies in explanations influenced decision-making.

Participant Recruitment

The study participants comprised clinical experts who were potential users of CDS tools designed for use in the intensive care unit (ICU) environment. Recruitment began by reaching out to current and former clinical collaborators to identify suitable participants. A purposive, snowball sampling method was used, allowing the identification of additional stakeholders as the research progressed [53]. A recruitment flyer was prepared and emailed to all potential participants. After participants signed the consent form, they scheduled an interview time using an online scheduler. Recruitment and data collection were conducted concurrently with data analysis, continuing until data saturation was reached [54].

Data Collection

Semistructured interviews were conducted from February to July 2024. The interview was divided into 3 main segments, each containing multiple open-ended questions. The questions for the first 2 segments were adapted from the study by Schwartz et al [55]. The first segment focused on understanding the participants' clinical experience and their general views on CDS and XAI. The second segment explored participants' thoughts on factors influencing their trust in CDS tools and how XAI contributes to it. In the final segment, participants were presented with 2 scenarios based on an AI-based predictive CDS and explainability modules developed in a previous study using electronic medical record data [36]. Detailed descriptions of these scenarios are provided in the "Scenarios" subheading. A pilot interview was conducted with 1 participant, leading to further refinement of the questions and interview duration. The interview guide is available in Multimedia Appendix 1. Interviews were conducted online via Microsoft Teams and recorded using the platform's built-in feature. Four team members (JR, AD, JL, and DB) with doctoral qualifications and expertise in qualitative research conducted the interviews, with at least 2 present at each session. Each session lasted between 45 and 60 minutes. Notes were taken during the interviews. All audio recordings were transcribed by a professional transcription service and deidentified upon return.



Scenarios

The CDS tool selected as the use case for this study was an algorithm that predicts the activation of an early warning score system, providing up to 8 hours of warning of potential patient deterioration. The algorithm was developed and validated using real-world data from a tertiary hospital in Queensland, Australia, and further methodological and technical details are available in prior publications [36,56]. The scenarios included encounter records, extracts with primary and additional diagnosis Systematized Nomenclature of Medicine codes, extracts indicating deteriorating alerts (red and yellow flags), and vital signs data. Explanations were generated by several post hoc explainers using real examples from the model's training and testing datasets. The selected use cases were constructed to demonstrate instances in which the model's predictions were accurate, while the corresponding explanations varied in their degree of correctness. This approach aimed to assess how domain experts not only see the explanations but also interpret and respond to discrepancies between model accuracy and explanation fidelity and to ensure that correct model predictions would not be disregarded solely due to imperfections in the accompanying explanations. Information was presented as a prototype of the tool planned for pilot implementation (Figures 1 and 2). Further information on patient diagnoses and procedures was presented to the participants when the scenarios were shown, to provide contextual information about the considered cases and to realistically simulate the clinical scenarios. These details are provided in Multimedia Appendix 2.

XSL•FO
RenderX

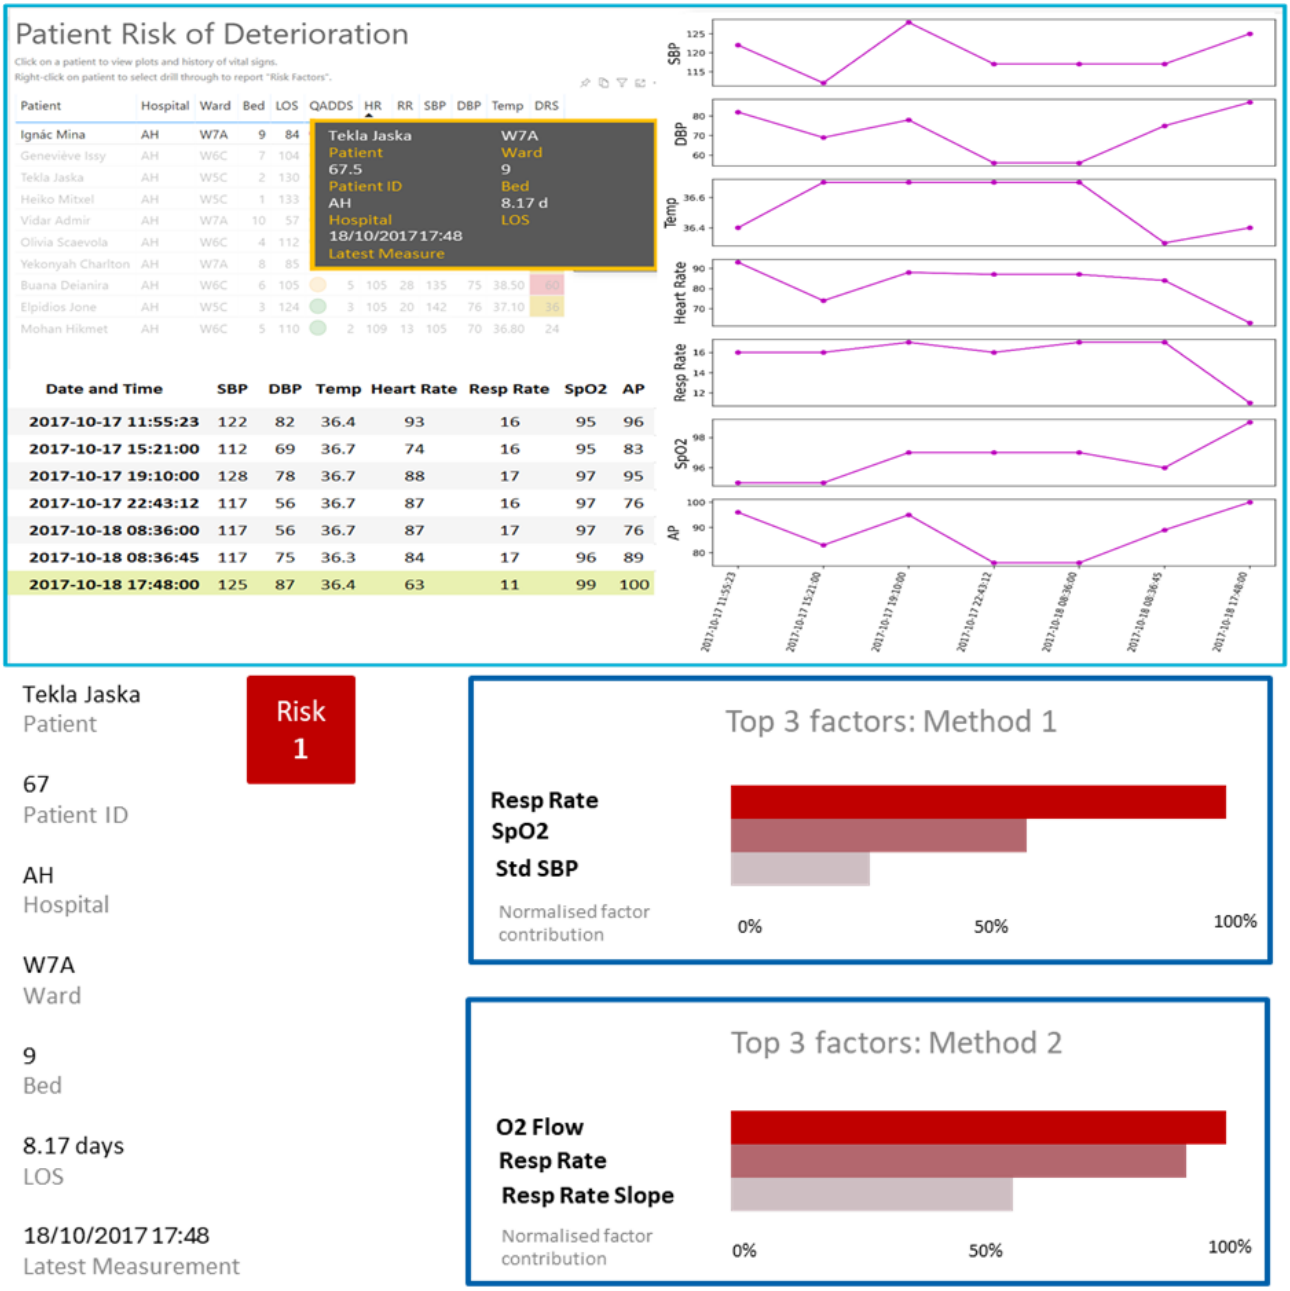


Figure 1. The first part of the clinical decision support (CDS) tool "(A)" showed a list of patients at risk of deterioration and recorded values of vital signs for selected patients in the last 24 hours, alongside the basic demographics. The second part of the tool "(B)" presents additional available information corresponding to the patient regarding the predicted deterioration risk. In addition to basic demographics about the patient, 3 main factors rationalizing the model prediction were presented, obtained using 2 different methods. The factors were ordered based on their normalized contribution in descending order. Both methods correctly predicted patient deterioration. The main contributor obtained with Method 1 matched the vital sign that triggered the alarm, unlike any of the contributors obtained with Method 2. AH: anonymized hospital identification; AP: arterial pressure; DBP: diastolic blood pressure; DRS: deterioration risk score; HR: heart rate; ID: identification; LOS: length of stay; Min: minimum; QADDS: Queensland Adult Deterioration Detection System; Resp: respiratory; RR: respiratory rate; SBP: systolic blood pressure; SPO2: oxygen saturation; Temp: temperature.

XSL•FO
RenderX

Figure 2. (A) and (B) illustrate results for a different patient. In this case, both predictive methods accurately identified patient deterioration, and both explainable artificial intelligence (XAI) techniques recognized the same contributing factor as indicated by the vital sign that triggered the alarm, but with differing ranks of importance. AH: anonymized hospital identification; AP: arterial pressure; DBP: diastolic blood pressure; DRS: deterioration risk score; HR: heart rate; ID: identification; LOS: length of stay; Min: minimum; QADDS: Queensland Adult Deterioration Detection System; Resp: respiratory; RR: respiratory rate; SBP: systolic blood pressure; SPO2: oxygen saturation; Temp: temperature.

Data Analysis

The analysis aimed to uncover domains related to what influences trust in XAI and how discrepancies affect it. Due to the lack of suitable existing frameworks that adequately addressed the issues discussed by participants for deductive analysis, an inductive open coding approach using grounded theory [57] was used, allowing themes to emerge organically from the data without any preconceived categories or theoretical framework. The data analysis was conducted using Microsoft Excel. The COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist is provided in Checklist 1.

Initial coding of each interview transcript was carried out by a qualitative researcher (JR). The coding was then sent to a second qualitative researcher (AD) for agreement checking. Consensus discussions were held, and all disagreements were resolved between the 2 researchers. Using the inductive approach, an initial codebook was developed after coding the first transcript. This codebook guided the coding of subsequent transcripts and was iteratively reviewed and updated following each consensus discussion. After completing the initial coding, the codes were grouped into broader domains. For each domain, the 2 qualitative researchers conducted a consistency check to refine the constructs and ensure all data were coded consistently. At this stage, 1 researcher (JR) also inductively summarized each text artifact into a statement that captured its meaning, referred

XSL•FO
RenderX

to as subconstructs. A consensus discussion was then conducted with the second researcher (AD), using the same method as the initial coding discussions, to further refine and condense the statements where needed. This iterative process of consistency checking at each stage enabled the study team to triangulate the data, incorporating multiple perspectives to strengthen confidence in the study's findings. After refinement, the preliminary findings were emailed to all interview participants, following their agreement to participate in a "member checking" process. Participants were asked to provide feedback on whether the preliminary findings captured the most important issues and on the clarity of the phrasing used for constructs and statements. Responses were received from 57% (8/14) of participants, comprising affirmative and/or constructive feedback. This feedback informed further refinement and changes to the final set of domains and constructs.

Ethical Considerations

Ethics approval for this study was obtained from the Commonwealth Scientific and Industrial Research Organisation (CSIRO) Health and Medical Research Ethics Committee (reference no 2023_074_LR). A privacy review of the study was also conducted by a legal counsel at CSIRO. A recruitment flyer, which included a link to the online participant information sheet and digital consent form, was prepared and emailed to all potential participants. The digital consent form was hosted in the CSIRO's secure REDCap (Research Electronic Data Capture; Vanderbilt University) application. The information sheet provided details about the study's purpose, privacy considerations, potential risks and benefits, and how the data would be collected and used. Upon completing their participation, participants were provided with an AUD $50 (approximately US $35) gift card.

Results

Participant Demographics

Clinical experts (N=14) took part in the interviews (Table 1). Experience levels were categorized as follows: "Junior"= <10 years of experience, "Mid"= 10 - 20 years, and "Senior"= >20 years. Overall, there was equal participation from both doctors (7/14) and nurses (7/14) working in the ICU environment, with 64% (9/14) in the adult, 29% in the pediatric (4/14), and 7% (1/14) in the neonatal ICU. Of the participants, 50% (7/14) were identified as senior clinical experts (4 females), whereas 29% (4/14, 2 females) and 21% (3/14, 2 females) were identified as mid and junior level, respectively. Participants were based in 5 states and territories of Australia, comprising the Australian Capital Territory, New South Wales, Victoria, Queensland, and Western Australia.

Table . Demographics of the interview participants.

Category and subcategory	Participants, n (%)
Role	
Doctor	7 (50)
Nurse	7 (50)
Experience	
Junior	3 (21.4)
Mid	4 (28.6)
Senior	7 (50)
Sex	
Male	6 (42.9)
Female	8 (57.1)
ICU[a] environment	
Adult	9 (64.3)
Pediatric	4 (28.6)

[a]ICU: intensive care unit.

Participants were also asked about their current use of CDS systems, which could be AI-powered or not. The majority (n=11) of participants indicated they had experience with CDS tools; however, they were not AI-driven. Crude rule-based scoring systems were still prevalent, and while they provided a framework for assessing risk, they lacked the maturity needed for real-time individualized care adjustments. Three participants indicated that they did not have any experience with computer-based CDS tools because their current systems were paper-based and relied on manual charting of patient observations. All participants recognized the potential of AI to address clinical challenges, and many felt that the systems currently in use were relatively simple and would benefit from further development and integration into everyday clinical practice.

Findings

Overview

An inductive thematic analysis using open coding identified 6 overarching domains. Of these, 3 focused on AI-driven CDS with XAI as a key component and are therefore reported here: (1) explainability and actionability, (2) trust, and (3) design

XSL•FO
RenderX

recommendations for AI-driven CDS with XAI. The constructs and subconstructs associated with these 3 domains are presented in Table 2. The number of participants refers to the number of participants who raised a construct at least once across interviews. For example, a participant may have mentioned an issue with high frequency in their interview, but it was only counted once to avoid potentially skewed data. Exemplar quotes for each of the subconstructs are provided. The remaining 3 domains identified broader use, concerns, and limitations surrounding AI-powered CDS tools, as well as implementation considerations for successful adoption. These additional findings are presented in Multimedia Appendix 3.

XSL•FO
RenderX

Table . Constructs and subconstructs of the 3 key domains identified in the qualitative analysis.

Domain, construct, and subconstruct	Exemplar quote
Explainability and actionability	
Need and usefulness of explainability (n=7)	
Complexity of both the patient condition and decisions to be made (n=6).	"…there may be less need for complex explanation when it's saying put patient X in bed X, because they're likely to move by this date as opposed to if I'm trying to diagnose a pneumonia which might be confused for a COPD type thing…" (P11, Nurse, Mid, Pediatric)
Clinicians' experience level (n=2).	"…but I think there's very much a role with the more junior staff who are learning…they're the ones who need the explanations more so than the senior people" (P10, Nurse, Senior, Adult)
AI[a] explanations, cognitive processes, and decision-making (n=13)	
Offset cognitive overload and prompt safety checks (n=7).	"…when there are times of cognitive overload, something that can sort through more information and facilitate a clear direction, that would be much better." (P9, Nurse, Junior, Pediatric)
Provide deterministic explanations that fit the clinician's mental model (n=7).	"…So the method two makes a lot more sense because…it fits with my ground truth..." (P14, Doctor, Senior, Neonatal)
Provide plausible explanations that can either reinforce or challenge a clinician's existing perspective (n=4).	"If it's a plausible explanation, then obviously I would have to rethink to determine whether that is the right thing." (P7, Doctor, Senior, Adult)
Avoid ambiguous explanatory factors as they may cause confusion (n=3).	"…the point you provide me with some information that comes out of context, am I better off or not? It is sufficient to make me less certain…" (P1, Doctor, Senior, Adult)
Application of AI CDS[b] explanations (n=13)	
Prompt patient review and be considered within the broader context of patient-related factors (n=12).	"…there's so many variables outside of obs that allow us to make decisions." (P5, Doctor, Junior, Adult)
In the setting of multiple explanations, can prompt the same clinical decision (n=3).	"The fact they don't agree is not [an issue], I can think of many examples where there are evidence that allowed us to reach the same conclusion..." (P1, Doctor, Senior, Adult)
Trust	
Influencing factors (n=12)	
Clinician age and experience (n=5).	"…the younger the clinicians are, the less they're frightened of it, maybe the more accepting they are of it…" (P10, Nurse, Senior, Adult)
Accurate predictions, which are trusted more than accurate explanations (n=6).	"…if it triggers that there's something going wrong, I would probably always take that seriously and so even if the explanation's not that great, it's up to us to…rule out what's going on with the patient…" (P13, Nurse, Senior, Adult)
Conflicts in decision-making stemming from information provided by AI-driven CDS (n=1).	"…these sorts of tools…become kind of bargaining chips between clinical team, because…data that is in black and white…will always be trusted more than someone's gut feeling or someone's intuition etc." (P5, Doctor, Junior, Adult)
Lived clinical experience and clinicians' understanding of the patient's situation (n=3).	"…the benefit for these systems is for less experienced people that haven't got…lived experience clinically…or my senior colleagues because we can't be at the bedside 24/7." (P14, Doctor, Senior, Neonatal)
Opinion leaders (n=2).	"…we want the clinicians who have some expertise in managing deteriorating patients to endorse and support the algorithm." (P7, Doctor, Senior, Adult)
Evidence-based and clinical utility (n=9).	"…if you demonstrated that in the type of hospital I am in, with the type of electronic systems and everything being similar, that the system always was better than all of the clinicians…. I would have to trust it more quickly...." (P2, Doctor, Mid, Adult)
Clinician internal calibration (n=11)	
Repeated exposure, consistent performance, reflection on clinical outcomes, and accuracy of predictions (n=11).	"…having that explainable element and…familiarity with using and trying previous AI or decision support tools successfully and that being helpful in my practice - would influence my views..." (P4, Doctor, Mid, Adult)
Impact of agreement level (n=12)	

XSL•FO
RenderX

Domain, construct, and subconstruct	Exemplar quote
Alignment with a clinician's mental model fosters trust (n=12).	"…what is it about various elements of the patient's profile that have made that tool perform in such a different way to what I was thinking..." (P4, Doctor, Mid, Adult)
Design recommendation for AI-driven CDS with XAI[c]	
Explanations are actionable and useful (n=10)	
Systems should present actionable data such as physiological trends, rather than standalone routine metrics, in a timely manner (n=10).	"…that's fairly well understood that the longer somebody stays the more at risk they are for hospital acquired complications.... It doesn't necessarily value add in that, but the physiological variables definitely." (P10, Nurse, Senior, Adult)
Systems should demonstrate in-depth predictive ability with detailed analysis of potential reasons for patient deterioration (n=3).	"…rather than just triggering for a temperature or a heart rate…, really putting it up front to say that it would be a sepsis trigger." (P9, Nurse, Junior, Pediatric)
Patient complexity and contextual factors (n=9)	
Provision of information beyond physiological data, such as the patient's history and comorbidities (n=9).	"…get the machine learning to pick up that…historical background of pre-admission and intra-admission factors..." (P9, Nurse, Junior, Pediatric)
Other recommendations (n=13)	
Simple, optional, and concise explanations (n=7).	"…the prediction that you had popping up as an overlay above the observations so that people could read them together would be helpful. Along with an explanation as to why, well even do you want the explanation?" (P12, Nurse, Senior, Adult)
The level of certainty and the potential for bias in prediction (n=6).	"…you need shades of confidence…maybe with confidence intervals, not just a score but some idea of how confident the system is." (P2, Doctor, Mid, Adult)
At-a-glance insights using clear graphics and minimal text (n=5).	"…if it took a lot of time and you had to make a decision about something…, then that would be kind of wasteful or distracting you from a patient." (P4, Doctor, Mid, Adult)
Color coding to indicate level of deterioration and transparent explanation (n=3).	"…whatever pops up on screen there's a little bit of explanatory detail and a bit of color coding will be that traffic lights or something else, basically saying this is what the AI model is predicting or directing…and this is why..." (P11, Nurse, Mid, Pediatric)
Information confined to specific intended use cases (n=2).	"So I trust this to give me a list of people that I should see, as a high priority and I can plan my workflow.... I do not trust it to tell me what dose of drug to use and what drugs to use on people." (P1, Doctor, Senior, Adult)
User-friendly, intuitive, and requiring minimal effort to use (n=1).	"The ones that actually get used clinically are the ones that require the least amount of effort..." (P5, Doctor, Junior, Adult)

[a]AI: artificial intelligence.

[b]CDS: clinical decision support.

[c]XAI: explainable artificial intelligence.

Explainability and Actionability

The domain explored when and why explainability is needed in CDS tools. It identified how effective explanations can enhance decision-making by helping clinicians manage cognitive load and focus on key details. It also explored how explanations influence decision-making, particularly when varying levels of disagreement arise between different explanation methods.

Subconstructs explored the context-dependent usefulness of explanations, where the need for explainability varies with clinician experience, task complexity, and decision type. Junior clinicians would benefit more from explanations for understanding AI outputs, especially in unfamiliar or complex situations, while reliance on detailed explanations would decrease in routine tasks or for experienced clinicians who intuitively assess clinical indicators. Junior clinicians may benefit from detailed explanations because they are still developing their clinical reasoning and may rely on AI outputs as a learning tool. In contrast, senior clinicians, drawing on extensive experience, may use AI mainly as a confirmatory aid, focusing on explanations primarily when outputs diverge from their expectations or offer novel insights. As AI tools may fail to capture the multifactorial nature of patient conditions and physiology, their role should be to provide direction on which physiological parameters to investigate further, with final decision-making remaining a human responsibility.

