Although patients can independently use the system, it may also create expectations that health care services cannot always meet. Some patients expected feedback from HCPs based on their reported data and were disappointed when this did not occur. However, some HCPs did proactively contact patients when they noticed a deterioration in asthma control. Personalized feedback is a key factor in achieving optimal outcomes and quality of care [41,47,48], but both patients and HCPs must have clear expectations and understand their respective responsibilities [49]. To ensure equity in care, it is also essential to establish routines for HCPs so that monitoring is streamlined and not dependent on the individual HCPs' engagement.

In contrast to the findings from self-tracking in Parkinson disease, where patients found tracking burdensome and were unsure what to monitor [50], our study showed that patients were guided by the system and adapted their monitoring to periods when they experienced a greater need. Thus, the patients were not bound to monitor at certain times, but when they were motivated. This ad hoc pattern, rather than a continuous approach to self-monitoring, adopts a symptom-triggered, pragmatic strategy shaped by perceived relevance, burden, and confidence in their self-awareness. While this adaptive use may support sustainable engagement, it can also limit the early detection of gradual changes in asthma control. This needs to be considered in both the design of the self-management system, including in the development of algorithms to give treatment advice, and in the guidance to patients. The latter may include instructing patients to repeat measurements when they feel well on a regular basis, even if not measuring continuously, to ensure that the system does not interpret poor results as a new normal if patients only measure when experiencing worse symptoms. In illnesses where symptoms are not easily acknowledged, for example, diabetes or hypertension, the incentives to track may be experienced differently.

Certain findings in our study are specific to asthma, such as the importance of monitoring lung function and adjusting medication in response to symptoms. The system's ability to support these tasks was central to participants' positive experiences. At the same time, several themes, such as the need for tailored support, usability, and integration into daily routines, are likely relevant to other chronic conditions. By distinguishing asthma-specific needs from general principles of digital self-management, the study contributes both to condition-specific knowledge and broader digital health research.

This study shows that digital self-management systems, such as the one described in our study, may contribute to a novel way of delivering health care for individuals with chronic conditions, but it also highlights difficulties that must be addressed. Our findings support the potential of digital tools to facilitate self-management but also highlight the importance of considering the broader context in which such management occurs. As May et al [51] argue, self-management can impose a *burden of treatment*, particularly when health care systems shift responsibilities to patients without adequate support. This underscores the need to view self-management not only as an individual behavior but as a socially situated practice shaped by interactions with HCPs, access to resources, and systemic structures [52].

Well-functioning self-management systems have the potential to optimize care, save time for HCPs, and deliver more cost-effective health care. Further research is needed to determine whether digital self-management systems improve patient outcomes. The ongoing randomized controlled trial will provide additional insights into this. Future studies should also focus on establishing the factors necessary to implement and integrate self-management for patients, and its use by HCPs in primary care in order to maximize its gain.

The findings of this study suggest several implications for the design of digital self-management systems. For instance, patients valued features that provided immediate feedback on their asthma status, which enhanced their sense of control. However, some struggled with interpreting data, indicating a need for clearer visualizations and integrated guidance. Nurses emphasized the importance of seamless integration with existing systems to avoid the duplication of work. These insights point to the need for user-centered design that accommodates varying levels of digital literacy and supports both autonomous use and professional collaboration.

Strengths and Limitations

In line with qualitative research traditions, particularly those using inductive content analysis, we formulated a broad aim rather than predefined research questions. This approach allows for openness to participants' perspectives and supports the exploratory nature of the study, where themes and insights emerge from the data rather than being constrained by specific hypotheses [36]. The use of semistructured interviews also facilitated an in-depth exploration of participants' experiences. Multiple researchers independently coded the data, enhancing credibility and reliability. Discrepancies were resolved through thorough discussions within the research team.

The data for this study were collected in 2021 to 2023. While digital self-management technologies continue to evolve rapidly, the key challenges identified by patients and HCPs, such as interoperability problems, varying levels of digital literacy, and their impact on attitude and motivation in using digital tools, remain highly relevant today. Nevertheless, there is a need for ongoing research to explore how digital health technologies may influence patients' and HCPs' experiences, engagement, and interactions with these tools.

A limitation of the study is the predominance of older patients (average age 65 years) and female patients. Age is a known barrier to adopting digital technology. However, participants

XSL•FO
RenderX

were generally satisfied with the system's usability, and younger users were unlikely to face additional challenges.

The interview guide was not pilot tested; however, it was carefully designed (by LJH, HH, MH), leveraging collective expertise and wide experience in the field. While it was neither formally validated nor pilot-tested, we ensured its robustness through several internal reviews and revisions. To facilitate participation among both patients and HCPs, interviews were conducted either online (via Zoom) or by telephone, based on the respondents' preference. While this approach enabled flexibility and accessibility, it may have limited the ability to observe nonverbal cues and establish rapport in the same way as face-to-face interviews.

We consider the number of interviews with patients to have been sufficient to achieve saturation. That only 6 specialist asthma nurses participated is a limitation; however, this reflects the total number of eligible nurses at the participating units.

The relatively low number of patients who volunteered to be interviewed potentially creates a selection bias where those who did not respond to the invitation might have had a more negative perception of the self-management system. There is also a selection bias concerning which patients initially chose to try the self-management system; however, this would likely be replicated in a real implementation, making our results relevant to future users of the digital self-management system. Yet, further studies involving a broader and more diverse group of patients, including those who chose not to engage with the self-management system, are needed to better understand barriers to adoption and to capture a wider range of experiences.

While the qualitative nature of the study does not guarantee the generalizability of the results, we argue that they are transferable to similar patient groups and contexts. Still, we cannot exclude that some patient groups cannot take advantage of the self-management system. To counteract that, HCPs must be observant and identify those and provide physical contact when needed.

Conclusions

This study provides novel insights into the real-world use of a digital self-management system for asthma, drawing on the perspectives of both patients and specialist nurses after extended use. A key contribution of this study is the identification of how digital self-management systems can both empower users and simultaneously shift responsibilities in ways that require careful negotiation between patients and HCPs. These findings underscore the importance of clear communication about expectations, roles, and responsibilities when implementing digital tools in chronic care.

Moreover, the study emphasizes the need for systems to be adaptable to individual needs and seamlessly integrated with existing digital infrastructures to support sustainable use. Patients and HCPs must know how to interact with and what to expect from these systems for them to promote a better way of delivering health care for people with chronic conditions. Clear communication about changes in workflow and responsibilities is essential to ensure successful implementation and improved health care delivery.

By focusing on asthma, a condition with specific self-monitoring and treatment demands, this study adds to the understanding of how digital tools can be tailored to support condition-specific needs while also offering transferable lessons for the broader field of chronic disease management.

Acknowledgments

We want to thank Björn Nordlund and colleagues at Medituner who were responsible for the randomized controlled quantitative study.

We also like to thank the primary care of Tiohundra in Norrtälje.

Funding

This work was supported by AFA Försäkring (190210).

Data Availability

The datasets generated and analyzed during the current study are not publicly available since the qualitative data collected cannot be shared without risking the study participants' privacy. For inquiries regarding the dataset, contact the corresponding author.

Authors' Contributions

MH, HH, and LJH were responsible for designing the study. MH, ND, and SR collected the data. LJH, MH, ND, and SR performed the initial analysis of the data. LJH, MH, ND, SR, GP, and HH were responsible for the final interpretation of the data. All authors contributed to writing, reading, and approving the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Telemedicine has rapidly expanded worldwide due to its convenience and accessibility. In China, an increasing number of hospitals have begun offering telemedicine services; however, patient utilization remains relatively low. Limited research has examined patients' behaviors during the process of adopting telemedicine services.

Objective: This study aimed to identify barriers to and enablers for patients using telemedicine services and to formulate implementation strategies.

Methods: We conducted semistructured qualitative interviews based on the Theoretical Domains Framework (TDF) to identify barriers and enablers to telemedicine utilization. Twenty-one patients who had used Peking University Third Hospital's telemedicine services were included in the interviews. Data were analyzed using NVivo 12.0 with deductive thematic analysis guided by the TDF. Moreover, a group of experts was assembled to devise potential intervention strategies.

Results: A total of 28 themes were identified, including 14 barriers and 14 enablers across 5 of the 14 TDF domains. The most frequently reported barriers were operational challenges, prolonged waiting periods from asynchronous communication, and doubts about therapeutic efficacy, whereas the most frequently mentioned enablers were the convenience of telemedicine, time conservation, and support from hospitals. On the basis of these factors, we devised 6 intervention strategies.

Conclusions: This study demonstrated that patients' utilization of telemedicine services was affected by several barriers and enablers, including system architecture and design, patient interactions using telemedicine, and external assistance. To enhance the utilization, these factors must be meticulously considered. This study also suggests strategies to enhance the utilization of telemedicine.

telemedicine services; Theoretical Domains Framework; barriers; enablers; patients; qualitative study

Introduction

With the rapid advancement of information technology, telemedicine services have expanded globally [1,2]. In China, the provision of telemedicine services by medical institutions has increased significantly since the COVID-19 pandemic [3]. Telemedicine services have expanded patients' health care options [4]. Telemedicine is thought to enhance the efficiency of health care services [5,6], decrease medical costs [7,8], improve patient satisfaction [9], and facilitate the equitable distribution of medical resources worldwide [10,11]. Despite the growing number of institutions providing telemedicine, patient utilization remains low. As of 2023, more than 3000 institutions had provided telemedicine services, delivering nearly 100 million virtual visits. Despite the seemingly large service volume, telemedicine accounts for only 1% of all visits [12], a proportion further validated by patient interviews [13]. Conversely, almost 20% of medical consultations in the United States were performed via telemedicine in 2020 [14]. The establishment of telemedicine services without corresponding

XSL•FO
RenderX

utilization has resulted in a significant waste of financial and human resources.

To enhance telemedicine utilization, it is crucial to identify and understand the factors influencing patient engagement. Previous studies have identified demographic factors, such as age [15], co-residence with children [16], and education [17], but these factors are difficult to change. Consequently, researchers turned to behavioral frameworks, such as the unified theory of acceptance and use of technology (UTAUT) [18], the technology acceptance model (TAM) [19], and the theory of planned behavior [20]. These frameworks have helped identify factors, such as perceived usefulness [21], ease of use [22], and social influence [23], as critical precursors to user intention. However, these models primarily focus on reflective processes, namely, how cognitive evaluations lead to the intention to use. Therefore, these classical models offer less granularity regarding the contextual barriers, habitual behaviors, and skill gaps that prevent intention from translating into actual usage in real-world health care environments.

The Theoretical Domains Framework (TDF) addresses this gap not by discarding prior theories but by synthesizing them into a more granular, intervention-oriented structure rooted in the capability, opportunity, and motivation system [24]. Thus, adopting the TDF allows for a true integration of classical constructs: for instance, the "perceived ease of use" in TAM is no longer just a perception but is further defined in operational context as "capability" (ie, the knowledge and skills domains); "social influence" in the UTAUT and the theory of planned behavior is recontextualized within "opportunity" (ie, the social influences domain); and "perceived usefulness" aligns well with "motivation" (ie, the beliefs about capabilities and beliefs about consequences domains) [25].

Therefore, the TDF effectively extends the theoretical boundary beyond the cognitive focus of TAM and UTAUT. By incorporating less-explored domains, such as environmental context and resources, the TDF captures the contextual drivers of behaviors that traditional models often overlook [26,27]. Its comprehensiveness enables our research to move beyond a simple prediction of adoption intention. Instead, it provides a diagnostic structure to identify relevant barriers and enablers affecting telemedicine usage [28,29]. Adopting the TDF thus situates our work within the existing literature, bridging the well-established cognitive constructs of TAM and UTAUT with the implementation-focused depth required for designing interventions aimed at improving patient utilization of telemedicine services in China.

Building on this theoretical foundation, this study targets patients who have used telemedicine services in China, aiming to examine their behaviors and psychological aspects during the telemedicine process. It used semistructured qualitative interviews based on the TDF to ascertain barriers and enablers to telemedicine adoption. Our research may offer actionable evidence to support the refinement of telemedicine platforms and the development of patient-centered service models in future practice.

Methods

Study Design

We conducted the survey in Beijing, a leading Chinese metropolis in the development of telemedicine. This study focused on tertiary public hospitals, which deliver the majority of telemedicine services in China and are highly trusted and sought after by patients [30,31]. Peking University Third Hospital, a tertiary public hospital, serves as the governing institution of the Beijing Telemedicine Quality Control Center [32]. It ranks among the top 10 hospitals in Beijing in terms of telemedicine user volume, with patients coming from dozens of provinces nationwide over recent years. The hospital provides both synchronous and asynchronous telemedicine consultations, covering the 2 predominant service models in China. Its extensive online services span the entire care process, including prediagnosis, diagnosis, and postdiagnosis.

Participants Recruitment

We used convenience sampling to select patients engaged in real-time video and asynchronous graphic consultations at Peking University Third Hospital. We accounted for patients' varied geographic locations, disease classifications, and socioeconomic statuses to ensure that the sample accurately represented the telemedicine-using patient community. The inclusion criteria were as follows: (1) at least one prior use of telemedicine at Peking University Third Hospital within the past 6 months, (2) willingness to participate in the interview, and (3) adequate communication skills to engage in the interview. Previous literature suggests that thematic saturation in qualitative interview studies is generally achieved before reaching 21 interviews [33]. Accordingly, the intended sample size was 20 to 22 participants in the preliminary phase. When the data collection process yielded no new information about the enablers and barriers influencing access to telemedicine services, data saturation was reached [34].

Interview Guide Development

We applied the TDF throughout the interview design, data collection, and analysis. The TDF guided the development of the interview guide, which included 1 to 3 questions for each of the 14 domains (eg, goals and intentions) [35]. For example, one of the questions was, "What do you know about telemedicine services?" Investigators with expertise in implementation science provided guidance to develop the interview guide. Moreover, we consulted with experts in hospital management, health policy management, and physicians to refine the outline. We conducted 2 preexperiments after the outline was initially finalized. The interview outline was refined slightly after the pretests, and the samples from the pretests were not included in the study due to slight changes. Table 1 presents the TDF domains and corresponding interview questions.

XSL•FO
RenderX

Table . Interview questions aligned with the Theoretical Domains Framework (TDF) domains.

TDF domains	Definition [26]	Definition in this study	Interview questions
Goals	Mental representations of outcomes or end states that an individual wants to achieve	Goals that patients hope to resolve using telemedicine	• What problems can telemedicine help you solve?
Intention	A conscious decision to perform a behavior or resolve to act in a certain way	Patients' willingness or plan to use telemedicine	• How did you know about telemedicine, and why did you try it? • How do you feel about it compared to the offline service?
Knowledge	An awareness of the existence of something	The patient's understanding of telemedicine	• What do you know about telemedicine services?
Skills	An ability or proficiency acquired through practice	The patient's practical ability to operate telemedicine independently	• Are you familiar with using telemedicine services? • Can you independently use telemedicine for online consultations?
Beliefs about capabilities	Acceptance of the truth, reality, or validity about an ability, talent, or facility that a person can put to constructive use	Patients' confidence in their ability to use telemedicine successfully	• To what extent do you feel capable of using telemedicine? • When you use telemedicine, is there someone to help you? If so, who and how?
Optimism	The confidence that things will happen for the best or that desired goals will be attained	Patients' positive expectations about the benefits of telemedicine	• Do you think telemedicine can benefit patients? • Is it beneficial to you? Please provide some examples.
Memory, attention, and decision processes	The ability to retain information, focus selectively on aspects of the environment, and choose between 2 or more alternatives	Cognitive aspects influencing telemedicine patients' memory, concentration, and decision-making	• Are there aspects that complicate the utilization of telemedicine services? Have you faced any particular challenges?
Emotions	A complex reaction pattern, involving experiential, behavioral, and physiological elements, by which the individual attempts to deal with a personally significant matter or event	Patients' emotional experiences when engaging with telemedicine	• How do you feel when you use telemedicine services? • How do you feel about telemedicine services compared to offline service?
Beliefs about consequences	Acceptance of the truth, reality, or validity of outcomes of a behavior in a given situation	Patients' perceptions of the benefits and risks of telemedicine	• What are the enablers of telemedicine services? • What are the barriers to telemedicine services?
Reinforcement	Increasing the probability of a response by arranging a dependent relationship, or contingency, between the response and a given stimulus	Incentives or feedback that motivate patients to use telemedicine	• What incentives can motivate you to use telemedicine services?
Social or professional role and identity	A coherent set of behaviors and displayed personal qualities of an individual in a social or work setting	Patients' perception of their role in health management and its alignment with telemedicine	• Have people around you (family members, friends, etc) used telemedicine services? • What attitudes do they hold about telemedicine services? • Does their perspective affect your decision regarding the visit?
Social influences	Those interpersonal processes that can cause individuals to change their thoughts, feelings, or behaviors	Impact of family, peers, and social norms on telemedicine use	• Do social environment and policies affect your use of telemedicine services? How?

XSL•FO
RenderX

TDF domains	Definition [26]	Definition in this study	Interview questions
Environmental context and resources	Any circumstance of a person's situation or environment that discourages or encourages the development of skills and abilities, independence, social competence, and adaptive behavior	External conditions and resources that facilitate or hinder telemedicine use	• Do you believe that the social environment and policies will influence your utilization of telemedicine services? What is its impact? • Does the availability of resources and support affect your use of telemedicine? How?
Behavioral regulation	Anything aimed at managing or changing objectively observed or measured actions	Patients' strategies to ensure effective use of telemedicine	• What changes are necessary for telemedicine services to succeed? • Do you have any other suggestions to enhance telemedicine usage?

Interview and Data Collection

The formal interview was performed via telephone and approved in January 2024. We secured the participants' informed consent and subsequently audio recorded the interviews using the software's exclusive features. Each interview lasted approximately 10 to 20 minutes. The interviews were conducted in Mandarin Chinese by the authors KL and YY, both of whom had professional training in qualitative interviewing and extensive experience in qualitative research (n=2, one male and one female, health management practitioners). Before each interview, the interviewer provided a brief self-introduction and overview of the interview content to establish rapport with the participant. Only 2 of the interviewers were present during the interview to create a conducive environment for communication. The recordings were transcribed into textual materials within 48 hours after the interviews, and the researcher recorded and sorted the data to ensure consistency. After each interview, participants were sent a prearranged text message, and their data were collected.

Data Coding and Analysis

Interview transcripts were transcribed, organized, and imported into the software NVivo (version 12.0; QSR International Pty Ltd) for coding. We conducted a deductive thematic analysis guided by the TDF and followed 3 steps [36,37]. First, the 14 TDF domains served as an a priori coding framework. Second, the transcripts were reviewed in detail, with relevant content identified and coded into themes. Third, these themes were categorized as either barriers or enablers within the corresponding TDF domains. When a theme was relevant to more than 1 TDF domain, it was assigned to the domain judged to be more closely aligned. Two authors (KL and YY) independently coded the transcripts. Coding discrepancies were resolved through discussion with a third author (YW) until consensus was reached. The coded κ for each level was greater than 0.90. To prepare the results, we tabulated the themes within each TDF domain and tabulated more prominent themes into barriers and enablers separately. A detailed description of the coding process, including example excerpts and coding framework, was provided in Multimedia Appendix 1.

Strategy Development

Following encoding and analysis, we assembled a multidisciplinary panel of hospital experts, including specialists in information technology, clinical practice, and hospital administration leadership. This collaborative endeavor integrated technical, clinical, and operational viewpoints via monthly interdepartmental meetings and methodically structured brainstorming sessions employing implementation science frameworks. Using the TDF model, the panel systematically formulated various intervention options aimed at addressing the identified barriers and enablers.

Ethical Considerations

This study was approved by the Medical Science Research Ethics Committee of Peking University Third Hospital (IRB00006761-M2024029). Participants provided informed consent. We stored the survey data, which were strictly managed to remain confidential. We offered a compensation of 100 yuan (US $13.8) as a token of appreciation to all participants for their involvement in the study.

This study followed established reporting standards for qualitative research and was reported in accordance with the COREQ checklist (Checklist 1).

Results

Participants and Institutions

All interviews were conducted from January to March 2024, covering a duration of 3 months. Twenty-five telephone interviews were conducted, of which 21 were considered legitimate for analysis. Of the 21 interviewees, 13 (62%) were women, and 19 (91%) held a bachelor's degree or higher. The majority (18/21, 85%) of the participants had full-time jobs. The mean interview duration was 13.7 (SD 5.7) minutes. All participants had used telemedicine services at least once, with a mean of 3.46 (SD 2.8) visits as specified in Table 2.

The patient has the ability to collect information	2 (2)

[a]TDF: Theoretical Domains Framework.

The barriers to theoretical domains were referenced a total of 71 times. Specifically, "environmental context and resources" was referenced 33 times; "memory, attention, and decision processes" was referenced 23 times; "beliefs about consequences" was referenced 8 times; "skills" was referenced 6 times; and "beliefs about capabilities" was referenced once. In contrast, the enablers of theoretical domains were referenced a total of 119 times. "Beliefs about consequences" was referenced most frequently, occurring 71 times"; "environmental context and resources" was referenced 37 times; "beliefs about capabilities" was referenced 8 times; and "skills" was referenced 7 times.

Barriers

Environmental Context and Resources

"Environmental context and resources" was the primary barrier. It primarily emphasized user-environment interaction and the functional categories of telemedicine services. On the one hand, user-environment interaction explicitly examined how the design attributes of app influence patient engagement. It encompassed interface usability and system intelligence. On the other hand, the limited variety of functions created barriers. If patients' medical needs were not fully met, they did not use telemedicine services.

> *The software design seems flawed, insufficient prompts and guidance mechanisms make navigation unnecessarily challenging.* [LQ, male, 2-time user]

> *The functions of online consultation are too limited. It would be great if they could be more diverse to meet more demands.* [KJ, female, 8-time user]

Memory, Attention, and Decision Process

The patients' memory, attention, and decision-making processes might cause barriers, including asynchronous communication and the complexity of the process. First, barriers arose from asynchronous communication between patients and physicians. Following patients' inquiries, they frequently endured prolonged delays before receiving a response from the physician, which significantly impacted patients' readiness to use telemedicine. Second, barriers emerged from the complexity of the process. The complexity of the process was referenced 8 times in the interview, exclusively by first-time users. Patients' attention was limited, but too many steps and jumps caused patients to resist the use of telemedicine services.

> *Sometimes we want to contact the physician proactively and leave a message there, but the physician can't see it. We can only wait for the physician to contact us. This is too passive.* [LJT, female, 2-time user]

> *I searched endlessly for the payment page but couldn't find it. The design isn't user-friendly.* [YY, female, 1-time user]

Beliefs About Consequences

"Beliefs about consequences" manifested as barriers from two primary concerns: skepticism about treatment effectiveness and fears of privacy infringements. Primarily, owing to inadequate

XSL•FO
RenderX

communication during telemedicine consultations, patients doubted the efficacy of telemedicine services. In addition, telemedicine necessitated the accumulation of extensive patient data, which led to concerns regarding the potential breach of personal privacy.

> *I believe that online medical consultations are not as reliable as in-person visits. In a physical setting, physicians can conduct thorough examinations, whereas online consultations rely solely on verbal descriptions.* [WWH, male, 1-time user]
>
> *I am genuinely concerned about the potential for my personal information or medical data to be leaked. Given the prevalence of telecom fraud, I prefer to go to hospital.* [YYX, male, 3-time user]

Skills

"Skills" emerged as a critical barrier domain, primarily manifested through deficits in digital health literacy and device operation proficiency. During the interviews, numerous patients indicated that telemedicine presented specific challenges for the older adults.

> *At our age, we're barely comfortable with basic smartphone functions like WeChat. Navigating these sophisticated medical platforms feels overwhelmingly complex.* [ST, female, 3-time user]

Enablers

Beliefs About Consequences

"Beliefs about consequences" was repeatedly highlighted as an enabler, reflecting patients' recognition of the benefits and potential outcomes of telemedicine. First, nearly all polled patients indicated that convenience facilitated their utilization of telemedicine services, with several patients reiterating this point consistently. Second, time conservation emerged as a key enabler, as telemedicine significantly reduced time expenditure, particularly for younger patients. Third, improved appointment accessibility was identified as a crucial enabler. Patients were able to schedule follow-up tests and obtain medications via telemedicine services without concerns regarding registration.

> *After we use it, we think it is really convenient, so we don't have to go to the hospital anymore, and it is not easy for us to go there.* [YY, female, 1-time user]
>
> *I think using this [telemedicine services] can communicate with the physician, the effect is similar, and it is much easier than offline, no need to ask for leave or go to the hospital.* [SST, female, 1-time user]
>
> *I've found departments are readily available on the telemedicine services platform. That's really helpful.* [TXM, female, 7-time user]

Environmental Context and Resources

"Environmental context and resources" was identified as an enabler influencing patients' use of telemedicine services. First, app usability emerged as an enabler, as patients typically perceived that simple operation enhanced their engagement with the telemedicine services. Second, support from the app or hospital proved essential, helping patients easily locate access to telemedicine services and substantially improving utilization. Finally, the comprehensiveness of platform functionalities was recognized as a crucial enabler, as an extensive range of telemedicine services facilitated patients' adoption and use.

> *Telemedicine services are straightforward. I like it.* [WZ, male, 5-time user]
>
> *The hotline service is particularly helpful. Whenever I encounter difficulties, their staff guides me through the process step-by-step.* [LJT, female, 2-time user]
>
> *We hope they'll keep expanding features so we don't have to make endless trips to the hospital anymore.* [PY, male, 2-time user]

Beliefs About Capabilities

"Beliefs about capabilities" evolved as enablers, reflected in two aspects: self-efficacy and prior successful experience. On the one hand, self-efficacy in digital health was largely associated with usage frequency, as expressed by confident users. On the other hand, patients' previous successful experiences influenced their utilization behaviors, as they drew upon earlier eHealth encounters.

> *I'm generally good at figuring out tech stuff. People around me always ask me for advice when they need online medical help.* [YY, female, 1-time user]
>
> *Having used other hospitals' internet services, I assume this APP should work fairly similarly.* [KJ, female, 8-time user]

Skills

"Skills" emerged as a crucial enabler in the use of telemedicine services. In particular, expertise in using mobile phones and information retrieval was frequently mentioned. Individuals with advanced mobile device skills were more inclined to use telemedicine services. In addition, proficiency in information-seeking behaviors was recognized as an enabler.

> *I'm quite comfortable using smartphones daily, so navigating these platforms seems easy.* [LLZ, male, 1-time user]
>
> *I independently researched all relevant information about telemedicine services. Honestly, I'm pretty good at finding what I need.* [YY, female, 1-time user]

Interventions to Improve Patient Utilization of Telemedicine Services

On the basis of these findings, we designed intervention measures addressing barriers and enablers through expert group discussions (Table 5). We assessed the importance of every domain by determining the frequency of citations throughout all transcripts. The domains "beliefs about consequences" and "environmental context and resources" were the most frequently cited, with 75 and 70 mentions, respectively, accounting for 40% and 37% of the total citations.

XSL•FO
RenderX

Table . Evidence-based interventions to improve telemedicine services utilization (n=190).

TDF[a] domains	Frequency, n (%)	Intervention	Implementation details
Beliefs about consequences	75 (39)	Enhance support for first-time users	• Pilot postdischarge coaching in orthopedics • Train family physicians to assist virtual visits
Environmental context and resources	70 (37)	Simplify app functions	• Suspend development of complex features • Optimize core functionalities • Streamline the patient's usage process
Memory, attention, and decision process	23 (12)	Enhance APP guidance and 24/7 support hotline	• Add real-time operation prompts • Enable automatic step progression • Develop an AI[b]-powered patient assistant • Provide step-by-step guidance • Establish rapid complaint resolution • Implement AI-assisted feedback tracking
Skills	13 (7)	Multichannel publicity	• Distribute instructional videos via WeChat or social media • Install interactive kiosks in clinics • Create a physician's promotional webpage
Beliefs about capabilities	9 (5)	Age-friendly adaptation	• Launch large-text interface • Create elderly-specific tutorials • Integrate voice command features

[a]TDF: Theoretical Domains Framework.

[b]AI: artificial intelligence.

In the "beliefs about consequences" domain, convenience emerged as a key factor encouraging patients to use telemedicine. Enhancing the experiences of first-time users was considered essential. It was advisable to offer supplementary services for patients using telemedicine for the first time, thereby enhancing their experience of its convenience.

Furthermore, in the "environmental context and resources" domain, the complexity of using the patient application represented the most prominent barrier factor. It was suggested to simplify the patient interface and limit the proliferation of complex features, hoping to facilitate patients' focus on critical functions to meet the needs of the majority.

Discussion

Principal Findings

This study conducts an in-depth exploration of the relatively underresearched area of telemedicine among Chinese patients. It is the first instance of using the TDF model for conducting interview-based surveys with patients regarding telemedicine, thereby enhancing the scientific rigor of the research. This study found that telemedicine services adoption is jointly shaped by 14 barriers and 14 enablers, including 5 of the 14 TDF domains. This study has found more behavioral and psychological influencing factors in patients compared to other studies. Barriers arose from operational complexity, concerns about privacy and efficacy, asynchronous communication, and so on. Enablers include high convenience and accessibility, simplified system functionalities, and external support. On the basis of identified barriers and enablers, we developed targeted intervention measures and prioritized them based on their relative significance as expressed by the interviewees. In conclusion, this study advances a comprehensive understanding of the determinants influencing this adoption and establishes a theoretical foundation for developing targeted interventions in telemedicine services.

Positive Feedback Mechanisms

Our exploratory analysis of usage frequency indicates that barriers and enablers change alongside patients' cumulative experiences with telemedicine services. First-time or infrequent users were more inclined to highlight challenges associated with accessing the platform and operating system, indicating the significant learning curve of initial usage. In contrast, frequent users recognized constraints in the scope and profundity of

XSL•FO
RenderX

accessible system functionalities while concurrently emphasizing convenience and efficiency as primary enablers. This transition suggests a possible positive feedback loop: as patients become accustomed to the system, operational obstacles lessen, and the perceived advantages of telemedicine become more prominent, hence encouraging further utilization.

This corresponds with previous research [13,38]. Similarly, in the TAM, it is believed that "perceived usefulness" influences behavioral intention [39]. Our research delineates a self-perpetuating feedback loop: utilization of telemedicine services leads to increased satisfaction and reinforced intention to use. This phenomenon highlights the importance of the first usage experience in telemedicine service adoption. Similarly, the anchoring effect in initial interactions profoundly influences long-term commitment. Facilitating smooth navigation and practical convenience during initial interactions might create positive behavioral anchors, promoting regular use of online telemedicine services. Previous research indicates that Michigan Medicine (Ann Arbor) has established a system that incorporates template instructions and anticipatory advice, which can enhance the patient utilization process [40]. Consequently, we advocate for the deployment of multimodal guiding systems, including artificial intelligence–driven triage and a human-assisted hotline.

Duality of Barriers and Enablers

Our study reveals that the utilization of telemedicine services is directionally modulated by coexisting enablers and barriers within the same theoretical domains. The 2 domains, "environmental context and resource" and "the beliefs about consequences," involve many barriers and enablers. Within the identical structural domain, both barriers and enablers arose, and the correlation between the two was notably strong.

The initial point is the discrepancy between functional complexity and operational simplicity. Within the "environmental context and resource" domain, patients simultaneously demand operational simplicity and comprehensive functionalities. To address patients' requirements of operational simplicity, we must reduce the challenges to assure accessibility. This aligns with the findings of our and other research from the viewpoint of physicians [25,41,42]. The complexity of system operation significantly affects both physicians and patients. However, excessive feature expansion paradoxically increases interface complexity, hindering core functionalities. This phenomenon aligns with intrinsic cognitive load theory [43]. In the development of telemedicine services, it is imperative to address this equilibrium. This is a critical aspect that we meticulously consider while devising potential intervention strategies.

The second aspect is the trade-off between convenience and privacy. The "beliefs about consequences" domain encompasses opposing factors: perceived convenience and privacy concerns. In the study, the convenience of telemedicine services is the most frequently mentioned enabler by patients. However, this depends on patients supplying comprehensive personal information, medical history, and privacy. This also results in an elevated danger of personal privacy breaches. Although the issue of privacy breaches is only mentioned once in this study, it is frequently cited as a barrier in many studies on the use of telemedicine services [44]. Patients tend to resist using telemedicine services due to the risk of privacy breaches [45]. This also results in a simultaneous presence of dependence on convenience and sensitivity to contradictions, leading to conflicting and hesitant feelings in patients during the usage process [46].

The Mismatch Between the Demand and Usage Capacity

In skills, digital literacy is a significant influencing element. Numerous interviewers highlighted the concern of digital literacy for older adults, despite the interviewers in the study being youthful. Older patients, despite increasing demand resulting from mobility restrictions and multimorbidity, face barriers due to limited digital literacy and adaptability [47,48]. In contrast, younger groups with technical skills demonstrate reduced demand. This generational mismatch hinders the use of telemedicine services by patients.

In establishing intervention strategies for telemedicine services, it is essential to address the requirements and features of both generations, rather than focusing on only one group. The alteration of text size was frequently referenced during the interview. Consequently, we devised an app modification strategy for the older people, offering extensive assistance while preserving the core functionality. We have also developed the "family affection account" feature, which enables children to assist the older adults in completing telemedicine-related processes.

Legal and Security Concerns

In research primarily focusing on Western populations, privacy concerns are often cited as a major barrier to adoption [41,49-51]. Yet, this barrier was not prominent in our study, with only one participant explicitly raising privacy-related concerns. We speculate on the possible reasons from both macro levels and micro levels.

At the macro level, the social discourse and privacy awareness in China and Western countries differ markedly. In Europe and the United States, privacy protection is widely discussed [52], whereas in China, discussions regarding medical data privacy are limited, and most patients have low awareness, leading to infrequent expression of privacy concerns [52,53].

At the micro level, Chinese patients typically exhibit a high degree of trust in health care institutions, largely due to their public and government-regulated nature [54], which may further reduce concerns about potential data misuse [55].

Limitations of the Study

This study has 3 main limitations. First, the sample consisted only of individuals who had already used telemedicine and were recruited from a single tertiary public hospital in Beijing, which may limit the generalizability of the findings. Future studies should consider including more diverse populations. Second, using a deductive approach to map participants' statements to TDF domains may result in inconsistencies across coders. To mitigate this inherent limitation of deductive analysis, we used double independent coding, with any discrepancies resolved through adjudication by a third coder. Given the high

XSL•FO
RenderX

consistency of participant narratives regarding barriers and enablers, we believe any residual impact is minimal. Third, as this study represents the first paper in a planned series, its primary goal was to identify barriers to and enablers of telemedicine adoption, thereby laying the foundation for intervention development. Thus, this study did not assess the effectiveness of proposed interventions. In future work, we will incorporate considerations of feasibility and other factors to prioritize specific interventions and rigorously evaluate their effectiveness.

Conclusions

This study offered vital insights by identifying barriers to and enablers of patients using telemedicine services based on the TDF model. These findings not only genuinely represent patients' experiences but also reflect the behavioral and psychological factors in using telemedicine services. This study revealed barriers, including operational difficulties, extended waiting times, and doubts concerning therapeutic effectiveness. Simultaneously, the enablers included the convenience of telemedicine, time conservation, and support from hospitals. Considering these criteria, we developed intervention strategies to enhance patients' access to telemedicine. This research offers a solid foundation for developing more targeted intervention strategies and holds substantial practical implications for improving the telemedicine experience for patients.

Acknowledgments

The authors would like to appreciate the generous time that the interviewed participants gave during data collection. The authors sincerely thank the reviewers for their constructive comments and valuable suggestions, which greatly improved the quality of this manuscript.

Funding

This work was supported by the National Natural Science Foundation (72204005) and Capital's Funds for Health Improvement and Research under grant number 2024-2-40915.

Data Availability

The datasets used in this study are available from the corresponding author upon reasonable request.

Authors' Contributions

KL and YY are co-first authors of this manuscript and contributed equally to this research. KL, YY, and YW planned and designed the study. KL and YY conducted the interview and collected and coded the data. ZS, HL, and YL assisted in organizing the interview records. KZ, XW, and ZH contributed the administrative and technical support of the study. KL, YY, and YW wrote the manuscript. All authors approved the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: South Asian communities in Canada face significant disparities in access to health care and experience higher rates of chronic conditions such as cardiovascular disease, diabetes, and hypertension. Hospital-at-Home services have the potential to improve access and outcomes, yet little is known about how these services are perceived and experienced by South Asian patients and caregivers. Understanding both barriers and facilitators is critical for culturally responsive implementation.

Objective: This study aimed to explore the experiences of South Asian community members with in-person hospital care and their perceptions, attitudes, and expectations regarding virtual Hospital-at-Home services, with the goal of identifying culturally tailored strategies to improve access, quality, and satisfaction.

Methods: A qualitative study using semistructured interviews was conducted with 20 South Asian community members in the Fraser Health region in British Columbia, Canada. Interviews explored experiences with in-person hospital care, perceptions of a virtual hospital service (also known as Hospital-at-Home), and recommendations for enhancing awareness and accessibility. Interviews were audio-recorded, transcribed, and analyzed thematically to identify key patterns in perceptions, experiences, and needs.

Results: Participants described multiple systemic barriers to in-person hospital care, including long wait times, overcrowding, transportation challenges, and difficulty navigating the health system. Cultural and religious needs, such as gender-concordant care and culturally appropriate food, were frequently unmet, while language-concordant care and family involvement were critical to positive experiences. Discrimination and assumptions based on ethnicity or age further shaped perceptions of care. Virtual hospital services were valued for convenience, comfort, reduced exposure to hospital-acquired infections, and support for family involvement. However, participants raised concerns about clinical quality, the absence of physical examinations, digital literacy, privacy, and home-based responsibilities. Acceptance varied by age, immigration status, and familiarity with technology. Participants emphasized the importance of culturally tailored outreach, leveraging community leaders, ethnic media, and peer testimonials to increase awareness and trust.

Conclusions: South Asian patients and caregivers recognize both challenges in traditional hospital care and potential benefits of Hospital-at-Home services. Implementation strategies that address systemic barriers, integrate cultural and linguistic considerations, and engage trusted community networks are essential to improving equity, access, and satisfaction. Findings highlight the need for culturally responsive, patient-centered approaches in the design and delivery of virtual health services for racialized populations.

Introduction

Background

The South Asian population, which includes individuals with ethnic roots originating from Bangladesh, Bhutan, India, Maldives, Nepal, Pakistan, and Sri Lanka, constitutes the largest visible minority or racialized group in Canada [1]. South Asians in Canada face a higher prevalence of cardiovascular disease, diabetes, and hypertension compared to other racialized groups [2,3]. While research suggests that genetic predisposition is a partial contributor [4], the observed health disparities likely also result from social and environmental determinants of health, such as access to higher education, employment opportunities, food security, experiences of discrimination, and access to culturally appropriate health care services [5-7]. It is important to recognize that South Asian populations in Canada are highly diverse, encompassing a range of languages, religions, socioeconomic backgrounds, and migration histories, all of which influence health experiences and outcomes. Previous research has shown that South Asians encounter significant barriers in accessing health care resources for chronic disease prevention and management [8]. Given the inequities and disparities faced by South Asian community members within Canada, innovative care strategies are needed to enhance access to culturally relevant care and improve health outcomes.

Virtual Health Care

Virtual health care, which uses remote technologies to deliver health services, has been identified as a key mechanism for improving access to care [9]. Specifically, virtual hospitals-at-home (commonly referred to as simply Hospital-at-Home) provide an alternative to traditional "brick and mortar" hospital admissions, allowing patients to receive the care they need from the comfort of their own home [10]. This care model has been increasingly used worldwide, accelerated by hospital capacity strains during the COVID-19 pandemic [11,12]. While admitted to a Hospital-at-Home, patients are monitored remotely using digital devices that transmit data to their multidisciplinary care team [10] and have daily virtual consultations via telephone or video, supplemented with home visits when necessary [10].

Research has shown that Hospital-at-Home models are both feasible and effective across various conditions [13]. Studies report that patients opt into virtual hospitals at high rates, and that this approach delivers high-quality care with fewer complications (eg, shorter hospital stays, lower incidence of delirium, and reduced rate of falls [14]). Patients and caregivers frequently express higher satisfaction with home-based care, citing increased comfort, privacy, and family engagement as key benefits [13].

Beyond individual benefits, Hospital-at-Home can alleviate system-wide pressures by reducing wait times, freeing up hospital bed capacity, and expanding access to care [15]. Despite these advantages, challenges remain. Some studies have noted higher readmission risk for patients with complex medical conditions, as well as increased caregiver burden in home settings [13]. Additionally, concerns about communication barriers and the need for structured care coordination highlight areas where further improvements are needed to ensure equitable and effective implementation of Hospital-at-Home [13].

Given the potential of virtual hospitals to enhance access to care, particularly for underserved populations, it is critical to understand and address the barriers to their adoption and use. This is especially important for racialized communities, such as South Asians in Canada, who already experience health disparities and face unique challenges in accessing virtual health services [16].

Virtual Health Use in South Asian Communities

While virtual care has the potential to alleviate barriers experienced by South Asian communities [17] in Canada, and research suggests positive attitudes toward integrating virtual services [16], significant barriers still exist for accessing these services. Studies have shown that age, gender, income, education, and language are associated with the ability to use health-related technologies among Panjabi-speaking (also known as "Punjabi") South Asian individuals in Canada [18] and that language preferences, education, age, and sex predict the use of virtual care among South Asians in Alberta [19]. In both studies, older adults, women, those with a preference for non-English communication, and those with lower educational levels were less likely to engage with virtual care [18,19]. A recent community-based participatory action research project in Surrey, British Columbia, Canada further supported these findings [16]. Through focus groups and photo voice activities, participants identified concerns about their ability to navigate new technologies as they age, gendered responsibilities limiting women's access to technology, and communication difficulties due to language barriers, literacy levels, and digital literacy [16].

Although virtual care is designed to support disease prevention and self-management, these services are often developed without equity in mind, are not culturally responsive, and are generally underused by South Asian populations in Canada [16]. The divide in access and engagement with virtual care services could further exacerbate health disparities faced by South Asian communities [8]. Given the relative novelty of virtual hospitals, little is known about their acceptance among South Asian communities. Future virtual care models must address known barriers to ensure equitable access.

Setting

Health care in British Columbia, Canada, is provided by a provincial health authority, 5 regional health authorities, and a First Nations health authority [20]. The Fraser Health Authority is the largest regional health authority, serving over 2 million people across 20 diverse and rapidly growing communities [21]. According to the 2021 Census, nearly 1 in 5 Fraser Health residents identifies as South Asian [22]. Fraser Health emphasizes understanding how religion, language, and cultural practices influence health to develop customized programs and services.

To better support South Asian communities, Fraser Health established the South Asian Health Institute (SAHI) in 2013, focusing on research, innovation, and evidence-based care [5]. Fraser Health's Virtual Health team supports the development

XSL•FO
RenderX

and implementation of new virtual care pathways across the region. One such pathway is the virtual hospital service. As Fraser Health serves 75% of South Asian residents in the province, it is essential to conduct patient-oriented research, or research done in direct partnership with patients, to understand what matters to South Asian communities when developing the virtual hospital [5].

Research Objectives

This patient-oriented research study aims to engage South Asian community members through 3 primary objectives:

1. Capture and understand the emotional experiences, as well as the perceived barriers and facilitators, of members within South Asian communities in the context of both in-person and Hospital-at-Home systems.
2. Understand the lived experiences of South Asian community members in navigating the health care system and identify gaps in accessing care.
3. Identify opportunities for how Hospital-at-Home services can be implemented to improve the access and flow of care among South Asian communities.