Trust

The trust domain examined factors influencing trust in AI-driven CDS, including clinicians' age, experience, intuition alignment, and the tool's predictive accuracy. It further highlighted how trust builds gradually through reliable performance and repeated use, enabling integration with clinical decisions. Specifically,

XSL•FO
RenderX

confidence would grow as users understand the evidence behind the algorithm and how it was developed. Validation of the XAI tools by multiple studies and investigators, particularly if in similar settings, would similarly foster trust. One of the most important determinants of trust was alignment with clinical instinct. A system that consistently produced reliable outcomes containing few discrepancies with expert clinical judgment would increase trust, while contradictions would undermine trust, particularly when there is a disagreement with the tool's predictions.

Design Recommendations for AI-Driven CDS With XAI

This domain outlines key design considerations for AI-driven CDS tools from the participants, focusing on when and how explanations are presented. It highlights delivering actionable, contextualized information through clear, concise explanations that focus on physiological trends and patient history. While centered on XAI-supported CDS, the findings also underscore the importance of communicating prediction certainty and potential biases to enhance decision-making without overwhelming users.

This means that insights must be actionable, focusing on physiological trends rather than routine metrics, and offering timely and relevant data. A detailed analysis of potential deterioration causes would be preferred over just alerts, with the potential to suggest actions such as specific tests to order. The ability to integrate additional variables could better predict outcomes, such as mental state deterioration, past clinical history, environmental factors, laboratory values, historical data, and, in pediatric settings, parental concerns.

From a user interface perspective, AI tools with concise and customizable presentation options would allow for variations in experience and complexity. Clear, fact-based explanations using bullet points or likelihood percentages were optimal for busy critical care settings, with additional guidance available if required. The provision of weighted graphs, CIs, graded risk indicators, and visual cues such as traffic-light systems allowed clinicians to assess and mitigate risk.

Discussion

Principal Findings

This study explored how explainability influences clinicians' trust, interpretation, and use of AI-driven CDS tools in the context of Australian critical care settings, with particular attention to how clinicians respond when different explainability methods produce different explanations for the same AI prediction. While trust and explainability have been explored in prior research [1,27,29,30,32,47-50], this study contributes novel insights by addressing the underexamined issue of discrepancies between explanation methods, a phenomenon increasingly recognized in technical XAI research [37,42-46] but not studied from a human-centered or clinical perspective. Our findings highlighted a broad range of factors that influence clinicians' use of and trust in AI-driven CDS tools, including how explanations are perceived, applied, and deemed useful, all of which directly informed key design and implementation considerations for XAI-driven CDS systems. The study also offers a novel contribution to the understanding of how explainability influences the determinants for establishing initial trust and overtime trust in AI-driven tools. Specifically, we delineate the positioning of explainability in supporting both perceived usefulness (for initial trust) and learned usefulness (for overtime trust) [58].

The study investigated the perceptions of Australian clinical experts on using explanations as part of their clinical decision-making and how explanations impact trust in XAI-driven CDS. The findings directly address RQ1 by answering how explainability influences clinicians' use, trust, and perceived usefulness of AI-driven CDS tools. The results showed that explainability plays a dynamic and context-dependent role in shaping clinicians' interactions with these systems. Consistent with the literature [29,59], the clinical experts in our study agreed that explanations are a valuable feature that enhances trust and the usefulness of AI-driven CDS tools. However, the necessity and value of explanations vary depending on the context and the clinician's experience. The importance of context-based explanations was similarly highlighted in the findings of Barda et al [60]. For more fundamental decision-making (such as bed allocation, ordering routine blood tests, and administering pain relief), explanations are often unnecessary and can be viewed as an optional resource. Additionally, experienced clinicians may rely more on their own clinical intuition and use explanations less frequently, while less experienced clinicians may prefer more detailed explanations to guide their decision-making. A similar finding was reported by Panigutti et al [49], where the explanation interface was found to be valuable in helping novices avoid mistakes and supporting collaborative decision-making tasks.

Drawing upon the integrative trust model proposed by Cabiddue et al [58], which identified perceived usefulness as a crucial determinant of initial trust in AI-driven tools, our findings reveal a stronger need for explainability during this nascent stage. Explainability is shown to be particularly instrumental in supporting perceived usefulness, especially when users are developing familiarity with the tool. Furthermore, the value of explainability appears to be moderated by user expertise. Novice users, who lack extensive clinical experience, may find explanations more useful in establishing initial trust compared to their expert counterparts. Conversely, the model highlighted learned usefulness as the key determinant for establishing overtime trust. A key finding of our study is that the importance of explainability diminishes overtime as users transition from perceived usefulness to learned usefulness. For expert users, in particular, the significance of explainability decreases notably once they have established confidence in the tool's predictions and rely more heavily on their clinical judgment. Once this level of trust is solidified, the contribution of explainability to learned usefulness becomes less pronounced.

The study further investigated whether partial or complete discrepancies between different XAI methods affect the trust and perceived usefulness of the tool. Participants viewed AI recommendations as an adjunct in decision-making and were not concerned by discrepancies in explanations, prioritizing their own patient assessments. They stressed the need for accurate AI predictions to maintain trust and avoid alarm fatigue.

XSL•FO
RenderX

Explanations were found most helpful when they aligned with clinicians' mental models and the patient's holistic condition. However, participants emphasized that the initial prognostic or diagnostic model predictions must be accurate, as too many false positives would erode trust in the system and lead to alarm fatigue. Alignment with clinicians' mental models is crucial for adopting AI-driven tools [1], as explanations that match these models foster trust, while large discrepancies can cause skepticism. Our study found that discrepancies in explanations enabled reflection through skepticism [59], a fundamental concept in human-centered XAI that encourages critical thinking over passive acceptance when evaluating explanations and building trust in the system [61]. In addition, clinicians often face complex decisions where different approaches yield the same outcome; explanations aligning with their thinking, despite discrepancies in key factors, did not significantly affect trust. However, repeated poor performance in predictions and explanations can lead to loss of trust, consistent with prior findings linking high AI performance to greater acceptance [62,63]. While previous studies have explored XAI's usefulness [64-67] and compared AI's prediction and clinical judgments [19,67,68], few have focused on how explanation discrepancies impact clinician decision-making. Addressing RQ2, our findings show that clinicians may tolerate some level of discrepancies between explanation methods as long as the AI prediction is accurate and the explanations remain clinically meaningful. Rather than dismissing the system, they respond evaluatively, using discrepancies to scrutinize the output, while maintaining trust when the system's outputs are accurate, actionable, and aligned with their clinical reasoning.

Finally, the study identified several design recommendations for successful use of XAI systems in clinical settings. Explanations should focus on actionable data, emphasizing physiological trends (eg, respiratory rate and blood pressure) over routine metrics such as length of stay. Instead of a single metric, the trend over a specific period of time should be shown to assist in making specific clinical decisions. Providing actionable recommendations, such as potential diagnostic triggers, was also suggested by some participants, a finding that was also echoed in related studies [60,69]. Alongside the explanation when a prediction is generated, AI-driven systems should incorporate contextual information on the patient's clinical history and clinical complexity. This is consistent with the literature that explored factors influencing medical experts' use of AI-driven CDS systems [1,70,71]. Multiple studies identified that a lack of a holistic perspective of the patient in the CDS recommendations provided hindered the system's adoption in the health care settings [50,70]. In adult settings, information on comorbidities and previous admissions provides valuable insights, while in pediatric settings, incorporating concerns from both parents and clinicians offers a more holistic view of the patient's condition. Some additional contexts that could be included are the underlying causes of physiological changes, including medication effects, movements, and so on. Providing contextual information along with explanations aligns with the mental model of collaborative practice, enabling colleagues to deliberate and discuss the broader context of a patient's condition to make informed clinical decisions [19].

Explanations need to be simple, concise, and presented in an optional format to avoid overwhelming clinicians. Some ways of visualization include using bullet points, likelihood percentages, and summaries to communicate essential information effectively. The level of detail should be customizable, enabling clinicians of different expertise to adjust the information shown according to their preferences. Ensuring that explanations are digestible would allow clinicians to focus on critical insights without sifting through lengthy text, with additional background and secondary details accessible on demand [72]. Aligned with our findings to prioritize accurate predictions, CDS systems should clearly convey prediction certainty and explanations, along with disclaimers about potential biases. This can be achieved by including CIs or graded risk indicators, alongside visual aids such as weighting graphs on both the predictions and corresponding explanations. Displaying AI confidence scores has been found to enhance trust calibration, leading people to trust the AI more when it shows higher confidence [27,73]. Predictions and their accompanying explanations should be presented within an optimal timeframe to ensure they are actionable, as alerts that come too early or too late can heighten clinician anxiety. The appropriate timing will vary depending on the hospital setting, patient cohort, and available resources, making it crucial to determine this in consultation with expert clinicians. Together, these design considerations demonstrate how explainability, when thoughtfully implemented, underpins trustworthy, context-aware, and user-centered integration of AI-driven CDS tools in clinical settings.

Our study strengthens the human-centered XAI literature by providing evidence from the Australian health care context, addressing a gap in prior research that has predominantly been conducted internationally [1,29,50,59,60,64,65,69,71,74]. We find that key insights from the state-of-the-art literature—such as the value of actionable, context-based explanations, and the variation in reliance on AI by clinician experience—are also relevant in Australian settings. Additionally, the analysis reveals new insights into clinicians' views and tolerance for discrepancies between explanations. Finally, our results highlight local nuances, including workflow considerations and concerns about overreliance in high-pressure environments, offering practical guidance for the design and deployment of AI-driven CDS tools with XAI in Australia.

Limitations and Future Work

One limitation of our study is the composition of the participant cohort. ICU settings are among the most critical in health care, where timely and precise decision-making is vital. This focus motivated our approach and guided our selection of clinical experts from this environment. Nonetheless, many of our findings, particularly those related to clinician trust, explanation usefulness, and balancing guidance with overreliance, may also apply to other clinical settings such as emergency departments or surgical units. However, it is important to note that differences in workflow, patient acuity, and team structures could influence how AI-driven CDS tools are used. Though our findings may apply to other domains with certain domain adaptation, further research is needed to assess the generalizability of our results beyond the ICU. Future studies

XSL•FO
RenderX

could examine perspectives from these additional settings and incorporate participants from other countries outside Australia to provide a more comprehensive understanding. Due to the study's qualitative nature, the findings should be interpreted with caution when considering generalizability. It is important to acknowledge that the scenarios used in this study were based on a desktop prototype, which may have constrained participants' ability to fully consider the scenarios within the context of real-world decision-making environments. Future research could explore the use of more interactive and immersive prototypes, such as those integrated into clinical workflows or simulated environments, to better capture the nuances of decision-making in practice. These future studies could include large-scale usability studies to assess the impact of these actionable insights and further support our qualitative conclusions. Further research should explore scenarios in which the CDS provides plausible yet conflicting predictions relative to clinicians' expected reasoning. Examining such cases would offer deeper insights into how explanations influence trust calibration and decision-making under conditions of disagreement. Future research could also focus on validating the design recommendations for AI-driven CDS tools, ensuring they are adaptable to various clinical scenarios and effectively address trust, safety, and usability concerns, thereby supporting widespread and ethical adoption in health care. This study contributed to the development of a checklist for XAI tools [75]. Evaluating explanations in development and trial phases using the checklist could help enhance trust, reduce risks, foster AI adoption, and determine the true clinical potential of applied XAI.

Conclusions

This study identified recommendations for developing trustworthy, user-centric XAI-supported CDS tools. Three key domains were identified, emphasizing the importance of trust and explainability in gaining clinician acceptance of AI tools. It also highlighted that discrepancies between different explanation techniques are not inherently problematic, provided the explanations are consistent with clinicians' mental model. While developing and deploying algorithms is relatively low-cost, the greater challenge lies in integrating them into clinical workflows, requiring acceptance by health care professionals. By examining user needs, our findings support the development of clinician-informed, actionable insights throughout the AI tool lifecycle. This approach can enhance trust, mitigate risks, and promote sustainable health care by aligning AI systems with clinical workflows and improving long-term patient outcomes through informed and effective use.

Abstract

Background: Mental health has become a growing concern among university students. According to the Healthy Minds Study National Report 2022 - 2023, 46% of students have been diagnosed with a mental health condition by a health professional, reflecting a nearly 50% increase from 2013 to 2021. While researchers have developed various technologies to help this issue, one significant aspect of the mental health management journey is often understudied—the role of mental health medication. Understanding how university students manage their medication for mental health symptoms in real-world practice has not been fully explored.

Objective: In this study, we aimed to examine university students' experiences in taking and managing their mental health medications. We want to understand the unique challenges in the mental health medication management process and their coping strategies, particularly examining the role of various technologies in this process.

Methods: We conducted semistructured interviews with 10 participants who are self-identified as currently taking medication for mental health diagnosis and are students at a university. Two researchers (JL and JS) open-coded the interview transcripts and notes and conducted a thematic analysis to identify 3 primary themes, which we detail in the Results section.

Results: We discovered that due to struggles with self-acceptance and the interdependent relationship between medication, symptoms, schedules, and life changes, the medication management process for students was a highly dynamic journey involving frequent dosage changes. Thus, students adopted flexible strategies of using minimal technology to manage their medication in different situations while maintaining a high degree of autonomy. Based on our findings, we propose design implications for future technologies to seamlessly integrate into their daily lives and assist students in managing their mental health medications.

Conclusions: In the paper, we conducted semistructured interviews with university students currently undergoing medication for mental health issues. The interviews aimed to uncover the challenges they encountered in their university lives, along with the coping strategies and technologies used to navigate these challenges. We found that students often rely on creative ways to use fixed alarms on their phones; however, they encounter numerous difficulties due to factors such as the flexibility of daily routines. Based on these findings, we proposed 6 design implications for how advanced technology could better assist university students in managing their mental health medications.

Introduction

Background

Researchers have recently observed that mental health challenges pose a significant concern, particularly among university students. According to the Healthy Minds Study National Report 2022 - 2023, 46% of students have been diagnosed with a mental health condition by a health professional, encompassing depression (30%), anxiety (36%), and other symptoms [1]. The reported data represent the highest rate in the 15-year history of the survey, reflecting a nearly 50% increase from 2013 to 2021 [2]. Recognizing the severity of these issues, many researchers have developed various technologies to assist, including chatbots [3-5], digital therapeutic applications [6,7], and wearables for passive monitoring [8-10]. Although these technologies have demonstrated positive effects, one significant aspect of the mental health management journey is often understudied—the role of mental health medication. According to the report, 40% of students with positive depression or anxiety screens had taken at least one type of medication in the preceding 12 months.

XSL•FO
RenderX

Since these medications often have a significant effect in mitigating and managing mental health symptoms, it is crucial to examine people's experiences in taking and managing these medications.

Despite the large population of university students using medications for mental health conditions, their strategies in managing those medications are relatively understudied. Most prior works on medication management strategies focused on older adults [11,12] and individuals with disabilities [13], often categorizing younger populations as "healthier." With the increase in mental health diagnoses, however, more university students are regularly taking medications to manage their mental health. Further, given their busy schedules and dynamic routines, ensuring adherence among this group is also difficult. For researchers aiming to develop technologies to address this issue, it is important to first understand the real-world practices of individuals in adopting various technologies for mental health medication management, the challenges they encounter during the process, and the hesitations with being more consistent with the medications. Recognizing the significance of this issue, our research delved into the challenges university students face in managing their mental health medication and the coping strategies they use to tackle these issues.

In this paper, we make three important contributions. (1) We pinpoint the unique challenges in the medication management process for university students with mental health conditions. (2) We delve into the coping strategies used by university students in addressing these challenges, with a particular focus on examining the role of various technologies in the process. (3) Based on our findings, we outline and discuss design implications for future systems aimed at assisting university students in managing their mental health medications.

Related Work

Mental Health Issues Among University Students

The prevalence of mental health issues among university students has been escalating, posing a growing concern. According to a recent study, nearly half of all lifetime mental health conditions start by the mid-teens and three-quarters by the mid-20s [14]. The discussion of mental health within university communities underscores the challenges that many students face during their collegiate journeys. The combination of heavy academic workloads, social pressures, and the inherent uncertainties associated with this exploratory phase of life contributes to an environment where mental health issues can manifest [15-17].

In recent years, there has been a discernible uptick in mental health concerns among students, with a notable rise in conditions such as anxiety, depression, eating disorders, and suicidal ideation [1,16]. These issues not only cast shadows over the overall university experience but also impede students' active participation in academic and extracurricular activities, leading to a considerable decline in their overall quality of life [2,18]. Due to the gravity of the situation, there has been a stronger push to spread mental health awareness. Between 2013 and 2023, there has been a substantial 7.8% reduction in the perceived stigma surrounding mental health issues, fostering an environment where individuals are more inclined to seek assistance [1,2]. This reduction in stigma has correlated with a 12.8% increase in the usage of psychotropic medications among university students during the same period [2].

While the surge in medication use reflects a growing acknowledgment of mental health challenges, the issue of mental medication adherence among university students remains underexplored. The efficacy of mental health therapy and psychiatric medication is contingent on consistent adherence to prescribed regimens. Factors such as academic pressures, social dynamics, and lifestyle transitions unique to the university experience may significantly influence medication adherence [19,20], thereby necessitating a nuanced understanding of this critical aspect of mental health treatment.

Mental Health Treatment: The Role of Medications

The treatment of mental illness frequently involves a combination of medication and mental therapy. Medications are typically prescribed when psychotherapies on their own are ineffective [18,21]. Medications play a crucial role in alleviating symptoms by influencing brain chemicals affecting mood and behavior [22]. Commonly prescribed medications include antidepressants, antipsychotics, and mood stabilizers [23]. Antidepressants are used to treat a wide variety of illnesses, such as major depressive disorder, general anxiety disorder, and obsessive-compulsive disorder [24]. When taking antidepressants, the dosage of the medication will help determine the effectiveness of the treatment. However, the higher the dose, the more likely a patient will experience side effects [25].

While psychiatric medications are integral components of mental health treatment, their effectiveness is also contingent on factors such as accurate diagnosis, tailored prescription regimens, and, notably, adherence to prescribed medications [26-28]. Adherence is the execution of a prescribed treatment plan with little to no error. This includes taking the correct medication at the appropriate dose, at the proper time, and with a proper frequency [29]. Adherence to psychiatric medication regimens is a critical determinant of treatment success, influencing the ability to manage symptoms and enhance overall functioning [30,31]. There are many factors that can influence a patient's capacity to adhere to medication, such as age, educational level, attitudes and beliefs toward medication, routines and schedule, stigma, dosage changes, and medication side effects [20,28,32,33]. We contribute to the existing literature by understanding how these factors affect adherence within the university student demographic, specifically for mental health medications.

Technology for Medication Management

In order to combat the issue of medication nonadherence, many studies have tested different types of adherence-related technologies. There is no universally recognized standard in medication adherence technology, making it difficult for patients to identify the most effective solution for their needs. These technologies encompass a wide range of tools such as smart pill bottles, sensors, self-reporting technology, mobile apps, and chatbots [34-37]. Smart pill bottles, for instance, can connect to the internet and record the time when a patient opens the

XSL•FO
RenderX

bottle, providing a timeline of adherence [38]. For mobile phones, there are many different types of modalities that can be used, such as phone calls, SMS text messaging, online surveys, as well as audio and video content [36,37,39,40]. However, depending on the features used, there can be challenges with user engagement, battery life, storage capacity, and ease of use [40].

Notably, the combination of mobile interventions with smart pillboxes has emerged as an effective method in supporting antidepressant treatment [41]. Mobile apps, in this context, serve not only to monitor adherence but also to provide medication education, track side effects and symptoms, and act as a communication channel with health care providers. This serves to address multiple pain points that are related to adherence, such as a lack of knowledge, forgetfulness, and low motivation [41]. This multilayered approach showcases the potential of technology to address medication adherence challenges while offering additional benefits in terms of education, monitoring, and communication within the health care ecosystem.

The exploration of using mobile adherence solutions also extends to artificial intelligence (AI). AI smartphone apps have also been investigated for their effectiveness in delivering reminders and encouragement for medication adherence for adults with noncommunicable diseases [26]. Conversational agents, also known as chatbots, are able to simulate human interaction in text, audio, or visual formats [42]. Conversational AI systems have been shown to help older adults remember to take their medications by tracking their daily activities and symptoms [26]. AI systems are able to collect and interpret data from a wide variety of different data structures, such as from electronic health records, clinical notes, and real-time physiological data in conjunction with sensors [42]. Furthermore, because of an AI system's ability to detect meaningful patterns in data, they also have the ability to provide personalized responses to better support user needs as well as foster patient/provider relationships [26,42]. In addition, the integration of these new technology-based approaches comes with several advantages, including easy implementation, cost-effectiveness, and extensive outreach [27,31]. Our research focuses on discerning effective versus ineffective technologies for medication adherence among university students and understanding how technology-specific factors influence adoption.

Methods

Interview Study Design

Recruitment materials were distributed through public university email lists and social media channels, initially targeting two universities and later expanding through snowball sampling. Participants were required to provide a ".edu" email to verify their student status. The study received approval from the Department of Human Research at Northeastern University (#23-04-19), and no direct contact with universities beyond publicly accessible channels was made. The recruitment materials clearly stated that participation was voluntary and would not affect participants' academic standing. After expressing initial interest, we emailed the consent form to the participants, outlining the study's purpose and content to prepare them for potentially sensitive interview topics before the interview. Students could contact the research team for additional information or consultation before providing consent, given the potentially sensitive nature of the study. If the participants wanted to proceed, we scheduled the virtual semistructured interviews through Zoom, which typically lasted an hour. After eligibility screening, 12 students were contacted for scheduling, and 10 completed both the survey and the interview. Two members of the research team were present for all interviews; one researcher led the interview while the other documented the discussion. We obtained audio recordings and transcripts only after the participants' initial consent. Each participant received a US $20 Amazon gift card via email after the interview. Given the sensitive subject of the interview, we provided participants information about the resources at the university's Health and Counseling center, and also provided them with the university's 24-hour helpline number to connect with a mental health clinician who is there to listen, guide, and help.