Methods

Overview

This qualitative study used semistructured interviews to explore the experiences, perceptions, and attitudes of South Asian community members in British Columbia, Canada, toward in-person hospital care and the emerging Virtual Hospital-at-Home model. The study was guided by a patient-oriented research approach, prioritizing the perspectives of patients and caregivers to inform culturally relevant virtual care strategies.

This study was guided by a steering group including members from Progressive Intercultural Community Services (PICS) Society [23], Fraser Health's Virtual Health department [24], Fraser Health's SAHI [25], and Fraser Health's Equity, Diversity, and Inclusion team [26], and academic partners from the University of British Columbia and King's College London.

Interviews were guided by a pragmatic epistemology, which seeks to generate practical findings that can be readily applied in real-world settings while also tolerating multiple truths [27]. Although all South Asian community members may be exposed to the same care environments, everyone has unique experiences.

Recruitment

Participants were recruited through convenience sampling using outreach by the PICS Society and the SAHI, and supplemented with community outreach efforts including social media, places of worship, and public libraries. The inclusion criteria were that participants must (1) identify as South Asian, (2) reside within the Fraser Health region, and (3) have been a patient in the hospital in the past year or have been a caregiver to someone in the hospital in the past year. Recruitment continued until thematic saturation was reached, when no new concepts emerged from subsequent interviews.

Data Collection

South Asian community members were interviewed to understand their lived experiences navigating the virtual health care system. A topic guide, adapted from previous Virtual Health patient partner workshops, was revised with feedback from community members and edited by Fraser Health's plain language team for clarity. The guide covered 2 primary domains: (1) experiences with in-person hospital care, including barriers, facilitators, and family involvement; and (2) perceptions of, and attitudes toward, the Virtual Hospital-at-Home model, including benefits, concerns, and strategies for community engagement. Interviews began with a screening question to classify participants as patients, caregivers, or both. A full interview topic guide is provided in Multimedia Appendix 1.

Thirty- to 60-minute, one-on-one interviews were conducted via Microsoft Teams, with the PICS Society providing technical support when needed to ensure participant access to the platform. To ensure accessibility, interpretation services were available in Panjabi, Hindi, Urdu, and Pashto. All interviews were audio-recorded with participant consent, transcribed verbatim, and translated where required by members of the research team. Interviews were conducted by EW and MK, who both had master's degrees and worked as a "Research Assistant" and the "Research and Knowledge Translation Lead" for the Virtual Health department at the time of interviews. All interviewees had no prior relationships with those conducting the interviews.

Data Analysis

Thematic analysis guided by the approach of Braun and Clarke [28] was conducted using NVivo (QSR International). First, transcripts were read repeatedly for familiarization. An initial set of open codes was inductively generated to capture salient features of the data. Codes were iteratively refined and grouped into higher-order categories. Themes were then developed through constant comparison across transcripts, paying attention to both convergent and divergent perspectives. Theme prevalence was assessed approximately by noting how many participants raised each theme, though exact tallies were not feasible given the conversational variability of interviews. Findings were also interpreted with attention to cultural safety and equity considerations relevant to South Asian communities in the Fraser Health region.

Coding was conducted by MK and cross-checked by MM; discrepancies were resolved by consensus. For multilingual interviews, translations were reviewed by bilingual team members to ensure conceptual equivalence. Final themes were reviewed and refined in consultation with the steering committee to enhance cultural validity. The steering committee did not influence the coding of raw data. Thematic saturation was achieved by the 17th interview; 3 additional interviews confirmed that no new themes emerged.

Ethical Considerations

This study received approval from the Fraser Health Research Ethics Board (H23-03144). Interested participants were sent a consent form, the topic guide, and a video explaining the Hospital-at-Home to review beforehand. Informed consent for

XSL•FO
RenderX

participation and interview recording was obtained verbally prior to the interview. To protect privacy and confidentiality, all transcripts were anonymized, and identifiers were removed prior to analysis. Data were stored securely on password-protected institutional servers. Participants were compensated with a US $14.86 gift card at the conclusion of their interview.

Results

Participant Characteristics

Twenty participants were interviewed (n=9 male, n=11 female). Participants were aged 19 - 79 years, most commonly between 60 - 69 years (6/20, 30%). Younger adults aged 19 - 29 (n=5), 30 - 39 (n=4), and 40 - 49 (n=4) years were also represented, along with 1 participant in their 70s. Interviews were conducted in English (n=15), Panjabi (n=3), Pashto (n=1), and Hindi (n=1).

Most participants were originally from India (14/20, 70%), with others from Afghanistan (3/20, 15%), and smaller representations from Iraq (n=1), Pakistan (n=1), and India and Fiji (n=1). Half had lived in the community for more than 10 years (n=10); the remainder were more recent arrivals (n=4 lived in Canada <1 year, n=5 lived here 1 - 3 years). Regarding immigration status, 9 were Canadian citizens and 11 were permanent residents.

Self-rated health was generally positive—6 participants (30%) rated their health as "very good," 6 (30%) as "good," and 8 (40%) as "average." Six participants (30%) reported having a chronic condition. Participants included caregivers only (7/20, 35%), patients only (6/20, 30%), and both caregivers and patients (5/20, 25%). Two participants also contributed professional perspectives, working in newcomer services and health care.

All participants had access to a smartphone (20/20, 100%), while 11 (55%) had access to a tablet and 11 (55%) had access to a laptop. Ten participants (50%) had all 3 devices, while 8 (40%) had only a smartphone. Device use was frequent—14 (70%) used devices daily or multiple times per day, 4 (20%) used devices regularly but not daily, and 2 (10%) did not regularly use devices.

Experiences of In-Person Hospital Care

Overview

Participants described a mix of challenges and positive experiences with in-person hospital care. Six overarching themes emerged: systemic barriers to accessing care, communication and language barriers, cultural and religious needs not met, family and caregiver roles, discrimination and bias, and positive experiences and gratitude. Experiences varied by age, gender, immigration status, and length of time in Canada. Older and more recently arrived participants reported more barriers than younger or Canadian-born participants.

Systemic Barriers to Accessing Care

Participants frequently reported challenges accessing timely and appropriate hospital services, including long wait times, overcrowding, transportation difficulties, and navigation challenges. These barriers contributed to frustration, fatigue, and inequitable access.

Long Wait Times

Wait times were among the most common challenges mentioned. Many participants described hours-long waits in emergency departments, sometimes extending overnight or across multiple days. As 1 participant shared, "we have waited with a broken wrist 28 hours" (P10, female, aged 60 - 69 years, >10 years in community). Another recalled, "you have to wait maybe sometimes 10 hours or more than that and you have a critical illness" (P20, female, aged 60 - 69 years, >10 years in community). Such prolonged waits were perceived as not only inconvenient but also unsafe when health concerns were urgent.

Overcrowding and Understaffing

Participants described hospitals as overcrowded and short-staffed, with patients left in hallways and nurses visibly stretched thin. One participant reported, "patients are all outside in the hallways. They don't even have proper rooms" (P13, female, aged 60 - 69 years, <1 year in community). Another observed, "sometimes you can see like the nurses are really tired, and then you see them overwhelmed with the amount of work" (P11, female, aged 19 - 29 years, >10 years in community). These accounts reflect how structural resource constraints were felt by both patients and providers.

Transportation Difficulties

Transportation presented another layer of inequity, particularly for patients without private vehicles. Some relied on long bus rides with multiple transfers, which became especially challenging for older adults and those with mobility issues. One participant explained,

> *The nearest hospital is like a 45 minute transit ride, but the bus doesn't go directly there. So I have to walk. For me as an able-bodied male, mid-20s, it's fine. But...for my grandma who doesn't drive and can't speak much English, it's very hard.* [P1, male, aged 20 - 29 years, >10 years in community]

Another recalled, "I rely on HandyDART, and if that's not available then my son would have to take time off work to drive me" (P17, female, aged 30 - 39 years, >10 years in community). These logistical challenges shaped how and when participants sought hospital care.

Navigation Challenges for Newcomers

For newcomers to Canada, navigating the health system added further barriers. Several participants spoke about confusion around referrals, insurance, and entitlements. One reflected,

> *I took around a year's time to understand what was MSP and how to access it. What is covered under it and what do I need other insurance for?* [P8, female, aged 30 - 39 years, 1 - 3 years in community]

Another highlighted misunderstanding about referral pathways:

> *You have to first go to a family doctor, and then if the problem is serious then you go to hospital. Many of the people don't have that understanding.* [P6, male, aged 40 - 49 years, >10 years in community]

XSL•FO
RenderX

Such experiences suggest that lack of system literacy can delay or complicate access to hospital care.

Language and Communication

Communication challenges were central to participants' accounts, particularly for older adults and newcomers with limited English proficiency, with many describing difficulties conveying symptoms, understanding instructions, or navigating interactions without the help of family. While some praised interpreters or language-concordant providers, gaps in communication were widely felt and often shaped the overall hospital experience.

Limited English Proficiency

Participants often highlighted the difficulty of explaining their health concerns in English. For example, one explained,

> *If I talk about my grandfather, they don't know how to speak in English...if they are taking them alone into the rooms, they can't express how they're feeling or they can't tell about their problems.* [P5, male, aged 19 - 29 years, 1 - 3 years in community]

Another noted, "when the other person is not from my community, the only hurdle I feel is the language" (P9, female, aged 30 - 39 years, 4 - 6 years in community). These challenges not only caused stress but also risked miscommunication in clinical encounters and increased reliance on family members acting as interpreters. One participant described, "she had a family member of hers that spoke on her behalf and communicated with the doctors" (P4, female, aged 60 - 69 years, >10 years in community). Similarly, another shared, "mom didn't speak English, so until I got there and started helping her she didn't have any good idea as to what was happening" (P14, male, aged 60 - 69 years, >10 years in community). While this reliance on family interpreters ensured patients could understand their care, it also created dependence on family members, sometimes leading to delays or added burdens. Participants also noticed changes over time, including greater availability of translators and culturally diverse staff. As one shared, "now they have translators everywhere, even in the parking. Greeters in the hospital who speak their language" (P17, female, aged 30 - 39 years, >10 years in community). Another noted, "everywhere there are translators in hospitals" (P18, male, aged 70 - 79 years, >10 years in community).

Language-Concordant Care

Participants expressed strong appreciation for health care staff who spoke their language, emphasizing that this reduced stress and improved trust. As one noted, "we prefer to go to [specific hospital] just because the nurses and all the other staff member do speak Panjabi. So it's easier for my grandparents" (P11, female, aged 19 - 29 years, >10 years in community). Another explained, "if the person is from South Asian communities and they are feeling shy or hesitating to say something in front of a White person, a South Asian doctor or nurse can help" (P5, male, aged 19 - 29 years, 1 - 3 years in community). Such accounts highlight how language-concordant care fosters both clarity and cultural comfort.

Cultural and Religious Needs Not Met

Participants frequently described hospital environments that did not align with their cultural or religious values. These included concerns about gender concordance with providers, lack of culturally appropriate food, and perceived insensitivity to religious practices.

Gender-Concordant Care

Gender of providers was an important factor for some participants, particularly for women from Muslim and Sikh backgrounds. One explained, "for me as a Muslim lady, I don't want anybody to touch me if he's a man and get naked in front of him while there is another lady available" (P20, female, aged 60 - 69 years, >10 years in community). Another recalled, "she would have preferred a female nurse, but they had a male" (P1, male, aged 19 - 29 years, >10 years in community). These accounts underscore how gender concordance shaped comfort and dignity in care.

Dietary and Religious Respect

Food was another area where participants felt their needs were not adequately met. Some reported being served meals that conflicted with their dietary or religious practices. For instance, 1 participant explained, "she was a very strict vegetarian, but they fed her beef" (P1, male, aged 19 - 29 years, >10 years in community). Others described hospital food as unappealing or culturally inappropriate:

> *It's a challenge because the hospital food is a challenge for them. They don't like it, obviously, because it's not their cultural food.* [P17, female, aged 30 - 39 years, >10 years in community]

Cultural Insensitivity

In some cases, participants felt their cultural or religious practices were disrespected. One recalled, "she had her religious books and statues by her bed and they moved to a corner by garbage, which is offensive to our religious practices" (P1, male, aged 19 - 29 years, >10 years in community). These incidents, though not universal, left lasting negative impressions and diminished participants' sense of respect for care. Participants recounted instances where staff failed to accommodate dietary and religious needs, sometimes in ways that were profoundly disrespectful.

Family and Caregiver Roles

Family members were described as essential to the hospital experience, serving as translators, advocates, and sources of emotional support. Yet participants also reported that hospital policies and circumstances sometimes limited family involvement, creating both barriers and additional burdens.

Restrictions on Family Presence

Some participants described frustration with restrictions on family members accompanying patients, even when needed for support or translation. One participant recalled, "they were not allowing my family members to come and sit with me" (P2, male, aged 19 - 29 years, <1 year in community). Another shared, "sometimes the person needs emotional support or they need someone from the family...but I can't go with her because

XSL•FO
RenderX

they don't have enough space" (P5, male, aged 19 - 29 years, 1 - 3 years in community). Such restrictions were perceived as leaving patients vulnerable and isolated.

Emotional and Practical Burden on Families

While family involvement was crucial, it often created strain. One participant described, "her son would take her, but he would have to take time off work in order to take her" (P4, female, aged 60 - 69 years, >10 years in community). Another reflected on balancing childcare with caregiving: "sometimes I have to be without food for long times...I cannot also go to the cafeteria with kids" (P9, female, aged 30 - 39 years, 4 - 6 years in community). These stories illustrate how the health system's reliance on families carries significant costs.

Preference for Family Caregiving

While family involvement can be burdensome, many participants preferred it over professional care for trust and cultural reasons. As 1 participant explained, "South Asian people...are more comfortable with their family member, rather than a nurse, doing certain tasks" (P17, female, aged 30 - 39 years, >10 years in community). This highlights how family involvement was not only necessary but often desired.

Discrimination and Bias

Although many participants spoke positively of their care, some described experiences of stereotyping, dismissal, or unequal treatment.

Stereotyping and Assumptions

A few participants reported feeling judged on the basis of cultural stereotypes. One explained, "because they're Indian, they obviously eat unhealthy and because of that they have high blood pressure and heart issues...without doing further research" (P1, male, aged 19 - 29 years, >10 years in community). Such assumptions left participants feeling unseen and unfairly blamed.

Unequal Quality of Care

Others felt that seniors and immigrants received less attentive or less culturally appropriate care. As one participant described, "I've seen that personally with my grandma, that they don't take seniors that seriously" (P11, female, aged 19 - 29 years, >10 years in community). Another reflected, "it's not very culturally appropriate...my grandparents' experience is not the same" (P1, male, aged 19 - 29 years, >10 years in community). These perceptions shaped trust in the system and influenced decisions about where and when to seek care.

Positive Experiences and Gratitude

Despite systemic and cultural challenges, participants consistently recognized skilled, compassionate care. One said,

> *The staff was very good. They were peacefully talking. The doctor was very nice. It was very good.* [P18, male, aged 70 - 79 years,>10 years in community]

Another reflected, "I have the best experience and I was very happy" (P3, male, aged 40 - 49 years, 1 - 3 years in community). Additionally, trust in providers' skill was often expressed as gratitude, even when other barriers were present. For instance, 1 parent stated, "I'm very grateful to all the doctors and nurses who provided care to my child" (P12, female, aged 40 - 49 years, <1 year in community). Such reflections reveal the duality of participants' experiences: systemic and cultural barriers coexisted with respect for the expertise and dedication of individual providers.

Perceptions and Expectations of Hospital-at-Home

Overview

Participants shared diverse perspectives on virtual hospital services, highlighting benefits, limitations, and conditions under which such care is acceptable. Five major themes emerged—convenience, comfort, and family support; cultural and generational differences; quality of care and clinical limitations; emotional safety, privacy, and trust; and barriers to access and technology. Participants' experiences and expectations reflected both practical considerations, such as travel and technology, and cultural and interpersonal factors influencing acceptance. Views often diverged across age, gender, and immigration status, with younger or Canadian-born participants more enthusiastic about virtual care and elders or newcomers expressing hesitation.

Convenience, Comfort, and Family Support

Overview

Participants consistently highlighted the practical and emotional advantages of receiving care at home. Virtual hospital services were valued for reducing stress, increasing comfort, and enabling family involvement, which was seen as supportive both physically and emotionally. Many participants described how being in a familiar environment could enhance recovery, while also reducing exposure to illness compared with hospital settings.

Avoiding Travel and Wait Times

Many participants appreciated the time-saving and stress-reducing aspects of virtual care. One noted,

> *I can be at home and go about my daily things and just wait for a phone call. I don't have to actually sit at all at an actual office anyway.* [P6, male, aged 40 - 49 years, >10 years in community]

Others highlighted avoidance of transportation challenges and hospital stress, stating it would allow them "to get help like at home...I don't have to stuck in the traffic and get stressed out" (P10, female, aged 60 - 69 years, >10 years in community) and "virtual hospitals would be more convenient. He won't have to worry about transportation waiting. Time to come and go" (P7, male, aged 60 - 69 years, 1 - 3 years in community).

Healing at Home

Being at home with family and in a familiar environment was viewed as beneficial for recovery. Participants described emotional and physical advantages: "you are around your family, that motivates you to be more good. I think that's the biggest thing that virtual can provide" (P2, male, aged 19 - 29 years, <1 year in community), and "if this virtual hospital help was available, then definitely he would have felt more better at home rather than at the hospital...we can read books for him, we can sit beside him" (P17, female, aged 30 - 39 years, >10 years in

XSL•FO
RenderX

community). Others emphasized comfort and food preferences, noting,

> *I feel more comfortable in my space...Benefits I can be with my family. That's the best benefit I can eat the food that I want.* [P16, female, aged 30 - 39 years, <1 year in community]

Reduced Exposure to Illness

Participants recognized the safety advantage of avoiding hospital-acquired infections: "It can help many people...rushing to the hospitals because of. danger of getting communicable diseases" (P12, female, aged 40 - 49 years, <1 year in community), and "with the virtual, then there wouldn't be so many people waiting for beds. hospitals have a lot of diseases going around" (P15, female, aged 19 - 29 years, >10 years in community).

Smooth Transitions from Hospital to Home

Several participants highlighted the importance of smooth transitions from hospital to home, emphasizing clear communication, rapid response in emergencies, and reliable monitoring. The availability of equipment and the teach-back style training were viewed as critical.

> *...how the South Asian will be educated...equipment will be there, they'll teach you how to use it. It's important that you use it properly.* [P4, female, aged 60 - 69 years, >10 years in community]

> *If something gets worse, who do I call first? That should be very clear.* [P15, female, aged 19 - 29 years, >10 years in community]

Home-Based Challenges

Participants noted that home environments can pose challenges during recovery, such as stairs, inaccessible bathrooms, or absence of hospital equipment:

> *My bedroom is upstairs and the bathroom is downstairs. After surgery, how can I manage the stairs?* [P7, male, aged 60 - 69 years, 1 - 3 years in community]

> *We don't have special hospital beds at home. Sometimes you need that equipment to recover properly.* [P12, female, aged 40 - 49 years, <1 year in community]

Routine household responsibilities, such as childcare, also limited the ability to rest: "I know if I go home, I have to cook for the other two children and I have to take care of them" (P20, female, aged 60 - 69 years, >10 years in community). Participants worried that home-based care could shift responsibilities onto family members, especially women and elders:

> *Yes, absolutely, definitely. When I am at the hospital, I'm just quite confident that I've been taken care of 100%. But if I am at home, it will put more pressure on me* [P10, female, aged 60 - 69 years, >10 years in community]

Cultural Norms and Generational Differences

Overview

Cultural norms, family expectations, and generational comfort with technology strongly influenced participants' perceptions of virtual hospital care. While younger participants reported ease with online platforms, older adults often struggled with technology and valued in-person monitoring. Cultural beliefs regarding family roles and appropriate care also shaped attitudes toward remote health care.

Generational Divide in Comfort with Technology

Participants highlighted that younger generations were more comfortable with technology, while older adults often struggled. One reflected,

> *For me, growing up in this generation, I'm not shy for technology, but for example, my grandparents, it's very a new world to them. So for them there is more of that disconnect.* [P1, male, aged 19 - 29 years, >10 years in community]

Similarly, a participant noted, "if I imagine my grandmother using this service, she might be overwhelmed with the tablet thing...she would just be like, I just wanna meet people in real" (P16, female, aged 30 - 39 years, <1 year in community).

Cultural Norms and Expectations of Care

Some participants described South Asian cultural preferences for in-hospital monitoring, emphasizing family support and safety:

> *I believe for the South Asian people this will not work very well...I would say at the hospital, I feel the care is around me 24 hours...So I think at the hospital we can get the maximum care.* [P20, female, aged 60 - 69 years, >10 years in community]

Others stressed the importance of culturally sensitive approaches, including language support: "I think having that community-centered culturally sensitive approach to healthcare is really important because this generic advice doesn't help the community" (P1, male, aged 19 - 29 years, >10 years in community).

Absence of Support Persons at Home and Immigrant Social Networks

Some participants identified the absence of support persons at home as a barrier to virtual care. As immigrants, many noted that they no longer have the robust support systems they relied on in their native countries. While they can manage their daily lives, participants expressed doubts about their ability to maintain the same level of self-care when unwell, particularly those living alone or with family members who work full time.

> *It's very hard because you don't have much people around you...You don't have a community...You don't have neighbors as we use to have uh back in in Asia or South East Asia, there's a lot of people around you...But here, because we are immigrant, it's very limited people that we know and it's not the bond even it's not that because of the type of living here as*

XSL•FO
RenderX

we all work or just us to take care of the family...So our relationship is very limited. [P20, female, aged 60 - 69 years, >10 years in community]

Quality of Care and Clinical Limitations

Overview

While participants acknowledged the convenience of virtual care, many expressed concerns about clinical quality. The inability to conduct physical examinations and the perception that remote care could be "lesser" than in-person attention were recurring issues. Participants suggested virtual care might be suitable for routine or minor issues, but not for serious medical concerns.

Value of Physical Examination

Many participants expressed concern that virtual care could not substitute for hands-on assessment:

In my view...the Virtual Hospital will not be very effective if the patient is not present in front of the doctor...virtual care will be only communication. [P3, male, aged 40 - 49 years, 1 - 3 years in community]

My knee problem...I wasn't sure how I could show my knees over the phone? [P13, female, aged 60 - 69 years, <1 year in community]

Perceptions of "Lesser Care"

Some participants worried that virtual hospital services could be perceived as inferior, noting, "I just feel like if it's online like people would think like, oh, you're not taking me seriously" (P11, female, aged 19 - 29 years, >10 years in community) and "they wouldn't fully be supportive...they would think ohh I would receive better care at a hospital rather than me taking my medications on my own" (P15, female, aged 19 - 29 years, >10 years in community). Participants suggested virtual care is appropriate for routine or minor concerns, while serious conditions require in-person attention:

If it's a small thing, then Virtual Hospital is better. But if it's like a big issue, then she would prefer in-person care. [P4, female, aged 60 - 69 years, >10 years in community]

Emotional Safety, Privacy, and Trust

Overview

Emotional well-being, privacy, and trust emerged as key considerations. Participants emphasized the importance of empathy and interpersonal connection, while also noting concerns about privacy at home and the potential for fraud or security issues.

Need for Interpersonal Connection

Participants emphasized empathy and human touch, even via remote communication:

Having that interpersonal touch as much as you can...sometimes having that personal touch makes them feel better. But through a phone, you don't really get that personal touch, so still making sure whoever is on the line is caring and kind. [P1, male, aged 19 - 29 years, >10 years in community]

Concerns About Privacy at Home

Some expressed difficulties discussing sensitive issues at home:

If I want to tell you something, but I don't want to tell other people at home it could be a concern. So it's better to go to Doctor [in person]. [P10, female, aged 60 - 69 years, >10 years in community]

Trust in Fraser Health's Professionalism

Participants generally assumed privacy and security were managed by a reputable provider: "I would also assume because Fraser Health is a reputed professional organization, they would have already taken all of these requisite steps to make sure their privacy is covered" (P6, male, aged 40 - 49 years, >10 years in community), and "I feel like Fraser Health has really good system for privacy" (P11, female, aged 19 - 29 years, >10 years in community).

Apprehension About Fraud or Scams

Some participants noted the risk of unknown numbers or digital communication: "Only thing is sometimes when you get a call from an unknown number, it seems like it might be a fraud" (P7, male, aged 60 - 69 years, 1 - 3 years in community).

Barriers to Access and Technology

Despite interest in virtual care, participants noted practical barriers related to technology and digital literacy. These challenges were particularly salient for older adults and recent immigrants.

Digital Literacy Challenges

Older adults may lack experience with technology: "Maybe having like info sessions at temples. helping teach the elders about how it works" (P1, male, aged 19 - 29 years, >10 years in community), and "if I imagine my grandmother using this service, she might be overwhelmed with the tablet thing" (P16, female, aged 30 - 39 years, <1 year in community).

Access to Equipment

Not all households have necessary devices: "Not just like assuming like they have a laptop on them...my mom's mom has never touched a computer in her life" (P1, male, aged 19 - 29 years, >10 years in community).

Suggestions for Building Awareness of Virtual Hospitals at Home

Participants consistently highlighted the importance of proactive outreach and awareness-building, noting that many newcomers and elders were unaware of existing programs. Outreach strategies were rooted in community-based trust networks, emphasizing cultural familiarity, word of mouth, and visible engagement in South Asian gathering spaces.

Leveraging Trusted Spaces and Leaders

Participants recommended outreach through temples, gurdwaras, and mosques, where health authority representatives could host training or information sessions. They stressed that engagement

XSL•FO
RenderX

would be more effective if facilitated by respected community leaders.

> *...meeting with the community leaders and they can like bring it to the community. I know at one of my temples...they have community members teaching them...maybe having someone from Fraser Health going in and doing a training session.* [P6, male, aged 40 - 49 years, >10 years in community]

Testimonials and Peer Influence

Most participants expressed hesitation about being the first to try the new program, preferring to hear positive testimonials from others before committing. They also mentioned that even a few negative reviews could deter their interest in the program. This reflects the strong sense of mutual trust and reliance on community members, which participants valued just as much as official information provided by the health authority. Hearing positive testimonials from peers was seen as essential to building trust and encouraging adoption.

> *...having like some kind of testimonial or proven proof that it is already worked before...that would just remove the stress or the doubt. Once it becomes like accepted as a normal thing, that would make it easy.* [P7, male, aged 60 - 69 years, 1 - 3 years in community]

Community Events and Visible Outreach

To engage South Asian communities, participants recommended venues such as libraries, community centers, places of worship, and networking events where community members regularly gather. Additionally, cultural and religious events, such as the annual Vaisakhi Day Parade held in Surrey, were identified as valuable outreach opportunities. Participants suggested setting up information booths equipped with printed materials, visual media, and representatives from the health authority to disseminate information about virtual care in the languages spoken by the community. They noted that organizations providing employment or settlement support (such as PICS) already use these channels effectively, demonstrating their potential for outreach. Furthermore, participants recommended collaborating with local South Asian–based nonprofit organizations.

> *...we have like festivals of the year, you know Vaisakhi, Culture Fest...maybe having like a Fraser Health pop up so community members can engage with it and educate it that way. Trying to get in the community where you can would be the best.* [P6, male, aged 40 - 49 years, >10 years in community]

Ethnic Media and Social Platforms

To reach a broader demographic, participants suggested using local South Asian newspapers, radio, or TV networks for individuals to share their lived experiences. This would particularly target the working population who often listen to the radio while driving. Additionally, some participants recommended using social media, a popular platform for news consumption, to further raise awareness.

> *I think doing more awareness about this virtual...talking with the people, providing more awareness to the people that they should know that such kind of program is existed.* [P7, male, aged 60 - 69 years, 1 - 3 years in community]

Discussion

Principal Findings

This qualitative study explored the experiences of South Asian community members in the Fraser Health region with in-person hospital services, and their perceptions and expectations of Hospital-at-Home models. Participants described significant systemic and cultural barriers in traditional hospital settings, alongside gratitude for providers' skill and compassion. When discussing Hospital-at-Home, participants articulated both enthusiasm for its convenience and comfort and concerns about quality of care, cultural alignment, and feasibility in their home environments. Taken together, these findings provide important insights for health system planners seeking to advance culturally safe and equitable virtual hospital services.

Summary of Key Findings

Participants' hospital experiences reflected 6 key themes: (1) systemic barriers, including long wait times, overcrowding, transportation, and navigation challenges; (2) communication and language barriers; (3) unmet cultural and religious needs; (4) essential but burdensome family and caregiver roles; (5) experiences of discrimination and bias; and (6) positive encounters characterized by gratitude and respect. These issues varied across age, gender, and immigration status, with older and more recently arrived participants reporting more barriers.

Expectations of Hospital-at-Home revealed 5 major themes: (1) convenience, comfort, and family support; (2) cultural and generational differences; (3) quality of care and clinical limitations; (4) emotional safety, privacy, and trust; and (5) barriers to access and technology. Across both sets of findings, participants consistently highlighted the central role of family, the importance of cultural sensitivity, and the need for accessible information delivered through trusted community channels.

Participants' mixed experiences with in-person hospitals provide essential context for understanding perceptions of Hospital-at-Home. Structural challenges, such as prolonged emergency department waits and overcrowded wards, reduced trust in the timeliness and equity of hospital care. For newcomers, health system literacy gaps compounded these difficulties, as participants struggled to understand coverage, referral pathways, and navigation. These frustrations may increase openness to Hospital-at-Home as an alternative, particularly if it can reduce wait times and enhance comfort. However, systemic inequities that disadvantage newcomers and elders risk being reproduced in virtual formats unless addressed proactively.

Comparison to Existing Literature

Previous research has extensively documented barriers to virtual health care access for South Asians. Studies by Zibrik et al [18] and Makowsky et al [19] highlight disparities in virtual care

XSL•FO
RenderX

access, while Dahal et al [29] and Hyman et al [16] emphasize the impact of socioeconomic factors on virtual health engagement. Notably, few studies have examined Hospital-at-Home programs within other racial or ethnic minority communities, limiting opportunities for direct comparison. This scarcity of literature underscores the novelty of exploring Hospital-at-Home acceptability specifically among South Asian populations in Canada and highlights the unique structural, cultural, and familial considerations identified in this study.

Findings from this study align with existing literature in confirming that language barriers, trust in health care providers, and digital literacy shape perceptions toward adopting virtual care. Moreover, consistent with Bhalla et al [30], community-driven strategies, such as the role of family members in health decision-making and the influence of social networks such as WhatsApp, play a crucial role in health care engagement for the South Asian community. These findings were echoed by participants of this study who noted their attitudes toward Hospital-at-Home care could be highly influenced by peer testimonials.

A key distinction of this study is its focus on Hospital-at-Home models rather than primary care or outpatient virtual services, which have been the emphasis of much prior research. While previous research has explored South Asians' engagement with digital tools for chronic disease management and primary care, this study surfaces concerns that are specific to the delivery of hospital-level care in the home. In particular, it contributes new insights on the role of the home environment, including the physical suitability of the space, the availability and involvement of family caregivers, the complexities of intergenerational living arrangements, and the burden of household responsibilities during recovery from acute episodes.

These burdens often fall disproportionately on women, particularly mothers, reflecting traditional caregiving roles common in South Asian cultures that persist postimmigration. Female caregivers frequently manage both direct patient care and household duties, reinforcing the gendered division of labor described in previous literature [16]. Recognizing this, Hospital-at-Home programs should incorporate gender-sensitive supports, such as education, respite resources, and guidance for safe patient care, to mitigate additional burdens on women.

Another critical finding relates to the health care system education to improve virtual care access. Dahal et al [29] emphasize the role of community organizations in supporting newcomers through education on health care navigation. Participants in this study similarly reported limited awareness of services such as urgent and primary care centers and the 8-1-1 line, resulting in unnecessary reliance on emergency departments. This highlights that health system literacy is a foundational barrier: without addressing these basic knowledge gaps, new service models such as Hospital-at-Home risk reproducing existing inequities rather than improving access.

Chowdhury et al [31] identified concerns about virtual care creating distance between patients and providers, a theme also present in this study. Participants feared that reduced in-person interactions could diminish care quality and trust. This included concerns about developing weaker relationships with providers due to the impersonal nature of virtual interactions, which participants felt could compromise the depth of care and empathy received. This concern reinforces the importance of maintaining strong communication strategies within Hospital-at-Home models to ensure services remain patient-centered and do not further alienate those who experience barriers to care.

While age, gender, and immigration status emerged as individual factors shaping experiences with Hospital-at-Home, our findings underscore the importance of viewing these dimensions through an intersectional lens. For example, older newcomers with limited English proficiency described significant challenges with both language and digital literacy, creating compounded barriers to adoption that were distinct from those faced by younger, Canadian-born participants who reported greater comfort with system navigation and technology use. Similarly, caregiving responsibilities were disproportionately reported by women in multigenerational households, highlighting how gendered expectations intersect with cultural norms and family structures to intensify the caregiving burden. Recent immigrants, regardless of age, also described limited awareness of alternatives to the emergency department, illustrating how immigration status interacts with health system literacy to shape health care–seeking behaviors. These examples illustrate that barriers to Hospital-at-Home adoption are not experienced uniformly across South Asian communities but rather reflect the cumulative and intersecting effects of multiple social identities. Recognizing these layered experiences is critical for designing flexible, equity-oriented models that can adapt to the diverse needs within South Asian populations.

Implications for Hospital-at-Home Implementation

Despite substantial evidence demonstrating the effectiveness of Hospital-at-Home programs in improving patient outcomes and reducing health care costs, significant knowledge gaps remain regarding how to scale these services across diverse populations [32]. This study addresses this gap by exploring the adoption barriers and enablers of Hospital-at-Home services among South Asian communities in the Fraser Health region, offering insights for culturally tailored implementation strategies.

Increasing awareness of Hospital-at-Home services in ways that resonate with South Asian communities is essential to enhance willingness to participate. Findings from this study indicate that South Asian communities prefer learning about Hospital-at-Home through trusted channels such as community organizations, cultural events, and peer testimonials. Additionally, benefits such as increased privacy at home, proximity to family members, and greater control over aligning care with cultural and religious practices were identified as factors that enhance the appeal of Hospital-at-Home services for South Asian patients.

From a systems perspective, raising awareness about how Hospital-at-Home fits within the broader health care system is equally important. Educating patients and caregivers about the structure of health care services and how Hospital-at-Home complements traditional hospital care can build trust, increase

XSL•FO
RenderX

understanding of its role in acute care delivery, and foster confidence in available escalation pathways. This system-level approach can help patients see Hospital-at-Home as an integral part of a coordinated healthcare continuum rather than as a stand-alone service.

Addressing individual barriers is also critical for sustainable and equitable adoption. Limited digital literacy skills among South Asian populations can be mitigated through multilingual education and training strategies that accommodate diverse learning styles. Designing user-friendly digital interfaces for Hospital-at-Home services is also critical to ensure accessibility. Furthermore, the study highlights the importance of explicitly considering family members and caregivers in Hospital-at-Home implementation. This includes developing caregiver-focused training materials, addressing family dynamics in care planning, and regularly evaluating caregiver experiences.

This study further emphasizes that preferences and attitudes toward Hospital-at-Home services are not uniform across South Asian communities, nor do they universally apply to all patient needs. For instance, while some participants appreciated the comfort and cultural familiarity of home-based care, others voiced significant concerns around privacy, data security, and the adequacy of clinical care delivered virtually. These diverging views underscore the need for flexible, patient-centered models that allow for individual choice.

Housing environments emerged as an important contextual factor influencing the feasibility of Hospital-at-Home care. Participants described challenges such as stairs, limited space for medical equipment, and crowded or multigenerational households, all of which could constrain the safety and acceptability of receiving acute care at home. These findings point to the need to consider how physical living environments intersect with the delivery of virtual hospital models. While a detailed policy analysis is beyond the scope of this study, it is important to acknowledge that housing affordability and adequacy are pressing issues in Canada, particularly in urban centers such as Surrey. Future research should explore how these broader structural determinants, including housing conditions, shape equitable access to home-based care models and whether supportive housing or community infrastructure can mitigate such barriers.

To ensure equitable and effective implementation, the design of Hospital-at-Home programs must incorporate sufficient resources to continuously engage diverse patient, provider, and community voices. This ongoing feedback process is critical for adapting services to reflect the cultural nuances, varied needs, and evolving preferences of South Asian populations, enabling the development of culturally informed strategies that foster sustained adoption and trust in Hospital-at-Home services. This study's qualitative findings informed a subsequent Experience-Based Co-Design initiative, which actively engaged South Asian community members in the cocreation of culturally responsive solutions to the challenges identified. Specific outcomes of this process included the development of culturally adapted training materials, multilingual communication tools, and revised care workflows to strengthen trust and clarity in care delivery. By linking this foundational research with participatory design methods, the broader project not only addressed knowledge gaps but also demonstrated a model for translational research, showing how community-engaged approaches can directly inform the design of culturally safe virtual care innovations.

Policy and System-Level Considerations

The findings from this study highlight the need for equity-focused policies and system-level interventions to enhance virtual care accessibility for South Asian communities in Fraser Health and beyond. A central implication is that health system literacy must be addressed as a prerequisite to virtual adoption; simply introducing Hospital-at-Home services without parallel education on how and when to use them may not improve access. South Asian patients may face barriers due to limited English proficiency and a lack of access to culturally competent care [33]. Policies should mandate the integration of multilingual virtual health services, including real-time interpretation and culturally responsive health communication strategies. This aligns with Fraser Health's ongoing efforts to improve accessibility through initiatives such as the SAHI.

Another critical policy recommendation is the standardization of digital literacy support within virtual care services. The findings of this study identified the problematic impact of technological barriers, particularly among older adults and individuals unfamiliar with digital tools. Policies should ensure that virtual care platforms are user-friendly and that comprehensive digital literacy training programs are offered as part of virtual hospital enrollment. This could include step-by-step tutorials, one-on-one technical assistance, and hybrid learning options that combine online and in-person training [34]. In addition, although only a minority of participants mentioned it, data privacy and security remain essential considerations in the design of virtual hospital services. Policies should ensure that multilingual and culturally tailored digital platforms also meet high standards of technological ethics, including secure data management and patient confidentiality, to build and maintain trust among diverse communities.

System-level reforms should focus on streamlining care pathways for virtual hospital patients. Participants expressed concerns about delays in care escalation and emergency response times. To address this, policies should define clear transition protocols between virtual and in-person hospital care, ensuring that patients requiring higher levels of medical attention can be seamlessly transferred. Emergency response times can be optimized through virtual triage systems to ensure virtual hospital patients receive timely interventions when needed [35] .

An additional consideration is the inclusion of family caregivers in virtual health planning. Individuals in South Asian households rely on family members and loved ones for health care navigation and support. Virtual care policies should recognize and integrate the role of caregivers, facilitating access to training, resources, and decision-making tools to support patient care effectively.

XSL•FO
RenderX

Finally, data-driven policy improvements are essential for ensuring that virtual care models address the specific needs of South Asian communities. These findings of this study highlight the importance of ongoing patient engagement and feedback mechanisms. There is a clear need to implement structured monitoring and evaluation frameworks that assess adoption, patient experiences, health outcomes, and engagement levels in virtual care programs. These insights should inform policy refinements to ensure equitable and effective virtual health services.

Strengths and Limitations

This study provides novel insights into Hospital-at-Home acceptability among South Asian communities in Canada, a population underrepresented in Hospital-at-Home research. Semistructured interviews in multiple languages enabled diverse perspectives across gender, age, and immigration status. Importantly, the study included voices of marginalized groups—such as elders, recent immigrants, and family caregivers—who are often excluded from virtual health research.

While this study provides valuable insights into the experiences of South Asian communities with virtual health care, several limitations should be noted. Recruitment challenges limited geographic diversity, with most participants residing in Surrey. As access to health services and digital infrastructure varies across municipalities, future studies should aim for broader regional representation to capture a wider range of experiences.

Another limitation is the reliance on referrals from PICS, which may have introduced selection bias. Participants recruited through PICS are likely to have stronger community connections and greater awareness of health resources, leading to a sample more engaged with the health care system than the broader South Asian population. This may result in an underrepresentation of those facing greater systemic and socioeconomic barriers. Nonetheless, the inclusion of participants with limited English proficiency, lower digital literacy, and newcomer status partially mitigates this concern by ensuring that marginalized perspectives were represented.

The reliance on online interviews is another limitation. While virtual interviews increased accessibility for some, they may have excluded participants uncomfortable with digital technologies or lacking reliable internet access, potentially missing the perspectives of those most affected by digital exclusion. Future research should incorporate alternative data collection methods, such as in-person or telephone interviews, to ensure more inclusive participation.

Despite these limitations, this study offers valuable insights into the structural and cultural barriers influencing virtual health adoption among South Asian communities. Future research should use diverse recruitment strategies and mixed methods approaches to enhance sample representativeness and ensure that equity-driven virtual care models are more inclusive of underserved populations.

Conclusion

This study highlights the complex and context-specific factors that influence South Asian communities' engagement with Hospital-at-Home and virtual care services. Barriers such as limited digital literacy, language challenges, caregiver burden, and lack of awareness about health care alternatives must be addressed through culturally and linguistically responsive strategies. At the same time, key facilitators such as trust in health care providers, the comfort of home-based care, and alignment with cultural and familial values offer important starting points for building more inclusive models of care. Ensuring the equitable implementation of Hospital-at-Home services will require sustained investment in community-specific education, caregiver inclusion, and ongoing feedback mechanisms that reflect the diversity within South Asian populations.

Acknowledgments

The authors sincerely thank the South Asian community members who participated in this study and shared their experiences, as well as the Steering Committee for their guidance and support throughout the project.

Funding

This work was supported by Health Research BC and the Health Research Foundation of Innovative Medicines Canada Team Grant in Virtual Care. The funders had no role in the study design, data collection, analysis, interpretation, writing of the manuscript, or the decision to submit the paper for publication.

Data Availability

The deidentified interview transcripts and other data generated or analyzed during this study are available from the corresponding author on reasonable request, subject to ethical approval and participant confidentiality agreements. Due to the sensitive nature of the data and the small community context, data cannot be publicly shared.

Abstract

Background: Women with cardiovascular disease (CVD) remain underserved due to gaps in recognition, diagnosis, and care tailored to sex-specific risks. Digital health tools have the potential to address these inequities, but many fail to reflect the distinct needs of women. In a prior review, we assessed 20 CVD apps and 22 wearables and found that only 25% (5/20) of apps and 40% (9/22) of wearables included any sex-specific content, such as hormone cycle tracking and life-stage considerations related to pregnancy or menopause. These findings confirm that current digital tools largely mirror the gender gaps seen in traditional care.

Objective: This study aimed to define the user requirements for a CVD app designed specifically for women. We sought to explore the unmet needs and challenges faced by female patients and their clinicians that current tools fail to address, and also to identify and prioritize features that would be most valuable and feasible to implement.

Methods: We conducted a qualitative study using semistructured interviews to explore the needs, preferences, and expectations of women living with CVD and their treating clinicians. Guided by the human-centered design framework, this work focused on the "Define" phase. A total of 20 participants in Switzerland were interviewed, including 11 women with CVD, 7 cardiologists, and 2 experts in regulatory and reimbursement. Participants were recruited through purposive sampling, and interviews were conducted online between April and July 2025. Thematic analysis was used to synthesize the data, highlighting design priorities and contextual factors relevant for developing a patient-centered and system-aware digital health tool.