The interviews primarily revolved around each participant's unique journey managing their mental health medication. We delved into their medication schedules, ranging from basic details like frequency to deeper explorations of personal challenges. Our focus also extended to the technologies used during this process, exploring both successful and challenging experiences. Acknowledging the individuality of each journey, we let the participant drive the interview and describe their experience in the later part of the interview, with some guiding prompts like, "Describe your most recent experience taking medication, such as today or yesterday." Researchers dynamically adjusted the interview questions based on each participant's unique challenges, aiming to capture a comprehensive understanding of their personal experiences in managing medications within real-world scenarios.

In addition to the interviews, we requested the participants to complete an online survey. This survey collected demographic information, basic medication information, and 1 scale measuring self-efficacy in medication use (SEAMS) [43]. The SEAMS is a 13-item scale assessing patients' confidence in taking medications as prescribed, scored on a 3-point Likert scale ranging from 13 to 39, with higher scores indicating greater self-efficacy. The survey was deidentified using participant IDs to protect anonymity.

Participants

In this study, we conducted 10 semistructured interviews with participants who are self-identified as currently taking medication for mental health conditions and are students at a university. We used the participants' university email addresses to verify their eligibility for the study.

Data Analysis

We carefully reviewed the interview transcripts and notes, adopting an open coding approach [44]. The data were coded independently by two researchers (JL and JS), with each focusing on specific segments. Subsequently, both researchers exchanged their individual codebooks, engaging in discussions

XSL•FO
RenderX

to harmonize and merge the codes by consensus. Following this collaborative process, we conducted a thematic analysis, adhering to the principles of grounded theory [45,46]. We reached data saturation with 10 participants and stopped further recruitment [47,48]. This analysis resulted in the identification of 3 primary themes, which we detail in the Results section.

Ethical Considerations

The study obtained the institutional review board approval from the Department of Human Research at Northeastern University (#23-04-19). Informed consent from participants was obtained before each interview. Given the sensitive nature of the data collected, personal identification was immediately removed postinterview. Participants were given the autonomy to self-report their diagnosis voluntarily and retained the right to withhold this information if they chose. Realizing the interview topic's sensitivity and the potential risk of disclosing private information, we ensured that recruitment of new participants ceased as soon as we reached data saturation [47,48]. Each participant received a US $20 Amazon gift card via email after the interview.

Results

Participants' Demographics

Two of our participants identified as male, while 8 identified as female (Table 1). In terms of racial identification, 5 participants identified as White, 1 as Hispanic, 1 as Black or African American, 1 as Asian, and 2 as Other. Among the participants, 3 were enrolled in undergraduate school, and the remaining 7 were attending graduate school. On average, participants reported taking 1.6 (SD 0.7) types of medications. All participants took medications at least once a day, with one individual taking additional medications weekly and another multiple times a day (Table 2). Regarding medication storage, 8 out of 10 participants only used the original pill bottle or blister; one used a 7-day drugstore-style pillbox, and another used both methods. In terms of technology used in the medication management process, 4 relied solely on memory, 4 used general digital calendar/reminder apps, and 2 used other technologies such as third-party medication and self-report apps. The average score for medication self-efficacy was 25.3 (scale value ranging from 13 as nonefficacious to 39 as efficacious), respectively. These scores suggest that there is no obvious ceiling effect in our sample, indicating that participants do face some challenges in their medication management.

Theme 1: A Dynamic Voyage: Managing Mental Health Medication Is Never a Static Process

A standout takeaway from all the interviews was the dynamic nature of managing mental health medication. In this section, we aim to illustrate the causes of this dynamic nature and its effects on medication management strategies.

Theme 1.1: Struggling With Self-Acceptance: Expectations of Reducing or Ceasing Medication

We noticed significant concern and hesitation regarding taking medication for mental health concerns, setting apart the expectations for mental health medication from those for treating chronic diseases related to nonmental conditions. Of the 10 participants, 9 did not commence medication immediately after receiving a diagnosis. For instance, Participant 5 had been diagnosed with a mental health condition for 16 years but only began taking medication approximately 10 years ago. This delay in medication initiation underscores that medication is not typically the first treatment choice for mental health challenges.

> *I just wasn't seeking medical help like medical or medicine intervention for a while.* [Participant 4]

Starting medication was often considered "a tough decision" by our participants, generating feelings of anxiety. This anxiety stemmed from various reasons. Initially, many associated taking medication with "having serious issues" and struggled to reconcile this notion within themselves.

> *For example, once you start going on medication, it's like, you have problems. It's more like admitting to yourself that you need help.* [Participant 2]

Moreover, uncertainty about the effects of medication caused anxiety. Participant 2 described embarking on taking medications as "taking a risk" since it is not clear why some people have different symptoms even on the same medications. Concerns also extended to potential long-term effects, particularly as mental health medication "has some influence on our brain" [Participant 8]. Another intriguing factor was the involvement of parents in this decision-making process, especially considering the changing relationships between university students and their parents during this pivotal time. Participants mentioned instances where their parents decided if they could take medication during their teenage years, or they felt the need for parental confirmation before starting medication in university while gradually assuming greater autonomy later on. We delve deeper into this transitional period in the latter part of this paper.

Due to concerns about taking mental health medication, although many patients ended up using it for a long time, they did not expect nor desire a long-term reliance on medications. Participant 4 and many others expressed that they did not anticipate medication being a lifelong necessity; instead, they hoped to gradually reduce and eventually stop taking it. Participant 8 expressed strong feelings on this:

> *I want to decrease overall medication usage. And I really hope that one day I will not rely on the medication.* [Participant 8]

This unique desire leads to more instability in managing mental health medication, unlike managing many chronic diseases where patients are comfortable maintaining a stable dose for extended periods [49]. Our participants consistently reevaluate their symptoms, actively seeking opportunities to adjust the dosage. This frequent reassessment significantly destabilizes the management of medication.

Theme 1.2: Dosage Changes and Medication Adjustments Are Common

In addition to the participant's willingness to reduce dosage, several other factors in real life may contribute to changes in dosage or even the type of medication. A common cause for adjusting dosage is the fluctuation in symptom severity. This occurrence is surprisingly frequent among our participants, given that mental health symptoms can be significantly and rapidly influenced by life changes, a common experience for university students. Participant 10 increased dosage after entering university to manage the heightened stress of schoolwork, while Participant 8 found a better balance and relied less on medication upon studying abroad for graduate school.

Insufficient effectiveness and significant side effects are substantial factors leading participants to alter their dosage or medication. We observed a noteworthy number of participants expressing the challenge of finding the right medication that works for them, particularly at the onset of their medication journey. Participant 4 described this process in detail:

> *You feel elaborate when you have to figure out what works for you. If you visit with a professional like a psychiatrist, and they prescribe something to the best of their knowledge. You have to stay on it for like 2 months to see the full effects, which means if it's something [that] doesn't work for you, you have to commit to it for 2 months, and then go back to the drawing board. Sometimes you have to wean off of it. It's like, hmm, start over.* [Participant 4]

Participant 1 also described people underestimating the risks when starting a mental health medication:

> *I know people expect sometimes it has an effect right away. I think it's not commonly known that within the first couple of weeks of taking medication are actually, if you're at risk for suicide, those are particularly volatile weeks for you in starting a medication, because it's a frequent occurrence that starting a medication can actually give people a sort of boost of motivation, almost that they need to follow through with any sort of suicidal ideation or self-harm.* [Participant 1]

This revealed a gap between theory and real-world experiences of taking medication, where there is more back and forth, which would complicate medication management strategies. To summarize, the previous descriptions explain why there are frequent changes in medication for university students with mental health issues, emphasizing the importance of recognizing and addressing these issues.

XSL•FO
RenderX

Theme 1.3: Medication Interlaces With Mental Health Symptoms

Aside from treating symptoms, medication for mental health establishes a complex and intimate relationship with mental health status. While many of our participants recognized the importance of taking medication on time, they also found this additional task to be stressful, which in turn deteriorated the symptoms.

> *I also constantly feel the pressure of stress which reminds me to take the medication that has been prescribed for that stress.* [Participant 1]

Participant 4 also found this process distressing "because you're altering your mental state in an attempt to fix your mental state." Mental health symptoms also impact participants' capacity to take medication that alleviates those symptoms. For instance, Participant 5 mentioned that during particularly depressive episodes, getting out of bed and accessing medication stored in the kitchen became challenging. As a result, the distinctive connection between mental health symptoms and managing medication designed to address those symptoms further complicates the process.

Theme 1.4: Transition Period for University Students

Besides the instability caused by medication and mental symptoms, the unique phase of being university students introduced further fluctuations in the medication management process. Many participants indicated significant changes in their medication routines upon entering school. This involved practical challenges such as differences in accessing medical services due to relocation and changes in insurance (typically transitioning from family to individual coverage). Moreover, this life stage shift represented a change in responsibility, prompting university students to manage their medication independently. As Participant 1 noted:

> *My mom would remind me a lot when I was at home. Almost daily or just even ask me if I had taken it, so I definitely lack that (at school).*

Participants also expressed that the decision to take medication was no longer solely their parents' responsibility, granting them more autonomy in decision-making. Predictably, this life transition resulted in unstable medication management strategies as university students adapted to a new lifestyle and worked on establishing new habits.

In this section, we discovered that the process of taking mental health medication was marked by instability and continual fluctuations, influenced by various factors related to the self, medication, and external events. This inherent instability prompted university students to develop flexible strategies for managing their medication, a topic we will delve into in detail in the next section.

Theme 2: Strategies for Managing Mental Health Medication Among University Students: Flexible and Creative Ways of Using Simple Technology

This section reflects the diversity of needs and corresponding methods university students use to better incorporate medication management into their dynamic lifestyles. Before exploring different strategies, it is crucial to delve into the motivation and consequences behind university students taking medication. This context is essential for understanding why they opt for specific strategies.

Theme 2.1: Motivation and Consequences: Symptoms

A large reason why our participants have developed or adopted strategies in the first place is due to the consequence of side effects or decline in mental health and/or performance that comes with missing dosages. Many of the consequences are experienced firsthand, while the motivation of others is driven by worry or anxiety. According to Participant 7,

> *If not taking my meds means that I feel horrible, or I have a depressive episode, or can't get the work done, or I don't show up in the way I want to enough times, I am motivated to take my meds on time. If I can't feel the difference, I'll spontaneously stop taking them, because I don't think they're making a difference. I think it's rarely me being motivated to take my meds. It's me being motivated to not feel like s**t.*

Further, due to the nature of many mental health medications, missing doses do not have an immediate effect on the user, which can cause the user to become more relaxed with their routine. Nevertheless, all of our participants recognized the importance of "being more consistent" and generally experienced heightened stress when missing a dose for an extended period, which could lead to a severe outcome. Participant 2 once took their own initiative to quit medication after forgetting to take medications for a few days and "was just kinda like, f**k it, I'm fine." However, this did not yield positive results, and Participant 2 had to resume their medication after a while when they felt the symptoms returning. This nicely characterizes why our participants find it so important to use different tools and strategies to aid them in their medication adherence.

Theme 2.2: Fixed Reminders Are Common But Not Enough

Many participants developed strategies involving alarms and reminders as parts of their daily routines. Of the 10 participants, 6 used the preinstalled iPhone clock app due to its easy access, and only a minority (n=2) sought out specialized apps such as Apple Health. Despite the use of various apps, all reminders were set at fixed times, typically aligned with their regular medication schedule. However, participants expressed that this approach is often insufficient for various reasons.

First, our participants sometimes do not immediately take their medication when the alarm goes off. For example,

> *If I'm just chilling at that point I'll just take my pill. If I am wrapping something up, like I'm playing a video game or watching a show and I have 5 more minutes left, I just gotta finish this thing.* [Participant 2]

Depending on their current activities, some individuals may choose to snooze the alarm if they are in the middle of a task. Moreover, if there is a longer delay before taking the medication, participants dynamically adjust the reminder time. For example,

XSL•FO
RenderX

if Participant 2 is not at home at 9 PM (the usual time of the recurring alarm), they turn off the 9 PM alarm and manually set a new alarm for 11:30 PM to be reminded later. They then repeat the snooze method until they have taken their medication. Some participants even use a backup reminder strategy at the beginning, setting two recurring alarms at different times in case they miss the first one.

Second, their medication routines might be closely tied to other schedules that do not adhere to fixed times. Participant 5's perspective highlights the significance of a system that acknowledges the variability in waking times of university students and emphasizes the need for reminders to adapt accordingly.

> *I wake up at not exactly the same time every day, and my medication routine is tied to my morning routine rather than a specific time. So setting an alarm that I need to take it at 9 am or 10 am every day isn't as useful for me.* [Participant 5]

In addition to the sleep schedule, Participant 3 also mentioned that their medications "don't do very well with skipping breakfast." This implies that having a meal is another crucial activity that participants need to consider when managing their medication.

The earlier discussions on schedules illustrate how routine activities related to medications occur at flexible times. Moreover, the situation could worsen if our participants have an irregular schedule on some days that disrupts their normal plan. For instance,

> *If I wake up sort of later in the day, and there's a lot that I need to do, I'm more likely to skip that normal morning routine that I stick with, which tends to just sort of push my medication to the back of my mind.* [Participant 1]

Academic tasks such as meetings are sometimes events that often get in the way. In those cases, taking medication will not be prioritized, and "sometimes I just end up forgetting because I don't have the allowance or the reminders anymore" [Participant 3]. In more complicated situations where Participant 5's medications were linked with meals, they missed a dose because the 7 AM meeting was earlier than their usual wake-up time, disabling them to take breakfast, which resulted in forgetting medications.

Due to the limitations of fixed alarms, some participants did not consider reminders and alarms to be the prioritized strategy, but rather viewed them as a double assurance. For Participant 9, they had a daily reminder but still usually took medications before the alarm.

To summarize, this perspective calls for a shift from a rigid, time-based reminder to a more adaptive and context-aware system. Participants expressed desire for technology that understands and integrates into their established daily routines. This ensures that medication reminders are not only timely but also align with their natural routines.

Theme 2.3: Physical Cues: A Simple But Effective Method

While acknowledging the limitations of digital reminders, several participants in our study expressed a preference for using physical cues to manage their medication. For instance, Participant 7 highlighted their reliance on a physical pill organizer right next to their bed. Similarly, Participant 10 strategically places their medications on their desk near their computer and backpacks. By keeping the pillbox visible and within their line of sight, they create visual cues that serve as reminders for medication intake. The preference for physical instruments is rooted in a sense of reliability and simplicity. This insight sheds light on the significance of environmental cues and the impact of visibility on adherence behavior.

Theme 2.4: Gaps Between Reminder and Actual Intake: The Paradox of Logging

While reminders are helpful in medication management, there is still a gap between setting up the reminders and actually taking the medications on time. Participant 3 shared a sentiment about how easy it is to become distracted and cast doubt upon oneself regarding whether they have actually taken their medication. When the alarm goes off, they have to walk over to the place where they keep their medication. If they are thinking about something else at that specific moment, they can forget whether they have taken it. Participant 2 also shared a strategy of turning the phone alarm off after, but not before taking medications to avoid uncertainty caused by distractions. In such cases, proper tracking and logs for medication become crucial. While a minority of our participants were logging their medication intakes, the majority of them (9 out of 10) were not doing so, even if they recognized the possibility and importance. This did not exactly align with our expectations of university students, who are generally more tech-savvy.

When discussing the requirements for a future system to assist with medication management, the most commonly mentioned keywords were minimal and simple. They do not want to "add an additional task" to their established routines, with self-reporting typically being considered one of those tasks. Participant 4 complained:

> *I'm like, not great at logging symptoms like, not great, basically just any longitudinal logging, like, I just don't love doing it.*

The need for logging was not just for medication but also for symptoms related to medication, such as moods and side effects. Similar to Theme 1.3, participants express a desire to monitor their mood and medication dosage to deduce a potential relationship, given the intricate connections between symptoms and medications. However, these efforts often face challenges, primarily due to the complexity and additional effort required for ongoing self-reporting. Here, we observed a paradox between the necessity of having this information and the reluctance to put in extra effort to acquire it.

XSL•FO
RenderX

Theme 2.5: Preserving Autonomy in Medication Management: Managed by Symptoms

In addition to finding ways to ensure they take medication on time, we also realized that our participants might occasionally decide to skip medication for various reasons. Among those reasons, an interesting factor was mental health symptoms. Because the primary motivation for taking medication is to treat the symptoms, some participants also manage medication based on symptoms. Participant 4 mentioned they never forgot to take medication for more than 3 days because, in that case, they would experience symptoms that reminded them to take their medications.

> *Is there a reason why today's harder than other days? Is there a reason why I'm doing more work to take care of myself mentally than other days? And then usually it'll be like, did I take my meds? No, I didn't, oh, shoot!*

In some cases, our participants would even take medication immediately once they felt the symptoms, usually for short-term effect meds. For instance, one of Participant 5's medications has a short-term effect. They expressed themselves as not having a good routine and taking medication immediately if they felt the symptoms, but would skip the next dose if it was too close.

All of these reflect participants' urgent needs to preserve autonomy in managing medication. That is part of the reason why, even if they acknowledge the limitations of oversimplified technology such as default alarms, they still choose to use it and adapt it in their own ways so that they can have full control over it.

Theme 3: Overcoming Obstacles in Seeking External Support

Besides coping with personal concerns, motivation, and the inconvenience of managing medication independently, our participants encountered numerous obstacles while seeking external support from various stakeholders. One of the most common barriers involved the difficulty in obtaining medication. In our study, all mental health medications were prescribed by doctors, necessitating patients to find a doctor, obtain a diagnosis, and then acquire a prescription. Many participants found this process overwhelming, primarily due to the multiple rounds of interactions with different professionals, particularly as most medications required issuance by specialists, such as psychiatrists. "It just ended up being a little bit too many phone calls and a little bit too much like I didn't have enough understanding on how," expressed one participant, who eventually gave up seeking medication due to the complex procedures on the first try. Participant 4 highlighted the frustration of starting the process repeatedly because of frequent relocations for school and changes in general practitioners. Additionally, Participants 3 and 8, who were international students, mentioned the extended difficulty in transferring prescriptions due to the US medical system's inability to validate previous diagnoses and prescriptions. Despite having local student insurance, Participant 8 continued to consult their doctors remotely in their home country and shipped the medication overseas. Some participants initially sought help from school medical centers but often faced long wait times.

Getting a doctor or prescription marked only the beginning, particularly for participants grappling with mental health issues. They placed immense importance on not just obtaining medical assistance but on finding a trustworthy and empathetic doctor. Participant 2, for instance, experimented with two therapists before settling on the current one, emphasizing the difficulty in locating a psychiatrist they genuinely trusted and perceived as caring. Participant 4 also remarked: "It's really hard to find a psychiatrist that you trust, that you think is caring." The recurrent theme of "caring" resonated strongly throughout the interviews. Participant 4, voicing frustration, explained,

> *It's not that they couldn't understand what I was saying. They were just like, that's normal, so it doesn't matter. (OR) I think that has a lot to do with being a woman and being young, and the experiences of people in those demographics within the medical system (said by doctor).*

Participants also voiced concerns about doctors overlooking the side effects of medications. One participant lamented, "Doctors are prescribing. Practitioners are not listening to me when I say that my side effects from this medication are harmful to me, and I do not want to take it anymore." Even Participant 5, who had a longstanding trust in their doctor, refrained from discussing concerns about the medication's long-term effects because, during the initial attempt, the doctor "kind of brushed it off a little bit and said I don't have dementia, and it's fine, and that maybe it's just depression." Similarly, Participant 10 shared discomfort with having the same doctor as their mother and found satisfaction in switching to a psychiatric professional who demonstrated genuine care and was willing to adjust the dosage to alleviate symptoms. Given the subjective and self-evaluated nature of mental health diagnoses and treatment, the trust placed in doctors became even more critical. Many participants sought to establish long-term relationships with trusted doctors and hesitated to switch, underscoring the pivotal role of trust in the management of mental health medications. Understanding this dynamic is essential in navigating the complexities of mental health care.

To summarize, these unique challenges related to various stakeholders hindered students' access to necessary medication, further disrupting their regular medication management routines. Considering these external factors tied to the broader system is crucial when designing technologies to aid in regulating mental health medication.

Discussion

Summary

In this paper, we conducted formative interviews with 10 university students and identified 3 themes and 9 subthemes reflecting their strategies and challenges in managing medications for mental health conditions (Table 3). In this section, we situate our findings within prior research and propose design implications for future technologies that support university students in managing their mental health medications.

XSL•FO
RenderX

Table . Mappings of themes and design implications.

Themes and subthemes	Design implications
1. A dynamic voyage: managing mental health medication is never a static process	
1.1. Struggling with self-acceptance: expectations of reducing or ceasing medication	Implications 1 and 5
1.2. Dosage changes and medication adjustments are common	Implications 1 and 3
1.3. Medication interlaces with mental health symptoms	Implication 1
1.4. Transition period for university students	Implication 1
2. Flexible and creative ways of using simple technology	
2.1. Motivation and consequences: symptoms	Implications 1 and 3
2.2. Fixed reminders are common but not enough	Implications 2 and 3
2.3. Physical cues: a simple but effective method	Implication 2
2.4. Gaps between reminder and actual intake: the paradox of logging	Implications 2 and 4
2.5. Preserving autonomy in medication management: managed by symptoms	Implications 1, 3, and 4
3. Overcoming obstacles in seeking external support	Implications 5 and 6

Identify State Changes in University Students Managing Mental Health Medication: Responsibility, Mental Status, and Self-Acceptance

During our study, we realized that mental health medication management for university students is a very dynamic process. Therefore, it is important to discuss the transitions between different states during the management process. In previous work, Caldeira et al [32] identified 4 states within the medication management framework: wellness, new task, erratic, and disruption. These states were categorized along two dimensions: medication regularity (routine vs nonroutine) and time scale (long-term vs short-term). The authors stated that changes in routines and medications can disrupt the most stable "wellness" state. This statement aligns with our findings. Based on the interviews, we further classified the specific changes in routines and medications that university students might encounter when managing mental health medications. For changes in medication, this includes but is not limited to starting medication, adjusting dosage, and changing the medication. For changes in routine, relocation, and shifts in personal status (examples specific to university students include entering a new school, graduating, and moving out from parents), these are special events that university students are facing. Although the overall categories of factors influencing state changes align with previous work, we do find and want to emphasize some differences. One important observation is that for psychiatric medications, the dynamic transitions are much more frequent, making the "new task state" more common than the "wellness state." Additionally, we found that the "wellness state" is not always the most desirable state for university students managing their mental health medication. According to our interviews, many participants, despite recognizing the chronic nature of their mental health symptoms, have a strong desire to lower their dosage or stop taking medication altogether. As researchers, it is crucial to acknowledge that the desire to reduce dosage can be an additional cause of state changes, beyond the introduction of new medication as mentioned in previous work.

In our study, we also want to highlight 3 additional factors that may contribute to changes in states, beyond routine and medication. The first factor is the change in responsibility. For our participants, who are university students, we found that many are gradually taking on more responsibility for managing their medications independently. This shift in mindset not only causes routine differences, such as the absence of parents' reminders (Participant 1), but also grants them more autonomy in decision-making. This change in responsibility leads to a series of changes in how they manage their medications. Therefore, including changes in responsibility within the framework is crucial for thoroughly discussing state transitions.

Mental status is another factor that can influence medication management states. Participant 5 mentioned that during particularly depressive episodes, even getting out of bed and accessing medication stored in the kitchen became challenging. For our participants, changes in mental status are common due to their diagnoses and the effects of medications. It is important to recognize that for the population we are targeting, fluctuations in mental status can significantly affect how they manage their medications and should be considered as a common factor to cause state changes.

Another factor is self-acceptance. While the stigma associated with mental health conditions may not be as prevalent among university students as in the past [50], there remains a hesitancy regarding medication, with many participants not viewing it as the best option. We observed variability in these concerns among our participants. Some mentioned feeling more at peace after several years of medication use. Given that intentional nonadherence remains a significant issue [51]—especially in our context—it is crucial to include the self-acceptance of medications in our spectrum of considerations to capture possible state changes.

XSL•FO
RenderX

Mutual Relationships Between Mental Status/Symptoms and Medication

In the earlier discussions, a key point emphasized by our participants is the complex process to "alter your mental state in an attempt to fix your mental state." This intricate relationship makes it challenging to ascertain whether changes in symptoms are attributed to medication or other factors. In many past studies discussing technology developed for medication management, the relationship between medications and mental symptoms was often underexplored, with the focus primarily on the management of medications alone [37]. For example, in a study by Stawarz et al [37] reviewing the functionality of 229 medication reminder apps, none of the 3 design requirements they summarized addressed symptom tracking. This is understandable since most chronic diseases are relatively stable, and traditionally, decisions regarding medication dosage and changes are based solely on clinical advice, not self-report. Consequently, the primary responsibility of a patient in managing their medication is simply to "adhere to that medication" [52]. In studies focusing on psychiatric medications, researchers are beginning to recognize this unique aspect of managing mental health medications related to symptoms, though they still encounter numerous barriers. For example, Papoutsaki et al [33] explored how individuals in an online health community track their symptoms and psychiatric medication dosages, particularly when attempting to withdraw from a medication. Members of the forums emphasized the use of daily diaries to track symptoms, and some even created charts to monitor the exponential decay of their previous dosage. However, this approach still heavily relies on self-regulation [53]. In our study, none of our participants used similar tools or social platforms to manage their medication and symptoms.

To further elaborate on the relationship between medication and mental symptoms, it is important to recognize their interdependence. Tracking changes in symptoms can help determine the effectiveness of the medication and the appropriate dosage. Conversely, fluctuating mental states can also affect a participant's ability to manage their medication. This intrinsic relationship complicates the medication management process. Some of our participants even mentioned managing their medication based on their symptoms rather than adhering to more routinized clinical advice. Although these actions are less standardized compared to those observed in online communities by Papoutsaki et al [33], the underlying rationale behind these behaviors is the same. The real-world practices we discovered suggest that a standardized medication regimen may not be adequate for participants who are actively engaged in a sensemaking process to understand the impact of their medications on their symptoms. In this context, technology should be designed to actively assist university students in understanding the relationship between their prescribed medications and their mental symptoms to prevent intentional nonadherence.

Design Implications

Based on our findings in interviews and discussions with previous works, we would like to present several detailed design implications. We hope that those implications can help researchers to design future technology that helps university students better manage their medications in 6 aspects.

Implication 1: Tracking the Relationship Between Mental Status/Symptoms and Medication

First, the system should have the capability to directly track and display potential relationships between medication and mental health symptoms. Other than an app only tracking medication dosage or mental status and mood, the system should proactively establish a relationship between those two factors. Second, it is also essential to record significant events that may influence mental status during the medication transition process, both those self-identified and automatically tracked. These events include but are not limited to starting medication, adjusting dosage, changing the medication, relocation, and shifts in personal status (examples specific to university students include entering a new school, graduating, and moving out from parents) according to insights from theme 1. With these functions in place, the system should be able to aid students in evaluating the impact of medication, thereby fostering trust and belief in the treatment.

Implication 2: Dynamically Adjust Reminders Based on Location and Schedule

We observed that participants typically linked their medication intake with routines and specific locations. In this context, they often encounter dissatisfaction with fixed reminders, particularly when they have flexible routines. This barrier prompts them to establish their own methods, such as creating backup reminders (theme 2). This finding aligns with previous research; for example, Stawarz et al [37] mentioned that medication reminder apps need to support the creation of backup reminders and routines. We aim to further elaborate on these broad design implications drawn from previous works. To design a future system that acknowledges and accommodates participants' existing approaches to medication management, we proposed the following actionable design suggestions based on our findings.

Broad Delivery Time Window Based on Sleep, Eating Schedule, Last Medication Intake Time, and Availability

The reminder's delivery time window should be set widely, especially in situations where medication does not necessitate a fixed intake time (which is the case in 100% of our interviews). Sleep and eating routines are major factors influencing medication timing; reminders should dynamically adjust to these daily patterns. The timing should also consider the previous intake, since many mental health medications have defined effectiveness periods and dosage limits. If one dose is taken early, subsequent reminders should be delayed accordingly. Finally, reminders must align with moments of actual availability. Sending notifications during classes, meetings, or other commitments often leads to missed doses. For university students, academic schedules and obligations should therefore inform the optimal reminder timing.

Deliver at the Right Place: Storage and Activity

Participants frequently used location cues as medication reminders (theme 2.3). They reported that generic phone pop-ups were often ignored, highlighting the importance of delivering

XSL•FO
RenderX

reminders in contextually relevant places. Effective locations typically include where the medication is stored and where related activities occur—sometimes the same place, such as keeping medication by the bed for nighttime doses. Delivering reminders near these locations can improve visibility and accessibility; for instance, an audio cue near a pillbox can prompt action as participants pass by.

Implication 3: Recognize the Potential for Immediate Medication Intake in Response to Symptoms

In our interviews, we also noted that, at times, medication management was loosely based on symptoms (theme 2.1). In severe cases, missing a dose and not promptly taking it could lead to a potential disaster (eg, Participant 7 unable to drive and needing to take the subway home). While the system should provide participants with considerable autonomy to decide in such situations, it is important to acknowledge that participants might take action when faced with these situations, and follow-up management should be adjusted accordingly. Although more discussion is needed, especially considering the limited accuracy of sensing those symptoms and the complicated decision-making process to ensure safety, immediate intervention might be necessary if medication nonadherence occurs in a dangerous situation (eg, while driving).

Implication 4: Striking a Balance Between Autonomy and Minimal Effort

We recognized a paradox in the medication management process: students desire control over their own routines but are hesitant to invest substantial effort in additional tasks, such as self-reporting (themes 2.4 and 2.5). While many of these challenges may arise from limitations in the technology they use [54], which could be better designed following the previous design implications, additional design strategies could enhance the overall experience.

Automatic tracking and background reminders can significantly alleviate the efforts students invest in the medication management process. However, false detections might lead to increased efforts for correction [55]. In such instances, these tracking and reminders should be easily modifiable with simple interactions akin to the one-click snooze technique for a phone alarm. This ensures that participants can maintain minimal effort while achieving more accurate and flexible management results.

Implication 5: Safeguarding Privacy in a Creative Manner

Many individuals express concerns about third-party apps accessing sensitive information or the potential for unauthorized access. Here are two strategies to alleviate these concerns. (1) Create pseudonyms for medication, especially for reminders displayed on the interface that other people might be able to see. This creative approach was suggested by one of the participants. By integrating a “personal encryption rule” into the process, the app can significantly desensitize the information related to medication management. (2) Deidentification, especially regarding academic information. In discussions about collaboration between academic institutions and medical services, despite understanding the regulations, many individuals remain concerned that disclosure of their symptoms, especially medications, might negatively impact their academic well-being (theme 3). One way to address this concern is to completely deidentify the data (name, email, phone number, and academic program). While complete anonymity may be challenging [56,57], implementing some form of redirection in the information transition process can help students build trust in the technology and increase adoption.

Implication 6: Enhance Communication With Other Stakeholders to Build Trust

Many participants conveyed that their doctors did not show sufficient care for their symptoms and side effects (theme 3). In a paper by Jo et al [58], the authors discuss how to support clinicians in planning the discontinuation of psychiatric drugs, including the types of information needed. While they considered factors such as trust issues, patient medical history, and insurance issues, they did not address how patient feedback might influence decisions about the regimen. In our study, we found that the relationship between symptoms and medications is crucial for managing mental health medications among university students. This relationship is typically best understood by participants through their daily experiences. Considering the lack of trust and communication expressed by some of our participants, we propose that participants should have the ability to use data previously collected on the mutual relationship between symptoms and medications. This would empower them to effectively discuss and influence medical decisions with their doctors. However, this should be under full control of the participants, taking into consideration privacy issues.

Limitations

This study is subject to certain limitations. First, the sample size is relatively small, restricting our ability to generalize the findings to a wider population. This limitation stems from the reluctance to disclose sensitive information. In our research, we specifically focus on a particular group of university students, requiring them to provide a “.edu” email address. Participants may be concerned about linking their academic details to mental health challenges, thereby impeding their willingness to take part. To address these concerns, aside from implementing deidentification measures, we only requested participants to disclose information related to diagnoses and medications if they were comfortable doing so. However, this introduces the potential for selection bias, as those who willingly participated in the interviews might already be predisposed to sharing such information. Despite acknowledging these limitations, our analysis of the interview data revealed numerous common patterns and reached data saturation, affirming the validity of our findings. Additionally, we provide the survey results encompassing demographic information, medication schedule, medication adherence, and self-efficacy. This information can assist future researchers in better contextualizing our results. Given the diversity in daily routine management, we are cautious about generalizing our findings to other population groups. Future research could target a broader population using less sensitive measures, such as surveys, to further validate our findings.

In our study, we refrained from collecting specific medication names for each participant due to privacy considerations. While

XSL•FO
RenderX

many participants willingly shared information about symptoms, medication working mechanisms (eg, immediate effects or delays), or even the exact names of medications, this practice impacted our capacity to systematically analyze varied strategies corresponding to different types of medications. Acting as an exploratory endeavor, we aspire for future studies to gather more comprehensive information, such as electronic health records, to further delve into these issues.

Conclusions

In the paper, we conducted semistructured interviews with university students currently undergoing medication for mental health issues. The interviews aimed to uncover the challenges they encountered in their university lives, along with the coping strategies and technologies used to navigate these challenges. We found that deciding to take medications is often a challenging choice for many students. The expectations for dosage reduction, the inherent uncertainty of medication effects, the intricate relationship between medications and symptoms, and the frequent life changes associated with university all contribute to a highly dynamic journey in medication management. As a result, students have developed various strategies to cope with these challenges, often relying on creative ways to use fixed alarms on their phones. However, they encounter numerous difficulties due to factors such as the flexibility of daily routines. Despite university students' strong desire to maintain autonomy in the medication management process, they still struggle to devote additional effort to self-reporting, creating additional challenges in building trust with their doctors. Based on these findings, we proposed 6 design implications for how advanced technology could better assist university students in managing their mental health medications.

Abstract

Background: Video consultations (VCs) are effective and beneficial, yet their use is being discontinued, and there is a preference for face-to-face consultations.

Objective: This study investigates how patients and health care professionals (HCPs) perceive patients' introduction to VCs, who use them, and what drives their use in Swedish primary care.

Methods: Six focus group interviews with 27 HCPs and 13 individual interviews with patients in primary care were conducted between August 2022 and May 2023. The interviews examined VC implementation and were analyzed using rapid assessment procedures.

Results: A total of five themes were identified: (1) challenging start with unprepared users and immature technology; (2) users and nonusers are perceived to have different characteristics, needs, and circumstances; (3) patient-related drivers: based on patients' preferences and opportunities; (4) HCP-related drivers: clinical suitability, assessment of patient needs, and preferences; and (5) societal and organizational drivers: the pandemic, demographics, and infrastructure. Patients and HCPs described the introduction of VCs as rushed and confusing, with limited guidance and support (theme 1). HCPs struggled to assist patients due to a lack of training and limited access to the patient-facing interface (theme 1). VC users were typically perceived as younger, digitally literate, and motivated by convenience or urgency, while older adults and those with language or cognitive barriers were often assumed to be nonusers (theme 2). VC use was shaped by patient preferences, accessibility, and clinical urgency (theme 3), as well as by HCPs' professional judgment and convenience (theme 4). Assumptions held by HCPs about patients' digital skills and preferences influenced whether VCs were offered, while patients' own assumptions about complexity or suitability affected whether they accepted them. Broader factors, such as digital infrastructure, platform usability, reimbursement policies, and the COVID-19 pandemic, also significantly influenced use (theme 5).

Conclusions: The rushed implementation potentially deterred some patients and HCPs from use. Misguided preconceptions and biases negatively influenced VC use and risked reinforcing existing disparities and contributing to digital exclusion. In addition, HCPs' and patients' preferences, which were related to their needs, waiting times, and different circumstances, and potentially misguided judgments of appropriateness, influenced VC use. Lastly, infrastructure, reimbursement, sociodemographics, and organizational type also drive VC use. To support more sustainable and equitable use of VC in primary care, developers should optimize VC applications' usability, implementers should deploy multiple strategies, health care providers should consider the potential of VC in care delivery, and policymakers should increase digital readiness. Further research should evaluate the effectiveness of different strategies for introducing patients to VCs, explore younger patients' and nonusers' perspectives, characteristics of HCP users, and differences between professional roles, as well as between consultation types.

Introduction

Background

The rapid increase in video consultations (VCs) is an example of the accelerating digitalization of health care [1,2]. However, despite this progress, some studies indicate that VC use, which peaked during the COVID-19 pandemic, has since declined [3-5].

Teleconsultations, such as VCs, are generally as effective as face-to-face consultations regarding clinical outcomes in primary care and mental health [6] and could, in some cases, be a superior alternative to telephone consultations (TCs) [7]. Additionally, both patients and health care professionals (HCPs) have reported high satisfaction with VCs [6,8-10]. Despite these positive findings, some patients and HCPs still prefer face-to-face consultations [9-11].

The way that the use of VCs is implemented might explain the discontinuation of VC use and preference for face-to-face consultations [12]. However, research on implementation is limited to only a few regions or countries and secondary care settings [13-15], with studies mainly investigating HCPs' experiences and organizational challenges [13]. While existing studies often focus on postimplementation satisfaction, they tend to overlook the implementation process, particularly from the patients' perspectives [16,17]. When patient introduction to VCs is described, it is often vague and lacks sufficient detail [18,19]. No studies have been found that conduct an in-depth investigation of patients' introduction to VCs.

In the research project ePrIm (implementation of eHealth in primary care), the overall aim was to explore how the implementation of eHealth in Swedish primary care affects the work environment of HCPs and patient satisfaction with care. The implementation of VCs was 1 of 3 case studies conducted in the project, the other 2 focusing on patients' online record access [20] and digital self-management of asthma. In this study, we focus on results from the VC case study, specifically on patients' introduction to VCs and perceptions of who may or may not want to use VCs.

Perceptions of who the users and nonusers of VCs are might influence VC use [21]. Although there is considerable research on the perceptions of VCs, little is known about the perceptions of who the users and nonusers of VCs are. In the context of this study, "perceptions" comprise the attitudes, beliefs, and subjective judgments held by HCPs and patients about VCs. This includes how they view the characteristics, needs, and potential use of VCs for different patient groups, as well as their opinions regarding the suitability of VCs for various medical scenarios. Further, few studies have explored the drivers of VC use and nonuse in-depth [21-23]; drivers in this study refer to factors influencing use either positively or negatively.

This study addresses notable gaps in the current research: patients' introduction to VCs, perceptions of users and nonusers, and the drivers of VC use, in a Swedish context. By collecting data from patients and HCPs, this study offers a comprehensive perspective on the factors influencing VC adoption and use. This dual approach is valuable because it allows for a holistic understanding of the potentially conflicting motivations, experiences, and barriers perceived by the 2 groups. By examining both sides, this study can identify discrepancies and areas of potential improvement, providing a richer and more nuanced understanding of VC use. Given the reported benefits of VCs for patients, HCPs, and society, it is vital to expand our understanding of why there is a risk of discontinuing their use in various contexts and why there remains a preference for face-to-face consultations.

Aim

This study aimed to investigate the dual perspectives of patients and HCPs on patients' introduction to VCs, perceptions of VCs users, and drivers of use in Swedish primary care. More specifically, this study investigated: (1) HCPs' and patients' experiences of patients' introduction to VC, (2) HCPs' and patients' perceptions of who uses or does not use VC, and (3) HCPs' and patients' experiences and perceptions of drivers of use or nonuse of VC.

Methods

Study Design

This study had a qualitative approach, using focus groups and individual interviews to capture the experiences and perceptions of HCPs and patients on the introduction and use of VCs.

Study Setting

Digitalization of health care services is widespread in Sweden. According to a national assessment, digital consultations (ie, consultations using applications that replace in-person consultations, eg, VCs) with physicians have increased from 10% in 2019 to 24% in 2022 [24,25]. Nearly all Swedes have internet access at home, and over 90% use it daily [24].

This study was conducted in Region Stockholm, 1 of 21 regions responsible for providing tax-funded health care in Sweden [26]. Tax-funded health care can be either publicly or privately managed, and a third of the care in Region Stockholm is privately managed [27]. This study involved both privately and publicly managed health care centers. The care fees are the same within the region but will vary depending on the patient's citizenship [28]. VCs cost the same as face-to-face consultations for the patient, although the care provider's reimbursement is lower for VCs [29].

The region's over 200 primary care centers (PCCs) and family doctor offices are the gateway to health care from which referrals

XSL•FO
RenderX

to specialized care are made when necessary [28] PCCs typically comprise a mix of HCPs.

Initially, direct-to-patient VCs were provided through online platforms and applications developed and managed by private health care providers [30]. Progressively, especially during the COVID-19 pandemic, platforms and applications have emerged in the public sector. *Alltid öppet* [always open] is such a platform, which was developed by the public health care provider Region Stockholm in 2018. *Alltid öppet* supports both VCs and consultations through chats between patients and HCPs and currently (2024) has 2 million users. PCCs can choose which digital services they offer through the platform, and, in some cases, this includes online appointment booking by the patients themselves. Parents can use the application on behalf of children younger than 13 years of age. Use requires authorization with electronic identification (eID). *Alltid öppet* was the VC service used by both HCPs and patients in this study.

Recruitment of Study Participants

All participants were recruited from 10 PCCs in Region Stockholm; 5 rural PCCs in the most northern part of Stockholm (Norrtälje), and 5 more centrally located PCCs with a variation in sociodemographic contexts (Jakobsberg, Hässelby, Liljeholmen, Gustavsberg, and Huddinge PCC).

All HCPs from the participating health care centers with experience in conducting VCs through *Alltid öppet were* invited to participate. All eligible HCPs were sent invitations via email with information about this study and were followed up with help from the PCC manager, who helped schedule the focus groups at times convenient for the volunteering HCPs. The participating HCPs also received information about this study before the interview. The focus groups consisted of HCPs of different professions: general practitioners (GPs), nurses, counselors, psychologists, and physiotherapists. The HCPs were also diverse with regard to their experience of using VCs with patients and as patients themselves. A total of 6 focus group interviews were conducted with 3 to 6 participants in each; in total, 27 HCPs participated. All but 1 focus group consisted of HCPs from the same PCC; the remaining group consisted of participants from 2 smaller PCCs.

Patients were recruited to the current study through a previously conducted survey about VC use through *Alltid öppet* [11]. Survey participants were eligible to participate if they were 16 years or older and had a VC through the *Alltid öppet* application from March to May 2022. Invitations to participate in the survey study were sent via text message. After completing the survey, respondents were invited to participate in the interview study. Those interested in participating received a link to a short questionnaire, separate from the survey, which also provided further information about the interview study. The questionnaire collected information regarding: contact details, demographics, and frequency of VC usage. A diverse group of respondents (Table 1) was then contacted via telephone and invited to participate. All participants received full study information; consent to participate and record the interviews was obtained before the interview. In total, 13 patients were interviewed.