Results: The interviews with women living with CVD and cardiologists confirmed the consistent gaps between existing care pathways and the specific needs of female patients. Both groups highlighted the lack of early symptom recognition, insufficient sex-specific guidance, and limited tools tailored to women's lived experience. While patients prioritized personalized education, emotional support, and features that address hormonal and life-stage–specific risks, clinicians emphasized clinical use, workload integration, and actionable summaries. Success was defined experientially by patients (eg, empowerment and reduced anxiety), and operationally by clinicians (eg, earlier detection and improved adherence). Willingness to pay was moderate among both groups, with patients favoring simplicity and clinicians emphasizing workflow integration and proven clinical use.

Conclusions: These findings highlight the importance of designing an artificial intelligence–enabled CVD app for women that meaningfully integrates patient empowerment with clinical workflows. A dual-value approach is essential, offering personalized tools that address emotional and lifestyle needs for patients, while supporting clinicians with concise, actionable insights. Early

reflections on regulatory and reimbursement considerations suggest that a modular, evidence-based rollout strategy would be key for long-term adoption and scale.

Introduction

Background

Cardiovascular disease (CVD) remains the world's leading cause of death, claiming nearly 18 million lives each year and impacting more than half a billion people globally [1-3]. Despite decades of progress in cardiology, these numbers underscore a persistent challenge: our current approaches to prevention, diagnosis, and treatment are not reaching everyone equally [3]. One critical blind spot is the under-recognition of sex-based physiological differences in cardiovascular health [4]. Women, in particular, are often underdiagnosed, undertreated, and underserved, partly due to atypical symptom presentation and a longstanding male-centric model of research and care [4]. This has serious consequences, including delays in diagnosis and poorer outcomes for women across the CVD continuum [5].

Digital health technologies offer a promising avenue to change this narrative. Mobile health (mHealth) tools, remote patient monitoring, wearable sensors, and artificial intelligence (AI)–driven decision support systems are reshaping how individuals manage their cardiovascular risk, bringing prevention, detection, and self-care into everyday life [1]. According to the World Health Organization, mHealth refers broadly to health care and public health services supported by mobile devices such as smartphones, wearables, and wireless sensors [6]. These tools can improve access to timely care, enable more tailored interventions, and potentially reduce long-term costs to the health system [7].

Evidence is steadily accumulating in favor of mHealth for cardiovascular care. For example, a systematic review by Coorey et al [8] found that mobile apps can support better blood pressure (BP) control, encourage healthy dietary habits, and reduce hospital readmissions for patients with CVD. Smartphone-based photoplethysmography, a technology that measures changes in blood volume using infrared light, has shown promise in detecting atrial fibrillation (AF) and assessing heart rate (HR) variability, offering an accessible, noninvasive, and scalable solution for early risk detection [9].

Wearable devices are also gaining ground as tools for continuous cardiovascular monitoring. Positioned on the wrist, chest, or hip, these devices can monitor HR, blood oxygen levels, sleep patterns, and physical activity using either photoplethysmography or ECG technology [10,11]. For instance, a study by Guo et al [12] involving more than 187,000 users identified more than 260,000 potential AF episodes, with confirmatory testing validating the diagnosis in most cases. A broader review of smartwatch-based interventions echoed these findings, highlighting improvements in lifestyle behaviors, medication adherence, AF detection, and reductions in unplanned hospitalizations [13].

Current State of CVD Apps and Wearables

Building on the well-documented unmet needs in CVD for women, we evaluated how effectively existing digital health tools, specifically mobile apps and wearable devices, address sex-specific factors in CVD. To do this, we conducted a structured review of 20 patient-facing CVD apps and 22 commercially available wearables. Each tool was assessed using the foundational and contextual dimensions of the sociotechnical framework for evaluating patient-facing eHealth interventions [14], which emphasizes both technical functionality and integration into real-world health contexts.

The results of this assessment, published in a separate study [15], revealed a significant gap: only 25% (5/20) of the reviewed apps and 40% (9/22) of the wearables incorporated sex-specific content. This included considerations such as the impact of hormonal changes, menopause, or pregnancy on cardiovascular health, factors known to influence symptom presentation, disease progression, and treatment needs in women. These findings reinforce the conclusion that digital health tools are not exempt from the systemic gaps that characterize traditional CVD care pathways [15]. Rather, they mirror the underrepresentation of women's needs in CVD. Addressing this gap is critical if we aim to develop digital interventions that are both equitable and clinically effective for women living with CVD.

Objectives

To address this gap, this study explored the user needs and requirements for a digital health app designed specifically for women with CVD. The primary objectives were (1) to understand the specific challenges and unmet needs that female patients and health care professionals encounter in cardiovascular care that are not adequately addressed by current digital tools, and (2) to identify and prioritize the features and functionalities that a new app should incorporate to better support sex-specific cardiovascular health management. Furthermore, the study did not only focus on the preferences and expectations of the primary users, such as patients and clinicians, but also considered broader system-level enablers and constraints, including clinical integration, regulatory requirements, and reimbursement considerations, to guide a practical and scalable development strategy.

XSL•FO
RenderX

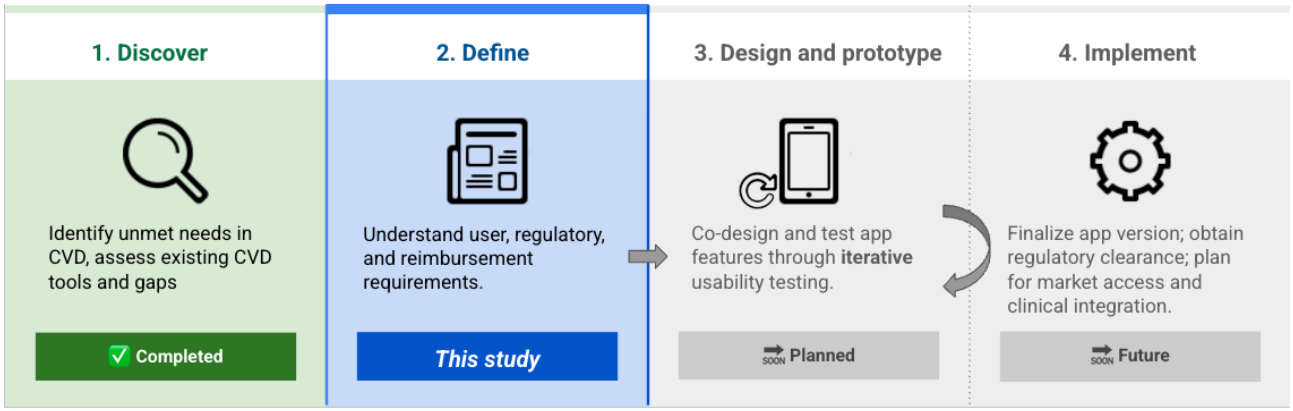
Methods

Overview

We adopted a qualitative research approach to explore the nuanced needs and expectations of both patients and clinicians. This methodology was chosen for its strength in capturing complex, context-dependent experiences and sociocultural factors that are often overlooked by quantitative methods [16].

Qualitative methods are increasingly used in health services and technology research, as they allow researchers to uncover the "why" behind user behaviors and preferences [17]. In our case, this approach helped surface the specific ways in which digital tools can support women across the CVD journey, and how clinicians view their potential integration into care pathways. These insights provide a strong foundation for user-centered feature development and iterative design.

Scope and Conceptual Framework



This study was guided by the human-centered design (HCD) framework, which places the needs, experiences, and preferences of end users, here, women living with CVD and the clinicians who care for them, at the core of innovation [18-20]. HCD is a structured, iterative methodology that unfolds across 4 key phases: discover, define, design and prototype, and implement. Each phase plays a critical role in ensuring that health technologies are developed not only for users, but with them [21,22].

The discover phase, which focuses on identifying the problem space and understanding unmet needs, was addressed in our previously published study that assessed the extent to which existing CVD apps and wearables account for sex-specific considerations [15]. That foundational work revealed significant gaps in digital tools for women with CVD, particularly around life-stage–specific guidance and personalized risk tracking [15].

Building on those findings, this study focused on the define phase. This stage aimed to deepen understanding of user needs through qualitative inquiry, synthesize priorities across user groups, and translate insights into clear design criteria. Specifically, we investigated the expectations, preferences, and contextual considerations of both female patients and clinicians to guide the conceptualization of a CVD app tailored to women's unique health trajectories.

The subsequent design and prototype and implementation phases, where iterative development, user testing, and real-world deployment take place, are beyond the scope of this study but will build directly on the requirements defined in this study. Figure 1 illustrates the HCD process guiding this study, with this study focusing specifically on the define phase, following earlier gap analysis in the discover phase.

Figure 1. Human-centered design approach for developing an app for women with cardiovascular disease. CVD: cardiovascular disease.

Sampling Strategy and Participant Recruitment

We used purposive sampling, a commonly used strategy in qualitative research aimed at capturing rich, experience-based insights from relevant stakeholders [23]. Patient participants were recruited in collaboration with the Women's Heart Health Program at the University Hospital Basel, a specialized cardiology outpatient program focusing on women's cardiovascular health. Inclusion criteria required participants to be women aged 18 years or older, have a confirmed diagnosis of CVD, access to email and the internet, and be comfortable using a teleconferencing tool.

Eligible patients were approached directly by the clinical staff in the Women's Heart Health Program, who explained the study and obtained written informed consent. Once consent was given, the signed forms and contact details were forwarded to the core research team at the University of Applied Sciences and Arts Northwestern Switzerland, who subsequently managed the coordination and communication with participants.

Cardiologists were recruited independently by the research team through targeted online searches and professional outreach via email. The participating cardiologists were recruited from 5 different hospitals and clinics, reflecting 3 care settings across Switzerland, including university hospitals, cantonal hospitals, and private practices, offering a diverse clinical perspective. And unlike clinical or patient experience, which can vary widely, regulatory and reimbursement requirements are governed by defined legal frameworks. Therefore, expert input was sought from two highly specialized professionals with national and EU (European Union)-level expertise, who provided focused guidance on certification and financing pathways for digital health tools in Switzerland and Europe.

All participants received study information and consent materials in both English and German and were given the option to choose

XSL•FO
RenderX

their preferred language. Interview duration ranged from 28 to 63 minutes, depending on the depth of participant responses. Recruitment took place between April and June 2025 and continued until thematic saturation was reached, that is, when no new themes emerged from additional interviews [23,24]. This was assessed continuously during data collection and analysis. For both patient and clinician interviews, saturation was monitored separately. We noted that by the tenth patient and sixth clinician interview, no substantially new themes were identified, and the final interviews largely confirmed and elaborated on existing patterns. The English version of the participant information sheet and consent form is included in Multimedia Appendix 1.

A total of 20 participants based in Switzerland were recruited: 11 women living with CVD, 7 cardiologists, 1 regulatory expert, and 1 reimbursement expert. The sample characteristics of the participating patients and clinicians are summarized in Multimedia Appendix 2.

Data Collection and Synthesis

Data were collected through in-depth, semistructured interviews conducted online between April and July 2025. In total, 2 tailored interview guides were developed: 1 focused on the patient experience and day-to-day disease management, and 1 directed at clinicians, emphasizing workflow, system integration, and implementation considerations. Both guides are provided in Multimedia Appendix 3.

A structured thematic analysis was conducted following the framework by Braun and Clarke [25,26], including familiarization with the data, initial coding, theme development, review, refinement, and final synthesis (see Multimedia Appendix 4 for detailed steps). We used a hybrid coding approach, combining deductive codes informed by prior work and study objectives, with inductive codes that emerged from the data, as described in Multimedia Appendix 4. Codes were grouped into broader thematic categories and, where relevant, mapped to stages of the patient journey (eg, early diagnosis support, treatment, and long-term management). Coding was supported using NVivo (Lumivero) qualitative data analysis software. Patient and clinician interviews were conducted and primarily analyzed by SP, while CJ and PV led the interviews with the regulatory and reimbursement experts. CJ further refined the thematic analysis, synthesis, and reporting. To mitigate potential researcher bias, coding was triangulated across the 3 coauthors (SRP, CJ, and PV), and discrepancies were resolved through iterative discussion. Any coding discrepancies between SP and CJ were addressed through discussions with PV until a consensus was reached. This process spanned from May to August 2025.

Ethical Considerations

The Ethics Committee of Northwest and Central Switzerland determined that ethics approval was not needed for this study, according to the Federal Act on Research involving Human Beings, article 2, paragraph 1 (reference number Req-2025-00491). All participants were briefed about the research background and signed a consent form agreeing to participate. Participant data were anonymized, access to identifiable source files was restricted to the first and second authors, and no participants received financial compensation, with the exception of the regulatory and market access experts who received consulting fees for their professional advisory contributions.

Results

Understanding the User Journey and Unmet Needs

The patient interviews revealed a consistent pattern of late recognition, emotional burden, and lack of gender-sensitive care in the management of CVD. Many women described experiencing a delayed or unclear diagnosis, often attributed to atypical symptom presentation and a lack of accessible, sex-specific information. Many had to self-educate or navigate their condition alone, especially at the outset, before a formal diagnosis was made. Emotional distress, stress, and fear, especially post diagnosis, were prominent themes. Participants spoke about the emotional toll that followed their diagnosis, including feelings of shock, sadness, fear, and uncertainty about the future. For some, the psychological burden was compounded by life-altering restrictions, such as being advised against future pregnancies or having to give up previously enjoyed activities like vigorous exercise.

There was a widespread perception among the participants that hormonal and life-stage influences (eg, pregnancy and menopause) are underacknowledged in treatment pathways. Only 18% (2/11) of patients received any sex-specific guidance, mostly about the potential dangers of getting pregnant with heart disease. Participating patients stated that they generally struggle with lifestyle adjustments, medication adherence, and managing comorbidities. When discussing the complexity of symptom management, participants frequently described difficulties in understanding medical instructions and uncertainty about how to respond to different symptoms or side effects. This was further complicated by external factors such as stress, an acknowledged trigger that patients knew could worsen their condition, yet felt largely powerless to control.

Digital tools are underused; only 18% (2/11) of patients had experience using CVD apps or wearables, for example, for ECG measurement, while the others expressed confusion, lack of awareness, or anxiety about using them. All participating patients agreed that gender-specific tracking would be beneficial. Table 1 highlights the main challenges and unmet needs faced by women with CVD along the care continuum, their current use of digital health tools, and how many participants referenced each theme in the interviews.

Table 1. Understanding the patient journey and unmet needs (n=11).

Themes and subthemes	Prevalence, n (%)
Early symptoms and diagnosis	
Unfamiliar with the disease at diagnosis	7 (64)
Atypical or no symptoms prior to diagnosis	6 (55)
Self-initiated education (eg, googling and support groups)	5 (45)
Emotional distress after diagnosis (shock, sadness, and fear)	6 (55)
Stress and psychological burden of the disease	5 (45)
CVD[a] perceived as a burden or life-changing event	6 (55)
Life stage and gender-specific care	
Not informed or addressed by HCPs[b]	9 (82)
Was informed about the impact of life stages (eg, pregnancy and menopause)	2 (18)
Perceived treatment as male-centered	4 (36)
Belief that women's CVD symptoms are often dismissed	3 (27)
Ongoing disease management challenges	
Difficulty with lifestyle and diet changes	6 (55)
Struggles with medication adherence or side effects	5 (55)
Difficulty understanding symptoms and instructions	4 (36)
Difficulty managing comorbidities	3 (27)
Anxiety before appointments because of uncertainties (eg, on potential progression)	2 (18)
Dealing with constant emotional overwhelm and fatigue	3 (27)
Use of existing digital tools	
Has not used any apps for CVD	9 (82)
Not aware of any helpful CVD apps	7 (64)
Prefers face-to-face care over digital tools	4 (36)
Feels overwhelmed or anxious by the idea of apps	3 (27)
Has used a step counter, hydration reminder, or menstrual tracker	3 (27)
Has used a CVD-related app or wearable (eg, for ECG[c] measurement)	2 (18)

[a]CVD: cardiovascular disease.

[b]HCP: health care professional.

[c]ECG: electrocardiogram.

Clinicians reported several diagnostic challenges stemming from atypical symptom presentation in women, compounded by limited awareness and insufficient referral pathways. They emphasized the mismatch between traditional risk models and real-world female presentations, which are often underrecognized or misattributed. Time constraints and health care system overload further exacerbate diagnostic delays. Despite acknowledging the lack of tools to capture hormonal or life-stage influences, 5 of 7 (71%) participating clinicians reported that they continue to follow standard monitoring protocols without sex-specific adjustments.

Only 1 of 7 (17%) interviewed cardiologists recommended CVD apps, while 6 of 7 (86%) cited lack of familiarity or trust in their use, with usability for older patients as the main concern. Integration of digital tools into clinical workflows remains controversial; some see potential for structured summaries and AI-assisted risk insights, while others worry about time burden or data security. There was strong agreement on the need for decision support tools that surface earlier warnings during high-risk windows such as menopause, pregnancy, or postevent follow-ups, with 5 of 7 (71%) participants citing this as an existing gap. Table 2 presents the key challenges and unmet needs encountered by clinicians throughout the clinical workflow, alongside their current engagement with digital health tools, and how many participants referenced each theme in the interviews.

XSL•FO
RenderX

Table 2. Understanding the clinician workflow and unmet needs (n=7).

Themes and subthemes	Prevalence, n (%)
Diagnostic challenges	
Atypical symptoms in women make the diagnosis more challenging	7 (100)
Lack of awareness and, accordingly, referrals	5 (71)
Limited time and capacity in care	3 (43)
Sex-specific gaps	
Symptoms misattributed or dismissed	7 (100)
Treatment paths not sex-sensitive and mostly male-focused	5 (71)
Monitoring practices	
Standardized tests, no sex differences	5 (71)
Limited tools for life-stage tracking in women (eg, pregnancy and menopause)	3 (43)
Workflow integration needs	
Desire for structured reports	6 (86)
Need decision support during diagnosis and follow-ups	5 (71)
EHR[a] integration	3 (43)
Use of existing digital tools	
Does not recommend CVD[b] apps to their patients	6 (86)
Low awareness of validated apps	6 (86)
Too many apps with low usability for older adults	5 (71)

[a]EHR: electronic health record.

[b]CVD: cardiovascular disease.

Desired Features and Functionality

Based on the patient interviews, several key themes emerged regarding desired features and functionalities for a CVD app tailored to women. Patients emphasized the importance of integrated support across the full care continuum, from early symptom awareness and diagnosis to daily management and communication with health care providers.

Core priorities included the ability to track vital signs, log symptoms, and receive tailored educational content specific to women's cardiovascular health. Medication reminders, stress management features, and dietary guidance were commonly requested. Also, 9 of 11 (82%) patients expressed interest in syncing the app with wearables to streamline data collection and support longitudinal tracking. Communication features, such as automated report generation and the ability to share real-time data with health care providers, were considered highly valuable, with 8 of 11 (73%) patients supporting real-time feedback or alerts when symptoms are concerning. Importantly, all participants favored sex-specific, personalized recommendations, but some voiced concerns about privacy, complexity, and the risk of being overwhelmed by notifications. Table 3 summarizes the key features and functionalities patients desire in a digital health solution, along with the main barriers and concerns, and indicates how many participants raised each point during the interviews.

Based on the interviews with cardiologists, several priorities emerged. The overarching emphasis was on improving diagnostic precision, treatment adherence, and patient-provider communication, while minimizing time burden and clinical noise. Clinicians expressed strong interest in receiving structured patient-generated data (eg, BP, symptom trends, medication adherence, and hormonal cycle data), especially when aggregated into concise, longitudinal reports. There was broad consensus (7/7, 100%) on the value of sex-specific insights (eg, menopause and pregnancy risks), particularly if tailored to life stages and actionable. However, real-time monitoring or alerts received more mixed responses. Most clinicians (5/7, 71%) preferred periodic summaries over continuous alerts, citing concerns around workload, liability, and alert fatigue.

Communication through the app was not favored by most clinicians, who instead preferred to retain current channels such as email, phone, or in-person visits. While 6 out of 7 (86%) found the ability to customize patient goals important, they highlighted that this must not increase cognitive or administrative burden. Concerns were raised about data quality, patient over-reliance on technology, and integration with existing clinical infrastructure (eg, electronic health records [EHRs]). Despite some openness to features such as AI-driven alerts or remote monitoring, most clinicians emphasized the need for evidence of clinical use and a clear focus on reducing, not increasing, workload. Table 4 summarizes the key features and functionalities clinicians desire in a digital health solution, along with the main barriers and concerns, and indicates how many participants raised each point during the interviews.

XSL•FO

Privacy and data security concerns	3 (43)
Lack of clinical use	2 (29)
Patients' over-reliance on the app	2 (29)
Motivation and sustained engagement by patients	1 (14)

[a]CVD: cardiovascular disease.

[b]EHR: electronic health record.

Contrasting the two perspectives revealed strong alignment between patients and clinicians on the value of tracking vital signs, providing sex-specific guidance, and offering educational content tailored to women's heart health. However, notable divergences emerged around communication, monitoring preferences, and the diagnostic support role of the app. Patients favored real-time feedback, interactive features, and personalized support, while clinicians expressed concerns about workload, data reliability, and legal liability, preferring structured summaries and limited app-mediated communication. These differences highlight the need for a dual-pathway design that

XSL•FO
RenderX

balances patient empowerment with clinical workflow and safety.

Table 5 compares the perspectives of participating women with CVD versus cardiologists regarding desired app features across the patient journey. It highlights areas of alignment and divergence across different phases of the patient journey, and identifies where design focus is most needed to address gaps and support user-centered implementation.

Table 5. User requirements comparison across the cardiovascular disease patient journey (patients vs clinicians).

Feature cluster	Patient perspective	Clinician perspective	Alignment
Symptom onset and early risk tracking	Many patients want tools to log symptoms, track hormonal cycles, and receive alerts for serious changes.	Clinicians track symptoms but prefer periodic summaries over real-time alerts due to workload and liability concerns.	Partial
Diagnosis support	Patients often seek symptom explanations and hope for diagnostic guidance from the app.	Clinicians are wary of misdiagnosis; some see the app as educational but not diagnostic.	Divergent
Treatment adherence and medication	High interest in medication reminders, side effect information, and adherence support.	Clinicians value adherence tracking and side effect reporting if actionable, summarized, and integrated into their workflow.	Strong
Education and empowerment	Nearly all patients want tailored, female-focused educational content (eg, videos, articles, and lifestyle advice).	Clinicians agree that education is a key benefit of the app, especially if it supports better patient engagement.	Strong
Sex-specific and life stage guidance	All patients emphasized the need for advice linked to hormonal changes, pregnancy, and menopause.	Most clinicians strongly support sex-specific features to address overlooked risks and life-stage changes.	Strong
Vital signs and lifestyle monitoring	Most want to track vitals (BP[a] and HR[b]) and sync with wearables for exercise, diet, and sleep insights.	Clinicians prioritize BP and HR and accept wearable data cautiously, questioning accuracy and clinical validity.	Moderate
Personalization and motivation	Strong interest in personalized advice and goal-setting features to support self-management.	Clinicians support customizable goals but are concerned about overburdening users or implying unsupported precision.	Partial
Communication with care teams	Many patients want in-app messaging, shared data, and reminders to feel more connected and supported.	Clinicians prefer structured reports and oppose app-based messaging due to time limits and workload.	Divergent
Monitoring preferences	Most prefer real-time feedback if needed, while some fear over-monitoring or anxiety from alerts.	The majority prefer summary reports; only a few support real-time data access or alerts, citing resource constraints.	Divergent
Trust, privacy, and usability	Simplicity and ease of use matter most; some express concerns about privacy and overalerting.	Clinicians worry about liability, data overload, and integration challenges; they prefer actionable, low-burden tools.	Moderate

[a]BP: blood pressure.

[b]HR: heart rate.

Success Metrics and Willingness to Pay

Patients defined success with the app in terms of greater control, improved understanding, and emotional reassurance. Key success indicators include feeling more in control of their heart health (7/11, 64%), increased awareness of sex-specific symptoms and conditions (6/11, 55%), and reduced anxiety or stress (5/11, 45%), along with better adherence to medication and more personalized guidance. For many, success is also tied to the app's ability to improve communication with health care providers and deliver trustworthy, up-to-date content.

Regarding willingness to pay, the average score was 7.1 on a scale of 1 to 10, with individual responses ranging from 3 to 10. Preferences for pricing models were mixed, with a slight preference for one-time payments (6/11, 55%), reflecting a desire for financial simplicity and predictability. Monthly models were preferred by 4 of 11 (36%) respondents for their flexibility, though some requested a free trial period as a prerequisite.

The primary factors influencing willingness to pay included the app's demonstrated usefulness, degree of personalization, sex- and age-specific features, trustworthiness, and perceived value for improving cardiovascular health. A few respondents flagged affordability and usability as potential barriers, highlighting the importance of designing an accessible and demonstrably beneficial tool. Table 6 provides an overview of patient-reported success metrics and expectations around payment for digital health solutions, including the number of participants who mentioned each aspect during the interviews.

XSL•FO
RenderX

Table 6. Patient-reported success metrics and payment expectations (n=11).

Themes and subthemes	Prevalence, n (%)
Perceived success indicators	
Feeling more in control of heart health	7 (64)
Increased awareness of sex-specific symptoms and conditions	6 (55)
More personalized recommendations	5 (45)
Reduced stress or anxiety	5 (45)
Increased motivation to manage health	4 (36)
Access to reliable and up-to-date health information	3 (27)
Improved medication adherence	2 (18)

[a]HCP: health care professional.

Clinicians defined the success of a CVD app through its impact on patient engagement, adherence, and health outcomes, rather than direct clinical decision-making support. The most frequently cited indicators of success included improved patient engagement and participation in care management (6/7, 86%), greater adherence to treatment (5/7, 71%), and better patient education and symptom recognition (5/7, 71%), particularly regarding sex-specific cardiovascular risks. Several clinicians emphasized the need for such outcomes to be validated through research before adoption in routine practice.

Adoption incentives included features that support remote monitoring, patient education, and AI-supported risk assessments, provided they are accurate and well-integrated. Seamless integration into clinical workflows and EHRs, a simple interface, and support for research and data sharing were also valued.

Regarding willingness to pay, clinicians expressed moderate interest, with a mean score of 5.3 (SD 1.3) on a scale of 1 to 10. Preferences leaned toward monthly or yearly pricing models, with a desire for a free trial period. Willingness to pay was highly conditional on the app's proven benefit to patient outcomes, usability, compliance with data protection, and ability to support research or institutional adoption. Table 7 provides an overview of clinician-reported success metrics and expectations around payment for digital health solutions, including the number of participants who mentioned each aspect during the interviews.

XSL•FO

[b]EHR: electronic health record.

Regulatory and Reimbursement Considerations

To complement the user requirements gathered from patients and clinicians, we conducted additional interviews with one regulatory expert (SN [nonauthor]) and one reimbursement expert (MF [nonauthor]), both with in-depth knowledge of the Swiss and broader European health care landscapes. This supplementary perspective is critical, as the app will be developed primarily for use in Switzerland, with a medium-term vision for deployment in other European contexts.

The regulatory expert assessed that an AI-enabled CVD app (AI-driven alerts and AI-supported risk assessments), designed to support women across the spectrum of symptom recognition, diagnosis, treatment adherence, and self-management, is likely to be considered a medical device under Swiss law. Specifically, if the app includes features such as AI-driven risk alerts, symptom tracking, and clinical report generation intended to support medical decision-making or influence health outcomes, it would fall under the Medical Device Ordinance as governed by Swissmedic. Depending on the final functionality, the app

XSL•FO
RenderX

would likely be classified as a Class IIa medical device, requiring compliance with regulatory obligations related to safety, performance, and quality assurance.

Given that the app would likely use algorithms to generate health risk scores and may eventually integrate with electronic health records or wearable data for clinical review, transparency of its AI functionalities (eg, AI-driven alerts and AI-supported risk assessments) and proper documentation of its performance are essential. Although Switzerland is not part of the EU, it has harmonized its medical device regulatory system with the EU Medical Device Regulation (MDR). Therefore, developers must ensure conformity with Annex I of the MDR, particularly concerning software validation, cybersecurity, and human oversight of AI outputs. Early consultation with Swissmedic, including use of their pre-submission guidance services, was strongly recommended by the expert to confirm classification and identify the most appropriate pathway to conformity assessment.

From a data protection standpoint, the expert added that the app must comply with the Swiss Federal Act on Data Protection, which aligns closely with the EU's General Data Protection Regulation. This includes obtaining explicit consent for processing health data, ensuring transparency in AI-based recommendations, and conducting a Data Protection Impact Assessment if sensitive data are used for profiling or personalized recommendations. Data must be stored securely in accordance with Swiss and European data security standards.

In terms of market access within Switzerland, the reimbursement expert explained that there is currently no established reimbursement pathway for digital health tools of this nature under the standard TARMED system (soon to be replaced by the new tariff system called TARDOC). However, several viable strategies exist. These include partnerships with supplemental insurance providers, integration into occupational health programs, or collaborative pilots with cantonal public health authorities focused on prevention and chronic disease management. Additionally, public-private partnerships involving academic hospitals could support real-world evidence generation, which will be critical for clinical validation and acceptance.

As the app evolves, modular feature deployment (eg, launching initially with educational content and lifestyle tracking before integrating AI-based alerts or EHR connectivity) may offer a lower-risk route to initial uptake. Positioning the app as an adjunct to care rather than a diagnostic tool can help mitigate medico-legal risks and facilitate clinician adoption. For future scaling into EU markets, preparation for CE (Conformité Européenne) marking and consideration of fast-track pathways like Germany's Digitale Gesundheitsanwendungen (Digital Health Applications) process would be key strategic steps. A summary of regulatory and reimbursement considerations is provided in Multimedia Appendix 5, focusing primarily on Switzerland, with additional insights relevant to potential midterm expansion into the EU market.

Discussion

Primary Findings

This study offers detailed insights into how digital health tools can be designed to better serve women with CVD by directly addressing long-standing gaps in diagnosis, treatment, and self-management. What distinguishes this work is its grounding in sex-specific lived experiences and clinician workflows; most existing tools and studies either generalize across populations or fail to capture the unique challenges women face across the cardiovascular care continuum.

Our findings confirmed the diagnostic blind spots long documented in the literature but go a step further by detailing how these gaps are experienced by women, especially the emotional toll of feeling dismissed or misdiagnosed due to atypical symptom presentation, and how clinicians themselves acknowledge the limitations of current care pathways and tools. We also identified a mismatch between what patients expect from digital tools (eg, personalized, real-time, and educational support) and what clinicians view as feasible or desirable (eg, structured summaries and low-disruption integration), echoing broader implementation challenges in digital health but offering concrete, user-validated features to bridge this divide.

Furthermore, this work goes beyond user needs to surface actionable priorities for design, regulation, and reimbursement. By mapping unmet needs to specific app features and clarifying stakeholder requirements, we contribute an applied framework for the development of a digital tool that is not only patient-centered but also clinically and systemically grounded.

Addressing Unmet Needs Across the Care Continuum

Our interviews with patients and clinicians confirmed the consistent disconnect between current cardiovascular care pathways and the lived experiences and needs of women with CVD. Both groups emphasized a clear gap in early recognition and diagnosis of CVD in women, often driven by atypical symptom presentation, a finding well-supported in the literature [4]. Women frequently report vague or nonspecific symptoms (eg, fatigue, anxiety, and back pain) that are either misattributed or dismissed, leading to delayed diagnosis and poorer outcomes. This aligns with clinical studies showing that atypical symptoms in women are associated with underdiagnosis and delayed care, a pattern historically described as the Yentl syndrome and reaffirmed in recent studies [27].

Clinicians similarly confirmed that CVD does not present in women as it does in men, often requiring multiple diagnostic steps and greater clinical vigilance. Yet, most participating clinicians admit to using standardized, male-centered diagnostic tools, with little to no adaptation for sex- or life-stage-specific risks (eg, menopause and pregnancy-related complications). This is consistent with research papers that highlight the lack of integration of sex-specific risk factors into clinical practice and guidelines [28,29].

Our findings also showed that there is a shared perception that awareness and education are insufficient, both for patients and providers. Patients often feel overwhelmed and underinformed, particularly about how hormonal changes might affect their

XSL•FO
RenderX

heart health. Clinicians acknowledge this gap, noting that many are not trained to assess or communicate about sex-specific CVD risks, confirming concerns raised in the literature about persistent gender bias in cardiovascular medicine [30].

On the digital health front, while most patients have not used cardiovascular apps, citing lack of awareness, complexity, or emotional overwhelm, many express openness to tools that are personalized, educational, and easy to use. Importantly, all patients agreed that features like hormone-aware symptom tracking and cycle or menopause-specific guidance would be valuable. Clinicians were generally supportive of a digital tool, provided it reduces workload and offers actionable insights. However, many remain skeptical due to workflow integration concerns, unclear clinical use, and insufficient validation, echoing findings from other studies that cite similar adoption barriers [14,31-33].

This shows a strong concordance between user-reported unmet needs in our research and evidence in the scientific literature. The development of a CVD app specifically designed for women presents an opportunity to bridge the identified diagnostic support and management gaps by offering sex-specific decision support and longitudinal symptom tracking across life stages, in a way that integrates meaningfully into both patient journeys and clinician workflows.

Balancing Patient-Centered Design With Clinical Workflow Integration

The synthesis of clinician and patient requirements revealed meaningful overlap in priorities for a CVD app tailored to women, particularly around core features such as BP, HR, cycle and symptom tracking, medication adherence tools, and educational content specific to women's cardiovascular risks. Both groups also expressed interest in incorporating wearable data, lifestyle tracking, and AI-driven alerts, but with key differences in expectations around data flow and engagement. To ensure alignment with human factors (HF) principles, app features and interface components should be conceptualized to minimize cognitive load, support workflow compatibility, and accommodate differentiated engagement preferences between patients and clinicians.

Patients consistently emphasized the importance of holistic, personalized support, especially around lifestyle guidance (eg, diet and stress management), menstrual and hormonal tracking, and emotional well-being. Our recent research, which reviewed 20 commercially available CVD apps, showed that only 25% (5/20) offered sex-specific content, reinforcing that sex-specific app features in CVD are rare and needed [15]. Patients also valued real-time feedback and communication, but with flexibility to self-regulate interaction frequency, a finding supported by previous research [34].

Clinicians, by contrast, largely favored periodic summaries over real-time alerts, citing concerns about information overload, workflow disruption, and medico-legal liability, concerns echoed across several reviews on eHealth implementation challenges [14,32,33,35], underscoring the importance of minimizing cognitive workload and supporting efficient information processing in clinical settings. There was strong support for automated, concise reporting tools to enable faster clinical decision-making, particularly if data is aggregated and actionable (eg, medication nonadherence flags, high BP trends, and cycle fluctuation). Importantly, clinicians stressed the need for sex-specific clinical insights (eg, pregnancy-safe medication guidance), aligning with calls in the literature to address gender gaps in cardiovascular risk assessment and care pathways [36].

Despite agreement on many core features, divergence between patients' and clinicians' requirements remains. Clinicians were skeptical of communication via the app, preferring existing channels (email and phone), whereas many patients desired low-barrier communication tools or asynchronous Q&A features. Additionally, clinician trust in wearable data remains limited due to concerns about accuracy, despite evidence that wearables can support prevention strategies and risk monitoring when used appropriately [10,37].

These findings underscore the need to balance patient-centered design with clinical workflow integration, ensuring that features valued by patients (eg, education, personalization, symptom explanation, and risk prevention) do not impose undue burden on clinicians. The app should prioritize structured reporting, passive data aggregation, and modular engagement options, and be framed as an adjunct, not a replacement, for in-person care. Differentiated user models, with patient-facing tools focused on behavior change, motivation, and real-time support, and clinician-facing tools optimized for decision efficiency and minimal disruption, can support better task-technology fit for both groups. Interface design should adhere to HF principles such as customizability by role, transparency of AI outputs, clear visual hierarchies, and user autonomy in alert settings, all of which were strongly echoed in user preferences. Usability must remain a central design principle, interpreted not only as ease of use but also through HF constructs such as interaction efficiency, information clarity, and minimization of user burden. Successful uptake will hinge on transparent validation, privacy safeguards, and clinical evidence.

Articulating Meaningful Success Narratives

The analysis of success metrics and willingness to pay highlighted distinct yet interrelated priorities between patients and clinicians that carry significant implications for the app's value proposition and sustainable adoption. While both groups identify improved patient adherence, better education, and enhanced engagement as key indicators of effectiveness, they differ in how success is defined and operationalized.

Patients tend to frame success in terms of personal empowerment and perceived well-being, such as increased awareness of sex-specific symptoms and conditions, feeling in control of their heart health, reduced anxiety, and improved ability to interpret symptoms and make informed decisions. Most patients cited greater motivation and personalized insights as important outcomes, and several emphasized a desire for the app to help them feel taken seriously in clinical encounters. These findings align with research demonstrating that digital interventions can significantly boost patient empowerment, knowledge, and self-management in chronic illness [13,38]. This experiential framing of success suggests that patients value both functional benefits (eg, symptom recognition and adherence

XSL•FO
RenderX

reminders) and emotional reassurance, and are likely to judge effectiveness through lived experience rather than clinical endpoints alone.

Clinicians, in contrast, emphasized evidence-based outcomes, such as reduced hospitalizations, earlier detection of complications, and measurable improvements in disease management. While some acknowledged softer benefits like improved communication or decreased workload due to better-informed patients, there was a consistent call for formal evaluation of impact, preferably through research trials, factors frequently noted in clinician acceptance studies [32,33]. This divergence highlights the importance of building a dual feedback system, one capturing patient-reported outcomes and engagement metrics, and another tracking clinical indicators that can be aggregated and validated over time.

In terms of willingness to pay, patients showed relatively high interest. Key influencing factors included the app's ability to improve cardiovascular health, offer sex-specific and personalized recommendations, and provide reliable, easily digestible information, echoing user preferences reported in patients' mHealth adoption literature [34]. Several patients noted the appeal of free trial options and transparent pricing, especially in light of economic constraints.

By contrast, clinicians expressed moderate willingness to pay and viewed app adoption as contingent on demonstrated clinical use, alignment with existing systems, and endorsement by institutions or guidelines. Most clinicians would expect the app to be provided at the health system or institutional level, particularly if it supports research or integrates with existing systems, factors shown as crucial for sustained clinician adoption in previous research [32,33,35].

Payment feasibility was primarily seen through the lens of institutional procurement rather than individual expenditure. This indicates that a tiered strategy could be considered, potentially offering direct-to-patient subscriptions for patients and licensing options or integration pathways for clinical and research settings. Such a dual-strategy may combine offering core low-risk features and premium add-ons directly to motivated patients, with an institutional offering that includes more advanced research data modules such as an AI-predictive model, EHR integration, and structured reporting and smart alerts. Free trials, outcome-based pricing, or inclusion in reimbursement schemes could improve uptake across both segments, as emphasized in similar research [39,40].

Overall, the findings suggest that to drive adoption and value across stakeholder groups, the app must articulate distinct success narratives, one rooted in empowerment and lived experience for patients, and one grounded in clinical efficiency and measurable outcomes for providers.

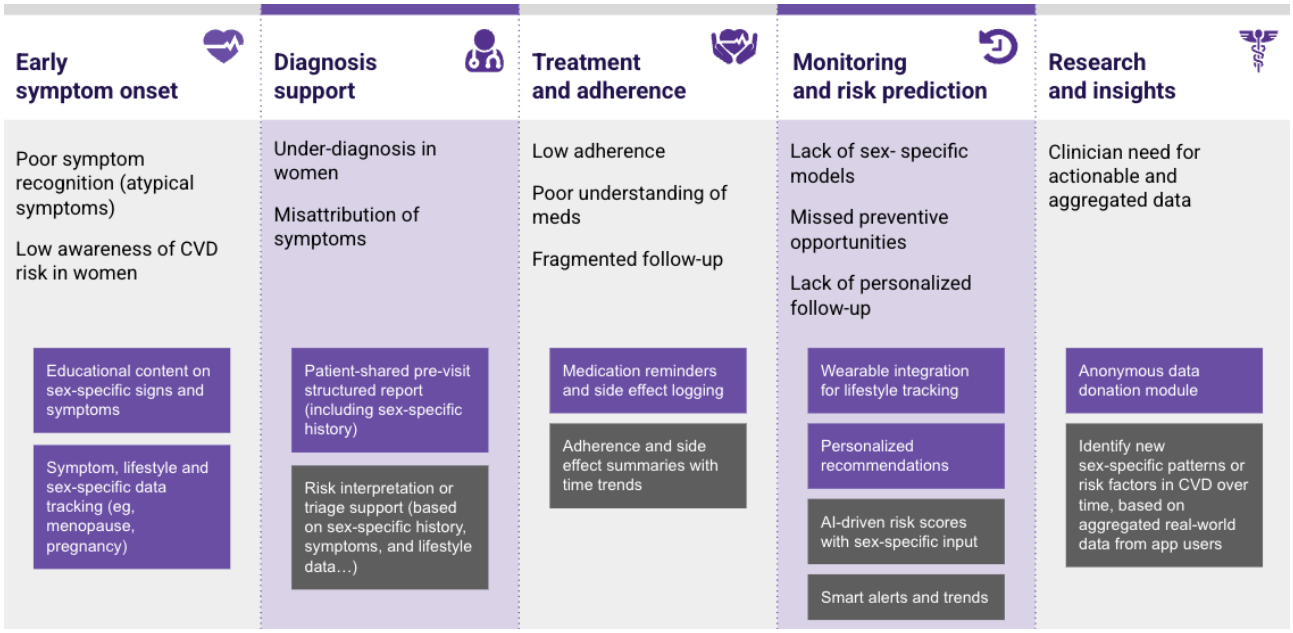
Regulatory and Reimbursement Implications

Incorporating regulatory and reimbursement expertise early in the development process helps ensure that the solution is not only clinically and user-relevant but also aligned with the legal, safety, and financial frameworks required for real-world adoption. Failure to consider these aspects at an early stage often results in substantial implementation barriers and limits the scalability and sustainability of digital health innovations [14,32-35,41].

From a regulatory standpoint, the expert confirmed that if the app includes AI-driven functionalities, such as personalized risk alerts, clinical report generation, or features that support diagnosis or influence medical decision-making, it would likely qualify as a Class IIa medical device under Switzerland's Medical Device Ordinance, harmonized with the EU MDR. This classification implies that the app must meet formal requirements related to software performance, cybersecurity, human oversight, and clinical evaluation, as outlined in MDR Annex I. Given the inclusion of health data processing and algorithmic personalization, the app must also comply with the Swiss Federal Act on Data Protection, which closely mirrors the general data protection regulation, including requirements for explicit user consent and transparency of algorithmic outputs. These recommendations align with recent regulatory reviews emphasizing the increased scrutiny of AI-based medical software and the importance of early consultation with regulatory bodies to validate classification and compliance pathways [42].

On the reimbursement side, the expert highlighted that Switzerland currently lacks a dedicated reimbursement pathway for digital health applications within the standard outpatient tariff system (TARMED), which is soon to be replaced by the new TARDOC system. In the midterm, TARDOC will be the key framework to monitor. According to the factsheet on digital health applications provided by the Federal Office of Public Health, digital tools, including AI applications, are expected to be classified as part of the infrastructure or personnel services [43]. This means they could potentially be reimbursed under specific TARDOC positions, such as those related to telemedicine. However, several alternative access models were identified, including partnerships with private health insurers, occupational health initiatives, and cantonal prevention programs. These strategies reflect recent calls in the literature for shifts in European digital health financing, which recognize the need for novel evidence-generation mechanisms to support the adoption and scaling of digital tools [44,45]. In Switzerland, reimbursement will likely depend on demonstrated value in real-world settings, particularly in enhancing adherence, promoting prevention, and reducing unnecessary health care use.