Data Collection

Data were collected using focus group interviews with HCPs and individual semistructured interviews with patients. The focus group interviews were conducted between December 2022 and May 2023, and the patient interviews between August and December 2022. The dates were determined by the project plan and the participants’ availability. The choice to use focus group interviews with HCPs and individual semistructured interviews with patients was motivated by the desire to capture the collective dynamics and shared experiences among HCPs in a group setting, while allowing for a more in-depth exploration of personal experiences and perceptions in the one-on-one patient interviews. Both the focus groups and the individual interviews were audio-recorded and transcribed verbatim.

All focus groups, except one, which was performed in person, were conducted through videoconferencing at their workplace. A semistructured interview guide was used in the focus group interviews. The guide was based on the overall project aim to investigate the implementation of VCs through *Alltid öppet*, its impact on the work environment and work processes, as well as the HCPs’ perceptions of patients’ introduction to and use of VCs. In this study, our focus is on the latter. Due to our limited access to HCPs’ time, we chose not to pilot the focus group interview guide but instead critically assessed it after each focus group to ensure all important aspects were covered. The interviews were 45 - 60 minutes long and, because they were conducted during the HCPs’ lunch break, lunch was provided as a token of appreciation.

The interviews with patients were conducted via telephone or videoconferencing, based on participant preference. The semistructured interview guide used in the interviews was pilot-tested, leading to minor changes. The interview guide was based on the overall project aim to investigate how and why patients use VCs and included questions about patients’ introduction to VCs and factors influencing VC use. The interviews were, on average, 30 minutes long and were conducted until data saturation was reached, at which point no new information emerged. After the interview, participants received a gift card as a token of appreciation.

The focus group interviews with HCPs were conducted by MH, the moderator, with at least 1 facilitator. IM, LJH, ND, and MT facilitated at least 1 focus group interview each. The facilitators assisted the discussions by asking follow-up questions or providing the moderator with questions to ask, and by observing nonverbal communication. IM conducted the individual patient interviews. The moderator and the facilitators were all female. MH is a researcher or lecturer with a PhD in medical

XSL•FO
RenderX

informatics, IM and LJH were both PhD students in digital health. LJH is also a practicing medical doctor who works at one of the PCCs included in this study but did not facilitate the focus group interview with HCPs from her PCC. ND also has a PhD in medical informatics, and MT has a PhD in medical science. MH, who moderated the focus group interviews, and IM, who conducted the individual interviews, had extensive knowledge and experience in qualitative research at the time of the interviews. MT, who, together with IM, conducted the analysis, also had extensive knowledge and experience in qualitative research. To minimize potential bias and maintain a neutral interview environment, the researchers did not disclose any personal goals or motivations related to this study to participants.

While data saturation was reached for patient interviews, it was not fully achieved for HCPs due to practical constraints. Due to HCPs' busy schedules, many were unable to participate, and for those who could, interviews were conducted only during their lunch breaks.

Analysis

Both the focus groups and individual interviews were analyzed using rapid assessment procedures (RAP) [31]. RAP was informed by the time-sensitive nature of the broader project and the need for structured yet efficient analysis. The broader project's different parts were conducted simultaneously, and as is often the case with research, the resources were limited. To conduct all the studies and meet the strict deadline, we had to choose methods that offered efficiency without compromising rigor. RAP allows for a systematic and flexible approach to analyzing qualitative data, facilitating the rapid identification and synthesis of key themes and patterns without compromising the depth and reliability of the findings. RAP has been successfully used in health care research, particularly in implementation and evaluation studies where timely insights are crucial [32,33]. RAP was thus selected because it is an established qualitative approach that enables efficient yet rigorous data analysis; in other words, it does not compromise depth when properly executed. To support consistency and reliability in this study, we used structured templates, independently piloted the coding approach, and held regular analytic discussions to align interpretations across researchers.

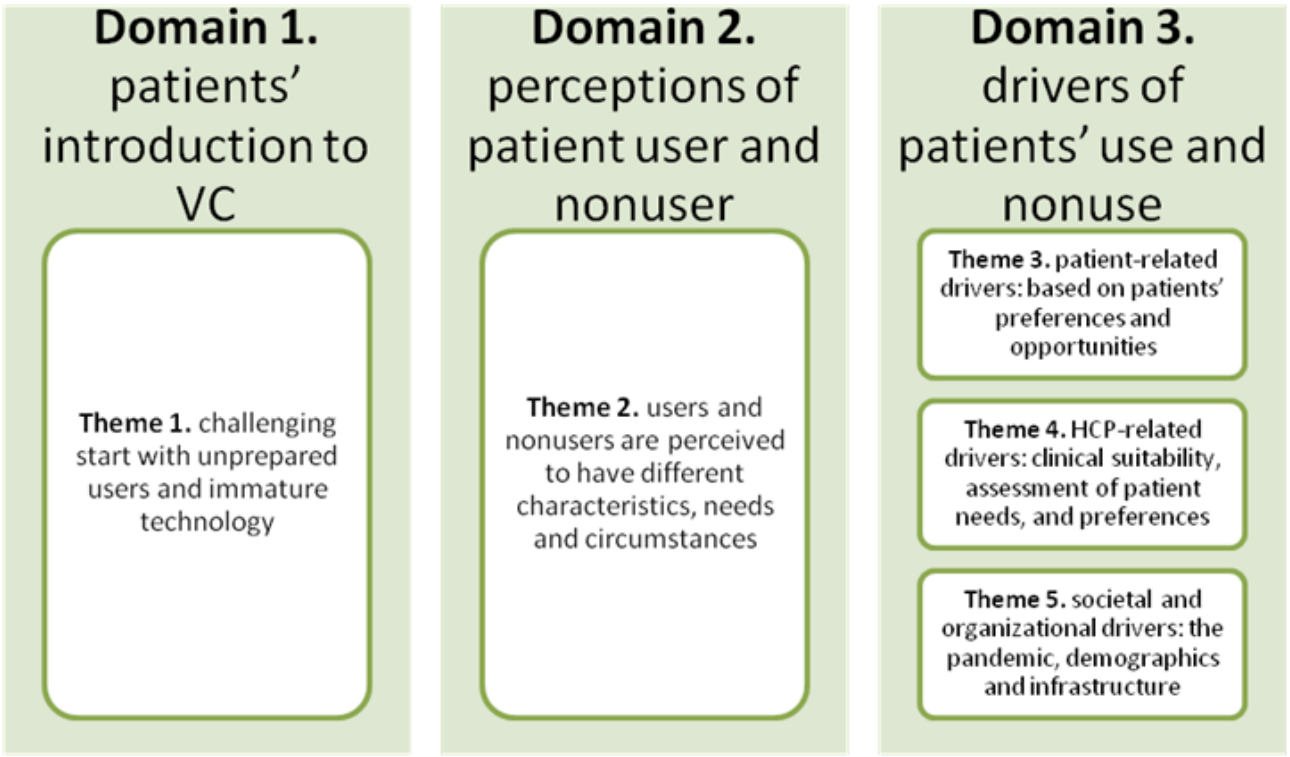
This study follows an exploratory qualitative design, allowing themes to emerge organically from the data rather than fitting them into a predetermined theoretical model.

Following the RAP methodology, the first step involved creating neutral domain-based templates based on this study's aim. For step 2, the templates were independently piloted with 1 interview by IM and MT. In step 3, the analysis and usability of the template were discussed to ensure intercoder reliability, and the domains were clarified and further piloted. Of step 4, when consistency in analysis was reached, the remaining interviews were divided between IM and MT, who summarized vital points. The final domains in the RAP template were (1) patients' introduction to VC, (2) perceptions of patient users and nonusers, and (3) drivers of patients' use and nonuse. In step 5, emerging key points were discussed and categorized, after which categories were grouped into themes. We recognize that perceptions of patient users and nonusers and drivers of patient use and nonuse overlap to some degree; however, we believe that there is a distinction that is worth exploring further. IM used NVivo (version 1.4; Lumivero) and MT used pen and paper.

This study was reported in accordance with the COREQ (Consolidated Criteria for Reporting Qualitative Research) [34]. This study used the generative artificial intelligence technology Grammarly (Superhuman Platform) to enhance the grammatical accuracy and vocabulary richness.

Ethical Considerations

This study received ethical approval from the Swedish Ethical Review Authority (reference number 2021 - 05096). All study participants provided written or oral informed consent before participating in this study. In accordance with the Swedish Ethical Review Authorities' requirements, participants were informed that their participation was voluntary and that they could choose to revoke their participation at any time. Transcribed interviews and focus groups were deidentified to protect the participants' privacy, and confidentiality was preserved when reporting results. In accordance with the ethical approval, patients were compensated with a gift certificate (200 SEK, equivalent to US $20), whereas HCPs received lunch during the focus group interviews.



Results

Overview

A total of five themes were identified under the three predefined domains: (1) patients' introduction to VC, (2) perceptions of patients as users and nonusers, and (3) drivers of patients' use and nonuse. The first and second domains had 1 theme each, while the third had 3 themes (Figure 1).

XSL•FO
RenderX

Figure 1. The identified themes under the 3 predefined domains, rapid assessment procedures, patients, and health care professionals, Region Stockholm, 2022 - 2023. HCP: health care professional; VC: video consultation.

Domain 1. Patients' Introduction to VC

Theme 1. Challenging Start With Unprepared Users and Immature Technology

In this study, the patients' introduction refers to all activities aiming to inform patients about the service and help them start using it.

Patients' introduction to VCs encountered many challenges. On the one hand, some patients had acquired the necessary eID and accessed the application due to the COVID-19 pandemic, using it to schedule COVID-19 tests and vaccinations, which facilitated the introduction of VCs. On the other hand, the need to promptly implement VCs due to the pandemic left little room for a structured introduction of VCs.

According to HCPs, patients were provided with brochures and instruction videos online but needed guidance to find them. With the invitation to a VC, patients were also provided with instructions for downloading the application and could receive additional assistance with the download, if required, from HCPs, either over the phone or physically at the PCC. Unforeseen issues occurred during the installation of the VC application, which HCPs had to assist patients with. Significant guidance was provided over the phone in the beginning. Assisting patients in using the services was challenging for HCPs because they lacked manuals and were themselves unfamiliar with the service. They also lacked access to the patients' user interface, which made helping patients navigate the VC tool difficult. Communicating with patients with language barriers and instructing older adults with physical impairments, such as poor eyesight, had also been challenging. According to HCPs, informal caregivers or relatives were important in assisting with the use and scheduling of VCs.

HCPs also expressed that there was some resistance from patients who did not want to acquire the necessary eID; the patients did not trust it due to reports of related fraud in the media. This was experienced as challenging by HCPs because they were not able to help those without an eID, and explaining this to patients was time-consuming. Getting started was particularly challenging for older patients, according to HCPs, presumably due to low digital literacy. Older adults were stressed and worried about technical difficulties. According to HCPs, patients were inexperienced, confused, and often became disconnected due to a lack of knowledge, leading to many planned VCs being converted to TCs. HCPs tried to find what worked best from case to case. Some of this confusion was believed to be related to the application's usability. The service itself was also described as unstable.

> *There was a lot of calling back and forth in the beginning since patients couldn't connect or didn't know how to.* [FG 1]
>
> *The application or the video feature had many bugs initially, it could…I mean, half of the consultations worked, and half didn't.* [FG 2]

These reported issues improved over time as both patients and HCPs became more experienced, and the application itself was updated and became more stable.

Patients' experiences aligned with those of the HCPs. They initially experienced technical difficulties and uncertainties at both ends. Although the introduction was confusing for some patients, they were familiar with the technical difficulties, which was something they had expected. According to patients, they

XSL•FO
RenderX

received information from HCPs, found information themselves, or coincidentally found out about the service.

> *[…] then they had long waiting times, so they said; "Would you consider having a VC?" Yes, that works…I wasn't aware it was possible to book a VC.* [P1]

Domain 2. Perceptions of Patient User and Nonuser

Theme 2. Users and Nonusers are Perceived to have Different Characteristics, Needs, and Circumstances

In this study, "perceptions" refers to the attitudes, beliefs, and subjective judgments held by HCPs and patients about patient users of VCs.

According to HCPs, patient users of VCs were usually young. Users were perceived to have a positive attitude toward VCs and varied needs. They saw the benefit of VCs, wanted contact urgently, had minor complaints, or were on sick leave. Patient users were almost always follow-up patients who did not need to come to the PCC. People with psychosocial needs were also common users. Further, patient users of VCs were perceived to have special circumstances. They usually had longer geographical distances to the PCC, worked full-time, or experienced other obstacles or barriers to physically attending a meeting at the PCC.

> *Those with social phobia thought VCs were great.* [FG 3]

According to HCPs, users were perceived to have certain capabilities; they were those who scheduled a VC themselves and those who often had less serious health care needs. HCPs expressed that by doing so, they used resources that should be allocated to patients with greater needs, something they perceived as unfair.

In contrast, according to HCPs, nonusers were usually older, although not all older patients were nonusers. Nonusers usually preferred or required face-to-face visits.

Patients also perceived VCs to be great for people struggling with mental health issues, for example, social anxiety, which prevented them from seeking care in person at the PCC. Moreover, patients believed that older people lacking digital literacy were nonusers. Having at least some digital literacy or experience of internet use was seen as a prerequisite to using VCs in order to be comfortable with them. VCs were also considered to exclude people lacking technical and language skills.

> *I think a large proportion of patients are excluded. Partly because they can't handle the technology, and then there is the language barrier.* [P2]

Domain 3. Drivers of Patients' Use and Nonuse

Theme 3. Patient-Related Drivers: Based on Patients' Preferences and Opportunities

Drivers in this study refer to factors influencing use either positively or negatively.

According to HCPs, the use of VCs was significantly based on patients' preferences. The majority of patients requested face-to-face meetings or TCs. These requests were assumed to be due to familiarity with face-to-face consultations and the need for contact. On the other hand, some VCs were scheduled at patients' requests, and patients sometimes requested a VC when HCPs would have preferred a face-to-face meeting. Moreover, some HCPs always checked the patient's ability to have a VC even when they thought VCs were appropriate.

> *For those scheduled for a VC, it's my impression that it's often the patient who requested it for some reason.* [FG 4]

Impatience or need for immediate contact was another factor influencing VC use, according to HCPs. Due to long waiting times for face-to-face consultations, a VC could be chosen in order to see an HCP sooner. According to HCPs, quick contact or the ability to have a consultation instead of rescheduling due to mild but contagious illnesses were influential factors for preferring VCs. Having sick children could be a factor influencing their caregivers' use of VC. Being on sick leave or geographical distance to the PCC were not only common characteristics of users, but also acted as drivers of VC use. Patients who had moved may want to remain in contact with a health care provider with whom they had an established relationship, ensuring continuity of care. Difficulties patients experienced in booking a VC were identified by HCPs as a factor negatively influencing use.

According to HCPs, immigrants, older persons, and teenagers are, in some instances, unable to acquire an eID. Moreover, some people could be constrained by law, for example, due to conservatorship, where they are unable to make their own decisions. Other patients simply did not wish to have eIDs, according to HCPs; as previously mentioned, they did not trust this due to reports of related fraud in the media.

Some patients expressed that VCs felt impersonal compared to a consultation at the PCC, saw no need to have VCs, and preferred face-to-face and TCs for inquiries. Others preferred face-to-face as an initial contact, while VCs were more appropriate for follow-up visits, while others thought that VCs could be used for the initial assessment. The ability to make the necessary assessments would also influence use, according to the patients, as would the type of care needed and their ability to reach the PCC. Patients thought VCs worked well when avoiding infections and when they were at home with children. Additionally, the opportunity to meet with a physician and the ability to have quick contact were factors that influenced use.

> *I think it's a great compliment, especially if you're like me. I'm quite sensitive to infections, so instead of scheduling a meeting when you have a cold or are at home with a child with a cold, you could schedule a VC.* [P3]

Theme 4. HCP-Related Drivers: Clinical Suitability, Assessment of Patient Needs, and Preferences

When deciding on whether to offer a VC or not, HCPs focused on the patient's complaint, what type of care this would require, their assessment of the patient's needs, and what combinations

XSL•FO
RenderX

of these factors made a VC suitable. Making these assessments had been learned over time, as there were no clinical guidelines they could follow.

While there are some routines surrounding infections, in cases where in-person assessments and investigations were required and where VCs would be inappropriate, most decisions of whether or not to use VCs were still based on the individual HCP's assessment. According to some HCPs, VCs were potentially inappropriate for mental health patients needing cognitive behavior therapy. VCs were also perceived as inappropriate in cases where communication could be challenging, for example, patients with cognitive impairment, or severe autism, and for complex patient cases, for example, patients with co-morbidities or very old patients. There was also an initial assumption that VCs would not work well for older patients, and while some HCPs expressed that this perception had changed over time, for others, this assumption was still a driver of VC use.

> *People with multiple illnesses, maybe older individuals. That's a patient group to which I, maybe wrongly, don't offer VCs.* [FG 5]

When physical assessments were not necessary, use was based on patients' needs. Patients' safety and integrity during a VC were considered important factors. If there were concerns for patients' safety or integrity during a VC, HCPs might choose to schedule a follow-up face-to-face consultation at the PCC instead of a VC. Moreover, third parties involved in the consultation, for example, translators, could further complicate the use of VCs, but the technology could also facilitate participation of, for example, sign language interpreters. HCPs also considered VCs functional for follow-ups and saw a time advantage in having shorter VCs, potentially releasing time to serve more seriously ill patients at the PCC.

Furthermore, VC use was based on HCPs' preferences and convenience. HCPs preferred a face-to-face first encounter with patients. Some HCPs only offered their patients a face-to-face visit, and others offered VCs, sometimes without an option to choose a face-to-face visit. Physicians doing their residency would also opt for face-to-face appointments for educational reasons. Some HCPs would schedule VCs when they worked from home or elsewhere, for example, due to mild infectious diseases, thereby avoiding sick leave and rescheduling of appointments. Further, some HCPs opted for TCs due to initial technical issues. Technical limitations could also affect their assessment, for example, making VCs suboptimal for skin conditions due to the low image resolution.

According to patients, continuity of care, that is, being able to have a VC with a familiar HCP, influenced their use. Patients relied on the HCPs' judgment, and HCPs' recommendations influenced their use of VCs. Further, 1 patient expressed a willingness to consider VCs if it benefited HCPs and their work environment.

Theme 5. Societal and Organizational Drivers: the Pandemic, Demographics, and Infrastructure

According to HCPs, the COVID-19 pandemic greatly influenced and accelerated VC use for both patients and HCPs. Social distancing was a catalyst for HCPs scheduling VCs to reduce the number of patients in the waiting room.

Sociodemographic factors were other influential factors according to HCPs. They believed that having younger and older patients unable to use VCs, for example, due to a lack of necessary software, might have influenced overall VC usage. Moreover, internet connectivity, or lack thereof, for example, in rural areas, was an issue that greatly influenced VC use. Changes to the software that enable VCs, and various updates, influenced the ability to conduct VCs. Seasonal differences had also been observed, with patients requesting VCs more during the winter and summer.

> *It feels like everyone wants digital [consultations] during summer or winter, but in spring and autumn, which are working seasons, they come in [to the PCC] more.* [FG]

HCPs expressed that the lower threshold for having a VC compared to a physical appointment at the PCC had led to an increase in overall appointments. Another influencing factor was the reimbursement system, which included fees and compensation for VCs but not for TCs. HCPs felt guilty about making patients pay for issues that could be resolved through a phone call, yet felt pressured to do so to increase PCC resources. Moreover, existing work processes also influenced the use of VCs. Nurses were sometimes unable to have VCs during emergency hours because they needed to be able to respond to potential emergencies at the PCC. Furthermore, VCs were viewed not as a replacement but rather as a complement to physical care.

Patients confirmed the influence of the pandemic on their use of VCs. For some patients, being able to use a public sector application for VCs was also important.

Discussion

Principal Findings

This is one of the few studies investigating patients' introduction to VCs, perceptions of VCs' users, and drivers of use in primary care. While the COVID-19 pandemic forced a rapid introduction of VCs into Swedish primary care, positively influencing VC use, the rushed, unstructured process might also have negatively affected VC use. Perceptions and preconceptions about users and nonusers were also influential. Among other drivers of VC use were both HCPs' and patients' preferences and judgments of appropriateness, as well as several broader organizational and societal factors.

Pandemic, HCPs, and Preconceptions Influence VC Use

One of the key findings of this study was that the COVID-19 pandemic and patients' introduction to VCs both positively and negatively influenced VC use. The pandemic's influence aligns with earlier research [17,23,35]. The pandemic positively influenced VC use by facilitating its introduction and accelerating its use. The pandemic, however, also rushed implementation, contributing to a challenging start. The technology was immature, and patients and HCPs were

XSL•FO
RenderX

unprepared, which also highlighted broader issues of societal and organizational readiness for eHealth adoption. The extraordinary circumstances may have increased openness to digital solutions and partially offset the effects of a suboptimal introduction. However, the hurried implementation may have led to poor user experiences, undermining trust and satisfaction with the service. These early frustrations may also have shaped long-term attitudes toward VCs, deterring some patients and HCPs from continued use. Under normal circumstances, a more structured rollout, one that included efforts to understand and address patients' concerns, might have improved acceptance and usability. However, given the urgency of the pandemic, such user-centered planning was likely unfeasible.

Another key finding of this study was how important HCPs were in the introduction of VCs. Most patients were introduced to the service by HCPs [36]. However, the lack of preparedness among HCPs contributed to many of the challenges they experienced. This issue has also been expressed by other HCPs, where initial usability and technical issues were attributed to the lack of training of some staff [18,37].