Design Implications and Next Steps



To translate the diverse and specific user requirements identified in this study into actionable design features, we mapped patient and clinician needs along the cardiovascular care continuum. Thematic synthesis of interview data revealed critical gaps and opportunities at multiple points in the patient journey, from early symptom recognition to diagnosis support, treatment adherence, ongoing self-management, and broader contributions to cardiovascular research. These findings aligned with persistent shortcomings in the literature, particularly around under-recognition of sex-specific symptoms [46], insufficient tailoring of risk assessment tools, and limited integration of digital health tools into routine care for women with CVD [15].

Figure 2 presents a high-level design framework illustrating how these needs will be addressed through core app features,

XSL•FO
RenderX

organized by phase of care. Patient-facing features are shown in dark violet boxes and focus on supporting the lived experience of women navigating cardiovascular conditions, such as personalized education, symptom logging, and wearable-integrated tracking. Clinician-facing features, in the dark gray boxes in the figure, prioritize workflow efficiency, diagnostic support, and data integration. It's also worth noting the interconnectedness of some of these elements. For example, the AI-driven risk alerts and clinical report generation depend on continuous, structured input from patient-generated data, including wearable metrics, symptom tracking, and medication adherence. Similarly, the research and insights feature, designed for clinician relevance, builds on aggregated app data to identify emerging sex-specific patterns and close gaps in clinical evidence.

Figure 2. Design implications across the cardiovascular patient journey in women. AI: artificial intelligence; CVD: cardiovascular disease.

This feature map provides a consolidated foundation for the next phase of development. It will serve as the blueprint for the initial prototype, which will undergo usability testing in an iterative design process, as highlighted in Figure 1 under the methodology section. Through repeated feedback loops with both patients and health care professionals, the prototype will be refined to ensure alignment with real-world needs and system-level constraints, ultimately enhancing adoption, clinical relevance, and long-term impact.

Limitations and Future Research

This study was conducted exclusively in Switzerland, which may limit the generalizability of the findings to other health systems or cultural contexts. Although all patients were recruited via a single university hospital partner, the clinic serves a broad public population and includes individuals with varying levels of health and digital literacy. Nonetheless, this limitation will be addressed in the next phase of the project through iterative prototyping with a more demographically and geographically diverse patient sample. Given that the primary goal is to develop a tool for use in Switzerland, with longer-term plans to expand into other German-speaking countries such as Germany and Austria, we believe the study was appropriately scoped for this stage of development. Broader geographic and cultural representation will be integrated in the next phase of the development, particularly during prototype testing and validation.

The sample size was relatively small, in line with typical qualitative research. While this limits the breadth of perspectives captured, we achieved thematic saturation, suggesting that the findings are sufficiently robust to inform the current design phase. Nonetheless, some stakeholder groups were not represented in this study. In particular, general practitioners and nurses were not included due to recruitment challenges and resource constraints. Their perspectives, especially those of general practitioners, who often serve as the first point of contact during early symptom onset, are crucial for understanding barriers to timely recognition and referral. Future phases of the development will include these stakeholders to ensure that insights from across the care continuum are reflected in the final design.

Conclusions

This study confirmed a persistent disconnect between existing cardiovascular care pathways and the specific needs of women living with CVD. Patients shared experiences of feeling underinformed, underheard, and underserved, particularly during early diagnosis support, due to atypical symptoms and a lack of sex-specific guidance. Clinicians acknowledged these challenges but admitted that current tools and workflows are still largely designed around male-centric risk models. Both groups agreed that digital health has the potential to bridge this gap but also highlighted different expectations; patients seek personalized education and empowerment, while clinicians prioritize clinical use, low burden, and workflow integration.

The participants' input showed strong overlap in desired core features, such as sex-specific symptom and cycle tracking, medication adherence tools, and tailored educational content.

XSL•FO
RenderX

However, divergences appeared around data communication and feedback. Patients favored more interactive, real-time support, while clinicians preferred summarized, actionable insights to avoid alert fatigue and liability concerns. These findings highlight the importance of modular, adaptable design, an app that offers flexibility in use, differentiated interfaces for patients and providers, and clearly defined roles for AI and automation.

These findings also inform key HF considerations for interface design. For clinicians, minimizing cognitive workload was critical; participants favored tools that provide actionable, low-effort insights rather than real-time data streams. Features such as passive data aggregation, structured dashboards, and summary reports were seen as more aligned with clinical workflows and information processing constraints. For patients, usability was tied to personalization, transparency, and flexible communication options. To ensure task-technology fit, the design must allow differentiated engagement based on user role, with modular, customizable features that minimize burden while maximizing relevance.

Success metrics also differed by perspective. Patients emphasized psychological and motivational benefits such as feeling in control, recognized, and informed, whereas clinicians focused on measurable outcomes such as adherence, hospital avoidance, and engagement. However, both agreed that success requires trust, usability, and relevance to daily life. These insights informed a dual-value strategy for app development, aligning patient empowerment with clinical efficiency.

Finally, our expert interviews highlighted that integrating regulatory and reimbursement perspectives early is key to a successful implementation. With features such as AI-supported insights and clinical data sharing, the app will likely qualify as a medical device under Swiss and European laws. Planning for staged implementation, starting with nonregulated educational features and expanding as validation and infrastructure grow, emerges as a practical strategy. However, long-term success and widespread adoption would largely depend on demonstrating real-world value and forming partnerships with insurers and public health programs.

Acknowledgments

The authors thank the Women's Heart Health Program at the University Hospital Basel for their instrumental role in patient recruitment. Artificial intelligence was not used to create, modify, or interpret the scientific content of the article. It was solely used as a proofreading tool to correct spelling and grammar, enhance clarity, and streamline phrasing. Abstract

Background: Delivering therapy through video consultations can increase the reach and impact of mental health care services. However, adoption varies, and there is a lack of professional consensus about the usefulness of video consultations in therapy settings.

Objective: This study aimed to explore mental health professionals' experiences with and attitudes toward video consultations across different clinical environments in the private and public health care sectors in Norway to inform the design of future digitalized services.

Methods: In this qualitative study, we recruited leaders and clinicians from public hospitals and private clinics. We conducted semistructured interviews that mapped individual experiences and attitudes concerning video consultations, as well as contextual aspects concerning the participants' professional environments. We used reflexive thematic analysis with an inductive, essentialist, and experiential orientation to analyze the data.

Results: A total of 24 mental health professionals (16 from public hospitals and 8 from private clinics) participated. Variations in their attitudes did not follow patterns reflecting the type of service or sector they worked in. Rather, attitudes seemed related to higher-level assumptions rooted in professional culture, societal values, and previous experiences. We generated six themes capturing and structuring the professional perspectives: (1) meta-perspectives on the digitalization of therapeutic rooms, (2) the "how" of service integration, (3) challenging therapist culture, (4) negotiating the limits of the digital therapy room, (5) creating clinical value from the digital format, and (6) adapting techniques and technology in digital therapy sessions.

Conclusions: To strengthen the adoption and impact of video consultations, we should direct attention toward higher-level societal and cultural aspects that shape attitudes and practices. We suggest incorporating digitalized therapy in education, facilitating personal experiences with video consultations, increasing the sharing of knowledge between clinical environments, and sparking innovation of both service models and technology.

Introduction

Background

Implementation of video consultations (VC) as an alternative for mental health care delivery addresses several practical barriers to patients' access to treatment [1-4]. The clinical outcomes of therapy delivered through VC are comparable to those of traditional in-person therapy for a wide range of mental health conditions, including depression, suicidal ideation, generalized anxiety disorder, and posttraumatic stress disorder [5-9]. Thus, studies investigating adaptations of psychotherapy practices to the VC format have emerged [10-14]. The literature on VC in services for severe mental illness and other less common mental health conditions is scarcer and inconclusive, but remains optimistic and encourages further research [15-19].

Hybrid therapy—the combination of VC and in-person therapy sessions—allows patients and clinicians to experience the benefits of both formats [20-24]. Previous research on the clinical use of VC has largely focused on comparing the service delivery alternatives in isolation. However, the flexible integration of both VC and in-person treatment modalities is increasingly treated as a promising approach for future mental health care services, potentially providing added value compared to using a single format [25-27]. Studies supporting hybrid models for delivering different types of clinical interventions have appeared in the literature [28-30], but there is a need for more research to develop ideal strategies for integrating VC as a component in routine hybrid services.

The adoption of VC varies significantly across mental health care [31,32], and the attitudes of mental health professionals contribute to this variation [33-36]. Some studies have shown that mental health professionals have largely positive attitudes toward VC, perceiving the format as acceptable and feasible for several clinical purposes [2,33,34,37-41]. Other studies have found greater diversity in perceptions of VC [42,43], and some have identified fundamental drawbacks reported by mental health professionals, such as feeling less present and experiencing a reduction in the quality of the therapeutic relationship [44-46]. Across studies, many report a lack of VC competency or an unmet need for support [14,35,36,47,48]. Furthermore, more experience with VC is associated with attitudes that are more positive [49-51]. Overall, mental health professionals show a preference for the traditional format [24,33,39], which is more evident than that of patients [37,48].

Organizational context is another factor that has been suggested as significant in influencing mental health professionals' attitudes toward and intention to use VC [35]. The public and private health sectors represent distinct organizational conditions. In Norway, the number of private actors offering on-demand mental health care services has increased during the last decade, typically including digital treatment alternatives and opportunities for quicker access to services [52]. In parallel, the proportion of the population with private health insurance (as a supplement to the basic public coverage) has grown significantly [53], which influences the demand in the market for private health services. This development might indicate a more innovative climate, higher responsiveness to user demands, and quick adaptations to digitalization trends among private practitioners. However, we know little about how the private mental health sector approaches VC [54-56]. Health care systems are generally complex and characterized by organizational silos that challenge knowledge sharing across clinical environments [57-59]. Such gaps are highly noticeable within the public health care sector but are even more evident between the public and private sectors [60,61]. Another important reason for the lack of knowledge about private mental health actors is that the private sector in Norway typically has fewer incentives to spend resources on research activities, while the public sector finances and conducts most of the studies on mental health care services.

Study Objectives

In summary, the topic of VC in mental health care lacks professional consensus. In this study, we aim to explore the experiences, attitudes, and contextual aspects related to mental health professionals' use of VC. The study will include professionals working in various services across public and private mental health care to capture a broad range of perspectives. Our ambition is to develop knowledge about factors that contribute to differences in VC adoption and attitudes to inform the design of accessible future health care services that reach more people.

Methods

Study Design

This study is a qualitative investigation of mental health professionals' experiences with and attitudes toward VC, as well as the professional contexts of the participants. The study uses a combination of convenience and snowball sampling strategies [62], digital semistructured interviews, and reflexive thematic analysis [63].

Study Setting

The study was conducted in Norway. The Norwegian national public health system provides universal health coverage. The private health expenditure of the population is generally low (14% in 2021) [64]. Mental health care is provided through primary and specialized services, the latter requiring the presence of moderate or severe psychiatric conditions and a referral from the primary services. Specialized psychiatric services comprise both district psychiatric centers (local outpatient clinics) and hospitals. The services are semidecentralized and organized based on catchment areas, aiming to provide equal access to care across all social strata and geography [65].

The 2 public sector sites of our study are St Olav's Hospital (Trondheim University Hospital) and Oslo University Hospital. The catchment area of St Olav's Hospital consists of both urban and rural areas in Central Norway and is characterized by greater geographical distances between inhabitants and services than the catchment area of Oslo University Hospital, which serves urban areas only. The 4 private sector sites of the study are all located in major cities of Norway. These private clinics provide services to people who are self-referred. Their clients can pay for the services themselves or through private health insurance.

XSL•FO
RenderX

Three of the private clinics in our study allow clients to book consultations directly through their websites, where clients can access information about available therapists and time slots. The fourth clinic requires clients to call, email, or submit a contact form. Two of the private clinics specialize in certain therapy orientations and patient populations, while the others offer more general mental health services. To protect the anonymity of the participants, we have chosen not to disclose the names of these clinics, as they are small, and the mental health professionals could be identified.

Recruitment

The sample of participants in this study was obtained through convenience sampling, which included a snowball strategy [62]. We contacted the leaders of psychiatric clinics at St Olav's Hospital, Oslo University Hospital, and several private clinics and invited them to take part as recruitment sites in our study (see Figures S1-S3 in Multimedia Appendix 1 for more details). The 2 public hospitals and 4 of the private clinics agreed to participate and approved the recruitment and data collection procedures. Two private clinics did not respond to our invitations. Both management and study participants at the clinical sites facilitated further recruitment of participants by informing colleagues about the project and sharing the project group's contact information.

The inclusion criteria were as follows: (1) working as a clinician or working as a leader of other clinicians and (2) employed at one of the public hospitals or affiliated with one of the private clinics. All heads of the units had approved their participation and accepted that the participants spent an hour of their day on the interview. We did not aim to achieve a representative sample to generate representative findings; rather, we aimed to develop empirical thematic insights that were transferable to both research and clinical contexts [66]. We sought to access a broad range of viewpoints and contexts that would allow an exploration of whether expected characteristics (eg, sector affiliation) and other nonpredefined aspects influence approaches to VC. Importantly, we also included participants working in services targeting severe mental illnesses. A lesson learned from our previous work is that researchers and services should consider patients living with severe diagnoses as candidates for digitalized services, although they are often excluded from the target groups of such interventions [67].

Data Collection

Data collection was carried out between May 2024 and December 2024. We conducted digital semistructured interviews addressing individual experiences and attitudes toward VC, as well as the participants' workplace and professional environment. The interviews were based on an interview guide developed by the authors for the purpose of this study (Multimedia Appendix 2). We used the secure web-based VC platform Join, delivered by the state-owned company Norsk helsenett. The duration of the interviews ranged from 45 to 60 minutes. We recorded each interview with an app developed by Services for Sensitive Data (TSD), owned by the University of Oslo. The interviews were automatically transferred to the secure TSD platform and transcribed by the University of Oslo's OpenAI Whisper technology.

Data Analysis

We analyzed the interview transcripts from a critical realist position, applying a method largely based on Braun and Clarke's [63] reflexive thematic analysis. We approached the data with an inductive, explorative, experiential, and contextualist approach [68]. The analysis was data-driven. It placed a direct focus on the participants' utterances rather than on language and latent meaning. A contextualist orientation was a natural choice to capture the features of professional cultures and clinical environments. Choosing the reflexive school of thematic analysis, we aimed to transparently communicate the impact of researcher participation, as well as analytic decisions and processes. We selected this method with the ambition of developing meaningful themes that can carry transferable insights across the mental health field [66]. Moreover, the analysis was conducted from a pragmatic perspective that considered current and future clinical practices. We followed the 6 phases of thematic analysis outlined by Braun and Clarke [69], with some minor adaptations (Multimedia Appendix 3).

User Representation

Two user representatives with lived experience, recruited through the Bipolar Association Norway, contributed to this study. The representatives provided feedback on the study in the early design phase and during the writing process. The purpose of this involvement was to ensure that the research aims, the methods applied to achieve these, and the angle used to present and discuss the findings are relevant, interesting, and valuable to people living with mental disorders, including severe conditions such as bipolar and psychotic disorders.

Ethical Considerations

The project obtained approval from the data protection officer at Oslo University Hospital (24/04658). All participants provided written consent to take part in the study. The consent forms included information about the purpose of data collection and how the data would be stored and processed. The forms emphasized voluntary participation, including the option to leave the study at any time without risking any consequences. Signed consents and interview transcripts were stored in the secure TSD database. To protect the privacy of participants, identifiable features of participants were removed by MS within the secure TSD environment before the data were exported for analysis.

The economic compensation offered only to the participants working in private clinics entails ethical consideration. Importantly, private practitioners' financial models conflict with involvement in research, which contributes to the maintenance of a knowledge gap concerning private health care services. Moreover, the project group holds the view that the compensation was not high enough to create any form of pressure for the private practitioners to participate in the study, only enough to compensate for lost income during the interview. Therefore, we evaluate the economic compensation to the participants working in private clinics as both ethically acceptable and reasonable.

Results

Overview

A total of 24 mental health professionals participated in our study (Figure 1 and Table 1), representing different demographic characteristics, geographical catchment areas, professional backgrounds, types of services, and target patient populations, as well as affiliation to either the public or private health sector. From the earliest phases of the analysis, we observed great variation in the participants' attitudes toward VC and in the amount of personal experience with VC as a therapy format. Figure 2 is a result of early familiarization with the data material (Multimedia Appendix 3). The figure provides a simplified overview of the 3 subgroups in regard to levels of VC experience and attitudes. The figure is based on subjective and exploratory screening of the main tendencies in the participant accounts. The most extreme values on each of the axes represent the most extreme participant views identified in this study sample, and the position of each data point is relative to the others. Taken together, the distribution of data points in the figure suggests that there is a tendency that VC experiences and VC attitudes are related and that the relationship between the two concepts is stronger at more extreme levels. Moreover, the figure indicates differences in the amount of experience with VC between the 3 subgroups. Nevertheless, a continuum of attitudes is represented in each group. Early screening of attitudes in relation to participants' characteristics indicated that variations in attitudes did not systematically follow affiliation with the public or private sector or the type of service the mental health professionals worked with.

XSL•FO
RenderX

Through the following phases of the reflexive thematic analysis, we constructed a set of 6 themes, with each theme belonging to a distinct level of abstraction (Textbox 1).

Textbox 1. Themes from the reflexive thematic analysis listed according to level.

Meta level

- Theme 1: meta-perspectives on the digitalization of therapeutic rooms

Service level

- Theme 2: the "how" of service integration

Therapist culture level

- Theme 3: challenging therapist culture

Clinical level

- Theme 4: negotiating the limits of the digital therapy room
- Theme 5: creating clinical value from the video format

Practice level

- Theme 6: adapting techniques and technology in digital therapy

Theme 1: Meta-Perspectives on the Digitalization of Therapeutic Rooms

The first theme connects the practice of VC to the overarching digitalization trends in society and health care services. The participants demonstrated opposing underlying values that naturally influenced their standpoints at lower levels (ie, the 5 other themes). Interestingly, these meta-perspectives did not seem to follow other key characteristics of the participants, such as age, gender, private or public workplace, clinic, or severity of the condition of their patient population.

Some viewed the increased attention paid to VC in mental health care as a symptom of the fast-paced digitalization of our communities, which reduces arenas for healthy ways of experiencing and relating to others. Using this rationale, VC practices contribute to an unwanted development toward more individualism and isolation. Thus, there is a need to safeguard some of these analogue spaces, especially traditional therapy rooms, which might be particularly important.

> *Personally, and on behalf of others, I find it very exhausting to interact so much digitally. It has an overhead cost, whose extent I think we don't fully understand yet.* [B4, resident doctor in psychiatry, public hospital]

> *Digital (encounters) enhance the extremely rational, intellectualizing way we relate to ourselves and others, which I believe results in more psychopathology.* [D1, specialized psychologist, private clinic]

The opposite viewpoint places digitalization in relation to new dynamics in the distribution of power and agency between patients and services. Since offering digital treatment can increase access to care and help balance the relational asymmetry of health care services, this viewpoint treats the expansion of therapy alternatives as a moral obligation.

> *They experience a higher degree of autonomy and control when they meet me at a screen's distance.* [A1, psychiatrist, public hospital]

> *We deprive some patients of the opportunity to show up—patients who would otherwise struggle because they must enter our arena. There is already an imbalance—an asymmetrical relationship. Therefore, I think we owe it to them.* [A2, specialized psychologist, public hospital]

Theme 2: The "How" of Service Integration

The second theme captures the diversity in VC integration strategies and emphasizes the relevance of exploring creative possibilities of VC use further. The data material contained descriptions of various service models involving VC in different ways, serving different purposes. See Textbox 2 for an overview of the service models identified in the study. The list demonstrates that using VC does not mean one thing. Rather, VC can be adapted to the specific needs of different clinical contexts. In practice, the participants often applied a combination of elements from the listed service models. We identified the most evident differences between the sectors in these dimensions. Some models were more available or exclusively implemented in the private sector, such as the digital hub of specialists. The hub allows personalization on several levels.

XSL•FO
RenderX

Textbox 2. Service models that integrate videoconferencing identified in the data material.

Only digital

- All consultations in a course of treatment are digital. One private therapist worked exclusively with video consultations (VC) from home. One public clinician worked with a fully digital intervention for relatives.

Digital first session

- All new patients attend their first session through VC. Later, they decide on the format. Used in a public service for bipolar disorder that served many patients referred directly from emergency wards.

Hybrid strategy (relational booster rationale)

- Hybrid courses of treatment where traditional consultations comprise a minority of meetings and are used to strengthen the therapeutic relationship. Patients typically live far away.

Hybrid strategy (content rationale)

- Hybrid courses of treatment where the format depends on the session's content. For instance, parts of psychiatric assessments where only verbal reports are needed can indicate a VC session.

Hybrid strategy (practical rationale)

- Hybrid courses where there is a preplanned strategy of using both formats to reduce travel or absence from daily activities. Target patients may have a network and activities they attend regularly.

Hybrid strategy (symptom-based rationale)

- Hybrid courses where anxiety-related symptoms are barriers to receiving services, and therapy starts off as VC, while the proportion of physical meetings gradually increases based on symptom reduction.

Hybrid strategy (staff flexibility rationale)

- Clinicians work from home on days when only digital appointments are scheduled to increase variety, flexibility, and satisfaction with work.

Ad hoc hybrid courses (short-notice changes)

- Traditional sessions may change into digital ones at short notice due to patients experiencing unanticipated events or problems with executive functions. VC sessions secure continuity.

Open booking (only private clinics)

- A client-centered service that allows anyone to book a VC session at a suitable time with the therapist they prefer, typically directly through a website. Some clinics also offer different durations of sessions.

Digital hub (only private clinics)

- Clinics provide information about therapists' competencies and preferred therapy orientations, offering a menu of therapeutic alternatives from which clients can choose the best match for their needs.

> *Here, you can choose someone who matches where you are in the therapy process, what your goals are, and how you like to work. I think this leads to faster improvement compared to going to someone at random.* [D1, specialized psychologist, private clinic]

Furthermore, working independently with more flexible opening hours in a private clinic allows more staff flexibility for practitioners:

> *It is nice to have some days at home, deciding for myself how I want to structure the day. I might have a consultation at nine, the next consultation at one. Then one at six, and the last one at eight. Depending on what the client needs. And meanwhile, I can just live my life.* [E2, psychologist, private clinic]

Hybrid, preplanned strategies for delivering therapy for practical and symptom-related reasons were applied across the sample. However, a few therapists also talked about using traditional sessions to boost the relational quality of mainly digital courses of treatment, where the effect of the physical conversation would be maintained for a while:

> *... then we can keep leveraging from that (physical) booster session in the other (digital) conversations.* [E3, specialized psychologist, private clinic]

An insight from this dimension was that the clinicians' presentation of how a VC service could work out is important, as it can shape patients' expectations. One of the participants worked with a completely digital support service for the relatives of patients with severe mental illness. The clinician described how the relatives accepted the digital service they were offered and that there were no requests for in-person meetings:

> *The thing about the (digital service to relatives) conversations is that they are video-only. Right? Even*

XSL•FO
RenderX

> *from the first session. So, you go into it with the expectation that we will only meet on video.* [B5, psychiatric nurse, public hospital]

Theme 3: Challenging Therapist Culture

The third theme is based on the participants' descriptions of VC as a deviation from tradition and something that challenges assumptions established in professional culture. Some participants described video practice as a threat to therapists' integrity, associating it with something less therapeutic than traditional therapy. Others said that VC could trigger a feeling of helplessness and less confidence in their role as therapists, a threat to their professional identity.

> *It's kind of taboo in a way ... I think some view it as somewhat poorer. That you don't really connect with the patient properly, when you don't meet and look this person properly in the eyes.* [B7, nurse, public hospital]

> *There is sometimes a need to initiate acute interventions, and then you don't necessarily get in the right position to act ... you feel more helpless on video.* [B2, resident doctor in psychiatry, public hospital]

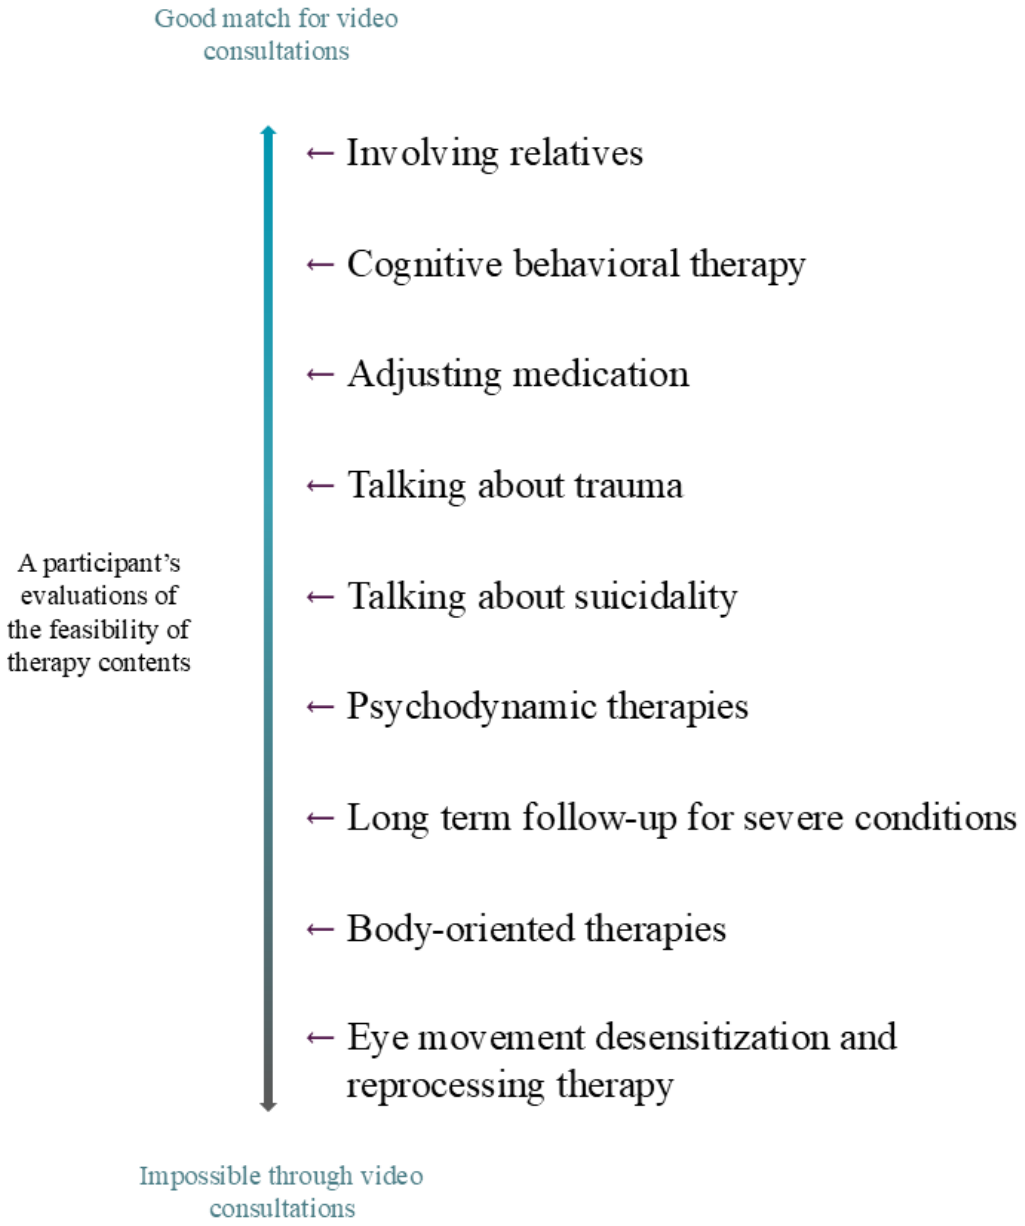
Nevertheless, several participants challenged their preconceptions through experience and developed new, accepting approaches to VC. They reflected on the norms and myths of psychotherapy and identified culture-based assumptions about digital therapies:

> *If people were used to sitting at home and talking, and that was the standard, I am pretty sure going to an office would have felt strange.* [A6, specialized psychologist, public hospital]

> *It has become imperative that the patient comes to the outpatient clinic and stays there for 45 minutes.*

> *I do not have any evidence to state that it is very effective or useful for either the patient or us. ... It is deeply ingrained in healthcare culture. Things like video consultations are not part of education programs. ... This influences what one thinks as a clinician.* [A7, specialized psychologist, public hospital]

As observed early in the familiarization process of the dataset, there seemed to be a trend that the most experienced VC therapists held more positive views, and vice versa. However, we also observed that private practitioners with more experience than employees from public hospitals conveyed diverse opinions. Interestingly, in private clinics, patients decide on the therapy format themselves when they book a consultation. Thus, some private practitioners may practice an even amount of VC therapy, even if they subscribe to a therapist culture that favors the physical therapy space.



Theme 4: Negotiating the Limits of the Digital Therapy Room

Theme 4 demonstrates the contrasts in professional opinions and rationales regarding the clinical purposes for which VC is suitable. All participants acknowledged that the digital therapy room was less appropriate when patients lacked social contact and activities in their daily lives or needed exposure to work with avoidance. Apart from this, their reflections on the feasibility of different therapy contents varied.

Figure 3 illustrates the continuum of the perceived feasibility of different therapy contents when delivered through VC, based on a participant who worked within the cognitive therapy orientation. The case presented in the figure demonstrates how participants typically had clear logic and presented a continuum of feasibility, defining the limits of VC. From the viewpoint in this case, eye movement desensitization and reprocessing therapy (EMDR) is the least feasible intervention using VC.

XSL•FO
RenderX

Figure 3. Illustration of a typical continuum of feasibility concerning different therapy contents when delivered through videoconferencing, based on 1 participant.

However, others expressed contrasting opinions. These perspectives on feasibility are demonstrated in the following extracts:

> *There are certain things that are not easy to do on video—that cannot be done on video. For example, trauma therapy with EMDR. It is completely impossible.* [A3, psychiatrist, public hospital]

> *I might think that EMDR works better digitally than other forms of therapy, because there are very few words.* [D1, specialized psychologist working with EMDR in traditional sessions, private clinic]

Similarly, while most participants talked about patients with psychotic disorders as the patient population least probable of experiencing value from VC, one of the clinicians working with this patient group remarked,

> *I think the patient can often surprise the clinician in that area, and they can often be better (than what the clinicians expect).* [B7, nurse, public hospital]

Finally, some mental health professionals demonstrated the importance of understanding the difference between the feasibility of carrying out interventions and the actual therapeutic value that is realized. In the context of services aimed at patients struggling with severe diagnoses and complex life challenges, a VC may not achieve the same outcomes as in-person contact. A participant stated that services and clinicians are at risk of misleading themselves in the following way:

> *"Now that we have digital tools, we actually get in touch with the patient. The patient attends the appointments. We are now in a position where we can talk to this person." However, the patient just sits there in their municipal apartment, isolated,*

XSL•FO
RenderX

> *without needing to go out. "But at least we get in touch with him!" I imagine that we might end up just believing that we have done something good.* [B4, resident doctor in psychiatry, public hospital]

Theme 5: Creating Clinical Value From the Video Format

The fifth theme revolves around the process of realizing therapeutic value from VC. The data material contained examples demonstrating that the video format, in some cases, comes with unique additional clinical benefits:

> *I have many clients whom I have never met in person. However, it was particularly interesting that with those I had met in person, I felt that more happened when we could talk on video, and I experienced more therapeutic breakthroughs with them after we started with video consultations. I found that a bit interesting.* [E2, psychologist, private clinic]

Several clinicians explained that the practical benefits of the video format mediated some of the extra therapeutic value. When patients do not need to spend much time travelling or spend energy overcoming practical obstacles and stress related to a physical meeting, more resources may be available for the purpose of the therapy session. Moreover, remote sessions often come with proximity to family members, which can result in more effective therapeutic processes:

> *They might have to sit on a bus for two hours each way, and then the entire consultation would end up talking about how terribly frustrating it had been. When you have a video consultation, you can really concentrate on what the underlying problem is.* [A3, psychiatrist, public hospital]

> *I had the opportunity to do things more quickly. I found out that it might be a good idea to talk to (the patient's) relative just to calm the situation and asked if that relative was present at home. The patient said yes, and then I got 15 minutes with the relative right away. And then that situation was solved. It wasn't an issue anymore.* [A6, specialized psychologist, public hospital]

Another application of VC is as an aid to regulate patients' level of activation. Facilitating a safe, less confronting therapy environment reduces the level of activation, providing patients with more opportunities to take part in and experience the effects of emotionally challenging therapeutic interventions:

> *If there is a really difficult conversation with a client where we are going to talk about our alliance, I might take the client out of the therapy room to help downregulate feelings, not having to maintain eye contact. We can use video to do the same. Sometimes, when we want feelings to be more intense, I prefer to be in the office.* [E1, psychologist, private clinic]

Theme 6: Adapting Techniques and Technology in Digital Therapy Sessions

The sixth theme is placed at the concrete level of therapeutic practice, covering pragmatic adaptations of therapy interventions and technical aspects of the technologies used for VC. One clinician always wore headphones during VC to optimize the dynamics of the conversation, rather than using the speakers:

> *I get the sound directly in the ears instead of it coming from speakers. That makes a difference.* [E3, specialized psychologist, private clinic]

Another clinician talked about how basic VC therapy skills provide great opportunities to carry out therapeutic interventions that traditionally depend on the physical environment of the therapy room. This clinician emphasized the importance of careful verbal guidance and attentive assessment of the patient's needs during VC:

> *I don't feel (that the video format) is an obstacle because I can guide them and see if there's something they need, find a slightly better chair to sit on, or if they have something they can hold in their hand, or if they're working on regulating themselves a bit. Grab a pillow or something like that. They can do that at home as well.* [D3, specialized psychologist using body-oriented methods, private clinic]

Several participants shared the opinion that there is potential for improvement for future VC practices. Some said that simply improving the information about VC directed at patients could strengthen implementation. Others talked about potential improvements in the technology; for example, how AI might enhance the liveliness of VC. Finally, multiple participants talked about the lack of safe and clinically validated software that can mimic whiteboards and paper-based tools that are typically used in traditional assessment and therapy sessions. Such technology already exists and is integrated into VC systems used in other professional contexts, but is not available for clinical use in mental health care.

> *If we get an AI as a video chat function, then we could have more visual dynamics. And I think these dynamics will elevate the experience.* [B2, resident doctor in psychiatry, public hospital]

> *If there were a function where you could incorporate questionnaires or some kind of interactive board in the video call (...) That could perhaps also address some challenges related to forms and documentation.* [A8, specialized psychologist, public hospital]

Discussion

Principal Results

This study explores experiences, attitudes, and current debates related to the role of VC in mental health care and challenges preconceptions identified in our own research environment and beyond. To our knowledge, this is the first qualitative study to explore the experiences and attitudes of mental health professionals across public and private settings on the topic of VC. Moreover, the study included perspectives from a broad selection of services, ranging from those targeting bipolar and psychotic disorders to on-demand services targeting clients with milder conditions and not requiring referrals. Our study identifies differences in VC implementation, experiences, and professional attitudes that support the existing literature

XSL•FO
RenderX

[31,32,42,43]. Contrary to the authors' expectations, key characteristics such as public and private sector affiliation and symptom severity of the target patient populations did not seem to shape the participants' views to a significant degree. Building on this, our study points out important areas to direct future efforts to increase the adoption and impact of VC.

Primarily, our findings demonstrate that higher-level aspects, such as societal values and cultural perceptions, are important in shaping professional attitudes. Psychotherapy and the therapist role are defined through the cultural value systems in society and in professional environments [70]. Thus, fundamental changes in mental health care services, such as the digitalization of the delivery of therapy, can be experienced as a cultural deviation from traditional models of psychotherapy [71,72]. In accordance with this notion, several participants talked about how traditional ideas about psychotherapy weaken the credibility of VC, although many forms of VC-delivered psychotherapy are supported by robust evidence [5-9]. This tendency indicates a lack of cultural familiarity with digitalized treatment and a lack of knowledge about the evidence-based applications of VC.

While the status of VC in clinical environments remains unclear, polarized approaches have been developed. In our study, the participants with the most critical attitudes typically conceptualized VC as part of purely digital, fast-paced, cost-reduction–focused services and, thus, a symptom of an unwanted development in health care. Research on the resistance to digitalized mental health services has identified similar viewpoints of clinicians who experience that technology conflicts with fundamental humanistic values in mental health care, resulting in resistance and stigma related to the digitalization of therapy [72]. This approach facilitates an all-or-nothing view of digitalized services instead of a nuanced perception of VC as a flexible tool that can be integrated in various ways in hybrid services, a model that is becoming increasingly applied in the literature [25-27].

Interestingly, even among the participants who held the most positive attitudes, we found conflicting views on whether VC is feasible for patients with severe conditions. These clinicians described the patient group as vulnerable and conveyed that it was their professional responsibility to protect these patients accordingly. However, adjustments to the service alternatives based on the vulnerable status of patient groups may not always result in better outcomes for the patients [73]. Furthermore, the exclusion of such patient populations may be based on stigmatic perceptions of the patients, which have been found to be relatively frequent among clinicians working in mental health care services [74,75]. Differentiating the treatment offered based on patients' diagnoses may preserve such preconceptions. Although the existing evidence pertaining to VC in services targeting these populations is still scarce and calls for more research [15-19], we encourage an inclusive and personalized approach and advocate refraining from excluding patients based on diagnosis alone.

Importantly, the education of mental health professionals plays a fundamental role in defining the scope of psychotherapy and conceptualizing VC. Currently, VC is mostly absent from the training of mental health personnel, which may promote more trust in traditional cultural perceptions of therapy and the limits of VC. Moreover, mental health professionals report low self-efficacy and a lack of training and support in clinics [14,35,36,47,48]. At the same time, the research field continues to produce new knowledge about VC, such as through studies focused on adapting basic therapeutic skills to the video format and studies on how we can maintain a feeling of connectedness in video sessions [10,14]. In addition, the body of literature covers adaptations of interventions within therapy orientations that are often closely associated with traditional settings and that emphasize sensory experiences and the atmosphere of the therapy room, such as psychodynamic transference [11], emotion-focused therapy exercises [12], and EMDR [13]. Our findings encourage the inclusion of knowledge about VC in the basic training of professionals to ensure that VC is incorporated from an early point.

We also found that the amount of personal experience with VC plays an important role in shaping attitudes, as it directly challenges established cultural assumptions. Several participants expressing optimistic attitudes stated that they had not been able to perceive VC as feasible and valuable before they had practiced it themselves and adjusted their preconceptions. These observations partly align with previous research showing that more experience with VC is associated with positive attitudes and less self-doubt as a therapist [49-51]. These findings are supported by research suggesting that one of the main drivers of adoption is clinicians' own personal experiences, proving that digital tools can result in clinical benefits [76]. Together with the literature, our findings emphasize the importance of personal experience to perceiving the value of VC. Thus, we suggest that services become aware of this tendency, demonstrate the beneficial effects for both service users and providers, and develop incentives for clinicians to integrate VC in their practice.

Finally, our study presents a range of creative and innovative therapy practices and service designs, suggesting that there is potential synergistic value in sharing local insights between professional environments. Several of the service models identified have been implemented only to a very limited degree across the clinical sites of the study, such as the digital hub or digital first sessions (see Theme 2 in the Results section). Some of these service designs have been mentioned in the literature but have not been tested in public settings in Norway [27]. Using insights and service models from both the private sector and innovative public sites may be valuable in future decision-making regarding service designs in public health care. Interestingly, few innovative activities revolve around the technologies used for VC, and clinicians report that the platforms they use lack the basic tools used in traditional therapy [24,41,46]. This indicates that there is room for improvement and further innovation in terms of clinical VC software, which has barely changed since the introduction of VC in mental health care.

Limitations

Although the method chosen for this study does not aim to produce generalizable findings, and although our findings can

XSL•FO
RenderX

still be transferable, we wish to explicitly acknowledge that the composition of our sample may have moved the analytical focus and the results in a more optimistic and progressive direction. For instance, several participants recruited from one of the public hospitals were involved in research and development, while two were involved in digitalization projects. We are also aware that the participants who decided to participate might have had more positive attitudes toward the topic of the research project than those who did not want to participate. This, combined with the authors' optimistic attitudes and roles in other digitalization projects closely related to the topic of this study, possibly influenced the angle we chose for this paper, which encourages digitalization in mental health care. Another limitation relates to the practical transferability of findings produced in this study in an international context, as all participants were recruited from Norwegian health care sites. Furthermore, the analysis is not exhaustive in discussing aspects that have an impact on the participants' viewpoints. For instance, regarding the private actors' contextual characteristics, the paper discusses the impact of incentives for practicing VC and whether VC use is voluntary or not to a very limited degree. An important research-related issue resulting from such differences in public and private sector contexts revolved around the recruitment for this study. Participants from private clinics received economic compensation of about US $110 because of slow recruitment due to the nature of the private practice financial model. Lost activity with paying clients results in reduced income, which is a barrier related to participation in research projects. The other participants did not receive similar economic compensation since they were all employed at university hospitals, where participation in research and development projects is integral. Future research should explore the effects of different organizational conditions in detail, which may be of great importance in developing attractive workplaces for mental health professionals and sustainable hybrid services.

Conclusions

This qualitative exploration emphasizes the multidimensional nature of professional perspectives on VC. Our findings underline how overarching societal and cultural ideas influence professional attitudes, logic, and, thus, clinical practice. Our ambition is that the paper challenges preconceptions about digitalized therapy and that it points to useful strategies for targeting problems concerning the limited adoption of VC. Educational institutions and services must promote a nuanced, evidence-based concept of VC and demonstrate benefits for both service users and providers. In addition, incentives for mental health professionals to practice VC should be developed and presented. There is unrealized potential in applying existing therapy adaptations and hybrid service models established in separate parts of health care systems, particularly for public clinics. In addition, there is room for innovation with regard to service designs that integrate VC and the technology platforms used to create unique value in hybrid services and to increase the attractiveness of the VC format in mental health care.

Acknowledgments

We wish to thank all the study participants and the two user representatives for their contributions to this study. This study is funded by the Research Council of Norway through grant 309264 (Forhelse Research Centre for Digital Health Services, a centre for research-based innovation).

Data AVailability

To protect the anonymity of the participants, the qualitative dataset generated during this study will not be available to readers. More information concerning the study settings is available from the corresponding author on reasonable request.

Authors' Contributions

MS wrote the manuscript. The other authors reviewed, modified, and suggested changes during the writing process. KLR, SRA, LNS, KJK, and MS designed and planned the study. KLR, SRA, HMI, and MS recruited participants. MS was the main interviewer. KLR participated as a supervisor and cointerviewer in the first 3 interviews. MS led the analysis with guidance from the other authors. KLR is the main supervisor of MS as a PhD candidate. SRA and LNS are cosupervisors.

Abstract

Background: Mobile health (mHealth) is increasingly used in teledentistry for telediagnosis and other services; yet, the perceptions of frontline clinicians and end-line users regarding these technologies remain unexplored.

Objective: This study examined the acceptability, feasibility, and usability of an mHealth model for telediagnosis from the perspectives of frontline clinicians and end-line users.

Methods: A qualitative study using focus group interviews was conducted with 15 participants, including frontline clinicians and end-line users. Frontline clinicians captured dental images via a smartphone app, while end-line users assessed them through an mHealth platform. Interview transcriptions were thematically analyzed using consensus coding.

Results: Thematic analysis identified 9 key themes: feasibility and perceived ease of use, perceived usefulness, compatibility, self-image and social influences, self-efficacy, voluntariness and behavior intention, anxiety, facilitating conditions, and attitudes toward a behavior. Participants considered smartphone-based photography acceptable and feasible for remote dental assessment. Facilitators and barriers to implementing the mHealth model were highlighted, and recommendations for improvements were proposed.

Conclusions: Cyclical education and professional development are essential to enhancing user confidence and technology usability. Addressing patient and clinician resistance through targeted education, improved communication, and operational upgrades such as camera grids, system integration, and simplified login can support adoption. This study highlights mHealth's potential in emergency dental assessment and screening, particularly for underserved populations, and underscores opportunities for interprofessional collaboration. Future research should explore broader clinical applications across oral health conditions.

Introduction

Traumatic dental injuries (TDIs) are prevalent [1] and demand urgent attention when accompanied by pain and/or bleeding [2]. Most patients with TDI presenting in emergency departments need consultation and evaluation from dental professionals [2]. However, the limited on-call availability of dental professionals in emergency settings often leads to unnecessary patient transfers and increased health care costs [3], an issue that worsened as dental emergency services declined during the COVID-19 pandemic [4]. To address these challenges, technologies for virtual dental examinations have been developed and implemented [5].

Mobile health (mHealth) facilitators have incorporated mobile phones and wireless technological devices into health care practices, supporting the promotion and maintenance of health, enhancing preventive care, improving clinical decision-making and operational efficiency, and enabling remote communication and interaction. This approach has gained widespread adoption among health care professionals and caregivers [6]. Key benefits of mHealth include increased accessibility to health care services, the provision of anonymous consultation, and decreased reliance on travel and physical contact. These advantages were particularly valuable during the COVID-19 pandemic, when social distancing measures were necessary [7].

The concept of mHealth as a modality of teledentistry, or more specifically, m-oral health [8], includes teleconsultation for treatment planning and review [9], telediagnosis with virtual examination [9-14], telemonitoring using patient-generated health data [15-18], telesupport with interactive multimedia [19], and teleintervention to improve therapy adherence and complication management [20]. Prior mHealth studies have demonstrated adequate diagnostic performance for the remote assessment of TDIs [10], dental caries [11], and oral cancer [12] using smartphone-acquired photographs. In a survey conducted in Saudi Arabia, more than 60% of dentists have used mHealth technologies to capture and/or transmit clinical photographs, and the majority of them were confident in the diagnostic accuracy using this approach [21].

Our recent work described a workflow for telediagnosis of TDI, where trained clinicians and students used a smartphone camera and app to capture dental photographs, uploading them to secure cloud storage. Remote dentists and dental therapists then reviewed the images, recorded dental findings, and provided clinical recommendations through the same pathway in reverse. While the quantitative performance metrics of this mHealth practice were promising, areas for improvement, such as image quality and professional development on dental photography and remote assessment, were also indicated [10].

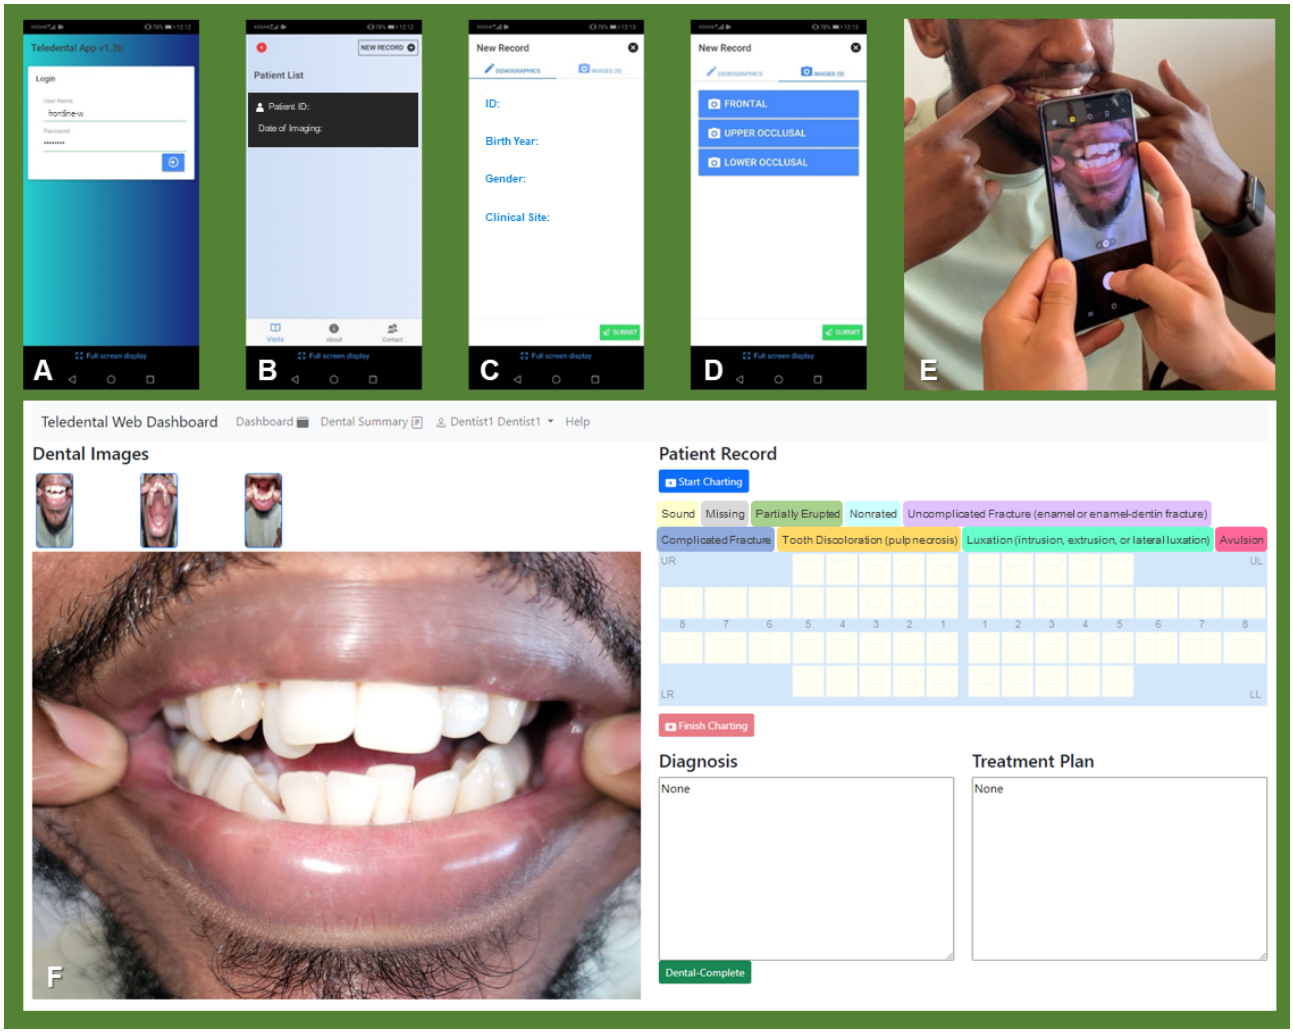
Within the Technology Acceptance Model (TAM), perceived ease of use and perceived usefulness are the determinants for an individual's intention to use a new technology [22]. Based on different roles and concerns, Wallis et al [23] categorized mHealth users as patients, frontline clinicians (point-of-care clinicians), and end-line users (academic experts). Building on a similar classification, the users of our telediagnosis model comprised human participants (patients and nonpatient individuals who provided consent for dental photography), frontline clinicians (those who captured dental photos), and end-line users (those who remotely assessed dental photos) [10]. When searching literature with keywords of feasibility, acceptability, usability, or user perception, we found that only a few studies have reported frontline clinicians' and end-line users' perspectives on specific mHealth models, practices, or technologies for dental care or oral health promotion [13,15-18,20]. Among these, only 1 study focused on telediagnosis [13], but their diagnostic method was not photography-related. Of further note, an earlier mHealth study reported the perspectives of parents and caregivers on a photographic telediagnosis model for the detection of dental caries [14], but they did not investigate the perspectives of frontline clinicians and end-line users.

Despite evidence that smartphone-acquired photographs can achieve acceptable diagnostic performance for several oral conditions, few studies have examined the perspectives of the 2 professional user groups essential to photographic telediagnosis, frontline clinicians who capture images and end-line users who interpret them. Prior work has focused on patients, caregivers, or nonphotography telemethods, leaving clinician-centered implementation questions unanswered. This gap matters because diagnostic accuracy alone does not guarantee real-world adoption. Human factors such as privacy concerns, workflow fit, training needs, and system integration also directly influence acceptability and sustained use. By exploring these clinician perspectives, this study addresses practical barriers and facilitators that must be resolved to translate promising diagnostic performance into scalable, safe, and equitable teledentistry services. This study therefore aimed to explore frontline clinicians' and end-line users' perspectives on the feasibility, usability, and acceptability of smartphone-based photographic telediagnosis for TDI.

Methods

Study Design and Setting

This qualitative study was part of a larger project and was reviewed and approved by the University of Minnesota Institutional Review Board (Study ID: STUDY00014736). The study setting consisted of multiple sites located in Minnesota (United States) and Khon Kaen (Thailand), including the University of Minnesota clinical site, Khon Kaen University clinical sites, and Minnesota State Fair research facilities. The quantitative component of the larger project has been reported recently [10]. Following that, a qualitative study design grounded in the TAM [22] and interpretivism [24] was used to evaluate the perspectives of frontline clinicians (dental photographers) and end-line users (remote reviewers) on their use of the mHealth technology to assess TDI. Qualitative study data were collected in November and December 2023 and analyzed from January to August 2024. The conduction and presentation of this study adhered to the COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines [25].



This study built upon our quantitative work of TDI remote assessments using an image acquisition app "Teledental" (Commonwealth Scientific and Industrial Research Organisation

XSL•FO
RenderX

[CSIRO]) and a web-based data management platform "Remote-I" (CSIRO; Figure 1). From August 2022 to July 2023, the photographs of teeth were captured by 11 trained frontline clinicians using the Teledental app, and then remotely reviewed by 5 licensed dental professionals (end-line users) using the Remote-I system [10].

In Figure 1, panels A-C show the "Teledental" app interface used by frontline clinicians to log in with individual passwords and enter patient data, including patient ID, birth year, sex, and clinical site. Panel D displays the app's imaging screen, which prompts users to capture 3 standardized intraoral views: frontal, upper occlusal, and lower occlusal. Panel E depicts 2 frontline clinicians participating in one-on-one calibration after completing a training session designed to ensure consistent image quality and adherence to capture protocols. Panel F shows the "Remote-I" platform interface used by end-line users to access the patient record created during calibration; when the cursor hovers over a thumbnail, the corresponding dental image is enlarged for review. End-line users examined all 3 images and charted dental conditions using a color-coded odontogram that included diagnostic categories such as uncomplicated fractures, luxations, and partially erupted teeth. The clinicians provided consent for the use of their images and data in the publication.

Figure 1. Workflow and interfaces of the mHealth app and platform used in this study for photographic telediagnosis of traumatic dental injuries.

Basic Security Measures

All researchers, frontline clinicians, and end-line users adhered to institutional review board–approved procedures governing data access and privacy. To limit image persistence on devices, the Teledental app was configured to prevent local storage of captured images; images were transmitted directly to a US-owned cloud service selected jointly by the research team and the vendor (CSIRO). Remote image review required authenticated access to the Remote-I platform; the platform's settings disallowed image downloads to end-line users' workstations. Study smartphones were purchased new from the vendor (Samsung), configured with restricted user permissions, and connected only to password-protected institutional Wi-Fi (eg, eduroam or hospital internal networks); installation of additional apps was prohibited; devices were centrally stored and managed by a key researcher in Minnesota and a key researcher in Khon Kaen. Individual user accounts and passwords were required for both Teledental and Remote-I and the passwords were changed periodically. Two-factor authentication was not used by study participants during data collection. All study personnel completed training in privacy and data-handling best practices, including HIPAA (Health

XSL•FO
RenderX

Insurance Portability and Accountability Act) principles [26], and compliance with those requirements was monitored.

Participants

All eligible frontline clinicians and end-line users who contributed to the preceding quantitative study were invited (consecutive sampling) and the full available cohort consented to participate, with the only exclusion being a frontline clinician who is a coauthor to avoid conflict of interest. The sample included a purposeful mix of roles and experience levels (dental students, general dentists, dental therapists, and dental specialists) across 2 countries. No participants were selected or excluded by demographic or professional criteria. To acknowledge potential recruitment influences, we report that University of Minnesota employees and student workers received modest incentives (US $40 and US $15, respectively) while participants based in Thailand did not. All participants were notified of the requirement to attend a 60-minute focus group interview through the Zoom app (Zoom Video Communications). Each focus group was composed of 1 to 6 participants according to their schedule availability. The participants based in the United States and Thailand were separated into different focus groups due to different time zones. The interviews were conducted in English by 2 US-based researchers together. All participants were capable of communicating in English during the Zoom interviews.

Data Collection and Instrument

Two moderators, ECS (a female dental hygiene faculty member with a Master of Science degree) and MS (a female Honors college student with a Bachelor of Arts degree) conducted each focus group interview, while BH (a male senior dentistry faculty member and the principal investigator [PI] with a Doctor of Philosophy and Doctor of Dental Surgery degrees) observed all sessions. Prior to the first interview, the moderators underwent training to adopt a neutral interviewing stance, ensuring that participants' perspectives were accurately captured. Since participants were recruited from frontline and end-line users of a previous study led by the observer, the moderators had a limited prior acquaintance with 3 participants. To maintain transparency, the moderators and observer introduced themselves and outlined the research objectives and content on the informed consent form and at the beginning of each interview. Before the interview with participants based in Thailand, the observer and moderators interacted with them in English for approximately 15 minutes via Zoom to confirm their proficiency and ensure effective communication. Only the participants and researchers were present during the interviews. Field notes were taken by the moderators during the sessions, and all interviews were audio-recorded and securely stored on a cloud server. After each focus group, participants were emailed the full study instrument and given 2 weeks to provide additional comments. To safeguard data quality and reduce risks of misinterpretation, a researcher (PP), a native Thai speaker fluent in English with graduate training in Britain, attended the Thai focus group to provide Zoom technical support and reviewed the transcripts from that session for accuracy. Although data saturation was defined as the point at which no new information emerged across 3 consecutive focus groups [27], we chose to interview all 15 participants in an effort to generate more evidence and decrease bias due to our small but very diverse sample size. Repeat interviews were not conducted.

The study instrument used for the interviews consisted of guided interview questions, exploring the perspectives of the frontline clinicians and end-line users. The interview questions were adapted from published resources [22,28-32] and were rephrased to reflect the context of this qualitative study and the mHealth technologies used. Subsequently, a multimember researcher panel with diverse expertise, including qualitative study design, medical informatics, clinical dentistry, dental public health, and special needs dentistry, reviewed and finalized the questions. The interview questions included in this study are presented in Table 1. The purpose of using this guided interview instrument for the interview was to gain a well-rounded perspective from the participants on their experience with the mHealth model and maintain consistency among all focus group interviews.

XSL•FO
RenderX

Table 1. Guided interview questions adapted from the Technology Acceptance Model.

Interview questions	References
• Tell us about the feasibility of using the mHealth[a] app or platform. What factors played a role?	[22,28]
• How do you feel this mHealth app or platform can contribute to working with dental trauma cases? (In terms of efficiency, usefulness, etc)	[22,28]
• How does this mHealth app or platform fit with the way dental trauma cases are examined and diagnosed?	[28,29]
• How do you feel the use of the mHealth app or platform may change the way you and other people in your profession, specialty or field are viewed?	[28,29]
• Did your previous experiences influence your use of the mHealth app or platform? Anything positive? Anything negative?	[28,30]
• How willing are you to use the mHealth app or platform to examine and diagnose dental trauma cases in the future?	[28,29]
• How likely are you to use an mHealth app or platform like the one we used in the future for dental trauma cases?	[28,31]
• How comfortable or uncomfortable did you feel about using the technology for dental trauma cases?	[28,30]
• Only to frontline clinicians: How might you have observed either potential distress or comfort from the patients or fairgoers enrolled in this study?	
• What attitudes do you believe your superiors have around your use of the mHealth app or platform to examine and diagnose dental trauma cases?	[28,31]
• What resources, knowledge, or assistance do you feel should be available when using the mHealth app or platform to examine and diagnose dental trauma cases?	[28,32]
• What do you feel went well with the mHealth app or platform? What improvements do you feel could be made with the mHealth app or platform?	[28,31]

[a]mHealth: mobile health.

Data Analysis

A consensus coding process was used to summarize and synthesize the qualitative data from the interview questions and determine the results [33,34]. Coders calibrated via Zoom before conducting any focus group interviews. This early calibration ensured alignment in coding practices and interpretation prior to engaging with the data, to maintain consistency across all transcripts. Memoing was used throughout the coding process to document coder reflections, emerging themes, and the rationale behind coding decisions. These memos supported transparency and helped track the coding development. The research team used a negotiated agreement strategy for intercoder reliability. Prior to data collection, coders collaboratively established a process for resolving discrepancies. When disagreements arose during coding, coders revisited the transcript, discussed their individual interpretations, and reached a consensus. The PI, who observed all focus group interviews, was also consulted to help resolve disagreements and ensure consistency. We used a hybrid coding approach that integrated both deductive and inductive strategies to analyze the focus group data. Initially, we developed a set of a priori codes grounded in our research questions and informed by the TAM [22], which provided a theoretical framework for examining participants' responses. As coding progressed, we remained open to emergent patterns and concepts, allowing for the creation of new inductive codes that captured unanticipated insights arising directly from the data. This flexible approach enabled us to systematically explore expected themes while also incorporating novel findings that enriched our understanding of participants' experiences [34,35]. After all interview sessions had taken place, a Zoom meeting among the research team was held to analyze and discuss the qualitative data, use the transcripts to identify common themes, and extract appropriate evidence, such as descriptive terms and quotes, from the participants' responses. The transcripts and findings were not returned to participants for review.

Ethical Considerations

This study was reviewed and approved by the University of Minnesota Institutional Review Board (Study ID: STUDY00014736). Written informed consent was obtained from all participants prior to data collection. All researchers and study personnel adhered to institutional review board–approved procedures governing data access and privacy. Compensation was provided to University of Minnesota employees and student workers, but not Thailand-based participants due to University out of country payment restrictions.

Results

Overview

A total of 7 interview sessions were conducted. Among the 15 study participants, 10 were frontline clinicians who took the dental photographs and 5 were end-line users who interpreted

XSL•FO
RenderX

the dental photographs from a distance. The 10 frontline clinicians included 5 general dentists, 1 pediatric dental specialist, 1 dental therapist, and 3 dental students. The 5 end-line users consisted of 1 pediatric dental specialist, 2 general dentists, and 2 dental therapists. The 6 dentists who acted as frontline clinicians and took dental photographs were all based in Khon Kaen (Thailand), while the other 4 frontline clinicians and the 5 end-line users were based in Minnesota (United States). Table 2 lists the focus groups, roles, professions, sex, and countries of the participants included in this qualitative study.

Data saturation was achieved within the 7 interviews as no new codes or themes emerged after the first 4 interviews. Thematic analysis of frontline clinicians' and end-line users' structured interviews revealed 9 main themes: feasibility and perceived ease of use, perceived usefulness, compatibility, self-image and social influences, self-efficacy, voluntariness and behavior intention, anxiety, facilitating conditions, and attitudes toward a behavior (Table 3).

Table 2. Focus groups, roles, professions, sex, countries, and years in practice of the participants (9 in the United States and 6 in Thailand); years in practice ranged from 0 to 20 years. All consented to publication.

Focus group and role	Profession	Sex	Country	Years in practice
1				
End-line user	Dental therapist	Male	United States	10
End-line user	General dentist	Male	United States	15
2

Table 3. Subthemes (code words), definitions, and representative transcript excerpts that contributed to theme construction.

Main theme	Definition	Subtheme	Example from transcripts
• Feasibility and perceived ease of use	• Statements that describe the feasibility and ease of use of the mHealth[a]	• Consistency • Login • Template	• "I think it was fairly easy for me just because I was comfortable using intraoral cameras before. I think it's something that would be kind of intuitive to a new user. It wasn't that difficult." • "I think the only negative thing, which we kind of figured out, was if the app was left unutilized for a certain amount of time, then it would time out and you'd have to sign back in." • "I want a guideline with the application while using. Kind of like a template to make sure pictures are being taken at correct angles."
• Perceived usefulness	• Comments relating to the usefulness of mHealth	• Access • Timely • Useful	• "I think it's beneficial because, in terms of increasing access, people might not always have access to dental services right away following trauma." • "mHealth could help get the treatment done faster if you could get diagnosis back quicker and in turn get patients treatment faster." • "Specifically speaking about usability, it was really user-friendly in terms of clicking on patient, reviewing what is in odontogram and chart."
• Compatibility	• Statements referring to the familiarity and integration of mHealth technologies	• Technology familiarity	• "I think with our generation in this day and age it is easier to use apps and the app wasn't that complicated at all, it was kind of like straightforward."
• Self-image and social influences	• Comments that describe the social perception of mHealth use	• Acceptance • Resistance	• "I feel like this would be viewed in a positive manner, in that we are taking extra steps to expand access to care through teledentistry and through this mHealth method of like this is easily accessible for patients." • "Some people might say well that's not truly seeing the patient or diagnosing the issue if you're not seeing them in-person since it's kind of a new area of dentistry, but I don't think I'd have any issue with performing teledentistry."
• Self-efficacy	• Statements that describe the user's beliefs in themselves to use mHealth	• Confidence	• "I was very comfortable with how to utilize the technology and then since I've used my phone a lot and taken a lot of images before, it was pretty streamline for me to be able to use."
• Voluntariness and behavior intention	• Comments referring to the user's intention to adopt or integrate mHealth into practice	• Reluctance • Intention	• "For me, I don't feel like it adds a lot to either the patient experience or patient care at the moment." • "I think I would definitely be willing to use it, like I was saying, like for screening patients, I think it's a very valuable asset to see how acute or how soon they would need to get in."

XSL•FO
RenderX

Main theme	Definition	Subtheme	Example from transcripts
• Anxiety	• Statements that describe the user's comfort level related to the use of mHealth	• Comfortable	• "I think it was very easy for me. I think it was something that I felt very comfortable being able to use, taking the images, making sure the images came out well. I felt very comfortable doing that. I know it may be more challenging for people who are not as familiar with being able to use that technology."
• Facilitating conditions	• Statements that describe user's view on what conditions are needed to implement mHealth	• Resources • More practice	• "I think the research team did a good job training us through this, the app, and showing us how to use it, and they even did a one-on-one calibration when we got the phones from them." • "I think if we did a few practice sessions it would help us a lot to be able to emulate what type of images we wanted to take and how we wanted them to look like. So providing some model images of what the appropriate images would look like, I think that would be beneficial."
• Attitudes toward a behavior	• Statements that describe a user's feelings about the use of mHealth	• Positive attitudes • Improvements	• "I was excited when I was using it. I thought it's something that I can definitely make a difference." • "Technology that would streamline the photo taking process, instead of needing to click. Something that would eliminate the need to save or change to the next photo manually. Also not having to login every time, save login for quicker future login."

[a]mHealth: mobile health.

Feasibility and Perceived Ease of Use

As a whole, the frontline clinicians based in Thailand and the United States found the mHealth app feasible and straightforward to use, stating the app itself was self-explanatory, simple, and easy to use. The frontline clinicians at the Minnesota State Fair (United States) used the technology more often and more consistently, while the frontline clinicians at clinical sites in Minnesota (United States) and Khon Kaen (Thailand) used the technology more sporadically. With this being said, frontline clinicians who used it more consistently found it easier to use than those who used it sporadically as they were more familiar with the technology.

Almost all frontline clinicians felt that a more streamlined login process is necessary to improve mHealth app use. They criticized the need to log in each use with a username and password, as it could be time-consuming. Frontline clinicians in the United States suggested some options for streamlining the login process, including facial recognition for login, the ability to stay logged in and/or the ability to save username and password on the login page. Both frontline clinicians in Thailand and the United States mentioned lighting and picture scale as potential barriers. Both parties suggested some type of template or guide to help with image flow, image angles, and image scale and believe this would make images more consistent. A frontline clinician also mentioned that at times he would have trouble focusing the image,

> *For some reason, when I was taking photos, I felt like I couldn't focus on what I wanted to focus on. Sometimes, I would take multiple pictures of the same thing and try to get a really good picture, but I couldn't get a clear image of things.*

End-line users had similar feelings to the frontline clinicians as far as the feasibility of the mHealth data management platform. Generally speaking, end-line users mentioned the platform itself was feasible, simple to use, user-friendly and straightforward. Regarding the mHealth platform, a dentist end-line user stated, "I think it's something that would be kind of intuitive to a new user."

A dental specialist and a general dentist mentioned that if a charting error was made, there was not a simple way to correct the mistake. They found the easiest way to correct it was to exit out of the platform and start over. They mentioned the importance of fixing this, because they believe teledentistry should be fairly efficient due to the volume one may be reviewing. A dental therapist end-line user stated that the most difficult thing was that the platform could be slow at times. Despite the hardships, overall end-line users found the learning curve to be manageable.

Perceived Usefulness

As a whole, frontline clinicians perceived the mHealth app to be useful. Several frontline clinicians believed that the mHealth app was beneficial, particularly for increasing access to dental

XSL•FO
RenderX

care and reducing the burden on emergency services. Frontline clinicians based in the United States commented, “People might not have access to dental services right away following trauma.” They also stated, “I believe this app is very useful and beneficial, especially like when kids get trauma and they don’t have a dental home, it gives them quick access to care.” Frontline clinicians in Thailand also thought that the app would be a game changer for teledentistry. Specifically, they thought the mHealth app was great for those in remote areas where they do not have a dental specialist.

Frontline clinicians in both countries did suggest they think the app would be more useful if it could include more information, such as patient age, radiographs, and better image quality. They also felt some limitations with its current scope of only TDI and suggested widening it to a broader and more general dentistry scope.

End-line users deemed the mHealth data management platform useful for teledentistry, especially for initial assessments. They mentioned its potential for timely diagnosis and usefulness when there is not a dental provider in the nearby area.

Similar to the frontline clinicians, end-line users also felt having more patient information, such as pain, chief complaint, chart notes, etc, would be beneficial and useful. They also mentioned that suboptimal image quality of some dental photos may hinder the diagnosis of minor trauma and recommended that this be addressed for future use.

Compatibility

Both frontline clinicians and end-line users felt that the mHealth app and platform were compatible with the way existing dental cases and TDI cases are treated. Meaning both parties felt the technology was not too out of the realm and could be useful for handling trauma cases. A frontline clinician and an end-line user eluded to the fact that “as a society we use technology every day, and some of the younger generations rely on technology so we are already familiar with it.” They stated that most people are using smartphones every day, so there likely would not be a learning curve for widespread TDI-based teledentistry. Future improvements for the mHealth app and platform, as recommended by the interviewees, included fine-tuning of the odontogram and patient chart displayed on the platform, and integration of the mHealth model with the practice management software available in the market.

Self-Image and Social Influences

The frontline clinicians expressed that using the mHealth app did not significantly alter their self-image or how they were perceived by others. They felt the app was generally viewed positively as a helpful tool in the dental care process. A frontline clinician in Thailand stated, “there have been no bad attitudes from superiors when using the application.”

Although frontline clinicians generally had a positive perception of using an mHealth app, some concerns were raised about patients questioning the provider’s competence if they relied heavily on the app for diagnosis. One participant mentioned, “If the parent sees a provider using the application on their child they may question their intelligence as to why they are not confident in diagnosing on their own.” They also alluded that older generations may potentially have similar concerns.

Four out of 5 end-line users felt that using a teledentistry platform, such as mHealth, would have a positive impact on their professional images. They mentioned it would showcase their adaptability to using new technologies. The other end-line user, a general dentist, thought that professionals in the field would not view him or his work any differently whether he used the technology or not.

The only concern mentioned was initially, there may be some pushback, as health professionals have seen this when implementing other new technologies until the entire team is familiar and comfortable with it.

Self-Efficacy

Frontline clinicians felt confident using the mHealth app after the initial training, citing their familiarity with smartphone technology as a contributing factor. One frontline clinician stated, “Once we had the training, I was very comfortable with how to utilize the technology and then since I’ve used my phone a lot and taken a lot of images before, it was pretty streamline for me to be able to use.” Another made a similar comment,

> *I felt pretty comfortable. I felt familiar with using a lot of apps and utilizing that app wasn’t very challenging, and then taking the images were pretty easy.*

All end-line users also felt confident in their ability to use the mHealth platform effectively after receiving the initial training. End-line users attributed their confidence to the training session and prior experiences with other electronic charting and dental record systems. There were no barriers or negative experiences in regards to self-efficacy reported by end-line users.

Voluntariness and Behavioral Intention

Frontline clinicians indicated a willingness to use the app voluntarily, recognizing its potential benefits in improving access to care and streamlining the diagnostic process. One participant said, “I think it’s beneficial because, in terms of increasing access, people might not always have access to dental services right away following trauma.”

They also suggested the app could be more widely adopted if it included additional features and addressed current limitations, such as the need for frequent logins and better image quality mentioned earlier.

There was a strong willingness among end-line users to adopt the mHealth platform for future use, especially for screening and remote consultations. Most of them saw it as a great triage tool to get their patients to the right place in a timely manner. End-line users saw it as a valuable tool for patient care and were open to integrating it into their daily practices, despite some initial hesitations. Per one end-line user, “I would definitely be willing to use it, I think it’s a very valuable asset.” Another end-line user stated, “I’d say I’m very likely to use it in the future.”

One end-line user, the dental specialist, was concerned with how the app would integrate into other dental practice software

XSL•FO
RenderX

in an attempt to have more patient information available for the reviewer. Another end-line user, a general dentist, thought it would be beneficial to be able to communicate with the patient through the app, whether that be through voice, FaceTime (Apple Inc), or text messaging.

Anxiety

The frontline clinicians overall seemed comfortable with using and capturing photos on the smartphones, as they use them regularly. Initial anxiety among frontline clinicians was noted due to the unfamiliarity with using the specific mobile app for dental assessments. Their anxiety lessened over time as they became more familiar with the process. Those frontline clinicians witnessed a wide range of anxiety among patients and state fairgoers who were getting their dental photos taken. The most anxiety from patients was reported in a Minnesota community clinical setting. Frontline clinicians attributed this mostly to privacy issues, stating that some of the patients are potentially illegal immigrants, and became hesitant once they found out their picture would be acquired. However, anxiety decreased among some patients once they fully understood the study purpose and applications as well as the photos taken were limited to their mouths. Minnesota state fairgoers were less anxious, as they had agreed to come to the research facilities and learn more about the study, and willingly came in to learn about the study, versus being at the dentist for an oral health issue. The frontline clinicians in Thailand did not notice much anxiety from their patients. They credited this to previous use of intraoral cameras during dental examinations and the fact that participants had previously gone through and provided an informed consent.

When it came to using the mHealth platform, end-line users were overall comfortable and felt the dental charting they did was straightforward. They did report anxiety when it came to system charting glitches, such as forgetting which teeth they had already marked as sound, and the accuracy of their diagnoses when the quality of some images was less than ideal.

Facilitating Conditions

Frontline clinicians appreciated the training sessions and written materials provided, which helped them navigate the app effectively. One frontline clinician in the United States stated,

> *I think the research team did a good job training us through this, the app, and showing us how to use it, and they even did a one-on-one calibration when we got the phones from them.*

The same interviewee thought that a couple of practice sessions and being provided with model images would have helped them have a better understanding and emulate the photo expectations. The frontline clinicians based in Thailand thought a video tutorial would have helped them better understand what angles they should take photos from. They found the most difficult part was needing to log in to the app and connect to the Wi-Fi every time they went to use the app.

When it came to resources, knowledge, or assistance, end-line users emphasized the importance of adequate training and support to maximize the platform's effectiveness. They felt the training they received from the research team was adequate, and liked the guidelines so everyone was working off the same standards. However, an end-line user suggested that going through a couple of cases together would have been even more of help.

As stated earlier in this article, end-line users felt that including more patient information, or integrating with patients' dental practice software to have access to patient dental history would make the diagnosis process easier.

Attitudes Toward a Behavior

Overall, the frontline clinicians had a positive attitude toward using the mHealth app, as it was straightforward to use and they recognized its potential to enhance dental care delivery. They thought that if this dental model were integrated more widely, it could make a significant difference, especially in areas with a shortage of dental health professionals. The mHealth model was seen as a step forward in leveraging technology to improve health care access and efficiency.

Frontline clinicians thought the experience could be even more positive by suggesting things, such as streamlining the technology by automating the photo-taking process to save and switch to the next photo without manual intervention, and user interface enhancements, such as making the app more child-friendly with colors or cartoons.

Overall, the end-line users' attitudes toward using the mHealth platform were positive. End-line users acknowledged its potential to streamline workflows and improve patient outcomes. They appreciated the convenience and accessibility it offered. Specifically, they noted the value of having standardized views for each patient and appreciated the ability to zoom in on the photos and the ability to chart multiple conditions on the tooth.

Despite the positive attitudes toward the platform and use, end-line users recognized some areas of improvement and future development. One suggestion in an attempt to standardize the diagnosis was to integrate the trauma guidelines into the platform for quick reference. Another end-line user suggested making the reviewing platform into an app that could be easily accessed with a smartphone to improve convenience during emergency situations.

Discussion

Principal Findings

This study revealed participant perspectives toward the mHealth app and platform. Participants highlighted improved and faster diagnosis, underscoring perceived usefulness, and generally found the system easy to use despite login and photo clarity challenges. The app and platform seemed compatible with current dental practices. Most users responded positively, though some worried patients might perceive overreliance on technology. Training increased confidence and reduced anxiety, leading to stronger self-efficacy. Some were ready to keep using the app, while others wanted improvements first, showing mixed intentions. Overall, users expressed positive attitudes toward its role in TDI assessment.

The 9 themes illustrate how TAM constructs operate in practice. Perceived usefulness related to faster diagnosis and improved

XSL•FO
RenderX

access, while ease of use was reflected in straightforward operation. Compatibility was evident through integration with existing practices, and self-efficacy was reinforced by training and calibration. Social influences appeared in concerns about patient perceptions and peer resistance, while voluntariness and behavioral intention were expressed in willingness or reluctance to continue use. Anxiety, facilitating conditions, and attitudes toward use further shaped adoption, underscoring the interplay between technical usability and human factors.

When implementing teledentistry in clinical settings, its impacts on oral health outcomes [35], patient satisfaction [36], and cost-effectiveness [35] are commonly taken into account, and these effects have been regularly reported in literature [16,17,20,35,36]. Despite our belief in patient-centered care [37,38], health care workers' roles are central to mHealth adoption. In this study, smartphone-based photography was regarded as feasible, acceptable, and usable for remote TDI assessment. The results suggested potential applications in the initial assessment of emergency cases (such as trauma) and in triage or screening contexts (such as dental caries), warranting empirical testing in settings serving underserved populations and within interprofessional emergency workflows [2]. A prior caregiver study using the same mHealth app for dental screening and caries assessment in children also supported its feasibility [14], but direct comparisons are limited and require confirmatory research. Several other studies have also highlighted the relevance of including frontline and end-line users' perspectives in the determination of feasibility, acceptability, and usability of mHealth technologies for dental care and oral health promotion [13,15-18,20]. Those studies reported benefits including diagnostic accuracy [13], communication [17], patient-provider relationship [17], efficiency [18], and medication adherence [20]. Compellingly, some users of a non–photography-related mHealth app recommended adding a photo-capture-and-forward function to it [15], which happens to be a key characteristic of our mHealth model. This could also imply the viability of smartphone-based photography in the mHealth modality of teledentistry.

Training and calibration were key facilitators for the use of this mHealth model, increasing comfort and confidence among both frontline clinicians and end-line users. Literature suggested that adequate training decreases uncertainty, strengthens self-efficacy, and enhances mHealth usability [10,15,39,40]. A recent scoping review has found approximately 20 teledentistry educational programs [41]. Building on this evidence, curricula should incorporate topics such as virtual communication and assessment, technology troubleshooting, billing, and ethics, to help learners develop teledentistry competencies. These could be complemented by simulated training and clinical practice [42]. Because familiarity enhances usability, periodic and continuous training is recommended to refresh skills and sustain competence.

Patient and clinician perceptions may pose barriers. Some older patients might view smartphone use during diagnosis as a sign of incompetence, while younger or tech-savvy patients were more accepting [43]. Education to improve digital literacy and highlight benefits can support adoption. Resistance from colleagues may also hinder uptake. Inclusive development, professional development, enhanced communication, and reduced operational burdens can facilitate acceptance [44].

This study is exploratory and focused on user perceptions rather than on product design or feature validation; nevertheless, participants also proposed technical suggestions. Consistent image quality is essential, and camera grids or templates could help. Integration of electronic patient records would strengthen utility, while governance and ethical frameworks addressing data linkage, artificial intelligence (AI), and security are needed [45,46]. Biometric or voice login could reduce screen contact while preserving security. Finally, a risk-averse "ethical brake" approach—safeguards that trigger additional verification before data sharing or high-stakes decisions—has been proposed to inform the design of login, data sharing, and reviewer feedback loops, helping minimize potential harms as mHealth and AI features are introduced [46].

To ensure trustworthiness, investigator and data source triangulation were used to test the validity [47]. The interview questions were created and reviewed by a multimember researcher panel. Two moderators and an observer were jointly involved in data collection and analysis. These approaches broadened the focus of this research and reduced researcher biases. Additionally, the data were collected from the participants of different roles (frontline clinicians and end-line users), qualifications (dental specialists, general dentists, dental therapists, and dental students), sexes (females and males), and locations (Thailand and the United States). This participant pool contributed to diverse perspectives and validation of data.

Using a focus group interview method presents certain limitations. Group composition was based on participants' availability rather than self-selection, which may have influenced dynamics. As noted in prior literature, dominant voices can shape group discourse [48]. To mitigate this, moderators were trained to foster inclusive participation, and follow-up emails were sent to all participants to invite additional reflections. Cultural differences between Thailand and the United States also warrant consideration, even though interviews were conducted separately by country. Prior research on communication styles suggested Thais might be more inclined to accommodate audience expectations, whereas Americans might prioritize balancing personal goals with audience interests [49]. These differing cultural norms could have influenced how frontline clinicians and end-line users expressed their views. Furthermore, because interviews with Thai clinicians were conducted in English rather than their primary language, some nuance may have been lost in cross-cultural expression; however, presession proficiency checks, member checking, and transcript review by a bilingual researcher helped mitigate this risk.

While no participants were selected or excluded by demographic or professional criteria, the small sample size remains a limitation. The operation of this mHealth model required 11 frontline clinicians to take dental photos and 5 end-line users to diagnose TDI; all except 1 frontline clinician (a coauthor) participated in this qualitative study. Limited generalizability due to small samples in telemedicine and telehealth research has been noted in an integrated review [50]. Nevertheless,

XSL•FO
RenderX

thematic saturation was reached early, with no new codes emerging after the fourth interview, and data collection concluded after 7 sessions. This suggests that the dataset adequately captured the range of user perspectives for this workflow, consistent with Guest et al [51] findings that as few as 6 interviews may be sufficient for thematic analysis and interpretation. Future work should include larger and more culturally diverse clinician samples and explore similar mHealth models to enhance transferability.

The incentive differences between countries stemmed from institutional funding restrictions, which prohibit disbursing school-supported funds to individuals not legally eligible to work in the United States. Although they did not affect participation rates, such disparities may have introduced subtle response biases or influenced perceived power dynamics. To promote equitable participation in future international research, investigators should consider globally inclusive funding mechanisms or secure domestic support within each participating country.

Interpersonal dynamics [52] and prior researcher-participant familiarity [53] may also influence participant responses. To mitigate potential courtesy bias and power dynamics arising from interviewer familiarity, reflexivity and bracketing strategies were used throughout the study. Moderators received training to foster inclusive dialogue, actively invite dissenting views, and minimize hierarchical influence during interviews. A structured interview guide (Table 1) was used to ensure consistency across sessions and reduce the influence of moderator bias or familiarity on discussion flow. Although the PI observed all sessions, he did not moderate or participate; his webcam and microphone remained off throughout. Participants were not supervised, assessed, or taught by the PI during or after the study period. Their feedback, whether positive or critical, was valued equally and anonymized during reporting to encourage candor. Follow-up emails invited dissenting views, further reducing social pressure and courtesy bias. Prior researcher-participant relationships have also been identified as a potential asset in qualitative research, helping to build rapport and facilitate open dialogue [53].

Future research should incorporate role-specific interview elements, mixed methods approaches, and patient perspectives, alongside cost-effectiveness analyses. With evidence supporting remote assessment of TDI [10], dental caries [11,14], and oral cancer [12], diagnostic capacities could expand to other oral conditions such as tooth wear [54], developmental defects [55], malocclusion [56], and temporomandibular disorders [57].

Scaling mHealth tools in emergency dental settings requires technical and training enhancements as well as policy and infrastructure support. Regulatory frameworks for teledentistry differ across jurisdictions and may lack explicit guidance for photographic diagnosis, raising concerns around licensure, liability, and documentation standards. Reimbursement for asynchronous services—such as image-based consultations—remains inconsistent, potentially limiting uptake in emergency departments and underserved communities. Moreover, integration with existing electronic health record systems and secure data transmission protocols is vital to ensure interoperability, privacy compliance, and operational efficiency. Addressing these regulatory, reimbursement, and infrastructure barriers is essential to move beyond pilot models and establish sustainable, scalable mHealth solutions.

Equally important is the role of educational and professional development in supporting adoption and innovation. Integrating photography-based mHealth workflow into emergency care requires structured training and clear protocols for photo capture and clinical assessment. Competency development in teledentistry should be incorporated into continuing education and dental curricula to prepare both current and future providers. At the system level, health care organizations can leverage the insights from this study to guide infrastructure planning, resource allocation, and policy for effective integration of mHealth technologies.

Conclusion

Within the study limitations, frontline clinicians and end-line users regarded smartphone-based photography as a feasible, acceptable, and usable mHealth tool for remote dental assessment. Strengthening self-efficacy through ongoing education and professional development will be essential, while patient and clinician resistance may be mitigated by strategies such as inclusive development, communication, reduction of operational burdens, and targeted training. Technical refinements, including standardized photo templates, integration with patient management systems, and streamlined login, could further enhance usability. Future research should pilot this model in larger and more diverse clinical populations, evaluate cost-effectiveness, and explore its integration into broader oral health workflows beyond TDI.

Acknowledgments

The authors acknowledge Minnesota Masonic Charities, International Association for Dental Research, the University of Minnesota Center for Global Health and Social Responsibility, and the University of Minnesota School of Dentistry for funding support. We also thank the research participants and university faculty and staff who made this possible through their involvement. Part of this work has been presented in MS's Honors thesis [58]. A publicly available preprint of this work was posted online following the manuscript's submission to the journal for publication [59].

Funding

This study was supported with a Department of Pediatrics Driven to Discover Grant by Minnesota Masonic Charities, a Regional Development Program Grant by the International Association for Dental Research, a Global Health Seed Grant by the University

Abstract

Background: Over 1 million Dutch people have diabetes, of whom 90% have type 2 diabetes. Studies show that lifestyle plays an important role in the course of type 2 diabetes. MiGuide (MiGuide Ltd) is an online platform that helps people adopt and sustain lifestyle changes. The platform is integrated into existing diabetes care within primary care. Previous research has shown that implementing new (eHealth) interventions is challenging and may reduce effectiveness. Mapping out the barriers and success factors in the implementation process is essential so that eHealth interventions such as MiGuide can be used effectively in regular health care.

Objective: This study aimed to evaluate the implementation of MiGuide within Dutch primary care.