Additionally, HCPs' preconceptions influenced VC use. Several HCPs admitted being less likely to suggest VCs to older patients, based on assumptions about digital literacy and willingness to engage with technology. Although some later recognized that age alone was not a reliable indicator of VC use, these assumptions likely shaped access to digital services in practice. These findings raise significant concerns about equity and inclusion in digital health care. When HCPs make assumptions about patients' abilities or preferences, particularly based on age, disability, language skills, or other perceived vulnerabilities, they risk reinforcing existing disparities and contributing to digital exclusion. Previous research indicates that most people with disabilities have an overall positive experience of VCs [38]. Additionally, although they encountered difficulties, patients who faced language barriers also reported high satisfaction with VC services [39].

Notably, the role of HCPs extended beyond simply offering or withholding VCs. Patients often reported relying heavily on HCPs' recommendations when deciding whether to accept a VC, underscoring the strong influence of provider endorsement. This dynamic aligns with prior research demonstrating the significant impact of HCPs on patients' willingness to adopt digital services [40].

In contrast, there is also reason to believe that bias regarding older adults and technology use exists among patients themselves. Several participants perceived older individuals as less likely to use VCs, reflecting common stereotypes around age and digital competence. This perception aligns with the concept of effort expectancy, a key factor influencing both the intention to use and actual adoption of technology [40], which may be negatively affected by assumptions that older adults lack digital literacy or confidence. If older patients expect VCs to be difficult or complex, these beliefs can undermine their self-efficacy and willingness to engage, thus reducing actual uptake.

Moreover, the initial challenges in introducing VCs in this case, particularly for older users, may have reinforced these negative perceptions, contributing to a cycle of continued nonuse or disrupted engagement. This suggests that both individual and systemic factors may interact to maintain digital exclusion among older populations. Without proactive efforts to support digital confidence and ensure accessible, user-friendly design, such exclusion risks becoming self-perpetuating.

In addition to individual perceptions, broader concerns about fairness also emerged as a factor potentially limiting the adoption of VCs. Some participants expressed the view that VCs might unfairly disadvantage certain patient groups, particularly those with more complex care needs, a concern echoed in earlier studies [17,41,42]. If VCs are perceived as excluding vulnerable or high-need populations, this could undermine their perceived value and legitimacy as a mode of care delivery more generally.

To summarize, the pandemic, HCPs, and preconceptions about and among patients influenced VC use both positively and negatively.

Preferences Influence Use and Are Related to Needs, Waiting Times, and Different Circumstances

Another key finding of this study was that VC use seemed to be greatly influenced by HCPs' and patients' preferences, which in turn were influenced by a range of different factors.

In our study, patients' preference for face-to-face consultations was related to their need for physical contact, which has been previously highlighted [17]. This could be related to the quality of VCs, where VCs do not fully emulate face-to-face interactions. Familiarity with face-to-face interaction was also thought to be related to its preference. To some extent, therefore, preference could be a matter of exposure and experience. The dynamic of an in-person meeting can also differ from a virtual one, negatively affecting the VC experience and preference. HCPs have, for example, reported less prepared patients who might try to multitask during the VC [30,37].

Challenges with waiting times within Swedish health care seem to be another significant driver of preference and VC use, according to both HCPs and patients. While VCs are offered and used for quicker contact, the waiting time could also drive inappropriate use of VCs. If VCs are chosen for their shorter waiting times, rather than their clinical appropriateness, this might negatively influence experiences and the intention to continue using VCs [11]. Moreover, as previously highlighted, VCs could reduce waiting times [37,43], whereas shorter VCs for simpler cases could allow time for severe cases. Since VCs could be offered as an alternative to rescheduling, a visit could reduce treatment delays.

Other factors that appear to influence preferences include geographical distance, seasonal factors or weather conditions, and health in general. Geographical distance could be related to accessibility for people in rural areas and those with busy schedules or mobility issues [23]. Weather conditions could also be related to mobility issues and comfort; for example, winter storms can hinder travel. It could also be related to conditions during these seasons, such as the increase in flu infections in the winter and allergies in the summer, where examinations and in-person consultations might be unnecessary.

XSL•FO
RenderX

Canadian HCPs have reported that virtual visits enable them to provide care during bad weather conditions [37]. This highlights the potential for VCs to address some of the seasonally related care delivery challenges, which could be considered during resource planning.

The ability of HCPs to choose when to have VCs offers control over their work and flexibility, which has previously been reported [35], and might positively influence their work environment, health, and preferences. However, technical issues could negatively influence their preferences and their perceived patient preferences.

Additionally, VCs have also previously been viewed as complementary due to a lack of research and quality, and usability issues have been reported as causing the preference for telephone or face-to-face consultations over VCs [9,23,37]. Further, the reports of patients requesting VCs could be evidence of an overassumption that most patients want or prefer a face-to-face consultation.

In a nutshell, personal preferences for VC or a face-to-face consultation, which heavily influence use, stem from different needs, waiting times, and different circumstances.

Potentially Misguided Judgments of Appropriateness Influence Use

Beyond individual preferences, another key finding was that both patients' and HCPs' judgments about when VCs are appropriate influence their use of VCs. However, these judgments did not always align with other research, revealing a tension between personal preference and actual clinical appropriateness.

For instance, patients in this study found VCs useful for initial contact, whereas many HCPs preferred face-to-face meetings for first-time encounters, viewing VCs as more appropriate for follow-ups. This perspective aligns with findings from a Norwegian study, where GPs expressed reluctance to use VCs with new patients [44]. Nevertheless, a systematic review of telehealth use during the COVID-19 pandemic showed that both initial and follow-up visits were commonly conducted via VC, suggesting that in practice, preferences and needs often adapt to context [45]. However, according to HCPs with experience from the pandemic, for some complex issues and with some patients, virtual care had been too time-consuming and had required more effort [37,46]. These concerns, while valid, also raise questions about how much of the perceived burden stems from a lack of support, training, or established workflows for virtual care.

According to both patients and HCPs, the ability to make clinically sound assessments was an important driver of VC use. A study on the transferability of in-person GP consultations to telehealth for patients with diabetes and cardiovascular disease found no clinical tasks that were not transferable [47]. The growing use of home monitoring tools further supports this potential. Yet, limited awareness among HCPs about what can be effectively managed virtually may unnecessarily restrict use.

Health conditions were also seen as factors influencing the use of VCs. HCPs have previously raised usability issues when assessing mental health patients as a reason for preferring face-to-face consultations [9]; however, there seems to be some nuances regarding mental health conditions. According to our findings, VCs are considered suitable for psychosocial issues in general, but some have not deemed VCs suitable for cognitive behavior therapy. Another group of conditions specifically mentioned by HCPs was skin conditions. As 1 HCP expressed, VCs are inappropriate for skin conditions due to poor imaging quality. Canadian HCPs have also reported challenges assessing skin conditions [33]. Appropriateness could depend on the quality of the devices used by patients and HCPs for skin conditions.

To sum it up, both patients' and HCPs' judgments of appropriateness influence VC use; however, the line between personal preference and actual clinical appropriateness is slightly blurred.

Infrastructure, Reimbursement, Sociodemographic, and Organizational Type Impact Use

Beyond preference and judgments of appropriateness, several organizational and societal drivers of VC use were uncovered.

This study highlighted a lack of infrastructure, potentially excluding some patients from using VCs. Restricted access to the necessary eID appears to exclude some patient groups, such as teenagers, a group that also faces barriers in other countries [18]. Language and disability-related barriers have also been attributed to the technology's shortcomings [18]. Internet connectivity issues, which have previously been described [18,37], can be more challenging in rural areas and contribute to some difficulties during the introduction, influencing substantial use. In addition, reliable systems and proper integration of the systems have been considered essential by HCPs [10].

As previously reported, reimbursement is another factor that influences VC use, both positively and negatively [23]. The reported guilt HCPs feel, in some cases, for charging for VCs highlights a potential issue with the current reimbursement system. There are also reports of work processes influencing use, where nurses might not schedule VCs at certain times. The influence of the work process on VC use has been previously reported [23], and the lack of redevelopment of workflows and routines has been described as being among the everyday challenges of VC implementation [13].

Further, the sociodemographics of the community served by the PCC are another influential factor, according to HCPs. For example, if the infrastructure, that is, eID, is not accessible to most patients, this might influence overall use and impact the HCPs' perceived usefulness of VCs and intention to use. This could also be further exacerbated by other clinicians' nonuse [19].

Whether or not the VCs were provided by a private or public organization also influenced patients' willingness to use the service. The choice between private and public health care has been extensively discussed in the Swedish media and has also been previously reported to influence the intention to use VCs [21]. This could be related to trust and credibility, as eHealth

XSL•FO
RenderX

users have expressed this as a necessity, where public actors were considered more credible than private actors [48].

To summarize, suboptimal infrastructure, organizational issues with reimbursement and work processes, as well as sociodemographics and organizational type, impact overall VC use.

Strengths and Limitations

A strength of this study is its inclusion of both HCPs and patients, offering a comprehensive view of VC use. The diversity among participants, including HCPs from various professions and centers, representing different socioeconomic areas, and patients with different characteristics and VC experiences, adds to this study's robustness.

However, the youngest patient user group was not included in this study, which is a limitation. As digital natives, younger populations may have unique perspectives on VCs, including different levels of digital literacy, preferences for communication modalities, and expectations of telehealth services. Their absence limits our ability to generalize findings to all patient demographics.

The relatively small sample size may also limit the generalizability of the findings, especially for HCPs, where data saturation was not fully achieved. However, including a diverse sample of HCPs across multiple roles and settings ensured sufficient information power, which was a strength that also reduced the risk of profession-related bias. Moreover, thematic consistency across discussions suggests key insights were captured despite the limited number of focus groups.

Additionally, there is a potential for selection bias, as patients and HCPs who chose to participate might have been more positively inclined toward VCs, potentially skewing the data toward more favorable perceptions. The focus group interview guide was not pilot-tested before data collection, which may have affected the clarity and consistency of the questions; however, we critically assessed the interview guide after each focus group to ensure all important aspects were covered and to improve the clarity of the questions. Furthermore, different tools were used in the data analysis process, both pen and paper and NVivo, which could have introduced inconsistency in the coding and interpretation of the data. Yet, the coding and analysis method used was discussed in detail between the analysts to ensure that the results would not be affected by the different tools used.

As most interviews were conducted remotely, there is a potential loss of details such as body language. However, studies comparing online and face-to-face interviews have identified strengths and weaknesses with both approaches [49], and given that we were interviewing patients and HCPs with experience of VCs, we deemed the method appropriate in this case.

A potential limitation of this study is recall bias, as interviews were conducted 2 years after the implementation of VCs. Participants' recollections may have been influenced by more recent experiences, making it difficult to capture initial reactions or challenges with complete accuracy. This may have led to an emphasis on enduring issues rather than transient concerns experienced during the early adoption phase. However, by including both HCPs and patients with varying degrees of VC experience, we aimed to mitigate this effect and capture a balanced perspective on long-term usability and adoption.

Implications and Future Work

Our findings have several key implications for stakeholders involved in the development and implementation of VCs in health care.

For developers of VC applications, this study highlights the importance of optimal usability to promote successful introduction and long-term use. Developers should prioritize extensive usability testing with both HCPs and patients before launch, ensuring the interface is intuitive and accessible to different user groups, such as older adults and people with disabilities. Continuous improvement based on user feedback is essential.

For implementers, a successful introduction of VCs requires multiple strategies. Patients' concerns need to be understood and addressed. Their digital literacy and self-efficacy also need improvement. Providing multilingual guidance, video tutorials, and accessible materials for nonnative speakers, individuals with visual impairment, and older adults is vital. As key actors in the implementation of VC, HCPs need to be better prepared, adequately trained, and supported. Educational and informational materials developed by physicians have been perceived as useful for clinics lacking prior experience and could be a potential solution to issues HCPs face [18]. Practical information regarding the guidance of people speaking other languages, those with visual impairment, and older people might also be beneficial. Additionally, training programs should help HCPs address biases and assumptions that could hinder adoption, particularly among vulnerable populations. Further, for filling the knowledge gap regarding the appropriateness of VCs and by being in discussion with both patients and HCPs, formulating clear guidelines may be key to fostering patient trust and expanding equitable use. Implementers should also assess and adjust workflows within health care organizations to minimize disruptions to service use.

Health care providers could consider the potential for VCs as a solution to some of the seasonal-related care delivery issues when resource planning.

For policymakers, this study emphasizes the importance of digital readiness, including reliable internet access and the necessary tools such as eIDs. Policymakers should invest in upgrading digital infrastructure to provide universal access, particularly in underserved areas. Additionally, supportive reimbursement systems for VCs should be established to ensure appropriate use, along with long-term investments in health care systems to reduce waiting time and improve service delivery. Enhancing health care providers' ability to implement new digital interventions is also crucial for building resilience in the face of future crises.

Further research is needed to evaluate the effectiveness of different strategies for introducing patients to VCs, with a focus on addressing inequalities. Studies should also explore younger patients' perspectives, as their digital habits and preferences

XSL•FO
RenderX

may influence adoption. Additionally, more research is required to understand how the characteristics of HCP users and nonusers affect VC usage. Future research could also explore differences in drivers of use across professional roles and between consultations with new vs known patients. Further, to better understand nonuse, future research should involve nonusers to gain their perspectives.

Conclusions

The pandemic facilitated the introduction of VCs and accelerated use. However, the rushed implementation of VC contributed to a challenging start, potentially deterring some patients and HCPs from use. HCPs played a vital role in the introductions and influenced VC use both positively and negatively. They were unprepared, which contributed to many challenges, and their misguided preconceptions risk reinforcing existing disparities and contributing to digital exclusion. However, patients also relied heavily on HCPs' recommendations when deciding to accept a VC. Moreover, patients' biases against themselves, reinforced by initial introduction challenges and broader concerns about fairness, may also influence VC use. In addition, HCPs' and patients' preferences, which were related to their needs, waiting times, and different circumstances, influence use. Further, judgments of appropriateness that also influenced use may be misguided. Lastly, infrastructure, reimbursement, sociodemographics, and organizational type were also uncovered as drivers of use.

Based on these findings, developers of VC applications should optimize usability, and implementers should include multiple strategies, including training programs, guidance, and assessing and adjusting workflows. Health care providers should consider the potential of VCs as a solution to some care-delivery issues when planning resources. Additionally, policymakers should invest in digital readiness, including upgrading digital infrastructure, creating supportive reimbursement systems, and long-term investments in health care systems. Further research should evaluate the effectiveness of different strategies for introducing patients to VCs, explore younger patients' perspectives, characteristics of HCP users and nonusers, differences between professional roles, as well as between consultation types. Nonusers' perspectives should also be explored.

Acknowledgments

We thank the participants for their contributions and the Alltid öppet management in Region Stockholm and Tiohundra administrators for facilitating data collection.

Funding

AFA Försäkring funded this work through the project "Recommendations for implementation of eHealth in primary care - ePrIm" (190210). The study was also supported by Uppsala MedTech Science and Innovation [https://medtech.uu.se/https://medtech.uu.se/], a joint strategic initiative between Uppsala University and Uppsala University Hospital.

Abstract

Background: Data dashboards are popular tools for supporting routine monitoring and decision-making in public health. Two dashboards were developed in Côte d'Ivoire to visualize laboratory data on HIV viral load (VL) and early infant diagnosis (EID) testing.

Objective: This study assessed the attitudes and experiences regarding data-driven decision-making and the VL and EID dashboards among existing and potential dashboard users in Côte d'Ivoire.

Methods: We conducted a qualitative study including 2 focus group discussions (FGDs) and 12 in-depth interviews (IDIs). The conceptual framework for the use of health data in decision-making guided the FGDs, and the Consolidated Framework for Implementation Research informed the IDIs. We used deductive and inductive approaches to analyze the interview data.

Results: The 26 participants were from 17 organizations; 11 (42.3%) were female. The participants reported a supportive data culture that valued data-driven decision-making and external pressure from the United States President's Emergency Plan for AIDS Relief (PEPFAR) that motivated data use. The dashboards were considered useful for monitoring performances and making decisions for service delivery and laboratory operations. Existing users used the dashboards regularly. Potential users expressed interest in the speed and ability to track progress. The participants considered the dashboards simple and straightforward compared to other analytical tools but suggested updating the dashboards more frequently and visualizing more data.

Conclusion: The study highlighted the importance of supportive data culture and the potential of dashboards to promote data use. However, challenges such as limited access to the internet and equipment for potential users need to be addressed.

Introduction

Progress around HIV/AIDS prevention and treatment has stagnated around the world [1], and the HIV response needs to be reinvigorated to achieve the 95-95-95 goals set by the Joint United Nations Programme on HIV/AIDS (UNAIDS) [2]. HIV viral load (VL) suppression and early infant diagnosis (EID) are important health and service delivery outcomes for monitoring timely and effective treatment, preventing transmissions, and assessing prevention of mother-to-child transmission. Using data and evidence strengthens the decision-making by country leadership and contributes to successful HIV responses [3]. To help achieve the targets for VL suppression and EID in Côte d'Ivoire based on high-quality data, the national VL and EID data dashboards provide information that supports the monitoring, evaluation, and decision-making in HIV-related services and programs.

Understanding the context, culture, and behavior around data demand and use is important to ensure the effectiveness of the tools that aim to support data-driven decision-making, especially in low- and middle-income countries (LMICs). According to a 2023 literature review, the main barriers to data-driven decision-making in LMICs include insufficient data use competencies, low data quality, inadequate data availability, lack of systems design and user-centered design, disconnect between data producers and users, unsupportive leaders, absence of organizational supports, misalignment in data needs between donors and local stakeholders, weak data use culture, and low individual motivation [4]. Evidence is limited to whether and how these barriers influence data-driven decision-making in HIV responses in Côte d'Ivoire, and such evidence will provide useful context for understanding the successes and issues with the VL and EID dashboards.

Dashboards are tools designed to support data-driven decision-making by visualizing quantitative data and supplying audit and feedback to decision makers and service providers [5,6]. Applications of dashboards are ubiquitous in public health, with purposes ranging from disease surveillance [7-9] and monitoring of quality and efficiency [10-14] to clinical decision support [15-18] and stock management, among others [19,20].

Despite the proliferation of dashboards in public health, studies that assess data needs and user experience of dashboard users are limited. After reviewing 1191 papers, the authors of a systematic review on public health dashboards identified only 18 user studies, while most studies describe only the design and technical development process of a specific dashboard [21]. Only a few of the 18 user studies considered data demands and self-efficacy of dashboard users [21], highlighting a notable gap in research that other reviews already identified previously [22,23].

This study aimed to fill the research gaps described above by answering the following questions: What were the attitudes and experiences of existing and potential dashboard users on data-driven decision-making in their organizations? What were the participants' impressions of the VL and EID dashboards?

Methods

Intervention Description

To respond to the need for a tool that consolidates and presents data in an accessible format, the publicly accessible, online dashboard for VL was developed in 2017 through the collaboration among the International Training and Education Center for Health (I-TECH), the Côte d'Ivoire Ministry of Health (MOH), the United States President's Emergency Plan for AIDS Relief (PEPFAR), the United States Centers for Disease Control and Prevention (CDC), The United States Agency for International Development, the Clinton Health Access Initiative, and the Kenyan MOH [24,25]. I-TECH obtained the software source code in the HTML for the Kenyan VL dashboard and adapted it for the Ivorian context to visualize monthly aggregate VL data from the open-source enterprise-level laboratory information system (OpenELIS; Digital Initiatives Group at the University of Washington [26]), the electronic laboratory information system in Côte d'Ivoire [27,28]. The visualization tool was Highcharts, and the data sources were monthly OpenELIS datasets at the laboratory level. The use case was to provide analyzed, critical information for monitoring program performance and progress toward achieving the goals for viral load testing and suppression and EID. The target users were the CDC and the PEPFAR implementing partners, policy makers at different levels of the MOH in Côte d'Ivoire, and clinical and laboratory service providers.

Data visualizations produced by the VL dashboard included bar charts and pie charts for the number of tests, turnaround time, and viral suppression with disaggregation by gender, age group, and reasons for seeking care. All charts except for the national average turnaround time could be disaggregated by month, region, district, clinical laboratory, or PEPFAR implementing partners. Users could access the disaggregated visualizations through the navigation tabs at the top of the dashboard webpage. A dedicated tab showed charts about viral suppression by gender, age, reason for the test request, and antiretroviral regimen. All data visualizations, source datasets, and a dashboard user guide were globally accessible and available for download.

In 2020 the EID dashboard was created based on the VL dashboard to display monthly aggregate EID data from OpenELIS [29]. The types of visualizations and functions are similar to those described above for the VL dashboard. More details about the development process, information visualized, and types of visualizations of the VL and EID dashboards were described elsewhere [24].

Study Design and Data Collection

We conducted a qualitative study including 2 focus group discussions (FGDs) and 12 semistructured in-depth interviews (IDIs). Specifically, the FGDs were intended to gather general perspectives that the participants converged or diverged on about data-driven decision-making and the VL and EID dashboards. The IDIs were intended to probe for greater depth of response with themes that arose in the FGDs. Data collection took place from September 2021 to April 2022 through in-person or online meetings.

XSL•FO
RenderX

The study population consisted of existing and potential users of the VL and EID dashboards. Existing users were staff members of national and regional clinical laboratories, the CDC office in Côte d'Ivoire, and PEPFAR implementing partners. Potential users were from MOH divisions and clinical laboratories that reportedly had not used the dashboards, but the I-TECH project team and existing users thought these entities would find the dashboards useful.

To enroll existing users, we purposefully sampled individuals who were already using the dashboards based on previous meetings to participate in the first FGD and subsequent IDIs. We then used snowball sampling to ask the FGD participants to introduce us to other existing users from additional organizations to participate in the IDIs.

To enroll potential users, we first purposefully sampled a staff member of the Programme National de Lutte contre le Sida (PNLS; National AIDS Control Program) who had shared with the study team that they had not used the dashboards. The study team also identified individuals who had not used the dashboards and were heads or deputy heads of the regional clinical laboratories in Côte d'Ivoire. We purposefully chose PNLS because, as the national technical group created by the MOH to guide the national HIV/AIDS response, PNLS knew about the dashboards but reported that they did not routinely use them. Regional laboratories might also be interested in the dashboards because they were referral sites that processed all VL and EID samples referred from other laboratories in the region. We invited identified potential users to participate in the second FGD and subsequent IDIs. Recruitment stopped once we confirmed that all targeted types of organizations were represented and that thematic saturation had been reached.