Methods: A qualitative study design was used, supplemented by quantitative data from patients. Five general practices participated. Three focus groups (FGs; at baseline, after 6 months, and after 12 months) were conducted with 3 general practitioners, 3 FGs with 8 specialized practice nurses (divided into 2 separate groups with 4 participants per group), 2 FGs (at 6 months and after 12 months) with 5 patients, and 2 FGs (at baseline and after 12 months) with 4 stakeholders from the management of the care group. The implementation process was discussed with health care professionals and management, and usage and user-friendliness were discussed with patients. The framework method was used to analyze the data. The following quantitative data were collected: patient characteristics, user data, and questionnaires at baseline and 6 months, assessing quality of life, usability, and diabetes self-care. The quantitative data were examined using exploratory analyses.

Results: Four themes were found in the qualitative data: “innovation,” “capability, motivation, and opportunity,” “processes,” and “setting.” Different factors within these themes played an essential role throughout the implementation process, such as facilities, technical difficulties, motivation, COVID-19, and the work processes. Areas for improvement were also identified. The supplemented quantitative data showed that usability scored below average at 6 months (mean 53.8; SD 9.3; n=8). Participants had a mean score of 0.84 (SD 0.13) on the EuroQoL-5 dimension and 81.9 (SD 13.4) on the EuroQoL visual analogue scale at baseline. Moreover, the average number of days someone exercised was 4.2 (SD 1.7), and the number of days someone ate a generally healthy diet was 5.1 (SD 1.3). Insufficient data on quality of life and diabetes self-care were collected at 6 months and therefore not presented in this study.

Conclusions: Implementation is a complex process with multiple barriers and facilitators. It is essential to explore the use of context-specific strategies that are aligned with the implementation process phase. Further research is needed to evaluate the next version of the MiGuide platform, which is being implemented in another setting with lifestyle coaches.

Introduction

In 2018, almost 1 million people were registered with type 2 diabetes mellitus (T2DM) in Dutch primary care [1]. This number has more than doubled since 2004 [2]. Approximately 90% of these people receive treatment in primary care [1].

Following Dutch treatment guidelines for standard diabetes care, patients receive an annual consultation with their general practitioner (GP) and a quarterly or biannual consultation with a specialized practice nurse (SPN). The consultations with the SPN include monitoring of weight, systolic blood pressure, hemoglobin A_{1c} levels, foot condition, and the occurrence of hypo- or hyperglycemia. Individuals with T2DM are also advised to lose weight and adopt a healthy lifestyle, such as sufficient physical activity and a healthy diet. Previous studies have shown that lifestyle plays an essential role in the disease progression of people with T2DM [3-8]. For example, increased physical activity, a healthier diet, and weight loss can lead to remission of T2DM [3,5]. According to the guideline, education on a healthier lifestyle should be provided alongside self-management strategies [9].

Self-management, which is the ability to manage symptoms, treatment, physical consequences, psychosocial consequences, and lifestyle changes, is inherent in living with diabetes [10]. The usage of eHealth self-management interventions for T2DM, such as smartphone apps, has demonstrated potential for adopting a healthier lifestyle. This especially applies to apps targeting diet and physical activity, which can improve health outcomes such as hemoglobin A_{1c}. Although self-management apps have potential, it is recommended to offer eHealth as a blended care solution [11].

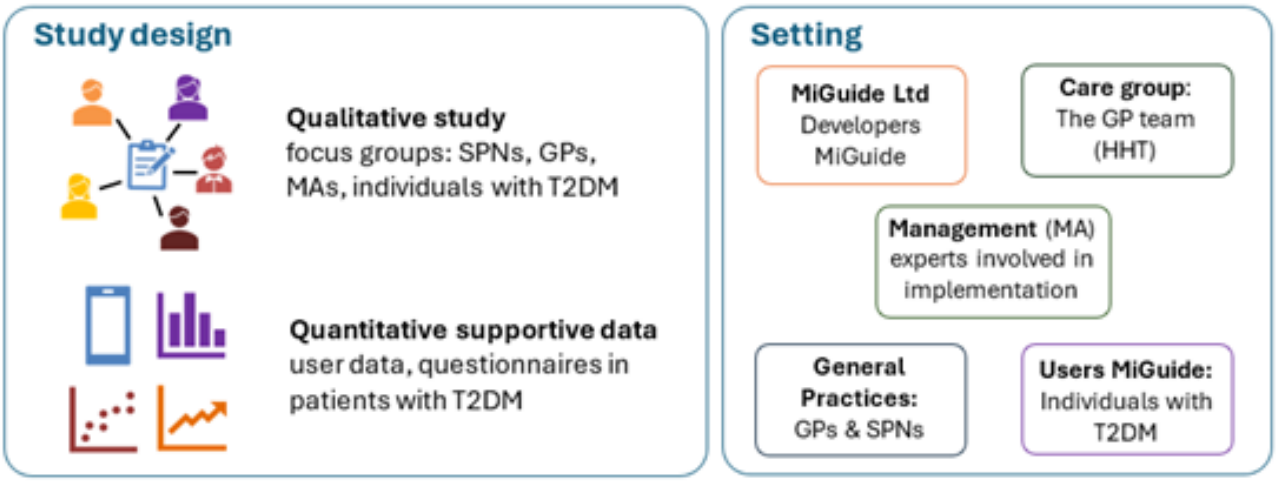
The success of self-management interventions regarding lifestyle and diabetes depends on the fidelity of the implementation process [12]. Implementation fidelity pertains to the extent to which an intervention is used as intended. Key elements include adherence, intervention complexity, facilitation strategies, quality of delivery, and participant responsiveness [13]. By evaluating whether an intervention has been implemented with fidelity, researchers and practitioners can better understand how and why an intervention works and the extent to which outcomes can be improved. This is crucial because there is often a gap between theory and practice in eHealth implementation. Often, eHealth solutions do not make it to practical use, and when they do, the adoption process is slower than anticipated due to various complex, multilevel challenges [14-17]. For instance, the patient, health care, and organizational levels should be considered [17].

For this study, we followed the implementation of MiGuide (MiGuide Ltd) in primary care. MiGuide is implemented as an integrated part of diabetes care and consists of an app and an online portal. The app allows individuals to track their food intake, physical activity, and specific goals. Lifestyle challenges, such as completing exercise goals each day and consultation preparation, are also available. Measurements, such as blood pressure and weight, are uploaded to the portal, which is accessible to GPs and SPNs. The content of MiGuide is based on the Dutch professional guideline for standard diabetes primary care. This study aims to examine the implementation of MiGuide in Dutch primary care. Our objectives are to identify the barriers and facilitators to the implementation of MiGuide in Dutch primary care and to evaluate the usage of MiGuide.

Methods

Setting

This study was conducted among Dutch general practices affiliated with the care group named the GP team (in Dutch: “Het Huisartsenteam” [HHT]) located in the province of Noord-Brabant. A care group is a partnership of several general practices to support logistics and the quality of care [12,18]. The care group HHT cooperated with MiGuide Ltd in an implementation project for the platform MiGuide. Five practices, for which it was technically feasible to link with the MiGuide portal, implemented MiGuide as part of their usual diabetes care. A management team with implementation experts guided the implementation process. It consisted of developers from MiGuide Ltd, eHealth implementation advisors from an external party, and the care group’s board members. MiGuide Ltd provided all instruction materials, provided the experts for training the GPs and SPNs, and was on standby for problem-solving and support. The care group had an intermediary role and informed the general practices.



Study Design

This was a descriptive qualitative study, supplemented by quantitative data from individuals with T2DM using MiGuide. The study was conducted in Dutch primary care between October 2020 and August 2022.

The “implementation fidelity model” [13] was used to examine whether the intervention was used as intended. To evaluate the implementation process, the following aspects were examined: barriers and facilitators, the impact on care pathways, including the transition of care from practice to home, and the role and experiences of GPs and SPNs. We assessed the implementation process at three levels: (1) the practice level from the perspective of GPs and SPNs, (2) the management level from the perspective of experts from the care group and MiGuide Ltd involved in the implementation process (ie MAs), and (3) the user level from the perspective of patients. Quantitative data were used to assess patients’ objective usage of MiGuide, their perceived system usability, and the impact on quality of life and self-care. Figure 1 gives an overview of the design, setting, and outcomes.

RenderX

Figure 1. Overview of the study design, setting, timeline, and outcomes. EQ-5D: EuroQoL-5 dimension; EQ-VAS: EuroQoL visual analogue scale; GP: general practitioner; HHT: the GP team (in Dutch: Het Huisartsenteam); MA: management; QoL: quality of life; SDSCA: Summary of Diabetes Self-Care Activities; SPN: specialized practice nurse; SUS: System Usability Scale; T2DM: type 2 diabetes mellitus.

Timeline and outcomes

Qualitative

Focus group	Timepoint 1 Nov and Dec 2020	Timepoint 2 Apr and May 2021	Timepoint 3 Oct and Nov 2021
SPN group 1 (n)	4	3, and 1 interview	3
SPN group 2 (n)	4	3	2
GP (n)	3	2, and 1 interview	3
MA (n)	4		5
Patients (n)		4	3, and 1 interview

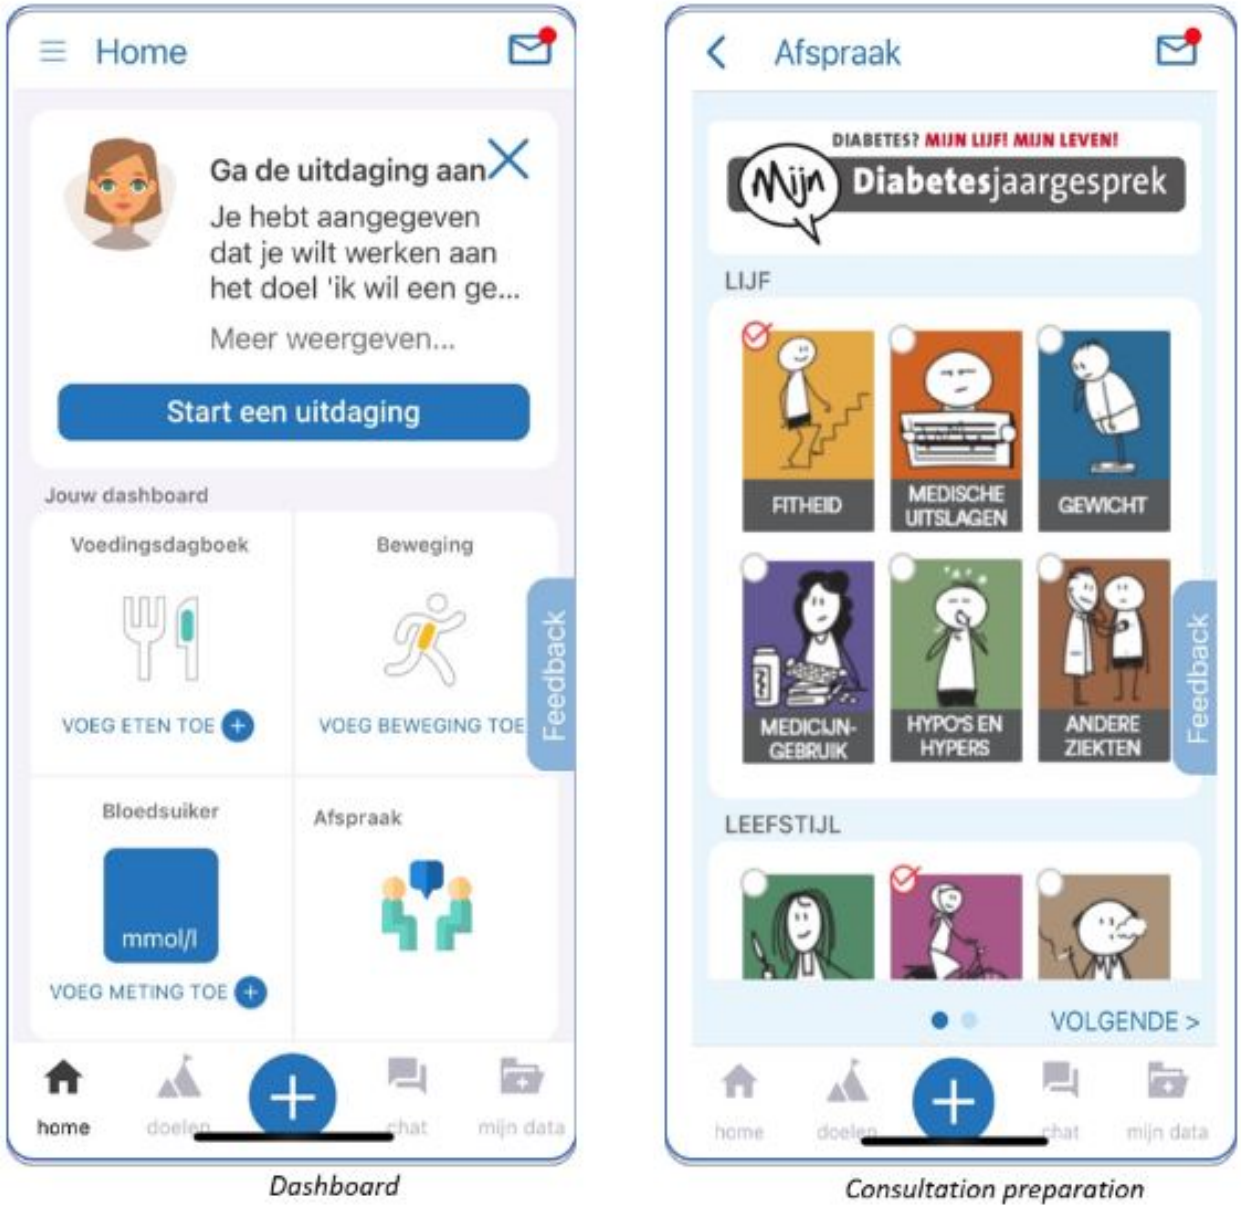
Quantitative

Data	Measurements	T0 (baseline)	T1 (6 months after start)
Baseline characteristics	Diabetes duration, medication, gender, length, weight, year of birth	x	
Usage MiGuide patient level	Number of logins; number and type of selected challenges; challenge completed yes/no; physical activity; type of physical activity; duration; number of consultation preparations; number of registered food diary entries		x
Questionnaires	QoL (EQ-5D and EQ-VAS)	x	x
	SUS		x
	SDSCA	x	x

Study Population and Procedure

Patients were eligible to participate in the quantitative study if they (1) were diagnosed with T2DM, (2) were able to read and communicate in Dutch, (3) were treated in a general practice within the care group, (4) had a smartphone (Android version 6.0 or higher [Google], or iOS version 11.0 or higher [Apple Inc]) with access to data connectivity, and (5) were not being treated in a hospital. During the initial phase of MiGuide's release, one of the exclusion criteria was the participant's unwillingness to share their data with their health care provider. This criterion was dropped when the second release of the app was launched in July 2021. The inclusion criteria for GPs and SPNs in the qualitative study were (1) being affiliated with the care group and (2) working with MiGuide. Patients also needed to use MiGuide to participate in the focus groups (FGs).

XSL•FO
RenderX



The general practices sent an invitation letter to eligible patients describing MiGuide and the study. Patients could download the app from the App Store or the Google Play Store. At onboarding, individuals indicated whether they agreed to share (1) their user data with their general practice and (2) their email address for research participation. MiGuide could still be used when an individual did not agree. Next, MiGuide Ltd asked for consent via email. Before the second release, users could only use MiGuide when they agreed to share their data for research purposes. As this was not a voluntary choice nor a valid consent, all participants who started using MiGuide before the second release were actively approached to ask for their participation in this study. At the end of the onboarding, patients could visit their GP to verify their identity and receive a unique QR code, but this was not mandatory to use MiGuide. The QR code facilitated the data connection between MiGuide, the health care professional (HCP), and the patient's medical data. No reimbursement was given for research participation.

For the qualitative part of the study, the care group invited SPNs, GPs, and MAs via email. Patients already using MiGuide were invited to participate via newsletters sent by MiGuide Ltd. All FG members were asked to consent to FG participation via email by the study team. After participation, they received a book about lifestyle and a reimbursement from MiGuide Ltd.

MiGuide Platform

MiGuide Ltd developed a platform consisting of an app and an online portal to guide individuals with T2DM in changing their behavior to adopt a healthier lifestyle (refer to Figure 2). The content is based on the content of consultations with GPs and SPNs (as described in Dutch treatment guidelines for diabetes in primary care).

Figure 2. Components of MiGuide.

XSL•FO
RenderX

The components of MiGuide are organized into the following categories: food diary, physical activity diary, goal setting, and data. The food diary has been improved since the second release by connecting it to an existing app from the Netherlands Nutrition Centre. The physical activity diary offers the possibility to connect with Google Fit. Goal setting offers different goals to enhance control of the following diabetes determinants: blood sugar, blood pressure, sufficient physical activity, prevention or minimization of complications, cholesterol levels, healthy eating and drinking, and healthy weight. The data category comprises the possibility to record blood pressure, blood glucose, weight, and consultation preparation. This data can be shared with the information system of the user's general practice if the user agrees to do so. The consultation preparation component allows users to send notes to their general practice about themes they want to discuss during a consultation with their GP or SPN. The themes they can choose from consist of physique, lifestyle, well-being, and self-care.

Data Collection

Qualitative Study

FGs and interviews were conducted using video conferencing platforms (Microsoft Teams or Jitsi). The FGs and interviews were audio-recorded.

FGs with GPs, SPNs, and MAs took place (1) during the initial adoption phase, (2) at 3 months after the implementation, and (3) at 12 months after the implementation (end of the study period). The FGs with individuals with T2DM took place (1) 3 months after initiating the use of MiGuide and (2) at the end of the study period.

To reach data saturation, we aimed for 5 GPs, 10 SPNs (divided into 2 groups), 4 MAs, and 4 patients. In cases where it was not possible to gather all members of an FG simultaneously, separate interviews were conducted to collect additional data.

Quantitative Study

Figure 1 provides the usage data of MiGuide, along with the questionnaire data collected at the user level. The usage data were gathered through an automated process. Users received in-app notifications at baseline and at 6 months to complete the questionnaires, with demographic characteristics collected only at baseline. Subsequently, MiGuide Ltd sent manual email reminders when participants had not completed the questionnaires.

Analysis

Qualitative Study

A thematic analysis based on the framework method procedure [19] was performed. At stage 1, the audio of all interviews was automatically converted to transcripts and pseudonymized. Two researchers (LvdB and LtL) became familiar with the interviews (stage 2) by checking and supplementing the transcription and making notes and summaries of the interviews. At stage 3, the researchers LvdB and LtL started coding the first transcripts using a mainly deductive approach. A concept codebook was created before coding, based on the implementation fidelity model and the above-mentioned aspects to evaluate the implementation process. The first 2 FGs with SPNs and the first of the other predefined FGs were coded independently by LvdB and LtL. At stage 4, the analytical framework (codebook) was further developed by comparing the independently coded FGs and agreeing on the definition of codes and categories by LvdB and LtL. If applicable, new codes were added to the codebook. The codes and categories were then applied to the remaining transcripts at stage 5. These transcripts were divided by LvdB and LtL and coded by one researcher. At stage 6, the data were charted into the framework matrix. Data from each transcript were summarized and provided with illustrative quotes. Each predefined FG was treated as a different unit of analysis, thereby assessing the implementation process at different levels: patient, GP, SPN, and MA. Finally, at stage 7, characteristics and differences between the data were identified. This process was supervised by senior researchers MJK and SHW.

Quantitative Study

Normally distributed numerical data were described as mean (SD). Nonnormally distributed numerical data were described as median with IQR. Categorical data were described as frequencies with percentages. Descriptive statistics were performed for the collected quantitative data using IBM SPSS Statistics (version 25) [20].

Ethical Considerations

The study did not fall within the scope of the Dutch Medical Research Involving Human Subjects Act, according to the Medical Research and Ethics Committee of VU Amsterdam Medical Center (2020.0708). Subsequently, a declaration of no objection was obtained from the Medical Research and Ethics Committee. Participants provided informed consent and were able to opt out from the study (refer to the "Procedure" section). Both quantitative and qualitative data were collected pseudonymously.

Results

Demographic Characteristics

In the qualitative study, 3 patients were male (3/5, 60%), all 9 SPNs were female (9/9, 100%), all 3 GPs (3/3, 100%) were male, and 5 MAs were male (5/6, 83%).

In the quantitative study, 58 participants were enrolled. Half were male (29/58, 50%), the mean age was 60.1 (SD 12.1), the median BMI was 30.3 (IQR 25.9-35.8), and 19% (11/58) of the participants were paired with the MiGuide portal. The demographic characteristics and number of paired patients per participating practice are provided in Table 1.

XSL•FO
RenderX

Table 1. Baseline data of participating practices.

Characteristic	Practice 1 (n=4)	Practice 2 (n=42)	Practice 3 (n=7)	Practice 4 (n=5)	Total (N=58)
Paired patients, n (%)	0 (0)	8 (19)	2 (28.6)	1 (20)	11 (19)
Age (years), mean (SD)	60.6 (7.0)	61.6 (11.3)	50.5 (11.7)	60.7 (19.3)	60.1 (12.1)
Male, n (%)	2 (50)	23 (56.1)	1 (14.3)	2 (50)	29 (50)
BMI[a], median (IQR)	27.9 (24.8-32.9)	30.3 (26.8-36.4)	32.3 (28.7-35.8)	25.7 (22.6-40.3)	30.3 (25.9-35.8)

[a]BMI data were complete for all participants except one individual in practice 2.

Quality of Life and Self-Care Baseline

At baseline, the mean EuroQoL-5-dimension score was 0.84 (SD 0.13), and the mean EuroQoL visual analogue scale score was 81.9 (SD 13.4). The mean number of days participants exercised was 4.2 (SD 1.7), and the mean number of days they followed a generally healthy diet was 5.1 (SD 1.3; refer to Table 2). Insufficient data were collected at 6 months (by 3, 4, and 6 participants, respectively); therefore, these data are not presented.

Table 2. Quality of life and self-care scores at baseline.

Questionnaire	Baseline value
EQ-5D (n=21), mean (SD)	0.84 (0.13)
EQ-VAS[a] (n=16), mean (SD)	81.9 (13.4)
SDSCA[b] (n=13), mean (SD)	
No of days of physical activity or exercise	4.2 (1.7)
No of days of glucose monitoring	1.4 (2.0)
No of days of foot care	1.5 (1.7)
No of days of a healthy diet (general)	5.1 (1.3)
No of days of a healthy diet (specific)	5.3 (0.9)
Nonsmoking, n/N (%)	9/11 (81.8)

[a]EQ-VAS: EuroQoL visual analogue scale.

[b]SDSCA: Summary of Diabetes Self-Care Activities.

Innovation

Patients were enthusiastic about the MiGuide concept but mentioned that the app was not intuitive for navigation. Later, during FG2, they reported that the app's design improved and looked clean and clear. They often used the MiGuide app daily, ranging from 5 to 60 minutes.

The 2 most frequently used functions were the food diary and physical activity tracking. Nevertheless, patients thought the food diary was too generic. They were also critical of the physical activity component: the point system was difficult to interpret. Some used pedometers and wondered why their results were not directly visible in the app. MiGuide Ltd immediately processed the food diary feedback after FG1, resulting in more enthusiastic patients during FG2. They were also positive regarding plans to change the physical activity functionality at a later stage. In the quantitative study, MiGuide usability at 6 months had a mean score of 53.8 (SD 9.3; n=8; range 20-90), which was below average.

Patients indicated that they rarely used consultation preparation; some used challenges, goals, and daily tips. This was also seen in the quantitative data (refer to Figures S1-S3 in Multimedia Appendix 1). During the FGs, patients stated that consultation preparation was not used because they thought it was not very useful for the SPN or themselves. For example, measurements were already available for SPNs, or patients wanted to discuss their T2DM during a consultation. They also mentioned that they already used the care group's app (ie, the HHT [Pharmeon BV] app) to access blood results and visits.

All patients, except one, said they expected to keep using MiGuide long-term. They expected a positive course of their T2DM while using MiGuide because it could motivate them to increase physical activity and eat healthier. Greater insight allowed them to make more impactful lifestyle changes. During FG2, they stated that they became more aware of their T2DM and that the app provided insight into their lifestyle.

> *For me, the app works very well. I mean, if I decide that day to misbehave and drink some craft beers, delicious, on Saturday night. Then I will put it in the app and think, "yes, this was not the best for me, but it was delicious." I think if you improve the app further, you will become aware of yourself. I think that is the most important part of the app. This is the reason I fill it in loyally.* [PT3 during FG1; April 22, 2021]

XSL•FO
RenderX

> *I have to admit, I never thought I would when they told me to lose 30 kilos first… At the time, I did not think it was a dot on the horizon; it was a dot behind the dot. And afterwards, with some attention, you can lose 20 kilos quite easily.* [PT3 during FG2; September 23, 2021]

SPNs and GPs mentioned that the MiGuide platform has potential, may be insightful, and looks nice. Initially, navigation on the platform was suboptimal. SPNs mentioned during all FGs that they were not working much with MiGuide and were not actively promoting it in their practices (refer to "Processes" and "Setting" sections). The GPs stated that mainly the SPNs worked with the app. They both experienced a low number of users (2-5 patients using the app per practice); while downloads increased over the year, SPNs indicated that patients stopped using the app, mainly due to the large number of notifications. One GP also said that patients stated that they were already using the HHT app or another app that helps with lifestyle changes and T2DM. The SPNs and GPs noticed that consultation preparation was not being used. Moreover, patients decided which features they wanted to use in the app without the guidance of the SPNs.

> *One of my SPNs has also downloaded the app herself and also tries to fill in things herself, but it does not seem to be very user-friendly. For example, with filling in food: if you have eaten salmon, for example, you have to click a lot to fill in the right amount of what you have eaten. The moment you have entered certain goals and you do not do it, you receive messages at the most impossible times that you have not achieved it or have not done it yet. This then causes people to say, "I do not need to get messages like that at midnight." Then they are done with it very quickly.* [GP1 during FG2; April 15, 2021]

At all 3 time points, the SPNs and GPs reported technical difficulties, mainly in linking the app with their information system via the portal and the QR code. The question arose among SPNs during FG1 if the connection with the information system was necessary and would add value. One of the GPs stated that they were happy that MiGuide was not directly linked to the information system and that they could find the data in a separate section instead of directly in the PT's record.

> *The problem with the fact that you cannot send via a safe environment is, of course, a pity. The link has not yet been made with [name of the information system]. Yeah, otherwise, it did not work out this week, so I have a hotline with [name of MiGuide employee], and they are resetting it, and yet, it is not running yet.* [SPN4 during FG1; November 10, 2020]

During FG1, the SPNs were asked about their expectations of MiGuide on PTs' lifestyle and self-management. They believed the app would enable better monitoring of individuals with T2DM and facilitate exchanging information. They found it useful for patients with an affinity for eHealth, and the app could provide patients with valuable insights into their lifestyle. However, there was some concern about whether the app would meet the needs of patients and whether they would view it as a self-management tool or would instead rely heavily on the SPNs for support. One of the GPs also stated that it is a great app for patients, with many interesting features, and that it would be better to focus on the self-management part of the app.

> *If PTs enjoy using such an app, I would like to encourage them to do so. Because I think it is a great app for PTs in itself, with a lot of interesting things in it, such as lifestyle advice and things like that. […] I think those things that the PT can do themselves that they are good. That is where I would focus. So, then it is a self-management app.* [GP2 during FG3; November 9, 2021]

During FG1, someone from MiGuide Ltd explained that MiGuide aimed to improve the patients' self-management. The patients could get more insight into their disease, improve their lifestyle using MiGuide, and hopefully have another type of conversation with their HCP due to the use of the consultation preparation function. A care group (HHT) representative emphasized that MiGuide aligned perfectly with their 5-year plan to prioritize the creation of a continuum between the patient and practice and the establishment of a connection between HCPs and patients, thereby providing blended care.

> *Which, of course, we see in recent years, that piece of lifestyle medicine, that it is increasingly well substantiated and that it really will become the leading way to apply it. At the same time, it is also complex to implement and introduce. So, it is not just the chronic disease itself, but also the rise of lifestyle medicine where we will find substance.* [MG1 during FG1; December 2, 2020]

During FG1, the MAs discussed that all patients should be invited to use MiGuide instead of inviting based on assumptions (eg, not asking because of the patient's age). However, accepting that the app is not for everyone is essential. HCPs could become frustrated if they aim to reach 100% of patients. The first 10%-20% could be easily reached; thus, HCPs should focus on this group. Knowing the benefits of using the platform could make it more appealing to those not initially enthusiastic about it. It may not work to convince individuals already resistant to new technology. Instead, a more promising approach may be to target individuals who already do a lot online (eg, planning e-consultations).

> *So yes, ask everyone, but also accept the no. There is already enough extra energy to get this off the ground, but do not try to pull the person up to their knees in the mud. They will follow. Focus on the group that wants it now and is also aware that it is not a solution for everyone, so the "digital unless" is also one that often passes by; there are always patients who are not language-skilled enough or who do not master this part. Accept that too, because if you think you have to achieve 100 percent, you will only frustrate yourself.* [CZ1 during FG1; December 2, 2020]

During FG2, the MAs discussed the requirements to initiate changes in the process at the patient level. A transition is needed for patients to have autonomy over their health. Concerns

XSL•FO
RenderX

remained about whether the process was clearly defined for the SPN and the patient and whether they could check the progress of their goals. Someone from HHT wondered whether the MiGuide platform could create an extra burden for SPNs.

The MAs envisioned a transition toward increased self-management for the patients, less workload in the practices, and eventually a decrease in the number of consultations.

Capability, Motivation, and Opportunity

The SPN or GP informed the patients about MiGuide and invited them to use it. During FG1, patients mentioned that they had not yet paired MiGuide with the QR code. One patient was wondering whether the connection would be acceptable to the GPs, as they had a high workload. However, the enthusiasm from their HCP encouraged the patients to use the app.

One patient reported difficulties logging into the app; 9 out of 10 times, they needed to start the app twice before logging in. This problem emerged a couple of weeks (2 or 3 weeks) before FG2 and resulted in less motivation to use it. Due to the availability and use of the HHT app, some patients explained that they did not need MiGuide (refer to the "Innovation" section).

The patients expressed that it is a matter of self-discipline, structure, and persistence to use or keep using the app.

> *I think the fact that you have diabetes should be enough. I think the motivation to fill it in should come from within yourself. If it does not come from yourself, then I do not think you will get it done.* [PT3 during FG1; April 22, 2021]

The enthusiasm of both patients and MiGuide Ltd stimulated the SPNs to work with MiGuide. The importance of enthusiasm from others was repeated throughout all FGs. The SPNs stated during the last FG that it would motivate and activate their enthusiasm if they were reminded by personal visits instead of only reminder emails from MiGuide Ltd or the care group.

> *In our role, we are really like, "Oh, that is new, and we want that, and we are going to work on that." Well, yes, SPN7 and I, if I speak for the two of us, we are also really always at the forefront of rolling out new things, implementing and informing patients about that, and collaborating…* [SPN9 during FG1; December 10, 2020]

During FG1 and FG2, SPNs expressed that they had little experience with MiGuide and needed more knowledge before working with the platform. They agreed that extra training was necessary and that more experience would help them use MiGuide in the long run. One GP stated that it should become completely "dummy-proof." MiGuide Ltd appreciated this feedback and organized extra demo sessions and masterclasses for HCPs to learn about the platform. The demo sessions helped motivate and activate the SPNs, as they became more confident in informing patients. Only some GPs followed the masterclass and demo session, but they were satisfied with the information they received.

During the initial implementation of MiGuide, SPNs mentioned that GPs did their best to be involved and to stimulate the use of MiGuide. However, over time, GP involvement decreased, and the SPNs felt less supported. They also mentioned that they did not experience much facilitation and support from the care group (refer to the "Processes" section). On the other hand, MiGuide Ltd and its helpdesk were accessible and helpful, which was valued.

Moreover, the FGs helped motivate SPNs by exchanging thoughts about MiGuide. The SPNs and GPs stated that the motivation and enthusiasm of HCPs were essential facilitators. Many HCPs were skeptical, leading to friction when patients wanted to use the app. It would help to see why the innovation is valuable (eg, a decrease in the workload). The added value could also be used in other practices to motivate them to implement the platform.

> *You know, if I tell a patient that they can come twice a year, I do not want to have to answer 80 more messages in those six months, because then I would rather have that they just come every three months, instead of twice a year, if I need to have so much other contact with the patient.* [SPN5 during FG3; October 6, 2021]

A participant from HHT explained that the 5 practices were informed by MiGuide Ltd, and documentation was prepared for these practices (eg, a manual and webinar). The initial release date was delayed due to technical issues (refer to the "Innovation" section). In the starting phase, the care group frequently contacted the first 2 practices and MiGuide Ltd about the implementation, which was acknowledged as a facilitator. During FG2, a participant from MiGuide Ltd stated that contact with the practices decreased while communication seemed essential. Nonetheless, practices were able throughout the implementation phase to contact MiGuide Ltd.

During FG2, the MAs also noticed resistance from the HCPs to use MiGuide as a standard method. SPNs and GPs felt that the benefit was too minimal and not immediately noticeable (it cost a lot of energy or time, and they did not immediately gain something in return). The MAs experienced the same issues while changing telephone appointments to digital (online) appointments.

> *That is true, and I am certainly not going to argue that online appointments are an advantage for the assistants. But make no mistake that they spent quite a while sabotaging you to prevent people from making online appointments. And why? Because that effect was not immediately apparent. They thought only when they experienced the effect, "We have to start enthusing about it." But before that, we were almost literally on top of it, just to keep saying, "No, do it now, do it now. The benefit will come to use later." That it will come later, that is just tricky.* [HHT2 during FG2; October 14, 2021]

Funding was an essential facilitator for implementing and integrating MiGuide into the practices. However, this could be a problem in the long term because there is no structural funding yet. The MAs also noticed that the FGs resulted in increased motivation among the SPNs to use MiGuide.

XSL•FO
RenderX

Processes

The SPNs expressed in FG1 and FG3 that the implementation of MiGuide was imposed upon them by HHT (ie, in a top-down manner). They indicated that the implementation process could have been improved if they had been allowed to provide input. The GPs also acknowledged these issues concerning the implementation within their practices. The top-down approach, along with other factors outlined under "setting," resulted in MiGuide having lower priority for both SPNs and GPs.

> *I think HHT wants to be upfront and do new things and try new things, and that is also a lot of fun. And sometimes you think, "Yes, it is already completely thought through in all layers," because the bosses behind their desks say, "Okay, we are going to do this, and MiGuide and is fun; we give it a chance." And eventually, we are the ones who need to do it. Yes, and then the question is whether it is thought through, like, do the SPNs have time? How should they do it? Do they have enough training, support, etc.? Yes, it sometimes is; yes, maybe not high enough on the list, I think.* [SPN7 during FG3; October 13, 2021]

As mentioned by GPs and MAs under the "Capability, Motivation, and Opportunity" subheading, it would motivate HCPs to know that the implementation of MiGuide would help reduce their workload in the longer term. SPNs were aware that there would initially be an increased workload due to the changes in their work processes (eg, becoming accustomed to the app and preparation time). During FG3, SPNs anticipated that the workload would further increase due to the potential for patients to ask questions via the app and the need to personalize the program for all users. However, they reported no differences in MiGuide use on daily care, workload, and job satisfaction since the previous FG. On the other hand, GPs expected during FG1 that the function of consultation preparation could positively influence SPNs' consultations because of the possibility of low-key communication.

> *With the daily process, not a lot, I would say. With diabetes, I have an average of 100; thus, then we still have over 2000 patients. So yes, I think it is a bit, as I stated earlier. I hope that patients are motivated to do more with their lifestyle and that they will receive feedback that it will work. And I hope, on the other hand, that the health care professional gets something out of it because patients will get to the consultation better prepared. That you have already answered their questions for an important part. Yes, and I hope that the app's usage over a longer period can replace the number of consultations. That these can be dropped.* [GP2 during FG1; November 17, 2020]

> *I had one patient who did prepare, but only 20 minutes before their appointment. They stated, "Oh yes, I forgot, but I need to do this for you." Yes, then I think, you do not need to do it for me; you should do it for yourself. And what they select, I cannot work with that, because this patient has a lot of mental issues, and they want to discuss this during the consultation. Yes, I cannot help them with that.* [SPN5 during FG3; October 6, 2021]

During FG1, MAs recognized the need for management to implement an innovation. They play a crucial role in providing necessary support, such as organizing webinars, creating guides, offering workarounds, being available for questions, motivating and stimulating individuals involved in the implementation process, and showing the progress of the implementation. One important aspect highlighted by the participants was that digital projects often differ from initial expectations. However, this difference is not viewed as a problem since continuous development and integration of feedback usually lead to improvements.

One aspect that needs to be considered is that it is difficult during implementation to immediately have a fully operational innovation. Therefore, managing expectations and ensuring clear communication about what aspects work and what aspects do not work is crucial. Failing to address these factors from the beginning could result in disappointment. Providing workarounds (ie, guidelines on what to do when encountering issues with the platform) and offering more intensive implementation coaching could facilitate a smoother transition. The first experience with the platform and the timing of the implementation were also pivotal, and greater emphasis could have been placed on the testing phase.

> *[…] but there are also a lot of them who take that step with a bit more difficulty than we do, and when they run into things like that, you quickly have an excuse to say, "Hey, wait a minute. That should not be done yet." That does then cause a delay, and it also ensures that you do not yet have the results, as you just asked for the study OZ1. If it is all there, and what do we think of it in practice?* [CZ1 during FG1; December 2, 2020]

A representative from HHT experienced difficulty with promoting MiGuide in the practices since it deviated from the regular work processes. Adopting MiGuide required HCPs to shift from a traditional medicine approach to a lifestyle medicine approach. The question remained as to how MiGuide could be integrated into daily routines. As mentioned under the "Capability, Motivation, and Opportunity" subheading, gaining insight into reports could be essential in demonstrating the results of SPNs' efforts. Communicating and gathering feedback could contribute to improving the implementation.

Setting

During all FGs, the SPNs and GPs expressed that there was too much going on in their practices, which negatively affected the implementation of MiGuide. The MiGuide platform was implemented during the COVID-19 pandemic, and this influenced the implementation process (eg, other work processes were needed during the pandemic). Furthermore, other factors in the setting greatly influenced the implementation process of MiGuide: reorganization, absenteeism, turnover, and being too occupied with usual diabetes care (ie, many disrupted patients due to COVID-19).

XSL•FO
RenderX

> *I have not paired any new people, and I also notice that I have experienced a very hectic summer here in the practice, so I was actually happy to be able to do my daily tasks, and because of that, I have made MiGuide a lower priority. Maybe not the idea, but I was glad that my days were done at some point or that I had done what I had to do, and yes, I found the summer quite tough, let's put it that way.* [SPN5 during FG3; October 6, 2021]

During FG1, SPNs stated that it would be easier to implement MiGuide when sitting across patients to show the app. After a year, GPs noticed that patients were coming back to the practice after the COVID-19 pandemic for regular consultations. These consultations could be the perfect opportunity to discuss MiGuide with the patients. They noticed that the strength of the MiGuide platform is the connection with the practice and that MiGuide Ltd could focus more on promoting this aspect (refer to "Innovation" subheading).

The MAs also recognized that the COVID-19 pandemic influenced the implementation process of MiGuide. For example, the explanation about MiGuide was held digitally instead of physically in the practices. This resulted in uncertainties about how the MiGuide platform, especially the app, worked. They also acknowledged other barriers in the setting of the practices: pregnancy leaves, absenteeism, turnover, and multiple programs (eg, Acceleration Program Information Exchange Patient and Professional 5 [in Dutch: Versnellingsprogramma Informatie-uitwisseling Patiënt en Professional 5] and the transition from one information system to another) being implemented and used in the practices.

During FG1, the ecosystem of the care group was mentioned as a great facilitator. The fit between MiGuide and the goals of HHT helped with the commitment to the project. The MAs also noticed that the process could have changed if people had met physically in the practices. It also helps when practices have embraced lifestyle medicine (refer to the "Processes" subheading).

> *At the beginning, of course, there was also the part that everyone was going to work more from home and more digitally. If that had not been the case, we might have been able to take MiGuide physically into the practices in the beginning, as was initially planned. So, I do not know if that would have changed the process, but that is perhaps still a point of attention.* [HHT1 during FG1; December 2, 2020]

Suggestions for Improvement

During the FGs, improvement possibilities regarding the MiGuide app were discussed. In this section, only feedback regarding not yet implemented features or processes is discussed.

FGs With Patients

Patients suggested several improvements for the MiGuide app. These included (1) the implementation of speech-to-text functionality, which would not only streamline the app's usability for the patients themselves but would also be helpful for the older population and individuals with visual impairments; (2) enhanced tracking of physical activity, with a preference for incorporating a pedometer or a calorie-based system for the physical activity feature; (3) the addition of medication tracking, including a medication management feature within the app; (4) a streamlined login procedure to simplify the login process and enhance user experience; and (5) the introduction of engaging physical activity challenges, reflecting a desire for more challenging elements regarding the physical activity feature.

FGs With SPNs and GPs

Suggestions regarding the MiGuide platform included (1) reduction of questionnaires to minimize the number of questionnaires for patients; (2) customizable notifications, allowing patients to personalize the frequency of notifications; (3) improved personalization, such as linking automatic questions to specific outcomes—for instance, when an outcome shows an increase, the platform can generate questions regarding potential factors such as medication changes or stress levels, which can then be discussed during consultations between the SPN and patient to identify strategies for improving outcomes; (4) a notification for consultation preparation integrated into the information system to alert HCPs when a patient has prepared their consultation; and (5) automated synchronization of blood pressure measurements to enhance user-friendliness.

Suggestions regarding the implementation of MiGuide included (1) preimplementation testing, in which a willing person could test the app and give feedback on their experience, allowing SPNs to familiarize themselves with the app, gain valuable insights, and ensure a smooth integration into their practices. This test phase also facilitates a foolproof system; (2) streamlining the manual by creating a concise version to enhance clarity and comprehension of MiGuide; (3) facilitating knowledge exchange among SPNs and GPs, including exchanging tips to improve the implementation process, and evaluating the current implementation process with colleagues; (4) involvement of GPs and the care group (HHT) to contribute to smoother adoption and usage of the MiGuide platform, with 2 or 3 responsible individuals designated to oversee implementation to ensure effective coordination and support; (5) involvement of other HCPs, such as physiotherapists or lifestyle coaches, to foster greater engagement and usage of the platform; (6) improving visibility via commercials, such as health insurance campaigns or newsletters from HHT, to encourage patients to use the app; (7) emphasis on report insights and best practices, providing practical examples to offer valuable guidance and facilitate evidence-based decision-making during implementation, while highlighting that workload would decrease after the implementation of MiGuide because this is experienced as the biggest motivator for HCPs to implement and use MiGuide; and (8) integration with the HHT app rather than functioning as a stand-alone tool, ensuring seamless integration into the existing HHT app and prioritizing ease of use for both patients and HCPs.

FGs With MAs

Suggestions regarding the MiGuide platform included (1) expansion of the MiGuide platform to include other chronic diseases beyond its current scope, such as CVRM and obesity. Suggestions regarding the implementation of MiGuide included (1) preimplementation planning and testing, in which it is

XSL•FO
RenderX

recommended to incorporate a phase for testing and developing a plan or workaround before the actual implementation; this tailored approach ensures that all aspects, including timing, motivation, technical processes, and user-friendliness, are thoroughly addressed to optimize the overall implementation process; (2) improved communication with HCPs and enhanced expectation management, as clear communication and proactive management of expectations will contribute to a smoother adoption and usage of the MiGuide platform, with interventions, comprehensive instructions, gathering feedback, and fostering a collaborative approach helping to improve communication; (3) securing structural funding to ensure the sustainability of the implementation, with efforts directed toward securing funding for ongoing support and maintenance of the MiGuide platform; (4) focus on engaging participating patients, acknowledging that achieving 100% engagement may not be feasible and that the focus should be on the group that is motivated and enthusiastic; (5) emphasis on report insights and best practices, as reports and practical examples offer valuable guidance and facilitate evidence-based decision-making during the implementation process; (6) integration with lifestyle programs or interventions, considering that the MiGuide platform is not yet a part of diabetes care and exploring opportunities to integrate the platform with existing lifestyle programs or interventions to enhance its utility, with integrating a lifestyle coach could further enhance the app's effectiveness; (7) involvement of other HCPs, such as physiotherapists or lifestyle coaches, who have more frequent interactions with individuals with T2DM and can foster greater engagement and usage of the platform; and (8) acceptance of trial and error, recognizing the iterative nature of the implementation process and being aware of the trial-and-error approach that allows for continuous learning, adjustment, and refinement.

Discussion

Principal Findings

The study examined the implementation of the MiGuide platform within 5 Dutch practices of a care group. During the implementation, it became clear that the adoption phase took longer than expected. The group of users was also lower than anticipated; however, this group was motivated and enthusiastic. When implementing an innovation, such as MiGuide, it is necessary to focus on engaging a small group of enthusiastic participants, continuously learning and reporting insights from this small group via an iterative process, and concentrating beforehand on expectation management. Furthermore, developing clear guidelines for the implementation and a workaround (ie, guidelines on what to do when encountering issues with the platform) and thorough testing of the innovation could contribute to a successful implementation. As discussed with the HCPs and MAs, the innovation should fit within their daily work, and there should be sufficient involvement from all parties within the practice to stimulate the adoption.

The COVID-19 pandemic had a big impact on the implementation of MiGuide. Other studies also examined the impact of COVID-19 on implementation and found that the pandemic resulted in unexpected situations and that the setting in which the innovation was delivered was essential for the success of the implementation [21-23]. This was also the case for MiGuide: an unforeseen transition from a physical implementation process toward a digital implementation process and more disrupted patients due to the pandemic, which increased the workload of HCPs. Therefore, MiGuide had a lower priority within the list of daily tasks of the HCPs.

Compared to the framework for implementation fidelity [13], adherence was relatively low, and therefore, implementation fidelity was relatively low in this study. Most patients used the app every day for 5-60 minutes, which aligned with the recommended "dose" and "duration"; however, the HCPs were still in the start-up phase (eg, sending out invitations) and were not actively promoting MiGuide 1 year after the start of the implementation. The potential moderators in the framework [13] should also be considered. Some participants stated that the platform was easy to use, while others had more difficulties, especially in terms of navigation. The strategies to facilitate the implementation and quality of delivery were relatively high due to the manual, webinar, and accessible support desk of MiGuide Ltd. This could be further improved by creating a workaround and discussing with the practices what their needs are to facilitate fitting strategies. The last moderator, participant responsiveness (eg, enthusiasm), was high among most patients, while it declined over time for HCPs. All these factors may have affected the implementation process of the MiGuide platform.

A scoping review conducted on the implementation of eHealth interventions for hypertension or diabetes [24] revealed similar barriers hindering the adoption. Among these barriers were technical issues, complexities associated with the integration of nonroutine processes, time and attention requirements for usage, centralized decision-making structures, high turnover, low HCP engagement, limited prioritization of the intervention compared to existing initiatives, shortage of funding, and ambiguities surrounding staff responsibilities during implementation. This review also emphasized that the likelihood of successful implementation increased when interventions align with and become an integral part of existing organizational goals and workflows [24]. Other studies also found similar barriers and facilitators and stated that the challenges around implementation are multilevel and complex [14,16,25]. Furthermore, when innovations are adopted, implementation science is not always considered, even though implementation science may ensure that innovations are making sustainable positive differences [26]. To successfully implement an eHealth innovation, such as MiGuide, it is essential to explore the use of context-specific strategies that are aligned with the implementation process phase [15]. MiGuide Ltd considered the importance of the fit of their innovation with current workflows and therefore changed the implementation setting from GPs and SPNs toward lifestyle coaches [27]. The upscaling of MiGuide is currently being supported through two programs: (1) CooL-MiGuide (a lifestyle intervention program reimbursed under the basic health insurance package in the Netherlands) and (2) MiGuide-Direct (a program focusing on the combined app of glucagon-like peptide-1 medication and lifestyle

XSL•FO
RenderX

interventions). This could help to scale up the implementation of MiGuide to reach a larger population.

Strengths and Limitations

This study had several strengths and limitations. An essential strength was the observational setting, which minimized the interference with the dynamics of daily practice and facilitated the inclusion of perspectives of HCPs and patients. A second strength was that MiGuide Ltd gathered the input after each FG, whereby the most frequently discussed suggestions were discussed and, when possible, addressed.

A limitation was that the quantitative data were insufficient for profound analyses due to the low sample size. This was partly due to the required adjustments in the consent procedure and partly due to a representative reflection of the real situation in which data are not easily obtained because of high dropout. Consequently, we were not able to conduct an extensive quantitative analysis as originally planned. It is therefore necessary to carefully interpret the study data due to the limited generalizability of the findings. In addition, it is essential to be aware of potential selection and social desirability bias, which may have occurred during data collection due to the pseudonymous character of this study. Furthermore, as previously discussed, the COVID-19 pandemic had a great impact on the implementation and the study.

Implications for Future Research and Practice

In this study, a minimal viable product was examined. In a future study, an improved version could be evaluated via a hybrid type II trial [28] with a focus on both implementations, usage, and outcomes. The focus could also be on the integration of the MiGuide platform with a lifestyle program or intervention. It would also be beneficial to include a more diverse range of HCPs, such as lifestyle coaches, and patients from different demographic backgrounds to enhance the generalizability of the findings. This study and the new setting could then be compared regarding barriers and facilitators for the implementation process. Moreover, potential risks—such as an over-reliance on technology or decreased face-to-face interaction between patients and HCPs, and possibilities for mitigating these risks—could be examined. The usage of artificial intelligence could also be a theme to further explore. MiGuide Ltd already incorporates artificial intelligence for two primary purposes: (1) the development of personalized content and (2) the analysis of user data and lifestyle patterns. Further possibilities with artificial intelligence could be explored.

Furthermore, it is essential to acknowledge that an eHealth innovation is a dynamic product that needs to be regularly evaluated and adjusted where necessary. The maintenance of eHealth also needs proper funding, as both are associated with ongoing costs. As stated by MAs and found in previous studies [15,29], not having structural funding is a barrier during the implementation process. Therefore, costs should be considered during further implementation of MiGuide. In a future study, the cost-effectiveness and economic impact of MiGuide, including how potential benefits may be distributed across stakeholders, such as patients and HCPs, could be assessed. A comprehensive cost-effectiveness analysis could also inform evidence-based policy decisions and support the development of sustainable reimbursement models for the broader implementation of digital health interventions such as MiGuide.

In addition, a designated implementation team could improve the success rate of the implementation. For example, a previous study found that implementation efforts with designated teams led to an 80% success rate versus 14% during implementation efforts that did not have such teams [30]. Although MiGuide Ltd gathered a team of experts in implementation, this could be further enhanced throughout the process and adjusted to the implementation phase.

Conclusions

This study evaluated the implementation of MiGuide, an eHealth innovation that promotes a healthier lifestyle among individuals with T2DM, within primary care. The implementation is a complex process, and barriers, also found in previous studies, such as technical issues and time and attention requirements for usage, were established by the participants. Essential factors for a successful implementation are engaging a small group of enthusiastic participants, continuously learning and reporting insights, and concentrating beforehand on expectation management and testing of the app. In addition, it is important to explore the use of context-specific strategies that are aligned with the implementation process phase. Further research is needed to evaluate the new setting with lifestyle coaches in which an improved platform is integrated.

Acknowledgments

We would like to thank Arjen Huizinga, Chief Executive Officer of MiGuide Ltd, who contributed to the data collection and the reviewing and editing of the manuscript.

Funding

This study was funded via a ZorgTech voucher from Innovation Quarter and by the National eHealth Living Lab. Innovation Quarter was not involved in the study design, data collection, interpretation, or manuscript writing.

Authors' Contributions

LNvdB, LtL, JJA, AV, SHW, NHC, and MJK contributed to the conceptualization and reviewed and edited the manuscript. LNvdB and LtL prepared the original draft and conducted the qualitative analysis. MJK conducted the quantitative analysis. LtL provided the visualization. LNvdB and MJK contributed to the methodology, validation, investigation, resources, and data curation.

Abstract

Background: Over-the-counter (OTC) hearing aids were introduced to improve the affordability and accessibility of hearing health care for adults with perceived mild-to-moderate hearing loss. While these devices have demonstrated effectiveness in cognitively healthy older adults—particularly in the domains of audibility, self-reported hearing ability, and speech recognition in quiet—their use and outcomes in people with dementia remain underexplored. This issue warrants further attention, as people with dementia often experience co-occurring hearing loss and may rely on OTC hearing aids to overcome cost and access barriers to prescription amplification. However, given the cognitive and functional challenges of dementia, it is unclear whether and how OTC hearing aids can support the hearing care needs of these individuals.

Objective: To explore interest-holder perspectives on the feasibility and acceptability of OTC hearing aids for community-dwelling older adults with dementia, identifying key facilitators and barriers that influence their use in this population.

Methods: Semistructured interviews were conducted with 45 participants across three interest-holder groups (15 per group): (1) community-dwelling older adults with dementia and hearing loss, (2) family caregivers of community-dwelling older adults with dementia and hearing loss, and (3) geriatric direct care professionals. Interviews were conducted and recorded via secure Zoom (Zoom Communications) videoconferencing, then transcribed and analyzed using thematic analysis.

Results: Participants endorsed several facilitators and barriers to OTC hearing aid use in people with dementia. Facilitators included increased accessibility, perceived affordability and value, and enhanced autonomy and control. Barriers included mistrust of OTC hearing aids, difficulty assessing candidacy due to unreliable self- and proxy reports of hearing status, caregiver uncertainty regarding device programming and adjustment, challenges evaluating device effectiveness, and concerns about caregiver burden and burnout from long-term device management.

Conclusions: OTC hearing aids offer meaningful advantages for people with dementia and their family caregivers. However, significant barriers must be addressed to ensure their feasibility and acceptability for this population. Future research should further examine and quantify these barriers to inform the development of tailored devices, services, and delivery models that promote successful OTC hearing aid use in people with dementia and their family caregivers.

over-the-counter hearing aids; dementia; hearing loss; older adults; caregiver; caregiving; assistive technology

Introduction

Background

Newly introduced over-the-counter (OTC) hearing aids have shown effectiveness among cognitively healthy older adults with mild-to-moderate hearing loss, particularly in the domains of audibility, self-reported hearing ability, and speech recognition in quiet [1-5]. However, there is limited evidence for their use in people with dementia. In this manuscript, we explore the perspectives of dementia-care interest-holders [6] on the benefits, challenges, and opportunities of OTC hearing aid use in community-dwelling people with dementia.

OTC Hearing Aids: Reducing Cost and Improving Accessibility

Among American older adults, age-related hearing loss affects about two-thirds of people older than 70 years and more than 80% of those aged 80 years and older [7,8]. For most of these individuals, hearing aids are the most effective therapy for age-related hearing loss [9], offering well-documented health benefits [10-13]. However, hearing aid adoption is low among older Americans with hearing loss—typically ranging from 30% to 40% [8,14,15]. To address this problem, in October 2022, the United States Food and Drug Administration (FDA) introduced regulations for OTC hearing aids, creating a new category of hearing aids available directly to consumers without a prescription. Previously, all hearing aids required a professional evaluation and fitting by a licensed hearing care professional. Today, OTC hearing aids—now widely available in stores and web-based retailers—allow adults with self-perceived mild-to-moderate hearing loss to purchase and fit hearing aids of their choosing. This change is intended to make hearing aids more affordable and accessible by removing the added expense and travel associated with seeing a licensed professional. Proponents of the new regulations anticipate that more affordable, widely available OTC hearing aids will substantially lower cost and access barriers to amplification, thereby facilitating greater hearing aid uptake among approximately 15 million Americans living with untreated hearing loss [8].

The reasons for low hearing aid adoption are multifactorial and include barriers other than cost and access, such as stigma, low readiness to address hearing loss, and poor hearing aid self-efficacy, among other factors [16-19]. Nevertheless, cost and access are formidable barriers to prescription hearing aids for many older adults [20,21]. First, conventional prescription hearing aids are expensive and not covered by Medicare. On average, a pair of prescription devices costs US $3600 [22]. This price may be cost-prohibitive for many older Americans with low or fixed incomes. Indeed, a recent analysis found that an out-of-pocket cost of US $2500 for hearing aids is a catastrophic, unaffordable expense for upwards of three-quarters of American adults with hearing loss [21]. Moreover, prescription hearing aids are geographically inaccessible to many Americans. Recent data indicate that audiologists are unevenly and inequitably distributed across the United States, clustering in metropolitan areas with low rates of self-reported hearing difficulty to the disservice of rural areas with greater self-reported hearing difficulty [23]. In short, those in rural or underserved communities may lack access to prescription hearing aids, irrespective of cost or insurance coverage. Together, the poor affordability and inequitable availability of prescription hearing health care necessitate an alternative approach. For many older Americans, OTC hearing aids offer this much-needed alternative.

OTC Hearing Aids: Considering the Needs of People With Dementia

While OTC hearing aids address cost and access, they also carry broader implications for older adults with hearing loss. OTC hearing aids introduce a new “do-it-yourself” service delivery model in which older adults assume responsibility for selecting, fitting, using, managing, and troubleshooting hearing aids. To date, a small but growing body of research shows that well-selected, generally healthy older adults with intact cognition can successfully self-program, use, and manage OTC hearing aids [1-5]. However, OTC hearing aids are not tested or designed for people with dementia, who may lack the cognitive ability to understand and use these devices. Although traditional prescription hearing care can also present challenges for people living with dementia, the lack of clinician involvement in OTC hearing aids introduces potential challenges that remain unexamined. This gap in the evidence for OTC hearing aids warrants further consideration. Older people with co-occurring dementia and hearing loss are a critical subpopulation of people with untreated hearing loss who—like the general older adult population—will rely on OTC hearing aids to overcome existing cost and access barriers to prescription hearing aids. If people with dementia are to benefit from OTC hearing aids, it is essential to explore their needs, perspectives, and capabilities for using these devices.

OTC Hearing Aids for People With Dementia: Potential Benefits, Challenges, and Opportunities

Like age-related hearing loss, dementia is prevalent in older adults. Approximately 10% of American older adults aged 65 years and older live with dementia, increasing with age to 20% of those aged 80 years and older and 40% for those older than 90 years [24-26]. Many individuals with dementia also experience co-occurring hearing loss. Among those older than 70 years with dementia, 79% have clinically significant hearing loss, rising to 94% of those aged 85 years and older [27]. For those with both conditions, untreated hearing loss can compound the effects of dementia on communication, exacerbating dementia-related behavioral and emotional changes such as depression, agitation, apathy, and social withdrawal [28-30]. Importantly, hearing aids may relieve the compounding effects of hearing loss on dementia. In people with dementia, hearing aid use is associated with reduced depressive, neuropsychiatric, and other problematic behavioral symptoms [28,31-33]. These health benefits broadly mirror the social and emotional health

XSL•FO
RenderX

benefits observed for hearing aid use in the general older adult population. However, fewer than one-third of people with co-occurring dementia and hearing loss use hearing aids [27,34]. In short—like the general older adult population—people with dementia benefit from hearing aids but demonstrate low adoption rates while facing high cost and access barriers to prescription hearing aids. Although people with dementia may face additional barriers to hearing aid adoption, cost and access are important barriers for people with and without dementia. It is thus essential to explore whether and how OTC hearing aids can provide inclusive access to affordable hearing health care for people with dementia.

It remains unclear whether OTC hearing aids are feasible and acceptable for community-dwelling people with dementia and their family caregivers. Without robust evidence on this topic, one can draw parallels between OTC hearing aids and the broader literature on everyday and at-home assistive technology use in older people with dementia. Here, studies consistently find that older adults with cognitive impairment, including dementia, both demonstrate and self-report greater difficulty understanding and managing a variety of everyday technologies compared with their peers without cognitive impairment [35-37]. In quantitative studies, these findings are statistically significant and show large effect sizes [35,37,38]. In qualitative studies, older adults with cognitive impairment report an array of overlapping, compounding challenges for at-home technology use, including memory deficits, difficulty attending to multiple processes, inability to follow sequential instructions, confusion interpreting technology-generated messages, low self-efficacy for technology use, and sensitivity to technology-related stress, among others [36,39,40]. Some people with cognitive impairment even forget what a given technology is intended to do or how it is meant to function [36]. Importantly, studies have found that manufacturer instruction manuals are typically unhelpful for older adults with cognitive impairment, including dementia, who may express optimism in their ability to follow written instructions but often fail to implement them correctly [36].

Considering these challenges, people with dementia will likely need family or other caregiver support to use OTC hearing aids. This is not unexpected, as people with dementia typically need help performing some or all instrumental activities of daily living (IADL), such as housekeeping, preparing food, taking medication, using transportation, shopping, managing finances, and using the telephone [41]. Similarly, people with dementia usually require some level of caregiver assistance for using traditional prescription hearing aids [42,43]. Yet OTC hearing aids have been developed for independent use, without explicit consideration of caregiver roles. In the absence of ongoing professional hearing services and counseling, it is unclear if OTC hearing aids are designed and delivered in ways that facilitate effective family caregiver involvement. It is further unknown if family caregivers are open to and comfortable assuming responsibilities for OTC hearing aid programming, use, care, and maintenance. Research is needed that explores the needs, perspectives, and capabilities of community-dwelling people with dementia and their family caregivers for using OTC hearing aids. This knowledge can inform the development of tailored devices, services, and supports that promote successful OTC hearing aid use in people with dementia and their family caregivers, thus ensuring that people with dementia can benefit from lower-cost, more accessible OTC hearing aids.

Study Objectives

This study explores perspectives on the feasibility and acceptability of OTC hearing aids as a pathway to hearing health care in community-dwelling older people with dementia. We conducted individual semistructured interviews with participants from 3 dementia-care interest-holder groups, including community-dwelling people with dementia and hearing difficulty, family caregivers of people with dementia and hearing difficulty, and geriatric direct care professionals with expertise in the care needs of older people with dementia and hearing difficulty. Using thematic analysis of the interview data, we aimed to identify (1) facilitators or advantages of OTC hearing aid use for community-dwelling older adults with dementia, and (2) barriers or disadvantages of OTC hearing aid use in these individuals. Study reporting follows the Consolidated Criteria for Reporting Qualitative Research (COREQ) guidelines.

Methods

Participant Groups and Eligibility Criteria

Participants were recruited to represent key dementia-care interest-holders directly affected by, or with knowledge pertaining to, OTC hearing aid use in community-dwelling people with dementia. Interest-holders represented three groups (15 each): (1) community-dwelling older adults with self- or caregiver-reported early to midstage dementia and self-perceived mild-to-moderate hearing loss, (2) family caregivers of community-dwelling older people with caregiver-reported early to midstage dementia and caregiver-reported mild-to-moderate hearing difficulty, and (3) geriatric care professionals who provide direct health care services to community-dwelling older adults with co-occurring dementia and hearing loss. Participants were recruited through a research registry of geriatric care professionals and family caregivers of people living with dementia, as well as via web-based advertising and word-of-mouth referrals.

To be eligible for inclusion, community-dwelling older adults with dementia met the following criteria: (1) aged 65 years or older, (2) non–nursing home resident, (3) self- or caregiver-reported diagnosis of early to midstage Alzheimer disease or related dementia, (4) education-adjusted Telephone Interview for Cognitive Status–modified (TICS-m) score of ≤27 out of 50 points consistent with the presence of dementia [44,45], (5) self-perceived mild-to-moderate hearing loss, and (6) ability to communicate in English and follow study procedures. We relied on self-perceived mild-to-moderate hearing loss rather than clinical audiometric test results to align with the FDA's printed candidacy guidelines for OTC hearing aids. Participants were not required to provide audiometric test results and could have any or no prior or current hearing aid experience.

XSL•FO
RenderX

Family caregivers were recruited separately from older persons with dementia (ie, caregivers and individuals with dementia were not enrolled as care dyads) and met the following inclusion criteria: (1) aged 18 years or older, (2) self-identified provider of informal or unpaid health care assistance to a family member who is a community-dwelling older person aged 65 years or older with co-occurring early to midstage Alzheimer disease or related dementia and mild-to-moderate hearing difficulty, (3) self-reported negative history of cognitive impairment or dementia, and (4) able to communicate in English and follow study procedures. Family caregivers could have any or no experience using hearing aids and assisting others in using hearing aids. To ensure study feasibility and accessibility, persons with dementia and family caregivers were not required to supply medical records confirming the dementia or hearing loss status of the person with dementia.

Geriatric direct care professionals were required to be at least 18 years old, able to communicate in English, and providers of direct health care services for community-dwelling older adults, including those with co-occurring dementia and hearing loss. They could be from any profession or geriatric care specialty outside of audiology, otolaryngology, and speech-language pathology. No specific hands-on hearing aid experience or knowledge was required.

Ethical Considerations

This study was approved by the University of Minnesota Institutional Review Board (STUDY00016265). Prior to enrollment, all participants gave informed consent or assent in accordance with institutional review board requirements. Individuals with dementia gave their verbal assent for participation, while written informed consent was obtained from a legally authorized representative. Family caregivers and geriatric direct care professionals provided written informed consent. Participant data were deidentified and stored on secure, password-protected servers to protect privacy and confidentiality. All participants were compensated for their time and contributions.

Descriptive Measures

We collected sociodemographic information from all participants. Additionally, several screening and descriptive measures were administered to characterize participants with dementia, including (1) TICS-m [45], (2) Hearing Handicap Inventory for the Elderly (HHIE) [46], and (3) Lawton-Brody IADL Scale (Lawton and Brody [47]).

We used the TICS-m as a quantitative measure of cognitive function [45]. The TICS-m is a widely used telephone-administered screening test of cognitive functioning designed for use when in-person assessment is impractical or infeasible. The test consists of 11 items (50 points total) covering several cognitive domains, including orientation to time and place, receptive and expressive language ability, verbal memory, calculation, and verbal abstraction. Scores have shown good sensitivity for detecting dementia in older adults when using a cutoff of ≤27 points for education-adjusted TICS-m scores [44]. In this study, TICS-m scores were adjusted for years of education using the corrections in Knopman et al [44] and required to meet the ≤ 27 cutoff, providing additional evidence for participants' cognitive function beyond their self- or caregiver-reported dementia status.

As mentioned previously, we relied on self-perceived hearing difficulty, consistent with FDA candidacy guidelines for OTC hearing aids. To provide additional descriptive information regarding the hearing abilities of participants with dementia, we administered the HHIE [46]. The HHIE is a validated self-assessment of hearing impairment consisting of 25 questions that measure situational and emotional effects of hearing loss in older adults. Each item presents a potential everyday impact of hearing loss, which the respondent rates as "yes," "sometimes," or "no." Each "yes" response is worth 4 points, "sometimes" is 2 points, and "no" is 0 points, giving a maximum possible score of 100 points for the highest level of perceived hearing difficulty. The results give a useful measure of subjective hearing difficulty; however, it should be noted that the HHIE is not specifically validated for use in people with dementia, who face challenges when completing health-related questionnaires. To improve feasibility for our participants, we introduced necessary flexibility into our administration of the HHIE. Whenever possible, we encouraged the older person with dementia to be actively involved in the completion of the HHIE—whether independently or together with a family caregiver. However, when necessary, family caregivers completed the HHIE for the individual with dementia based on their own perception of the person with dementia's hearing difficulty. HHIE scores were only used descriptively and were not used to determine eligibility or classify participants, given the lack of validation in dementia populations.

We used the Lawton-Brody IADL Scale to quantify independent living skills and the level of assistance participants with dementia require for completing IADL tasks that involve self-management skills that may be relevant to OTC hearing aid use [47]. The Lawton-Brody scale includes eight questions covering the following functional domains: using the telephone, shopping, food preparation, housekeeping, laundry, transportation, medication management, and finances. Each item is rated dichotomously as able (one point) or less able (0 points). Points are summed to give a total score, and dependence is defined as a score <8 points for women and <5 points for men due to differences in traditional gender roles [48]. The questionnaire may be administered to either persons with dementia or family caregivers. In this study, we requested that a family caregiver complete the Lawton-Brody whenever possible, as people with dementia may be hesitant to report functional deficiencies in the home. If a family caregiver was unavailable, the person with dementia completed the questionnaire independently.

Interviews

Participants completed an individual interview conducted via secure Zoom (Zoom Communications) videoconferencing. Interviews followed a semistructured interview guide consisting of open-ended questions designed to gather interest-holder-perceived facilitators and barriers to OTC hearing aids for community-dwelling older people with co-occurring early to midstage dementia and hearing loss (Multimedia

XSL•FO
RenderX

Appendix 1). Consistent with semistructured qualitative interviewing techniques, each interview followed a set of predefined questions; however, the interviewer followed the participant's lead in conversation and asked tailored follow-up questions as appropriate. Participants were allowed and encouraged to explore any issue of interest to them at the intersection of hearing loss, communication, hearing aid use, dementia, and dementia caregiving.

Each interview began with a brief introduction to OTC hearing aids and their main differences from prescription hearing aids, focusing on factual distinctions between regulatory categories to avoid biasing participant responses. Subsequent interview questions followed the main steps of the OTC hearing aid consumer pathway, eliciting participant views on determining OTC hearing aid candidacy, purchasing OTC hearing aids, configuring OTC hearing aids, assessing OTC hearing aid benefits, and using, maintaining, and troubleshooting OTC hearing aids. The interview guide was adapted for each participant group but maintained the same overall structure and sequencing of topics to ensure the similarity of interview content across participants. Interview guides for each participant group are included in the Multimedia Appendix 1.

Several accommodations were needed for individuals with dementia. For most participants with dementia, a family member assisted with Zoom and other study logistics. In these cases, family caregivers were instructed to allow the person with dementia to answer interview questions independently and to assist only as necessary to help the participant understand study directions and remain on task. Additionally, interview questions were modified as needed to ensure understandability for participants with dementia, who present with individual differences in cognitive and language ability not well predicted by their self- or caregiver-reported dementia status and quantitative measures of cognitive functioning. However, even with question modifications, participants with dementia often could not answer all interview questions. In these cases, participants with dementia were included in the study if they demonstrated an understanding of the definition of OTC hearing aids through their responses and engaged in the interview by providing independent and relevant answers to a subset of the interview questions.

The interviews were conducted by the first author, a female audiologist (AuD) who, at the time of the study, was a doctoral candidate and clinical researcher with formal training and experience in clinical audiology, qualitative interviewing, and dementia-related research. No prior relationship was established between the interviewer and any participant before study commencement. Participants were informed that the interviewer was an audiologist and researcher conducting a study on perspectives regarding hearing aid use and dementia. To minimize potential bias, participants were not informed that the study focused specifically on OTC hearing aids until the interview. The interviewer has a professional interest in improving hearing care for people living with dementia and remained attentive to ensuring that participants' perspectives guided the interviews.

All interviews were audio-recorded, transcribed verbatim, and anonymized. Interviews typically lasted between 30 and 60 minutes each. No repeat interviews were conducted. Field notes were not taken during or after interviews. The University of Minnesota Institutional Review Board approved the interview guide and all study procedures.

Data Analysis

Interview transcripts were reviewed and analyzed in NVivo 12 (QSR International Pty Ltd, 2022). We used reflexive thematic analysis as our methodological orientation, following Braun and Clarke's [49] six steps for thematic analysis: (1) familiarization, (2) generation of initial codes, (3) search for themes, (4) review, (5) name and define themes, and (6) write-up. First, 2 qualitative coders independently read the deidentified transcripts to familiarize themselves with participant responses (step 1). Then, the coders convened to discuss emerging patterns, using an inductive approach, and generate an initial coding framework (step 2). The coding framework considered all participants together—rather than partitioning them into their interest-holder groups—to facilitate subsequent comparison and contrast of participant perspectives. Next, the 2 coders individually coded one randomly selected transcript from each participant group and convened to compare interpretations and refine/clarify the coding framework. The first author coded all remaining transcripts, with the second coder double-coding 20% of transcripts to ensure consistency of code application. During this process, regular meetings were held to review codes, and disagreements were resolved through discussion. After coding was complete, the coders collated codes into themes and subthemes (step 3), which were subsequently reviewed, named, and defined by the research team (steps 4 and 5). The resulting themes were grouped under 2 main headings, which frame the results narrative (step 6): (1) facilitators or advantages of OTC hearing aid use for community-dwelling older adults with dementia, and (2) barriers to or disadvantages of OTC hearing aid use in these individuals. Formal data saturation thresholds were not prespecified; however, no substantially new themes emerged during later analysis, suggesting that saturation had been reached. Transcripts and themes were not returned to participants for comment, correction, or feedback.

Results

Participant Characteristics

The study included a total of 45 participants split equally between the 3 interest-holder groups (15 each). No eligible participants declined to participate, and no enrolled participants withdrew from the study. Most family caregivers and direct care professionals were female, consistent with published demographics of both groups [50-52]. Family caregivers had a mean age of 62.7 (range 32-79, SD 13.1) years, and just over half had experience assisting their care recipient with hearing aids (n=8). Direct care professionals had a mean age of 46.7 (range 26-74, SD 14) years and all but one (n=14) reported assisting their patients with routine hearing aid use, such as insertion and removal, changing batteries/charging hearing aids, and routine cleaning/care. In contrast with family caregivers

XSL•FO
RenderX

and direct care professionals, people with dementia were predominantly male. This outcome was somewhat unexpected, as Alzheimer or related dementia disproportionately affects women; however, it is also well documented that men are more likely than women to have hearing loss [53]. Participants with dementia had a mean age of 82.1 (range 68-95, SD 7.7) years, and most were current hearing aid users (n=11). Detailed participant characteristics are provided in Tables 1-3.

Interview Themes

In the following sections, we present key themes and subthemes generated from the thematic analysis process described above. Table 4 outlines these themes and provides exemplar quotes for each.

Table 4. Themes and descriptions.

Theme	Description
Facilitators	
Accessibility	Participants emphasized the ease of obtaining OTC[a] hearing aids and the benefit of eliminating the need for recurrent office visits for hearing aid fittings and adjustments.
Affordability	Participants appreciated the lower cost of OTC hearing aids, with some highlighting their potential to offer better overall value for individuals with dementia.
Autonomy and control	Participants valued the freedom, flexibility, and autonomy to try OTC hearing aids independently, noting that this approach could also reduce stigma associated with traditional hearing care.
Barriers	
Mistrust of OTC hearing aids	Participants expressed skepticism about the quality, customization, and ethics of OTC hearing aids, particularly regarding their ability to meet the needs of people with dementia.
Assessing OTC hearing aid candidacy in people with dementia	Participants were concerned about the ability of people with dementia to accurately self-classify their hearing loss and questioned the reliability of family caregivers' assessments without professional guidance.
Caregiver-facilitated programming and adjustment	Participants doubted whether family caregivers could effectively program and adjust OTC hearing aids without professional support.
Assessing the effectiveness of OTC hearing aids	Evaluating the benefit of OTC hearing aids was seen as challenging, particularly when distinguishing the effects of hearing loss versus cognitive decline on communication.
Ongoing OTC hearing aid use and caregiver burden/burnout	Family caregivers and direct care professionals expressed concerns about the additional responsibilities OTC hearing aids might place on family caregivers, particularly given the challenges of caregiver burden and burnout.

[a]OTC: over-the-counter.

Facilitators of OTC Hearing Aid Use in People With Dementia

Overview

Across the 3 interest-holder groups, participants identified important facilitators/advantages of OTC hearing aid use for community-dwelling older people living with co-occurring dementia and hearing loss. Under this heading, we identified 3 main themes described below.

Facilitator Theme #1: Accessibility

Consistent with the FDA's rationale for OTC hearing aids, participants in all 3 groups expressed optimism that OTC hearing aids can increase access to hearing aids for older people with dementia. Improved accessibility, participants noted, benefits many older adults with hearing loss and not solely those with dementia. However, participants also explained that better access to amplification has particularly high salience in the dementia caregiving context. Family caregivers and direct care professionals highlighted the advantage of eliminating the need for recurrent office visits to fit and adjust prescription hearing aids. Both family caregivers and care professionals emphasized that dementia caregiving is "consuming" [caregiver, wife, age (years) in the range of 60s], involving round-the-clock care, including providing transportation to and from frequent health care appointments for dementia and its complications. From this perspective, a subtheme emerged that family caregivers may view recurrent hearing aid office appointments as "burdensome" [care professional, female, age (years) in the range of 50s], a "struggle" [care professional, female, age (years) in the range of 40s], and "too hard." [caregiver, daughter, age (years) in the range of 60s] As a result, many family caregivers are "apt to not show up for the appointments or not do it at all." [care professional, female, age (years) in the range of 50s] Conversely, participants across groups viewed accessing OTC hearing aids as a fast, easy, and convenient alternative. As one person with dementia remarked, OTC hearing aids are "probably the easiest way to start." [person with dementia, male, age (years) in the range of 90s]

Participants explained that the time and travel involved in prescription hearing aid fittings are not only inconvenient but can also have financial, social, and emotional ramifications. Family caregivers and care professionals explained that people with dementia spend large amounts of time seeing health care providers. This "time investment" [care professional, female, age (years) in the range of 40s] is costly for individuals with dementia and their family caregivers. For caregivers, the cost is often measured in terms of the financial and employment consequences of taking time off work to transport care recipients with dementia to health care appointments.

As one family caregiver remarked:

> *If I have to schedule with the audiologist … it requires me to take time off work and then travel there, so it's*

XSL•FO
RenderX

> *costly in a number of ways, you know?* [caregiver, daughter, age (years) in the range of 60s]

For people with dementia, the cost is measured indirectly in lost time for social engagement and other activities. As one family caregiver commented:

> *Going to the audiologist is not the most exciting thing for her [care recipient]. I mean, she's kind of missing out on other activities and social opportunities and things if she's having to go to a lot of appointments.* [caregiver, granddaughter, age (years) in the range of 30s]

Many family caregivers and care professionals also raised concerns about the emotional impact of health care appointments on people with dementia. They shared that health care visits, including audiology appointments, can be difficult experiences for people with dementia, who may struggle to recognize, navigate, and understand large medical buildings and unfamiliar health care providers. One care professional commented on this challenge for prescription hearing care and shared how OTC hearing aids might help:

> *As they get further into the dementia, going to a new doctor or a place that's different—like having their hearing checked—being in that office situation can be scary for them. So if it's [hearing aid fitting] something they could do at home with a loved one, that would definitely be helpful for them.* [care professional, female, age (years) in the range of 40s]

Similarly, one care professional observed:

> *Sometimes the medical buildings are hard to navigate… and that can be overwhelming for people with dementia. So, I think it'd be easier being able to go to the pharmacy up the street or something they're familiar with to buy hearing aids.* [care professional, female, age (years) in the range of 20s]

Put simply, one person with dementia anticipated that if they decided to purchase OTC hearing aids, "it would be easy to get there." [person with dementia, female, age (years) in the range of 80s]

Facilitator Theme #2: Affordability

Participants in all 3 groups identified affordability as a key advantage or facilitator of OTC hearing aid use in people with dementia. Indeed, participants felt that more affordable hearing aids benefit all older adults, including those with dementia. However, perceptions of cost took on greater nuance in the context of dementia caregiving. Rather than emphasizing cost alone, many family caregivers spoke about value (ie, expected benefit/worth relative to price). The value subtheme was exemplified by a subset of family caregivers who shared that although they could afford prescription hearing aids, they questioned their benefit for people with dementia. Several family caregivers shared that the progression of dementia seemed to make their care recipient content to avoid conversation. They wondered if their relative was interested in hearing better and participating in conversations—and, in turn, whether expensive hearing aids were worth the cost. For example, one family caregiver reflected:

> *The interesting thing about Alzheimer's is like … he's happy in his own little world and so he likes being with people—but no, he doesn't necessarily want to talk … or be part of the conversation. That's not necessarily important to him right now. So, it makes it like … what's it gonna cost me? What's gonna be the benefit?* [caregiver, wife, age (years) in the range of 60s]

Family caregivers also raised concerns about whether people with dementia can take full advantage of the more expensive advanced features and professional fitting services that come with prescription hearing aids. Many noted that Bluetooth technologies, smartphone apps, and other hearing aid accessories are "technically more challenging than people with dementia can work with" [caregiver, daughter, age (years) in the range of 70s] and would, therefore, go unused. Several family caregivers also questioned whether people with dementia can provide sufficiently meaningful, reliable input to justify the added cost of professional hearing aid adjustments. As one family caregiver said,

> *It might be better that they go to an audiologist and really get the exact fit for what they need, but my husband is at the point right now where he can't tell you what the exact right fit is, so that's not applicable to him.* [caregiver, wife, age (years) in the range of 60s]

Finally, family caregivers expressed concern about the expense of prescription hearing aids relative to their high risk of being lost or damaged by people with dementia. One family caregiver explained:

> *A lot of dementia patients lose things. So honestly, if I think he's [care recipient] gonna lose his hearing aids again, I'm gonna go with the cheapest ones around because they're only gonna last until the next time he loses 'em.* [caregiver, wife, age (years) in the range of 60s]

Importantly, many family caregivers felt that lower-cost OTC hearing aids could mitigate their concerns about the value of hearing aids for people with dementia. For example, one family caregiver remarked:

> *I would hate to get those professional hearing aids and either they're lost or damaged, or she can't utilize them in the way they need to be. Yeah, I could swallow it a little bit easier if it's a thousand-dollar OTC hearing aids.* [caregiver, daughter, age (years) in the range of 50s]

This and other family caregiver responses suggest OTC hearing aids may help shift caregivers' value calculations in favor of purchasing and trying amplification.

Facilitator Theme #3: Autonomy and Control

Another facilitator theme emerged around control—or the freedom, flexibility, and autonomy to efficiently try OTC hearing aids and make decisions about them. Across all 3 groups, several participants saw OTC hearing aids as an opportunity for people with dementia and their family caregivers to "scope out hearing aids for themselves" [care professional,

XSL•FO
RenderX

female, age (years) in the range of 50s] and more rapidly evaluate their benefits. As one family caregiver put it:

> *I think that, in general, to have a fast way … to just get a hearing aid to your person and see if it works is a wonderful, wonderful thing.* [caregiver, wife, age (years) in the range of 60s]

Relatedly, many family caregivers and care professionals highlighted the advantage of quickly gauging the likelihood of hearing aid tolerance and acceptance in people with dementia. One care professional explained:

> *With OTC hearing aids, they [family caregivers] could probably get a general idea of if they're [care recipients] gonna be compliant with hearing aids right away.* [care professional, female, age (years) in the range of 30s]

Additionally, a prominent subtheme emerged around stigma. Direct care professionals stressed the deep-seated stigma and "embarrassment" [care professional, female, age (years) in the range of 30s] that accompany a diagnosis of age-related hearing loss. Receiving this diagnosis, participants explained, means a person is "labeled as old now" [care professional, female, age (years) in the range of 40s] and—especially for community-dwelling persons with dementia—may invoke fear of losing independence. As a result, those with dementia may avoid seeing a hearing care professional altogether. Several care professionals felt OTC hearing aids could help circumvent stigma by giving older adults with dementia and their caregivers the autonomy and control to try hearing aids "on the sly without actually having it in their medical records." [care professional, female, age (years) in the range of 50s] One care professional explained:

> *They [community-dwelling people with dementia] don't want hearing loss to be another thing that makes them feel incapable of taking care of themselves … They're at home. They don't want to move, so then they don't want to bring attention to their hearing.* [care professional, female, age (years) in the range of 20s]

Many care professionals and family caregivers felt that some people with dementia would be more open to OTC hearing aids, which allow them to try amplification without "admitting to a loss." [care professional, female, age (years) in the range of 50s] or "involving other people." [person with dementia, male, age (years) in the range of 90s] As one family caregiver reflected:

> *It might be easier for him [care recipient] to accept not going in to see a doctor … There might be an advantage that I could at least introduce him to hearing aids this way.* [caregiver, wife, age (years) in the range of 60s]

Barriers to OTC Hearing Aid Use in People With Dementia

Overview

Although participants described meaningful potential facilitators/advantages of OTC hearing aids for people with dementia, they also identified several unaddressed barriers or disadvantages. Below, we describe 5 main barrier themes.