The conceptual framework for the use of health data in decision-making (referred to as the "data use framework" hereafter) informed the interview guides for the 2 FGDs [4,30]. The data use framework builds on the Performance of Routine Information System Management (PRISM) framework created by the MEASURE Evaluation group [4,30,31]. The framework highlights key activities that most directly influence data demand and use and subsequently the building blocks in the health system and ultimately health outcomes. We chose to focus on the activities that would influence data demand and use to see if and how they were reflected in the participants' responses.

The relevant constructs of the Consolidated Framework for Implementation Research (CFIR) informed the interview guides for the IDIs (Table 1) [32,33]. The CFIR is a meta-theoretical framework designed to explain the factors that affect translation of interventions into practice and their sustainment in practice across different contexts [32,33].

The interview guides were initially developed in English and later translated into French. The FGDs and IDIs were recorded, and comprehensive notes were taken. On average, the FGDs lasted 59 minutes, and the IDIs lasted 32 minutes. The recordings were transcribed verbatim in French and translated into English for analysis.

A combination of deductive and inductive approaches was used to analyze the data. Codes were created using the activities that influence data demand and use from the data use framework, the CFIR constructs, as well as those derived from the data. All transcripts were coded by one primary coder (YH). YH first chose one FGD transcript and one IDI transcript to code with the initial codebook that consisted of the deductive codes. After adding inductive codes to the codebook, YH revised the coding in the first two transcripts and continued coding the rest of the transcripts. Any subsequent changes in the codebook or coding approach were applied to transcripts that had been coded previously. We summarized the coded information into themes that corresponded to the research questions. The two frameworks served as the basis for the themes, with additional themes derived from the data that did not fit the constructs of the two frameworks. Two additional team members (YRK and PHA) reviewed the coded data and thematic summaries to validate the analysis and ensure consistency in interpretation. The coding and thematic analysis were conducted in ATLAS.ti (8 Windows; ATLAS.ti Scientific Software Development GmbH).

Ethical Considerations

This study was determined to be nonhuman participants research by the University of Washington Institutional Review Board and approved by Côte d'Ivoire Comité National d'Ethique des Sciences de la Vie et de la Santé (CNESVS, Ivorian Institutional Review Board; reference number 006 - 21/MSHP/CNESVS-km). All participants were unpaid volunteers and provided written informed consent. To ensure data confidentiality, the data collected were stored in a project-specific, encrypted instance of Google Drive managed by the secure server environment of the University of Washington that is compliant with the US Health Insurance Portability and Accountability Act (HIPAA) guidelines.

Results

Overview

We conducted one FGD and 7 IDIs with existing users and another FGD and 5 IDIs with potential users. There were 26 participants across the FGDs and IDIs; 11 (42.3%) were female; 17 organizations were represented (Table 2). The participants from the CDC and PNLS were program officers; the participants from the PEPFAR implementing partners were clinical program leads or strategic information team members; and the participants from national or regional referral laboratories were heads or deputy heads of the laboratories.

Data-Driven Decision-Making

Data Use Context

According to all the participants in the FGDs and IDIs, their organizations used data in decision-making, and there was no difference between the organizations of the existing users and those of the potential users. Not only would the leaders use data in decision-making, but different units and levels within each organization also used data in their work, even if some units or levels were not seen as decision makers. Data were used routinely to monitor technical and operational performance as well as ad hoc under special circumstances to assess the situation, identify problems or needs, and make decisions to solve problems or make improvements. The most common areas where the participants used data to monitor were laboratory operational processes (eg, nonconformity of samples, sample flows, and turnaround time) and lost-to-follow-up clients for VL testing.

Data Demand, Data Use Infrastructure, Data Users, and Data Producers

The FGD with existing users revealed convergence among PEPFAR implementing partners in demands for data, data use infrastructure, and internal processes that engaged data users and producers (Table 3). PEPFAR implementing partners, not directly providing services, used both laboratory and clinical data to monitor laboratory operational processes and progress of HIV program implementation. Laboratory data were from OpenELIS, and clinical data were exported from the electronic health record for HIV clients into Microsoft Excel spreadsheets. These organizations had data management units that compiled and validated the data collected from the clinical laboratories in the implementing districts. The programmatic units then received the processed data and conducted data analyses to monitor or evaluate progress achievements and shortfalls. The analyses informed leaders in deciding how their organizations could support the clinical laboratories to address areas of improvement.

While 3 referral laboratories (11.5% of the 26 participants) used data to inform laboratory operations and clinical decision-making, 4 other laboratories (15.4%) used data only for laboratory operations (Table 3). Three participants (11.5%) from 2 national referral laboratories and one regional referral laboratory shared that they not only used operational data from OpenELIS to monitor nonconformities and improve sample flows and result validation, but they also actively contributed to clinical decision-making by examining data on testing results and whether a client was on time for a test. The 10 participants (38.5%) from the rest of the referral laboratories were most interested in laboratory operational data and viewed themselves as suppliers of data to the clinicians for making decisions. As an existing user noted, "we give [the clinician] his result so it's

XSL•FO
RenderX

a chain which we play a part in," describing laboratory staff as data providers.

Table . Data demanded, data use infrastructure, and uses of the data demanded at the 2 types of organizations where most participants of this study worked in Côte d'Ivoire in 2021 - 2022.

Themes	CDC[a], PEPFAR[b] implementing partners	Referral laboratories
What data were demanded	• Laboratory data on VL[c], EID[d] • Clinical data on active client case • Pharmacy data on filled prescriptions	• Data on laboratory operational process
What infrastructure supported data use	• OpenELIS[e] • Clinical records (electronic health records for HIV clients; Excel spreadsheets)	• OpenELIS
What issues were understood or addressed using data	• Identify districts or laboratories with performance issues • Track lost-to-follow-up clients for VL testing or treatment • Identify clients with unsuppressed VL	• Bottlenecks in sample flow • Nonconforming samples • Turnaround time • Workload
What decisions or strategies were made using data	• Follow-up with specific districts, laboratories, or clients	• Improve workflow • Follow-up with satellite laboratories about nonconforming samples

[a]CDC: US Centers for Disease Control and Prevention.

[b]PEPFAR: US President's Emergency Plan for AIDS Relief.

[c]VL: viral load.

[d]EID: early infant diagnosis.

[e]OpenELIS: open-source enterprise level laboratory information system.

External Pressure

The participants from PEPFAR implementing partners and the Retro-CI laboratory, established and funded by the US CDC, shared that how they used data in decision-making was heavily influenced by PEPFAR and the MOH.

The participants from the laboratories in the public health system shared that their data use behavior already existed to support internal performance monitoring and address MOH data requirements. They would share their existing data with donors or partners in the areas that these external entities supported, eg, HIV testing and donated equipment. An existing user stated that they reported data to PEPFAR every month because they were supported by PEPFAR, "but it's really not (PEPFAR) who influence our activity," indicating that the laboratory maintained operational independence despite donor reporting requirements.

Data Quality

When asked how data quality issues affect how often they used data for decision-making, the participants shared that data timeliness had a more direct impact on the frequency of data use. All existing users who participated in the first FGD shared that they had internal processes to ensure the quality of the data in the dashboards. Four participants from the second FGD with potential users shared that, since they had technical validations, the data quality should be fine. However, one participant disagreed, stating that, despite the processes and units that were intended to ensure data quality, there were still missing data or poorly documented data on paper forms that decreased data quality.

VL and EID Dashboards

Frequency of Using the Dashboards

Three existing users shared that they used the dashboards monthly; 2 said quarterly; and one said every 6 months because they were most interested in stock shortages, but they said that the dashboards were not up to date on stock. One existing user said they only used the dashboards on an ad hoc basis because the dashboards were not updated as frequently as they preferred.

Reason for Using the Dashboards

The existing users considered the dashboards useful tools for identifying and raising awareness of problems and important references for communicating with other laboratories. An existing user from a national referral laboratory felt excited and relieved that the dashboards were available because they provided direct evidence of laboratory performances, and there was no need to guess how the performances had been. An existing user at a PEPFAR implementing partner agency was interested in the performances of other similar organizations, which the dashboards showed, so that they could cross-compare and "boost our team to work more."

After examining the dashboards briefly during the FGD and IDIs, potential users shared the reasons that would motivate them to use the dashboards were serving as a model to peers ("people outside the laboratory can copy us and seek to get in touch with us to see how we have achieved this" [IDI with potential user 5]); accessing information quickly for decision-making ("very quickly we know where [tasks] get stuck [in the workflow] and what quick decision to take." [FGD potential user 5]); and monitoring progress toward targets ("good

XSL•FO
RenderX

to know that we have feedback [from the dashboards] about our implementation of the national guidelines." [IDI with potential user 1]).

Facilitators

All existing users were confident that they themselves and the colleagues who used the dashboards routinely at work were capable of using the dashboards. The FGD participants within each group converged that the design of the dashboards was nice, the colors were beautiful and distinct, and the layout was easily readable. Two existing users (of the 16; 12.5%) shared that the need for the dashboards was common across the PEPFAR implementing partners and the US CDC, so the motivation for using the dashboards already existed.

The participants shared that the relative advantages of the dashboards were simplicity and straightforwardness compared to other data analysis and visualization tools such as Microsoft Excel or Microsoft Power BI. Compared to static data spreadsheets, the visualizations on the dashboards showed a lot more information in an interactive way. The participants explained that, since the configurations and structures of the dashboard interface were predefined, accessing specific information was faster and easier for people who monitor performances routinely. One potential user at a regional referral laboratory thought that, compared to Excel, which could also visualize data, the dashboards were faster and more straightforward, and it was also a direct way to convey information to others who wanted to learn about the VL and EID activities of the laboratory or the region. One potential user and one existing user highlighted the benefit of an interactive tool that could quickly display information that they needed, for example, meaningful disaggregation by population group, whereas Excel spreadsheets were static. As one potential user noted, ("with a simple click, […]we do not need to go and redo the calculations again [in Excel] to be able to access the information").

Although one existing user perceived Excel and Power BI as more versatile in analyzing data exported from OpenELIS, they acknowledged that the dashboards were "accessible" (IDI with existing user 4). Sometimes if she "had not finished analyzing [data exported from OpenELIS], [she] will take the information from the dashboards," indicating that the dashboards provided faster access to analyzed information that was useful for decision-making.

In terms of market pressure, the existing users converged during the first FGD that they were aware of other organizations, especially PEPFAR implementing partners, that were using the dashboards. In the subsequent IDIs, an existing user shared that

> *generally all the partners in Côte d'Ivoire use the dashboards, I exchange with colleagues in other organizations, and everyone refers to the dashboards* [IDI with existing user 5]

Most potential users (9 out of 10; 90%) did not know of any organization that used the dashboards. The only participant who had prior knowledge came from PNLS, which oversees all HIV-related activities in the country.

Potential Barriers

Three existing users (of the 16; 18.8%) shared that, although they were able to use the dashboards without difficulty, they were concerned that new users might need internet connections and computers or tablets to access these online dashboards. Both groups of existing and potential users would like to have more information and training or coaching on using the dashboards. One existing user thought that training or coaching would be useful for new users to orient themselves around the layout and functions of the dashboards, noting that "[new users] may be impressed, but the use will be difficult, they need explanations and coaching." Indeed, all but 2 potential users (80%) had not heard of the dashboards through any training or awareness session, making it the primary reason why they had not used them.

Suggestions for Improving the Dashboards

The most mentioned suggestion was updating the data displayed in the dashboards more frequently. Four existing users (25%) and 3 potential users (30%) suggested updating at least every other week, with more near–real-time updates being preferred. One potential user cautioned the others during the FGD about having an ideal world with near real-time data updates, since there was a natural trade-off between the speed of posting data and the necessary biological and technical validations in the laboratory operational process. Therefore, weekly updates might be the most ideal scenario that the dashboards could realistically achieve (FGD potential user 5).

The participants also suggested various information to add to the dashboards so they can meet the needs of the organizations better. Three existing users (18.8%) and 2 potential users (20%) would like to have more indicators about the laboratory operational process and service quality, eg, the number of noncompliant and rejected samples and testing validity. Information about when and why major disruptions in laboratory services happened was highly requested by all but 2 existing users to provide context around suboptimal performance. The potential user from PNLS would like the dashboards to extend to all laboratory testing related to people living with HIV rather than just VL and EID.

Discussion

Principal Findings

This study highlights the integral role of data-driven decision-making in HIV program implementation and laboratory operations in Côte d'Ivoire. The findings reveal that data are widely used across organizational levels to monitor performance, address challenges, and inform decisions, but application varies between referral laboratories and PEPFAR implementing partners. While some organizations focus on operational monitoring, others integrate data into clinical decision-making, reflecting differences in roles and priorities. While existing users valued the dashboards for tracking performance and benchmarking, potential users faced barriers related to access, awareness, and training. Concerns about the need for additional indicators suggest opportunities for improvement. Strengthening capacity-building and data integration could enhance the impact

XSL•FO
RenderX

of the dashboards on decision-making. Articles that describe dashboards displaying HIV-related data are not uncommon [34-40]. This study not only describes the features of the VL and EID dashboards in Côte d'Ivoire but also explores contextual factors, dashboard complexity, hardware availability, and internet connectivity that influenced the dashboard user experience.

The participants not only recognized the importance of data but also reported concrete behaviors of using data in decision-making. The recognition and behaviors were shared by both leaders and other staff members in an organization. This data culture, especially among leadership, seemed to be more supportive than in some LMICs reported in other studies [41,42]. The finding in our study could reflect a sample of participants who highly valued data, since more than half of the participants were existing dashboard users and had monitoring and evaluation as one of their key responsibilities.

We observed a virtuous cycle starting from a supportive data use culture at PEPFAR partner organizations and clinical laboratories in Côte d'Ivoire, which made people willing to use the VL and EID dashboards in their work. MOH supervisors can use the dashboards to provide regular feedback and comparative results to health facilities and laboratories, showcasing to both the data producers and users how the submitted data were used and enhancing the value of data collection and use [43-45]. The perceived value of data ultimately fed back into a supportive data use culture.

The participants at clinical laboratories shared that they submitted data to PEPFAR implementing partners monthly in addition to the routine data collection and use process established by the MOH. This indicates parallel data systems due to donors' data demands, which may have been burdensome and led service providers to view themselves only as data producers [4,46]. Having access to useful tools such as the VL and EID dashboards that visualize the data that the laboratories submitted might motivate them to assume the role of data users [47].

All participants reported that their organizations had processes to validate data or ensure data quality, which gave them confidence in the quality of the data they collected, reported, and used. Key data validation or quality assurance activities include using the data validation report in OpenELIS, the electronic laboratory information system, and conducting routine data quality assessments. Our prior research supports this impression by showing that OpenELIS, the electronic laboratory information system feeding data into the dashboards, improved data timeliness and completeness significantly [48]. However, since poor data quality remains a barrier to data-driven decision-making in LMICs [41], more targeted research is necessary to understand the correlation between data quality, users' confidence in data quality, and actual data use behaviors.

The findings about how the study participants viewed the dashboards conformed with what other studies reported, but the perceived facilitators and barriers for using the dashboards were an addition to the evidence. Ease of use was one of the most assessed dashboard characteristics [21], and the study participants found the VL and EID dashboards simple and straightforward. Simple innovations have a higher likelihood of effectiveness due to their ability to enhance user satisfaction and shorten the learning curve [49-51]. For dashboards that intend to simplify the data synthesis and analysis process for users, low complexity is an important determinant of effectiveness.

The market pressure from peer organizations may have motivated existing users to use the dashboards. This phenomenon was especially present among the organizations that worked directly with PEPFAR. It would be interesting to explore among the potential users who work indirectly with PEPFAR if the same phenomenon would apply when some potential users start using the dashboards while others do not. Late adopters often face significant pressure to implement innovations, especially when competitors or colleagues have already adopted them; when others in the field are using an innovation, individuals and organizations may feel compelled to follow suit [52]. In order for market pressure to exist, potential users first must know about the innovation. Marketing the dashboards through training and awareness activities as tools for building an organization's credibility could be necessary before market pressure can build.

The existing users, all based in Abidjan or other urban areas, were concerned that potential users in other regions of the country might not have the necessary equipment or Internet connection to access the online dashboards and that they might need training to learn to use the dashboards. It is important to ensure the precondition of necessary equipment is met for achieving the outcome of increased user pool in the future [53]. Providing training or a support hotline might also be useful strategies to engage potential users [54].

Limitations

The FGDs and IDIs were carried out by I-TECH personnel who were involved in the development and implementation process of the dashboards, potentially leading to social desirability bias in reporting barriers or issues. However, since we explained to the participants that the study was formative rather than evaluative, the social desirability bias might not have manifested to a great extent. Other limitations include potential difficulties in recalling or misunderstanding the questions. To partially address these limitations, we provided explanations of the interview questions and encouragement to offer honest critiques and suggestions for improvement.

In addition, the study sample was purposively selected and not intended to be statistically representative of all existing or potential users of the dashboards. Since this was a qualitative study, we did not collect objective observations or produce quantitative estimates of the phenomena discussed by the informants. Thus, we were unable to assess how common particular experiences or opinions may have been. Future mixed methods research could help corroborate the qualitative insights reported by triangulating them with quantitative data on dashboard use patterns and implementation outcomes.

Finally, since a single study team member coded all transcripts, there is a possibility of subjective bias or limited interpretive diversity in the coding process. This risk was mitigated by

XSL•FO
RenderX

independent review and validation of the thematic analysis by 2 additional team members.

Conclusion

This study demonstrated that decision makers and program staff in Côte d'Ivoire's HIV response all valued data-driven decision-making. They recognized the utility of the HIV VL and EID dashboards in monitoring performance and guiding decisions. While PEPFAR partners valued laboratory, clinical, and pharmacy data and used them in client- or program-level monitoring, laboratories demanded data on laboratory operational processes to improve workflow and quality control. These insights contribute to the broader understanding of effective data use and dashboard design in Côte d'Ivoire.

Acknowledgments

We thank the Ministry of Health, Public Hygiene, and Universal Health Coverage (MSHPCMU) in Côte d'Ivoire and all implementing laboratories for the continuous collaboration. We thank Marisa Van Osdale at I-TECH for program management; Ahoua Koné at the University of Washington for her guidance and insight on the Ivorian context; and the project interns and data consultants at I-TECH CIV.

The US Centers for Disease Control and Prevention reviewed the paper but had no influential role in study design, data collection, analysis, and interpretation.

Funding

This work was supported by PEPFAR through the US Centers for Disease Control and Prevention under the terms of cooperative agreement #NU2GGH001968-05-00 awarded to the University of Washington. The findings and conclusions in this paper are those of the authors and do not necessarily represent the official position of the funding agencies.

Abstract

Background: Living with asthma—especially in its severe forms—can significantly impact daily life, including social activities, work, travel, and household responsibilities. Collaboration between patients and health care professionals (HCPs) is frequently lacking, particularly regarding treatment goals. Self-management has been shown to mitigate the negative effects of asthma. Technical solutions might support self-management for patients with chronic diseases and their collaboration with HCPs.

Objective: This explorative study aims to understand how patients and HCPs experience the use of a digital self-management system for asthma monitoring.

Methods: This qualitative study was conducted at 5 primary care centers in Sweden and involved 20 participants: 14 patients who had utilized the digital self-management system Asthmatuner for at least 6 months and 6 specialist asthma nurses. Individual semistructured interviews were analyzed using qualitative content analysis to explore patterns and relationships within the data.

Results: We identified 1 main theme, that is, "data-supported empowerment," and 3 subthemes, that is, (1) empowerment by awareness, knowledge, and learning; (2) contact health care-patient; and (3) managing the monitoring. The theme of data-supported empowerment emerged as a synthesis of these findings, reflecting how the self-management system enabled patients to take a more active role in managing their medications and health. While most patients did not monitor their data continuously, they engaged with it when they felt it was necessary. Some patients expressed expectations of personalized follow-up from HCPs based on their monitoring data; however, these expectations were not always fulfilled. We also revealed a need to adapt and clarify the overlapping responsibilities of patients and HCPs.

Conclusions: The digital self-management system for asthma was well received by both patients and HCPs, as it promoted empowerment. Clear communication about changes in workflow and responsibilities is essential to ensure the successful implementation of digital systems and improved health care delivery.

KEYWORDS

asthma; digital health; empowerment; primary care; self-management; user experience

Introduction

Health care faces multiple challenges, including an aging population, a growing number of individuals living with chronic diseases and multimorbidity, increasing demands from the public, limited resources, and expanding medical possibilities [1]. These challenges highlight the need for innovative approaches to health care delivery, particularly in primary care, where most chronic disease management takes place [2-4].

Person-centered care and patient empowerment are necessary to meet the needs of persons with chronic conditions [5-8]. The World Health Organization defines empowerment as "a process through which people gain greater control over decisions and actions affecting their health …" [9]. To achieve patient empowerment, the patient needs to understand his or her role,

XSL•FO
RenderX

possess the necessary knowledge and skills, and be in a facilitating environment.

The concept of self-management is widely used in chronic care contexts and often refers to patients' ability to manage symptoms, treatment, and lifestyle changes. Individuals with chronic conditions are often expected to take significant responsibility for their daily care and disease self-management [10]. However, this has also been critiqued for placing responsibility on individuals without sufficiently acknowledging structural, relational, and contextual factors that shape health behaviors [11,12]. While there is no universally accepted definition of self-management, this study adopts the definition: "… the individual's ability to manage the symptoms, treatment, physical and psychosocial consequences, and lifestyle changes inherent in living with a chronic condition" [13]. Self-monitoring is a key component of self-management, as it enhances awareness and provides actionable information [10,14]. Effective self-management can improve health outcomes, reduce health care utilization, and lower overall health care costs [15-18]. In this study, we focus on the use of digital tools that support patients in their everyday self-management of asthma, while recognizing that such tools are embedded in broader care practices and relationships.

Digital health technologies have shown promise in supporting self-management of chronic conditions [19], with positive effects reported for both patients and health care professionals (HCPs) [20,21]. Asthma, a chronic respiratory disease, affects approximately 10% of the Swedish population, with higher prevalence among adult women [22,23]. Living with asthma—especially in its severe forms—can significantly impact daily life, including social activities, work, travel, and household responsibilities. Patients often report psychological distress and dissatisfaction with the continuity of care in primary settings. Moreover, collaboration between patients and HCPs is frequently lacking, particularly regarding treatment goals. These findings underscore the importance of structured patient education, which may be enhanced by digital health solutions [24].

In Sweden, asthma and chronic obstructive pulmonary disease nurses are registered nurses with several years of clinical experience and specialized training in respiratory care, including university-level courses in asthma, allergy, and chronic obstructive pulmonary disease. Their responsibilities encompass patient assessment, spirometry testing, education on disease management and inhalation techniques, smoking cessation support, and coordination of individualized care plans. These nurses play a central role in long-term follow-up and in supporting patients' self-management [25].

Digital technology has the potential to improve both the health and care of patients with asthma [26-29], but there is limited evidence concerning patients' experiences and their views of digital intervention in the self-management of asthma [28,30]. Customizable treatment plans and self-management through the self-monitoring of lung function and symptoms appear to be more effective than other forms of asthma self-management [31]. The digital tool AsthmaTuner (MediTuner AB) is a Conformité Européenne–marked self-management system that offers personalized treatment recommendations based on daily lung function and symptom monitoring [32].

The user experience of digital self-management interventions will have an impact on patients' and HCPs' adoption and continued use of such tools and is therefore important to understand. According to ISO 9241 - 210, user experience is "a person's perceptions and responses that result from the use or anticipated use of a product, system or service" [33] and includes emotions, beliefs, behaviors, and responses before, during, and after use, shaped by system functionality, prior experiences, and context.

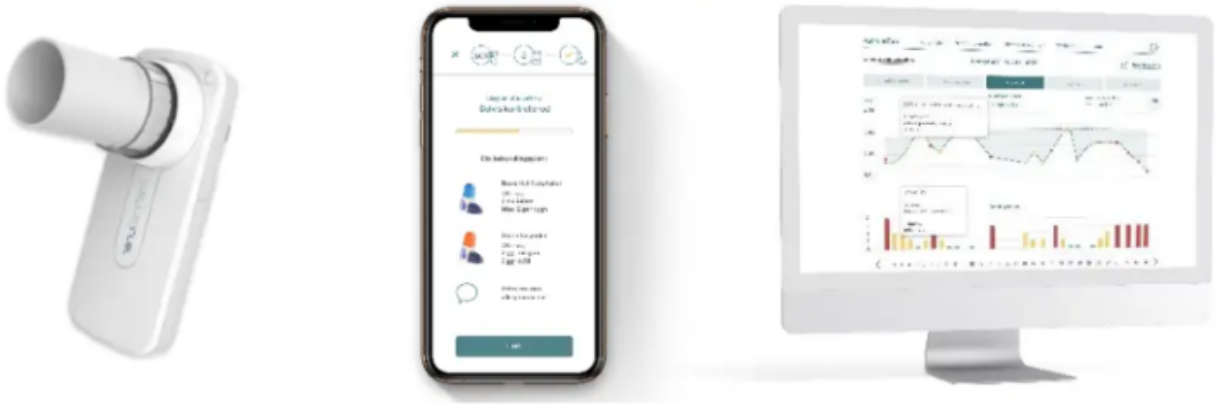
This explorative study aims to understand how patients and HCPs experience the use of a digital self-management system (AsthmaTuner) for asthma monitoring.

Methods

Study Design

A qualitative approach was used to understand the experiences of patients and HCPs. The data were collected through semistructured interviews with patients and specialist nurses who had used the self-management system AsthmaTuner for at least 6 months. The COREQ (Consolidated Criteria for Reporting Qualitative Research) has guided the reporting of this study [34] (Checklist 1).

Study Setting



The study took place at 5 primary care centers in Region Stockholm, Sweden. These centers are part of the primary care service in Tiohundra AB in Norrtälje. Norrtälje is the largest municipality area-wise in Region Stockholm; it is sparsely populated and has an aging population, and its inhabitants have lower socioeconomic status than other parts of Region Stockholm. This demographic and socioeconomic profile more closely resembles that of many municipalities across Sweden outside the major urban centers, making Norrtälje a relevant case for understanding primary care in rural and semirural contexts nationwide.

The Self-Management System—Asthmatuner

Asthmatuner is a Conformité Européenne–marked self-management system for monitoring asthma. It consists of a portable wireless spirometer that can be used to measure lung function and a mobile app through which patients answer questions about their current asthma symptoms in conjunction with measuring their lung function. The app provides patients with a treatment plan based on their current symptom estimates and lung function. Figure 1 demonstrates an overview of the AsthmaTuner components. The treatment plan is presented in 3 levels—controlled, partly controlled, or uncontrolled—and suggests how the patient should take their medication. The app presents a view of trends in their symptoms and their lung function [32].

XSL•FO
RenderX

Figure 1. Overview of the components of the AsthmaTuner self-management system (wireless spirometer, patient app, and health care professional [HCP] interface).

In addition, the self-management system includes an interface for the HCPs where patient data can be viewed and treatment plans prescribed. Being able to view patient data allows the HCPs to identify patients with poor asthma control in need of follow-up.

Study Participants and Recruitment

Patients were recruited from the intervention arm of an ongoing randomized controlled trial in which 200 patients were given access to the self-management system, while the 200 patients in the control group were assigned to usual care and received a written or verbally communicated treatment plan. Written informed consent was obtained from all participants before inclusion.

Letters with information about the qualitative study were sent from the primary care centers to all patients who had used the self-management system for at least 6 months and were 18 years or older. Patients who responded to the invitation were subsequently contacted to schedule an interview. Invitation letters were sent out in 4 rounds as new patients became eligible. In total, 14 patients, 11 female/3 male, aged 44 to 76 years, mean age 64.5 (SD 10.1 y), participated in the study.

To ensure variation in the sampling, we applied a broad inclusion strategy to capture a wide range of experiences relevant to our study objectives. We used participant recruitment across different primary care centers from various geographic locations to reach a diverse audience, enhancing the representativeness of our sample. Despite a small sample, it corresponded roughly to the larger group regarding age and gender.

All specialist asthma nurses working at the participating primary care centers were approached and agreed to be interviewed (N=6). No further details (age or gender) about the nurses will be reported to ensure their privacy.

Data Collection

Semistructured interview guides were designed by the research team and used for the interviews (Multimedia Appendices 1 and 2). Semistructured interviews were chosen to allow for both consistency across interviews and flexibility to explore participants' individual experiences in depth. This method is well suited for qualitative research aiming to understand complex and personal phenomena, such as the use of a self-management system in health care settings [35]. The guides were based on previously constructed interview guides and modified using the team's experiences of qualitative interviews. They were not pilot-tested due to time constraints. The interviews were conducted in Swedish either by phone or online, recorded, and transcribed verbatim. This approach allowed for greater flexibility in scheduling and reduced the need for travel or physical presence, which was particularly important given the participants' varying health conditions, time constraints, and geographical locations. The interviews lasted 20 to 45 minutes, and no repeat interviews were performed. Only the interviewer and the participant were present during the interview. None of the interviewing researchers had any prior relationship with the patients, and they were not involved in patient care. The first author worked as a primary care physician at one of the participating care centers and, therefore, did not participate in data collection to avoid biased responses.

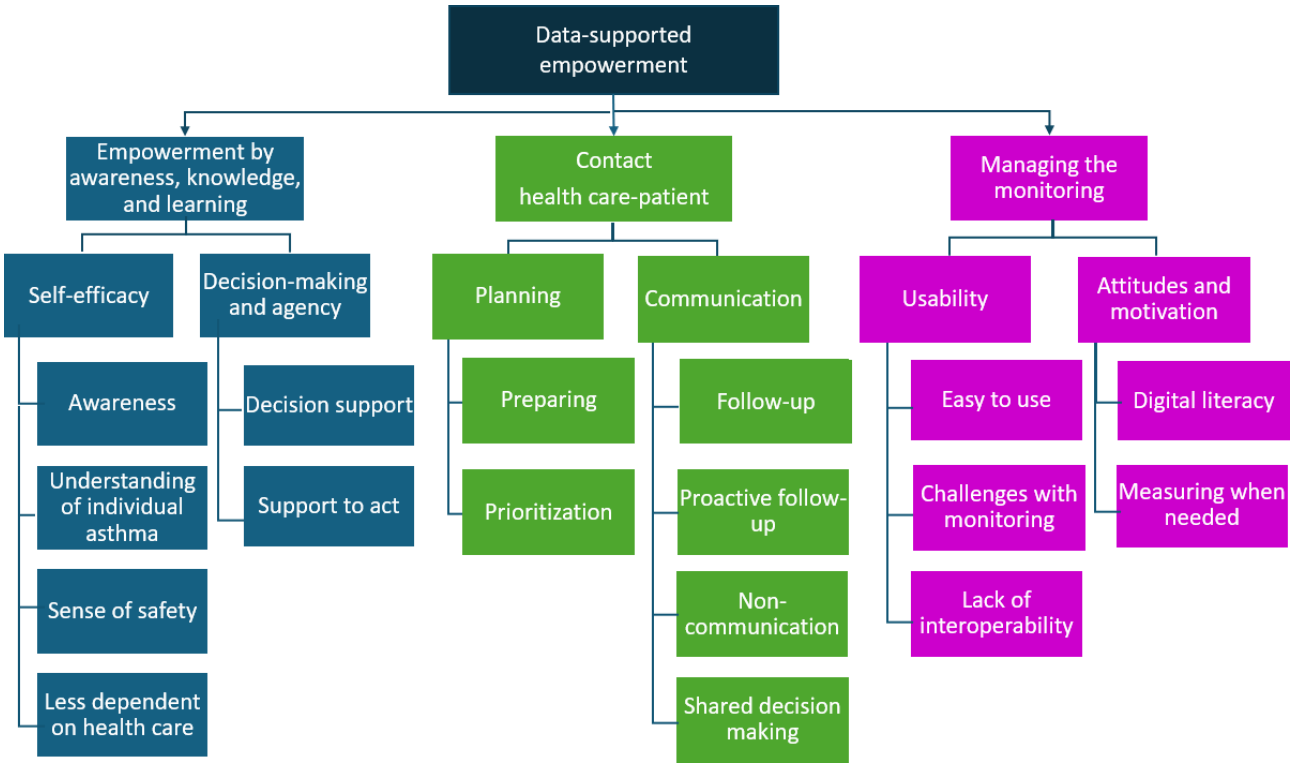
The first 10 patient interviews and all the nurses' interviews were performed during 2021 to 2022. To reach data saturation from the patient interviews, 4 additional interviews were conducted in 2023. Since these interviews did not present any new findings, we concluded that saturation had been reached.

The participant checking of transcripts and analysis was not done to reduce the burden of participating in the study.

Data Analysis

The interviews were analyzed using an inductive content analysis approach guided by Graneheim and Lundman [36].

LJH, MH, ND, and SR performed the initial coding. They read all the transcribed interviews and shared the work of identifying relevant meaning units and the initial coding. To identify codes and subcategories, the coding process was first performed on the interviews with patients and nurses separately. ND, MH, and SR performed the initial coding of the patient interviews, and LJH and MH took the main responsibility for coding the nurses' interviews. When subcategories had been identified, they were compared, and similarities and differences between the nurses and patients emerged. At this stage, the decision was made to continue the categorization and identification of subthemes jointly for both groups. This not only reduced the repetition of the findings due to similarities between groups but



XSL•FO
RenderX

also enabled us to highlight the subcategories where nurses and patients expressed different experiences or opinions. To enhance transparency and support the trustworthiness of the analysis, we include an example of the coding process in line with the COREQ checklist [34] in Table 1. The complete results, with all themes and categories, are presented in the results section (Figure 2). The coding was structured according to the approach described by Graneheim and Lundman [36], where meaning units were condensed, coded, and grouped into subcategories and categories through an iterative interpretative process.

Table . Example of the analytical process, showing how meaning units were condensed, coded, and grouped into subcategories and categories, following the qualitative content analysis approach described by Graneheim and Lundman [36].

Subthemes of data-supported empowerment and their categories	Subcategory	Meaning unit
Empowerment by awareness, knowledge, and learning		
Decision-making and agency	Support to act	"I notice tendencies, like now it's getting a little worse. And then I can start premedication before the values get too affected, so my asthma doesn't have to become so bad." [Patient 2, female, 58 years old]
Self-efficacy	Understanding of individual asthma	"I get an understanding of my asthma and when it gets worse. By measuring continuously, I know how I'm doing, and I can control my activities and my medication." [Patient 14, female, 52 years old]
Contact health care-patient		
Communication	Proactive follow-up	"Sometimes they have called and said, 'I keep ending up in the red zone. What's wrong?' They have contacted us then, just as they should when the device tells them to." [Specialist nurse]
Communication	Noncommunication	"… I would have liked to have more feedback. But that doesn't really have anything to do with the app." [Patient 11, male, 71 years old]

Figure 2. Main theme, subthemes, categories, and subcategories.

Consensus regarding the categories and themes was reached through an iterative process in a dialogue between all four coders and HH, who also read all the interviews. The meaning units were translated into English after the analysis was completed.

XSL•FO
RenderX

Ethical Considerations

The study received ethical approval by the Swedish Ethical Review Authority (2019 - 01898). All study participants gave written informed consent. All transcribed interviews were pseudonymized before analysis, to ensure the participants privacy was preserved. Study participants were not reimbursed for their participation, in accordance with the ethical approval.

Results

Overview

The analysis resulted in the identification of 1 overarching theme: data-supported empowerment, which built on three subthemes: (1) empowerment by awareness, knowledge, and learning; (2) contact health care-patient; and (3) managing the monitoring. Each subtheme encompassed several categories relevant to both patients and HCPs, with some subcategories applying to only one of these groups (Figure 2).

Rather than aiming to identify a single main theme from the outset, the analysis explored patterns and relationships within the data. The theme of data-supported empowerment emerged as a synthesis of these findings, reflecting how the self-management system enabled patients to take a more active role in managing their medications and health. While most patients did not monitor their data continuously, they engaged with the data when they felt it was necessary. Some patients expressed expectations of personalized follow-up from HCPs based on their monitoring data; however, these expectations were not always fulfilled.

Empowerment by Awareness, Knowledge, and Learning

Overview

The self-management system facilitated awareness, understanding, and knowledge of the patient's condition and supported patients in taking a more active part in their care and treatment. Self-efficacy and decision-making and agency thus became the main categories of the subtheme empowerment by awareness, knowledge, and learning.

Self-Efficacy

The category self-efficacy refers to participants' perceived ability to manage their asthma effectively, including interpreting symptoms, adjusting medication, and making informed decisions about daily activities. This interpretation is grounded in Bandura's concept of self-efficacy, which emphasizes individuals' belief in their capacity to influence outcomes through their actions [37]. Most patients experienced that monitoring gave them a better awareness of how asthma affects their well-being, and HCPs described how patients who used the self-management system became more interested in their condition and treatment.

For some patients, monitoring not only gave them a better awareness of asthma in general but also a higher level of understanding of their individual asthma.

> *It gives me an understanding of my asthma and when it gets worse. By measuring continuously, I know how I'm doing, and I can control my activities and my medication.* [Patient #14, female, 52 years old]

Patients who experienced this increase in awareness, which was also acknowledged by HCPs, used the monitoring to follow their lung function and adjust their treatment, and the monitoring also helped them to identify situations and factors that triggered exacerbations, such as different allergens or infections.

Several patients stated that the monitoring gave them a sense of safety because it helped them to determine whether their symptoms were caused by their asthma or something else, but also because they were encouraged to adjust their treatment if needed.

> *I get good advice through it [the system]. It makes me feel safe. And my asthma has been great since I started using it.* [Patient #4, female, 68 years old]

Some patients felt less dependent on health care as a result of using the self-management system since they could manage their asthma based on the treatment recommendations provided.

Decision-Making and Agency

The self-management system provided patients with information about their asthma control and suggested dosage adjustments of medications based on their current symptoms and lung function. Both patients and HCPs found that the self-management system served as an important decision support tool for the patients and gave them support to act on the suggestions.

> *Yes, it feels like when I get bad measurements, I should increase [the dose of my medication]. Or it says I should take a bit more Bricanyl. I think it's brilliant.* [Patient #6, male, 61 years old]

> *I notice tendencies, like now it's getting a little worse. And then I can start premedication before the measurements get too affected, so my asthma doesn't have to become so bad.* [Patient #2, female, 58 years old]

Contact Health Care-Patient

Interactions between patients and HCPs were affected by the self-management system, and 2 main categories were identified: planning and communication.

Planning

The self-management system was used by both patients and HCPs to prepare for planned follow-ups. Patients used it to recall variations in asthma control since the last visit, enabling them to give more informed answers.

HCPs used the data for prioritization when deciding which patients were most in need of active follow-up.

> *This way, I get better control of how the patients with asthma are doing. And I can call the right patients; I can prioritize the patients who need to come here.* [Specialist nurse #1]

XSL•FO
RenderX

Communication

Patient monitoring enabled digital follow-up. Patients and HCPs could discuss the data via phone or video consultations. The system was used for proactive follow-up, where nurses contacted patients with deteriorating asthma control and offered guidance. HCPs appreciated it when patients contacted them based on system alerts.

> *Sometimes they've called and said, "I keep ending up in the red zone. What's wrong?" They've contacted us then, just as they should when the device tells them to.* [Specialist nurse #3]

However, there were also cases of noncommunication, where some patients experienced a lack of feedback from the HCPs, and some had problems contacting their specialist nurse.

During regular follow-ups, the data provided by the system were used for shared decision-making, where patients and HCPs examined and reflected on the collected data together.

> *During a follow-up visit, you look at the registered data together with the patient, discuss how they have been, and try to find out what it was that made them deteriorate.* [Specialist nurse #5]

Managing the Monitoring

Usability and attitudes and motivation were the 2 main categories related to the management of monitoring.

Usability

Patients and HCPs agreed that the self-management system was easy to use. The HCPs noted that most patients did not have any problems using the system and were pleased to discover that older patients also managed to use the technology successfully.

> *I am surprised at how many patients, even older people, can handle the digital technology, electronic identification, and an app like this* [Specialist nurse #1]

Even though all patients thought the self-management system was easy to use, they also experienced some challenges with the monitoring. The most important challenge was remembering to use the device. Patients found that the option to use a reminder in the app was helpful, but after using it for some time, some patients got so used to the reminder that they no longer reacted to it.

HCPs did not report any challenges with monitoring, but instead a lack of interoperability, specifically concerning the need for the double documentation of the patient's medications and treatment plan in the system's care portal and the patient's electronic health record.

Attitudes and Motivation

Digital literacy affects the patient's attitude and motivation when deciding whether to try the self-management system. HCPs described how patients with high digital literacy were eager to try the self-management system, while those with low digital literacy were more reluctant and needed more support to make it work. For some patients, wanting to challenge themselves and learn how to use a new technology was a motivator.

> *I thought, "this is going to be interesting. I must try this!" And then I also thought, as I often do, if you find that something is difficult, then you should definitely learn it.* [Patient 8, female, 74 years old]

Patients were encouraged to use the self-management system at least once a week, although after using it for a while, most patients started measuring when needed, usually in connection with periods of exacerbation of their asthma. Some patients, however, planned to use it more regularly before a health care appointment to provide additional data on their current asthma control for the HCPs, indicating some variation in patients' tracking strategies.

> *I might not use it regularly, but when I start to feel that something is off, I immediately start using it, and then I can see, Yes, my asthma's not good now. I'll have to take more medication.* [Patient #2, Female, 58 years old]

Discussion

Principal Findings

We found that the use of a digital self-management system for asthma was appreciated by patients and HCPs, as it supported empowerment and proved beneficial for both patients and HCPs. The system helped patients gain better knowledge about their chronic condition and provided them with tools and skills to manage the disease. The data generated by the system enabled HCPs to prioritize patients with greater needs for follow-up, thereby supporting a more efficient allocation of health care resources. By empowering patients who are willing and able to take greater responsibility for their own care, the system also allowed HCPs to dedicate more time to those requiring direct personal contact. However, self-monitoring is not without challenges. It demands additional effort and management from both patients and HCPs [38,39], highlighting the need to adapt existing health care delivery models to accommodate these new responsibilities.

The main theme, data-supported empowerment, was facilitated by patient-generated health data. This was particularly evident in 2 of the 3 subthemes: empowerment by awareness, knowledge, and learning, and contact health care-patient. The system helped patients learn about factors affecting their asthma symptoms, making them better equipped to manage their condition and proactively adjust their medications to prevent exacerbations. These findings are supported by previous research that has shown that digital technology can support patients in better understanding their symptoms and condition [30,40-43].

Consistent with earlier studies, the patient-generated health data provided by the system functioned as decision support for HCPs, helped patients become more informed, supported self-care, and contributed to shared decision-making [44,45]. These experiences align with Bandura's definition of self-efficacy as the belief in one's ability to organize and execute actions required to manage prospective situations [37].

Including both patients and HCPs in the study enabled the identification of differences in their experiences of using digital self-management tools. The subtheme Empowerment by awareness, knowledge, and learning was emphasized more by patients than by HCPs. However, HCPs appreciated the patients' improved empowerment and self-efficacy and believed that this would positively affect the patients' asthma control. Physicians have expressed similar views on patient-generated health data and have advocated for digital solutions to improve care [46].