Barrier Theme #1: Mistrust of OTC Hearing Aids

Across all 3 groups, many participants expressed a general mistrust of OTC hearing aids. This theme emerged from a variety of statements revealing apprehension, hesitance, and skepticism about the quality and effectiveness of OTC hearing aids and their associated support services. Specifically, some participants raised concerns that OTC hearing aids may lack sufficient customization of their frequency responses to match individual hearing losses. These participants viewed OTC hearing aids as simple "amplifiers" [caregiver, wife, age (years) in the range of 70s; care professional, female, age (years) in the range of 60s; person with dementia, male, age (years) in the range of 70s], which they believed to be too "generic" [caregiver, daughter, age (years) in the range of 60s; caregiver, wife, age (years) in the range of 60s] for people with hearing loss—especially those with dementia whose hearing loss is further complicated by the effects of cognitive decline. A participant with dementia commented:

> *I am suspicious of [OTC hearing aids] … because it's not talking about my hearing in each ear. It is trying to be an amplifier. I got a friend who doesn't wanna pay for [prescription hearing aids]. He says, 'I'll a buy a set of those [OTC hearing aids].' And I said, 'Good luck. You're gonna waste your money.'* [person with dementia, male, age (years) in the range of 70s]

A subtheme emerged in which participants questioned the competence, training, and expertise of OTC hearing aid vendors and customer support staff. Across groups, participants overwhelmingly endorsed the need for readily available, knowledgeable, and trustworthy technical support to facilitate OTC hearing aid use in people with dementia. At the same time, participants expressed uncertainty that OTC hearing aids would include "any technical assistance that you can count on." [caregiver, daughter, age (years) in the range of 70s] Specifically, participants raised concerns that the people who sell and service OTC hearing aids may have insufficient training and experience in hearing loss and hearing aids—and, therefore, might not provide helpful, actionable recommendations. This sentiment was especially prominent among people with dementia. As one participant with dementia remarked:

> *Well, not being familiar with buying over the counter, the clerk would not know how to explain properly how to do it versus a doctor at the clinic.* [person with dementia, male, age (years) in the range of 80s]

Along the same lines, another participant with dementia said:

> *I don't know if it [OTC hearing aids] would be easier. 'Cause sometimes they don't know exactly what you need or to tell you how to use it.* [person with dementia, male, age (years) in the range of 70s]

Participants with dementia, in particular, expressed doubt about the ethics and morality of the people who sell and service OTC hearing aids. They described feeling skeptical—"iffy" [person with dementia, male, age (years) in the range of 70s]—about

XSL•FO
RenderX

the veracity of the "smiley ads" [person with dementia, male, age (years) in the range of 70s] for OTC hearing aids and questioned their underlying motives. Many participants with dementia felt that OTC hearing aids only emphasized sales and profits at the expense of older adults living on fixed incomes. As one participant with dementia explained, "you could be fooled by somebody that's just trying to make some money." [person with dementia, female, age (years) in the range of 80s] Another participant with dementia asked:

> *Who's on the other side of the counter? … I wouldn't even consider that. Not at all. To me that would be like a crapshoot.* [person with dementia, male, age (years) in the range of 80s]

Barrier Theme #2: Assessing OTC Hearing Aid Candidacy in People With Dementia

An important barrier theme emerged around assessing OTC hearing aid candidacy in people with dementia. According to FDA regulations, OTC hearing aids are intended for adults with perceived mild-to-moderate hearing loss. However, many care professionals and family caregivers questioned the accuracy and reliability of perceived hearing loss in people with dementia. Both participant groups overwhelmingly agreed that people with dementia cannot accurately self-classify their degree of hearing loss. Specifically, a subtheme emerged surrounding the memory demands of self-assessing one's hearing loss. As several family caregivers and care professionals noted, age-related hearing loss gradually "creeps up" [care professional, female, age (years) in the range of 50s] on older adults, thus requiring them to recall and reflect on their hearing experiences over both long and short periods of time. Many people with dementia, participants explained, do not have the memory and cognitive capacity to remember and compare their listening experiences. As a result, family caregivers and care professionals were doubtful that people with dementia could accurately describe their hearing loss progression and categorize its severity relative to others' hearing ability. One care professional explained:

> *I think people with dementia could identify profound hearing loss—that they can't hear. But anything less, you add the complication of dementia. What are they not remembering? To say mild or moderate versus getting moderate to severe, they wouldn't know.* [care professional, female, age (years) in the range of 40s]

During semistructured interviews, many participants with dementia struggled to answer questions about determining their own candidacy for OTC hearing aids. However, those who could respond shared a similar opinion. For example, when asked if he was confident in self-classifying his degree of hearing loss, one participant with dementia responded:

> *Probably not because it comes on so gradually. And after you've been living with the condition, you sort of just accept that's the way your hearing is … It gets integrated into your life.* [person with dementia, male, age (years) in the range of 80s]

Family caregivers and care professionals agreed that in many cases, family members would be responsible for determining OTC hearing aid candidacy for people with dementia. However, family caregivers lacked confidence that they could accurately classify their care recipient's degree of hearing loss without a professional hearing examination. Here, a notable subtheme emerged regarding the challenge of separating the effects of cognitive decline/dementia and hearing loss on communication in people with dementia. Many family caregivers shared that they were unsure if they were observing symptoms of cognitive decline or hearing loss. As one family caregiver reflected:

> *I don't know if she's [care recipient] not holding that conversation because she doesn't have the capacity and the wherewithal to hold that conversation, or if she's really not hearing the other person speak.* [caregiver, wife, age (years) in the range of 70s]

Given the challenges described above, participants in all 3 groups felt it was important that people with dementia have a professional hearing examination regardless of their or their family's interest in OTC hearing aids. A care professional commented:

> *Even though it's over the counter, I still feel like there would be a need for… some type of evaluation and referral from a specialist. Not just that the caregiver says, 'Well, I've been talking recently, and they've not been responding back.'* [care professional, female age (years) in the range of 30s]

Similarly, one participant with dementia explained:

> *People try to guess their hearing loss. But you have to use technology to figure it out. You have to sit in that box. And they do the little noises back and forth, and then when you're done each ear is tested for its own hearing.* [person with dementia, male, age (years) in the range of 70s]

Barrier Theme #3: Caregiver-Facilitated Programming and Adjustment

Participants in all 3 groups overwhelmingly expressed uncertainty and trepidation about the process of programming and adjusting OTC hearing aids for people with dementia. First and foremost, there was strong agreement that by and large, people with dementia cannot independently self-program and customize OTC hearing aids—regardless of the specific self-programming or fitting process used. Indeed, many family caregivers and care professionals pointed out that people with dementia—even in the early stages of the disease—often need help using everyday technologies such as smartphones, televisions, computers, and tablets. Similarly, participants anticipated that family caregivers would play a significant role in programming and adjusting OTC hearing aids for people with dementia.

However, participants questioned whether family caregivers possess sufficient knowledge, skills, and experiences to program OTC hearing aids for care recipients with dementia. Some participants highlighted that family caregivers are not "educated in hearing" [person with dementia, female, age (years) in the range of 80s], while others stressed that many dementia caregivers are themselves older adults who may face barriers to learning and using new technologies. As one family caregiver reflected:

XSL•FO
RenderX

> *When you think about it, a lot of the people that need hearing aids are old, right? And most people my age do not understand technology very well and they wouldn't be able to program hearing aids for their spouse.* [caregiver, wife, age (years) in the range of 70s]

Most participants expressed a preference for and confidence in professional hearing aid programming and adjustments. Across groups, participants emphasized the complexity of human hearing and hearing aids, along with the education and training of licensed hearing care professionals— "there's a lot to hearing," [caregiver, daughter, age (years) in the range of 60s] one family caregiver commented. Participants especially valued professional expertise in programming and adjusting hearing aids based on an individual's audiometric thresholds, behavioral responses, and preferences. Specifically, several family caregivers and participants with dementia viewed hearing care professionals as uniquely attuned to "the correct questions to ask" [person with dementia, female, age (years) in the range of 80s], a person with hearing loss—including those with dementia—when tailoring and optimizing an individual's hearing aid settings. As one family caregiver explained:

> *I'd prefer [care recipient's hearing aids] be programmed by a professional who asks the questions and compares, 'How is it now? How is it not now?' Whether that same quality of observation could happen with me doing it—I don't know.* [caregiver, husband, age (years) in the range of 70s]

Similarly, one participant with dementia shared:

> *I'd rather go to someone that [programmed hearing aids] all the time…. Because they had probably done a lot of work with people with hearing aids, so they would know a lot of questions to ask about how I was hearing.* [person with dementia, female, age (years) in the range of 80s]

In particular, family caregivers were unsure if they would ask the right questions of their care recipient when programming OTC hearing aids. This concern was magnified by a subtheme regarding the challenge of obtaining reliable self-reports of sensory symptoms from people with dementia. Both family caregivers and direct care professionals emphasized that people with dementia lose the "self-reflective ability" [caregiver, wife, age (years) in the range of 70s] and "correct words" [care professional, female, age (years) in the range of 40s] to clearly identify and describe bodily and sensory sensations. Consequently, participants expressed concern that family caregivers would not be able to elicit and properly interpret feedback from their care recipient to facilitate effective OTC hearing aid programming. As a result, caregivers anticipated that they "[would] not trust" [caregiver, wife, age (years) in the range of 60s] and "would not feel confident" [caregiver, daughter, age (years) in the range of 60s] in their "amateur" [caregiver, husband, age (years) in the range of 70s] programming results. Several participants with dementia echoed this sentiment, one of whom explained:

> *She's [family caregiver] good with a lot of things, but I don't know that she's an expert in that [OTC hearing aid programming]. She is not educated in hearing, and I believe that you have to be educated with the body in order to work with improving hearing.* [person with dementia, female, age (years) in the range of 80s]

One family caregiver summarized her concerns about using an OTC hearing aid for her care recipient:

> *I think [programming is] the major disadvantage, not knowing if you've programmed it for the best quality of hearing, especially for somebody else* [caregiver, daughter, age (years) in the range of 60s]

Barrier Theme #4: Assessing the Effectiveness of OTC Hearing Aids

Following OTC hearing aid programming, participants raised concerns about their ability to assess the effectiveness of OTC hearing aids in people with dementia. Across groups, most participants felt they could determine if OTC hearing aids were helpful to some degree—but they questioned their ability to judge whether the devices had been "optimized" [caregiver, wife, age (years) in the range of 60s] or had achieved a person with dementia's full hearing potential. Here, participants sought assurance that OTC hearing aids had delivered "the very best benefit" [caregiver, wife, age (years) in the range of 70s] for speech understanding and communication. However, many participants felt such assurance could only be obtained by seeing a hearing care professional for a prescription hearing aid fitting. Participants in all 3 groups expressed trust and confidence in a hearing care professional's ability to ensure hearing aids are "correct… and fit beautifully enough for [people with dementia] to hear." [care professional, female, age (years) in the range of 30s] As one participant with dementia explained when discussing hearing aid programming:

> *Since I'm a perfectionist, I wanna talk to somebody who is in the [hearing aid] business.* [person with dementia, female, age (years) in the range of 80s]

Without the assistance of a professional, participants in all 3 groups were unsure how they would assess and quantify the effectiveness of OTC hearing aids. Specifically, family caregivers and direct care professionals noted two prominent subthemes described earlier: (1) the challenge of separating the effects of cognitive decline/dementia and hearing loss on communication in people with dementia, and (2) the challenge of obtaining a reliable self-report of sensory symptoms from people with dementia. Together, these 2 challenges made family caregivers and direct care professionals apprehensive about evaluating the amount and extent of OTC hearing aid benefit in people with dementia—"it's tricky because you're also observing cognition," [caregiver, wife, age (years) in the range of 70s] one family caregiver noted. Another family caregiver reflected:

> *When you have cognitive decline, all parts of the brain are dying literally and not functioning as well. It takes [care recipient] longer to process things that are said. And I might have less confidence in [care recipient's] ability to describe it [hearing aid performance].* [caregiver, wife, age (years) in the range of 70s]

XSL•FO
RenderX

Most participants emphasized the importance of programming OTC hearing aids for optimal speech understanding and communication; however, several family caregivers and direct care professionals raised concerns about the possibility of sensory agitation from poorly fit OTC hearing aids. Responses in this subtheme emphasized the sensitivity of people with dementia to changes in their environment and sensory inputs. Namely, participants wondered if suboptimal OTC hearing aids could produce uncomfortable sound quality or acoustic feedback that might make a person with dementia startled, agitated, frustrated, or withdrawn. Participants raised specific concerns about "loud sounds," [caregiver, daughter, age (years) in the range of 40s] "echoing," [care professional, female, age (years) in the range of 70s] "ringing," [care professional, female, age (years) in the range of 20s] and "buzzing" [care professional, female, age (years) in the range of 50s] as likely sources of sensory agitation from hearing aids that might be overlooked or poorly managed in OTC hearing aids. Notably, participants lacked confidence in both people with dementia and their family caregivers to accurately identify, assess, and resolve these issues. One care professional explained:

> *If they [people with dementia] can't tell you that the [hearing aid] volume is too loud, it could be echoing and stuff. You never would know that because they have dementia, and they just won't talk at all because the sound in their ear is not correct… like a buzz or a ringing.* [care professional, female, age (years) in the range of 70s]

Adding further challenge, caregivers and care professionals felt they might have limited time to identify and resolve OTC hearing aid issues before their care recipient might become frustrated or uncooperative. Here, a subtheme emerged for the tendency of people with dementia to "give up early" [care professional, female, age (years) in the range of 40s] on new technologies. Several participants stressed that if the effectiveness and benefit of OTC hearing aids were not quickly apparent, a person with dementia might abandon the devices altogether. One family caregiver explained:

> *My husband [care recipient] would expect me to be the expert on it [OTC hearing aids], and then if it didn't work, he'd get cranky at me, and he might give up.* [caregiver, wife, age (years) in the range of 60s]

A participant with dementia shared his own expectations for immediate OTC hearing aid benefit:

> *If it's [OTC hearing aids] wrong, I wouldn't have any idea what to do. It's so simple…. You put it [hearing aid] in your ear and press the button. If it doesn't work… that isn't right.* [person with dementia, male, age (years) in the range of 80s]

Barrier Theme #5: Ongoing OTC Hearing Aid Use and Caregiver Burden/Burnout

Family caregivers and direct care professionals agreed that the challenges of OTC hearing aid use in people with dementia extend beyond the initial purchase and programming. Indeed, both groups stressed that OTC hearing aid use is an ongoing commitment involving daily responsibilities for hearing aid use, care, maintenance, and troubleshooting. Across groups, participants had differing views on the amount and type of hearing aid tasks a person with dementia could complete independently, reflecting individual differences between care recipients. Nevertheless, participants concurred that family caregivers would need to assume ultimate responsibility for overseeing and managing continued OTC hearing aid use for a person with dementia—especially as their cognitive and functional abilities further declined. This responsibility emerged as a significant concern. Nearly all family caregivers emphasized their multiple competing caregiving responsibilities, with many describing themselves as overwhelmed, overloaded, and burned out. For this reason, many family caregivers questioned their patience and capacity for self-learning and implementing OTC hearing aid tasks without the assistance of a hearing care professional. "The caregiver needs to be supported and educated to be successful… that's pretty important in dementia care," one family caregiver explained [caregiver, daughter, age (years) in the range of 60s]. Another family caregiver shared her initial reaction to learning about OTC hearing aids on television:

> *What I thought about [OTC hearing aids] is, I would find it challenging to figure out. I have to say as a caregiver and being kind of burned out that I'm not as confident doing things as I used to be. I mean, I'm aging, too, but I think it has more to do with being overwhelmed and burned out. It's harder for me to learn things right now that I would normally be able to manage.* [caregiver, daughter, age (years) in the range of 60s]

Another family caregiver echoed this perspective:

> *I can figure out technology without any problem…but I get very frustrated very easily when I have to do anything on my own. It's not that I can't do it, it's just that you have so much on your plate that if somebody puts one more thing on your plate, it puts you on overload.* [caregiver, wife, age (years) in the range of 70s]

Family caregivers were unsure if the challenges of long-term OTC hearing aid use would be worth their effort. Here, family caregivers returned to the subtheme of value discussed earlier; however, they augmented their previous calculation of price versus expected hearing aid benefit with a new calculation of their caregiving work (cost) versus observed hearing aid benefit. In this context, family caregivers anticipated that their work would be substantial while OTC hearing aid effectiveness would be uncertain or unclear (returning to an earlier barrier theme—see Barrier #4). Furthermore, family caregivers questioned whether their care recipient would be cooperative, compliant, or equally invested in using OTC hearing aids. As one family caregiver described:

> *It's [OTC hearing aid use] one more thing to do. It's questionable benefit…. And unclear how much cooperation you're gonna get from your partner. And you learn where to fight your battles.* [caregiver, husband, age (years) in the range of 70s]

Another family caregiver elaborated:

XSL•FO
RenderX

> *It's always gonna be how much work is it versus the benefit. That's always gonna be, as a caregiver, the scale you're in.* [caregiver, wife, age (years) in the range of 60s]

Finally, when considering whether she would use OTC hearing aids with her spouse, who has dementia, one family caregiver shared her competing priorities as a dementia caregiver: "I need to make my husband's [care recipient] life easier, but I also need to make our lives easier." [caregiver, wife, age (years) in the range of 60s].

Discussion

Principal Findings

This qualitative study explored the feasibility and acceptability of now widely available OTC hearing aids for community-dwelling older people with dementia and their family caregivers. We approached this question from the perspectives of key dementia-care interest-holders via semistructured interviews with individuals from three interest-holder groups: (1) community-dwelling older adults with co-occurring dementia and hearing difficulty, (2) family caregivers of community-dwelling older adults with co-occurring dementia and hearing difficulty, and (3) geriatric direct care professionals. Using thematic analysis, we identified and described specific facilitators and barriers to OTC hearing aid use in community-dwelling older people with dementia. Below, we discuss our findings and their clinical implications.

Facilitators of OTC Hearing Aid Use in People With Dementia

Facilitators or advantages of OTC hearing aid use included accessibility, affordability, and autonomy/control. While these benefits extend to older adults in general, our participants highlighted their specific importance within the dementia caregiving context. In terms of accessibility, participants endorsed the benefit of OTC hearing aids in eliminating the recurrent in-person appointments typically required for prescription hearing aid fitting and adjustments. Participants felt that removing the need for in-person appointments could make hearing health care more feasible and palatable for dementia caregivers and their care recipients. Additionally, participants appreciated the affordability of OTC hearing aids. However, family caregivers tended to emphasize value considerations rather than cost. Here, family caregivers viewed OTC hearing aids as a potentially better value than prescription hearing aids when considering their care recipients' simple listening environments, low technology proficiency, and high proclivity for losing/damaging hearing aids and other technologies. Finally, participants also identified the benefits of OTC hearing aids in the realm of autonomy and control. Across interest-holder groups, participants appreciated the autonomy and flexibility OTC hearing aids offer for deciding when, where, and how to try hearing aids for people with dementia. Participants viewed this enhanced control as particularly important within the context of stigma, noting that the combined stigmas of dementia and hearing loss may prevent individuals with dementia from seeking or agreeing to formal hearing testing or prescription hearing aids. Participants in all 3 groups agreed that OTC hearing aids could offer a more discreet alternative by allowing people with dementia to circumvent formal hearing testing and documentation of prescription hearing aid use.

These findings generally align with the larger hearing aid and dementia caregiving literature. Regarding accessibility, the benefits of OTC hearing aids are evident. Studies show family dementia caregivers bear heavy responsibility for transporting their care recipient to health care appointments, which can contribute to caregiving-related emotional, psychological, financial, and physical burden [54,55]. Furthermore, health care appointments may—as our participants discussed—cause emotional and physical distress for people with dementia, particularly when health care providers are not specifically trained in dementia [56]. Given these considerations, our participants' desire to avoid recurrent in-person hearing aid appointments is understandable and may constitute a significant advantage for OTC hearing aids in the dementia caregiving context.

Our participants' preference for lower-cost, more affordable hearing aids is unsurprising and consistent with the underlying rationale for OTC hearing aids. However, our family caregiver participants made an important distinction between value and cost. To date, most studies on barriers to hearing aid adoption emphasize cost and affordability. Research, however, has shown that value perceptions can also drive hearing aid purchase decisions [57,58]. For older adults broadly, perceived hearing aid value may include emotional, social, quality, and price considerations [58]. Our results suggest that these factors may operate differently in the dementia caregiving context, where family caregivers consider their care recipient's functional limitations when forming expectations of hearing aid benefits relative to price. By lowering the cost of amplification, OTC hearing aids may play a unique role in improving perceived hearing aid value for people with dementia and their family caregivers.

Our participants' emphasis on control and patient autonomy is consistent with the priorities of early policy and critique documents that led to the formal introduction of OTC hearing aids, though somewhat less consistent with the OTC hearing aid regulations themselves [59]. Autonomy is seldom discussed in the context of OTC hearing aids, possibly because it is viewed as an aspect of accessibility. Indeed, accessibility does contribute to the ease of obtaining OTC hearing aids. However, our family caregivers and care professionals viewed control as having significance beyond more easily obtaining hearing aids. Specifically, our participants emphasized the importance of autonomy for overcoming stigma-related barriers to hearing aid adoption in people with dementia. Among older adults, dementia and hearing loss each carry stigma—but together, their impact may be even more harmful. For older adults living with both dementia and hearing loss, the 2 stigmas may combine to produce unique fears around loss of independence, aging, and social isolation [60-65]. Although the adoption of OTC hearing aids still requires some acknowledgment of hearing loss, these devices may help overcome stigma by giving older people with dementia and their caregivers the autonomy to circumvent

XSL•FO
RenderX

formal medical documentation of hearing loss and hearing aid use.

Barriers to OTC Hearing Aid Use in People With Dementia

Although participants endorsed several facilitators of OTC hearing aid use in community-dwelling older people with dementia, they also described meaningful barriers that tempered their enthusiasm. From our participants' responses, we identified the following barriers or disadvantages of OTC hearing aid use: mistrust of OTC hearing aids; assessing OTC hearing aid candidacy in people with dementia; caregiver-facilitated programming/adjustment; assessing the effectiveness of OTC hearing aids; and ongoing OTC hearing aid use and caregiver burden/burnout.

Our findings broadly support and add nuance to the emerging literature on consumer attitudes toward and barriers to OTC hearing aid use. In our study, mistrust emerged as a substantial barrier to OTC hearing aid use for people with dementia and their family caregivers. A recent study of consumer attitudes toward OTC hearing aids also describes trust barriers to OTC hearing aid use. In a survey of 1377 adults without prior hearing aid experience, Singh and Dhar [66] found overall low interest in OTC hearing aids, which they largely attributed to a lack of knowledge and trust in OTC hearing aids. In our study, some participants' mistrust stemmed from misinformation or lack of knowledge, such as the belief that OTC hearing aids are simple, one-size-fits-all amplifiers. However, participants also conveyed deeper mistrust regarding the competence, motivations, and ethics of those who sell and service OTC hearing aids. Here, it is plausible that people with dementia and their family caregivers may have heightened mistrust of OTC hearing aids compared with the general population. Research indicates that individuals with dementia are particularly vulnerable to financial fraud and exploitation [67,68], potentially leading those with earlier-stage disease and higher self-awareness to approach new products and sales claims with increased caution. Additionally, family dementia caregivers have been shown to harbor mistrust for a variety of dementia care services and interventions, stemming from previous negative experiences and a strong desire to protect their care recipients [69,70].

As discussed previously, both family caregivers and care professionals raised serious concerns about the accuracy and reliability of self-perceived hearing loss in people with dementia. This concern is supported by numerous studies in the general older adult population demonstrating that even without known cognitive impairment, self-reported hearing ability is generally unreliable compared with measured audiometric thresholds [71-73]. However, as our participants highlighted, this problem may be even more pronounced in people with dementia. In a recent study, Kim et al [74] found lower concordance between self-reported and audiometric hearing status in older adults with cognitive impairment than in those without. Notably, the authors also found poor sensitivity of proxy-reported hearing ability in older adults with cognitive impairment, suggesting that family or friends' hearing loss judgments are an unreliable substitute for self-report in this population [74]. Our qualitative results echo these findings, indicating that family caregivers not only lack confidence in their care recipient's self-reported hearing status—but also in their own ability to assess and categorize their care recipients' hearing and communication abilities. Interestingly, our family caregiver participants attributed this lack of confidence, in large part, to the challenge of distinguishing the effects of hearing loss and dementia on communication—an observation echoed in other published studies [31,75]. This insight could help explain the finding of Kim et al [74] of poor sensitivity for proxy-reported hearing loss in their sample of older people with dementia.

Our participants also expressed concerns about the process of programming and adjusting OTC hearing aids. Participants in all 3 groups agreed that people with dementia cannot independently program and adjust OTC hearing aids. This sentiment is well supported by a host of studies documenting the myriad challenges and barriers faced by people with dementia when using both everyday and assistive technologies [35-37]. However, our family caregiver participants also lacked confidence in their own ability to assist their care recipients with OTC hearing aid programming.

While there are few studies of OTC hearing aid use in community-dwelling dementia caregiving dyads, Convery et al [76] found that in a sample of older adults with a range of cognitive abilities, lay partner participation in the OTC hearing aid self-fitting process did not significantly influence or improve outcomes. The authors suggest that fitting outcomes might have improved with knowledgeable support from trained personnel [76]. Here, it is important to consider—as some of our participants mentioned—that many partners and caregivers of older people with co-occurring dementia and hearing loss are themselves older adults who may encounter challenges in using technology. Studies show that older adults face a variety of barriers to technology use, including lack of knowledge, age-related vision loss, and fine motor difficulties, as well as negative attitudes and anxiety toward technology [77-79]. Our family caregiver participants, who were primarily older adults, exemplified these barriers, expressing great apprehension about their technology proficiency and hearing aid knowledge. Notably, in this context, our caregivers' concerns about technology use were compounded by the previously mentioned barrier surrounding self- and proxy-report of hearing ability in people with dementia. In short, our family caregivers lacked confidence in their care recipients' ability to self-report changes in hearing to guide caregivers' programming decisions, and caregivers were also unsure if they could intuit whether they made the correct programming decisions.

Across interest-holder groups, participants were unsure if they could accurately assess the effectiveness of OTC hearing aids in people with dementia. Specifically, our participants raised concerns that self- or caregiver-programmed settings might be suboptimal in ways that could go undetected—potentially leading to sensory agitation, missed benefits, and hearing aid abandonment in people with dementia. To our knowledge, no research has examined the effectiveness of self- or caregiver-fit OTC hearing aids in people with dementia. In the general older adult population, self-programmed OTC hearing aids have consistently shown comparable outcomes to prescription hearing aids [1-5]. However, outcomes of OTC hearing aids in dementia

XSL•FO
RenderX

caregiving dyads are yet unknown. This uncertainty may have contributed to our participants' strong preference for prescription hearing aids and professional guidance. However, this finding is broadly consistent with the results of recent consumer surveys, which show that most adults with self-reported hearing difficulty prefer having professional assistance with their health care [66,80]. Research is urgently needed to determine how OTC hearing aid outcomes compare to those of prescription hearing aids in community-dwelling people with dementia and their family caregivers.

Last, our family caregiver and care professional participants stressed the need for ongoing caregiver involvement to support long-term OTC hearing aid use in people with dementia. Here, our family caregiver participants raised serious concerns about adding OTC hearing aid responsibilities to their already significant caregiving load. Many described feeling overwhelmed and burned out, echoing a large and well-established literature on caregiver burden, burnout, and stress among informal dementia caregivers [81-84]. Furthermore, several of our caregiver participants questioned whether OTC hearing aids would be worth their caregiving effort, especially if the OTC hearing benefit was unapparent and their care recipient was apathetic or uncooperative about using hearing aids.

Considerations of caregiver burden/burnout augment the value theme described earlier to include caregiver perceptions of their work/effort for OTC hearing aid use versus the expected or observed OTC hearing aid benefit. Caregivers may use this calculation of work/effort versus benefit to decide whether to (1) initiate OTC hearing aid use for their care recipient, or (2) continue using OTC hearing aids with their care recipient. Research shows that although people with dementia prefer to be included in important decisions, caregivers often make important medical and treatment decisions for them [85]. In this case, caregivers may ultimately decide whether to invest time and energy into using OTC hearing aids with and for their care recipient. It is important to note that this situation is not unique to OTC hearing aids; it also applies to prescription hearing aids. Indeed, research shows that caregiver assistance is an important determinant of successful prescription hearing aid use in people with dementia [42]. However, the lack of professional support and services for OTC hearing aids could add additional stress on caregivers, potentially increasing the caregiver burden involved in hearing aid use. Research is needed that compares caregiver outcomes for prescription versus OTC hearing aids.

Clinical Implications and Future Directions

Overview

Findings from this study highlight several ways in which OTC hearing aid devices and service delivery models could be better aligned with the needs of people with dementia and their caregivers. Unless and until major cost and accessibility barriers to prescription hearing aids are removed, people with dementia may turn to OTC hearing aids to afford and access hearing health care. Thus, addressing the barriers identified in this study is essential.

Implications for Device Design

Participants emphasized perceived challenges related to device complexity, difficult-to-navigate controls, and unclear or insufficient user feedback during use. These findings point to actionable opportunities for OTC hearing aid manufacturers to improve usability for people with dementia and their caregivers. Design considerations informed by participant perspectives include the following:

- Simplified, intuitive programming and troubleshooting workflows that reduce the cognitive load required to set up and adjust devices.
- Dedicated caregiver-assisted programming pathways that allow caregivers to complete or oversee key steps in the setup and adjustment process.
- Caregiver-oriented tools or interfaces that help validate and verify whether amplification settings are appropriate and functioning as intended.
- Clear, interpretable system feedback that communicates both correct and incorrect steps in formats accessible to users with dementia and to caregivers providing assistance.
- Physical design features that minimize handling complexity, including clearly marked controls and components that are easy for both people with dementia and caregivers to understand and manipulate.

Implications for Service Delivery and Caregiver Support

Participants consistently emphasized that people with dementia are unlikely to use OTC hearing aids successfully without meaningful caregiver involvement. Perceived challenges included difficulties with initial setup, troubleshooting, and day-to-day management of the devices. These findings point to several opportunities for strengthening service delivery models and caregiver supports:

- Brief caregiver-focused training modules delivered in person, by phone, or through app-based tutorials to assist with device setup, programming, and troubleshooting.
- Simplified written, visual, or video-based instructions tailored to dementia caregiving dyads that reduce cognitive load and clarify step-by-step processes.
- Optional caregiver-tailored remote onboarding or coaching sessions to compensate for the absence of professional fitting services, especially during initial use.
- Caregiver-centered guidance and expectation-setting, including strategies for monitoring benefit, recognizing device malfunction, and supporting consistent use.

Together, these supports reflect opportunities for behavioral and educational interventions aimed at reducing caregiver burden and improving the likelihood of successful device use.

Future Research Directions

Further research is needed to evaluate the feasibility and acceptability of OTC hearing aids for people living with dementia and their caregivers. Priority areas include the following:

- Hands-on trials in both laboratory and home settings to observe device use, errors, and points of breakdown.

XSL•FO
RenderX

- Quantifying the magnitude and consequences of identified barriers, including which barriers are most consequential for real-world outcomes.
- Examining caregiver capabilities and roles, including how caregiver burden, health literacy, and technology experience shape outcomes.
- Developing and pilot-testing tailored interventions, device refinements, and service delivery supports informed by the themes identified in this study.

In addition, research is needed to better understand the effectiveness of OTC hearing aids for people living with dementia compared with traditional prescription hearing aids. Clinical trials should evaluate outcomes and benefit domains to clarify when, how, and for whom OTC hearing aids may provide appropriate amplification to support communicative function.

Limitations

A key strength of this study is its inclusion of multiple different perspectives, providing a more robust exploration of the question than any one interest-holder group alone. However, several important limitations should be noted.

One consideration is that most of our participants with dementia were current hearing aid users. This outcome resulted from our inclusion criterion requiring that participants with dementia self-report mild-to-moderate hearing difficulty. During recruitment, we found that people with dementia who already used hearing aids were more likely to self-identify as having hearing difficulty than those who did not use hearing aids. Additionally, our sample of participants with dementia was predominantly male. This imbalance may reflect the dynamics of our caregiver-mediated recruitment pathways, in which caregivers and community partners more frequently referred male care recipients. Gender differences in the prevalence of age-related hearing loss may also have contributed to this pattern [8].

We also relied on self- or caregiver-reported hearing loss and dementia status rather than confirmed medical diagnoses. This approach was chosen to ensure the feasibility and accessibility of this study for dementia caregivers and people with dementia, for whom additional testing or records requests would have been cumbersome and likely infeasible. In terms of hearing loss, our use of self-reported hearing ability aligns with OTC hearing aid candidacy, which does not require a formal hearing evaluation. Although audiometric results would have been informative for cross-checking self- and caregiver-reported hearing ability, all participants reported mild-to-moderate hearing difficulty consistent with OTC hearing aid candidacy guidelines. Regarding dementia status, our reliance on self- or caregiver reports introduces some uncertainty regarding participants' cognitive abilities and underlying conditions. However, the combination of self- or caregiver report with the TICS-m cognitive test increases confidence that our sample includes people with early to midstage dementia.

Finally, our study required that participants speak English, limiting the potential racial and ethnic diversity of our sample. Family caregivers and people with dementia who do not speak English may face distinct challenges in using OTC hearing aids, which warrants further investigation.

Given these limitations, caution is warranted when generalizing the findings to women, new hearing aid users, and individuals who do not speak English. Even so, the themes identified in this study point to several opportunities to improve the user experience for many potential OTC hearing aid users with dementia. Future research should more comprehensively characterize the needs of users from different backgrounds and with different levels of hearing aid experience.

Conclusions

This study identified and described interest-holder-perceived facilitators and barriers to OTC hearing aid use in community-dwelling people with dementia and their family caregivers. Key facilitators or advantages of OTC hearing aid use included improved accessibility and affordability, as well as enhanced autonomy and control. However, significant barriers underscore the complexity of OTC hearing aid use in this population. Interest-holder–perceived barriers included mistrust of OTC hearing aids; assessing OTC hearing aid candidacy in people with dementia; caregiver-facilitated programming/adjustment; assessing the effectiveness of OTC hearing aids; and ongoing OTC hearing aid use and caregiver burden/burnout. Future research should further explore and quantify these and other barriers toward the development of tailored devices, services, and supports that promote successful OTC hearing aid use in people with dementia and their family caregivers. Such work is essential for ensuring that people with dementia can equitably benefit from the introduction of lower-cost, more accessible OTC hearing aids.

Acknowledgments

We are deeply grateful to the participants who contributed their time, insights, and energy to this study. The authors did not use generative artificial intelligence to generate any part of this manuscript.

Abstract

Background: Informal caregivers of people living with chronic kidney disease commonly experience mental health difficulties. However, there is currently limited access to scalable psychological interventions such as those using e-mental health platforms. Furthermore, there is an absence of such interventions tailored for this group of caregivers, which may limit acceptability.

Objective: To inform future e-mental health intervention development, this study aimed to explore preferences for e-mental health interventions among informal caregivers of people living with chronic kidney disease.

Methods: A total of 13 informal caregivers of people living with chronic kidney disease participated in semistructured interviews. Eligible informal caregivers lived in the United Kingdom and were recruited via nonprofit organizations and social media advertisements. Semistructured interviews followed a topic guide exploring caregivers' e-mental health intervention preferences. Data were analyzed using manifest content analysis.

Results: A total of 4 categories and 13 subcategories were generated. "Design preferences" illustrates key intervention design features that were important to caregivers, such as involving caregivers and other interest-holders in the design process. "Content preferences" describes the information caregivers valued in an intervention, such as information about chronic kidney disease and resources to support caregivers. "Support preferences" reflects the characteristics of support caregivers preferred if support was available as part of the intervention, such as peer support and providing support that accommodates individual preferences. Lastly, "Dissemination preferences" describes methods caregivers recommended to promote intervention uptake, such as engaging communication strategies and trusted and accessible sources of information.

Conclusions: Caregivers identified a number of e-mental health intervention design and delivery preferences that should be considered when developing e-mental health interventions for caregivers of people living with chronic kidney disease. To ensure such interventions are acceptable, feasible, and relevant, co-design approaches should be adopted during the intervention development process.

Introduction

Background

Chronic kidney disease (CKD) impacts over 800 million people worldwide, is a leading cause of death globally, and significantly impacts quality of life [1-3]. Informal caregivers (caregivers) play a vital role in supporting people living with CKD, providing medical, practical, and emotional support [4-7]. Research suggests caregivers experience worse mental health (eg, symptoms of depression and stress) compared to noncaregivers [8], with caregivers reporting negative impacts, such as high levels of burden, poor quality of life, and mental health difficulties [4,6,9-11]. For example, studies have shown that between 30% and 60% of caregivers of people living with CKD experience symptoms of depression [7,10,11], which is higher compared to the general adult population [12,13]. Consistent with these findings, qualitative research shows that caregivers of people living with end-stage kidney disease experience mental health difficulties due to the caregiving role and could benefit from psychological and emotional support [14]. Ensuring caregivers receive acceptable, feasible, evidence-based mental health support is important not only to ensure caregivers maintain their own well-being, but also because their mental health can also impact the mental health and well-being of the person living with CKD [15,16]. However, caregivers experience multiple barriers to accessing mental health support, such as mental health stigma and negative views of mental health support, limited time due to caregiving responsibilities, and prioritization of the needs of the care recipient [17-19]. All of these barriers may contribute to the low uptake of mental health support among caregivers [20-22].

e-Mental Health Interventions to Support Caregiver Mental Health

e-Mental health (e-MH) interventions offer one way to provide accessible mental health support to caregivers, given these interventions can be accessed flexibly, without the need for travel or being available for regular appointments [23,24]. The flexibility offered by e-MH interventions can overcome some access barriers experienced by caregivers, such as a lack of time or reliable availability to attend appointments with a mental health professional [17,18]. Additionally, a priority setting initiative highlighted the use of technology as a key research and clinical priority to enhance support for caregivers [25]. e-MH interventions, specifically internet-based cognitive behavioral therapy (CBT) interventions, have been shown to be as effective as comparable in-person interventions among the general population [26], with evidence showing e-MH interventions are also effective for caregivers [27,28].

Although e-MH interventions have been developed for other groups of caregivers (especially caregivers of people living with cancer or dementia) [29], to our knowledge, there are no e-MH interventions tailored to caregivers of people living with CKD, despite interest in this type of intervention [7]. Tailoring e-MH interventions to the intended population has been shown to be important to improve intervention acceptability [30,31]. Additionally, existing mental health interventions for caregivers of people living with CKD identified in the literature are in-person and group-based [32], which may not align with intervention preferences identified by caregivers of people living with CKD [7]. Therefore, the development of an e-MH intervention tailored to the preferences of caregivers of people living with CKD is important to provide accessible mental health support for this group, while ensuring the e-MH intervention is acceptable, feasible, and relevant in practice.

Approach to e-MH Intervention Development

To develop an e-MH intervention tailored to the preferences of caregivers of people living with CKD, the Medical Research Council framework for the development and evaluation of complex interventions will be followed [33]. This framework emphasizes the importance of considering context and involving interest-holders during the intervention development process as a strategy to enhance the acceptability and future implementation potential of interventions [33]. Our previous research has explored self-help intervention preferences among caregivers of people living with CKD [7] and how interest-holders who may be involved in implementing interventions for this group of caregivers (eg, health and social care professionals, mental health care professionals, and staff at nonprofit organizations) viewed e-MH health interventions for caregivers of people living with CKD [34]. We have also explored caregivers' current experiences accessing and receiving support from both informal, such as friends and family, and formal, such as health and social care professionals, sources [18]. This study further explores caregivers' e-MH intervention preferences to provide insights that can be used to inform the development of an e-MH intervention that is acceptable, feasible, and relevant to caregivers of people living with CKD.

Aim

This study aimed to explore e-MH intervention preferences among informal caregivers of people living with CKD.

Methods

Study Design

A qualitative study using semistructured interviews and manifest content analysis [35] was conducted. Results are reported following the SRQR (Standards for Reporting Qualitative Research) checklist [36] (Multimedia Appendix 1). The study sample and data collection procedures are the same as our previous qualitative study exploring caregivers' experiences of accessing and receiving support [18].

Ethical Considerations

Ethical approval was obtained from the University of Exeter Psychology Research Ethics Committee (reference 513911) and from the Swedish Ethical Review Authority (dnr 2022-03068-01). Informed consent was obtained from participants prior to data collection. A professional transcription company transcribed audio files, and the resulting transcripts were deidentified by the research team prior to data analysis.

Sampling

Convenience sampling was used to recruit caregivers using advertisements shared by CKD and/or caregiver nonprofit

XSL•FO
RenderX

organizations (eg, via newsletters, email listserv, organization websites, and social media posts), paid and unpaid social media posts on study-specific social media pages, and contacting caregivers who participated in a related study [7] and expressed interest in taking part in an interview. Study advertisements included images of people with a range of genders, ages, and ethnicities to encourage participation of caregivers with diverse backgrounds. Caregivers interested in taking part in an interview contacted the research team via telephone or email. Caregivers were eligible to participate if they were at least 18 years of age, caring for an adult living with CKD, and residing in the United Kingdom, with eligibility confirmed by a research team member via telephone or email prior to the interview.

Data Collection

Between May 2022 and June 2023, a total of 13 semistructured interviews with a mean length of 63 (range 43-87) minutes were conducted by CC via Microsoft Teams (n=12) or telephone (n=1). The interview guide was partly informed by related qualitative research [17,37,38] and explored topics including support needs, e-MH intervention preferences, and potential barriers and facilitators to intervention use (Multimedia Appendix 2). Before the interview, caregivers were provided with a brief, written description of an e-MH intervention (Multimedia Appendix 2) based on existing low-intensity CBT interventions that have been developed for caregivers experiencing anxiety and/or depression [31,39]. The e-MH intervention was described as a CBT-based online program (eg, app or website) designed to support caregivers experiencing anxiety and/or depression. The intervention content was described as including CBT-based activities and materials (eg, goal setting and behavioral activation), in addition to including information relevant to caregivers of people living with CKD (eg, diet and relevant support services). The intervention was also described as including support from a trained professional, with the option for support to be provided in-person at a convenient location (eg, community center, GP office, or kidney care unit) or via telephone, video-call, email, or SMS text message. The types of support the trained professional would provide were described as including understanding the caregiver's mental health needs, supporting the caregiver to use the intervention and work through the CBT-based activities, and directing caregivers to additional sources of support (eg, programs within the community, hospital, etc). Interviews were conducted until a rich understanding of intervention preferences was achieved, and no new categories were generated [40]. This was discussed iteratively during data collection by JW and CC.

Data Analysis

Manifest content analysis with inductive coding was conducted by 2 researchers independently (CC and AS) [35]. All transcripts were read and then coded independently by CC and AS for data familiarization. Coding was undertaken by first creating condensed meaning units, followed by developing codes to describe the condensed meaning units. CC and AS generated categories and subcategories based on their initial coding, resulting in the development of 2 sets of categories and subcategories. CC and AS then held a workshop where they reviewed both sets of categories and subcategories, discussed similarities and differences, and came to a shared understanding of the categories and subcategories that best reflected the data. A single, revised version of categories and subcategories was developed by CC and shared for feedback with AS. This version of categories and subcategories was then shared for feedback with JW and PF, resulting in the development of the final set of categories and subcategories. Trustworthiness was established by having 2 independent researchers code the data prior to discussion, keeping memos throughout analysis, peer examination of categories and subcategories by 2 additional research team members, and inclusion of quotes to support the categories generated during the analysis process [41].

Researcher Characteristics

Interviews were conducted by CC, who also led data analysis. CC has a public health background and, at the time of the study, was a PhD candidate with experience conducting qualitative research related to caregiver needs and intervention preferences. AS has a community and public health background and has completed training courses in qualitative research. JW has a PhD in Psychology, was the doctoral supervisor of CC, and has extensive experience conducting, teaching, and supervising qualitative research. JW's research focuses on informal care and mental health. PF is an expert in CBT with extensive qualitative research experience, including research related to kidney disease. Additionally, PF has lived with CKD for over 25 years, during which he has experienced all forms of kidney replacement therapy and is currently on hemodialysis. LvE is a female professor in caring sciences, a psychologist, and specializes in mental health in people affected by somatic disease and their informal caregivers. LvE has extensive experience in teaching, conducting, and supervising qualitative research. RS is a health psychologist and an expert in research on coping with chronic somatic illnesses, interventions (both face-to-face and eHealth) in this area, and has worked extensively with both quantitative and qualitative methods. There are no preexisting relationships between the research team and participants.

Results

Sample Characteristics

Caregivers were all female, aged 52 (SD 13) years on average, lived in England (n=12) or Wales (n=1), and had a White (n=11) or South Asian (n=2) background. Caregivers often worked full- or part-time (n=7) while supporting their spouse (n=8), and had been providing care for an average of 7.2 (SD 7.6) years. About half (n=7) of care recipients were receiving kidney replacement therapy (dialysis or transplant). Caregivers provided support with a mean of 10 (SD 6) care-related activities, including cooking, communicating with the medical care team, emotional support, managing symptoms, and running errands. Sample characteristics are summarized in Table 1, with select individual characteristics with caregiver pseudonyms available in Multimedia Appendix 3 to facilitate the interpretation of supporting quotations.

[b]Individuals not receiving kidney replacement therapy were either not at a stage of disease that required dialysis (n=5) or were receiving conservative kidney management (n=1).

Qualitative Results

Content analysis generated 4 categories and 13 subcategories reflecting caregivers' e-MH intervention preferences (Textbox 1).

XSL•FO
RenderX

Textbox 1. Overview of categories and subcategories.

Design preferences

- Considering safety
- Engaging and user-friendly design features
- Involving caregivers and other interest-holders in the design process
- Supporting flexible usage
- Tailoring to cultural and chronic kidney disease (CKD) caregiving contexts

Content preferences

- Providing information on CKD and how to support the care recipient
- Supporting emotional well-being

Support preferences

- Accommodating individual support preferences
- Knowing support is available
- Ensuring support providers have the right knowledge and skills
- Providing peer support

Dissemination preferences

- Engaging communication strategies
- Leveraging trusted and accessible sources

Design Preferences

Overview

This category describes e-MH intervention design features and characteristics that caregivers felt could help ensure an e-MH intervention is considered relevant and could enhance their engagement and trust in the intervention. This category includes the following five subcategories: (1) considering safety, (2) engaging and user-friendly design features, (3) involving caregivers and interest-holders in the design process, (4) supporting flexible usage, and (5) tailoring to cultural and CKD caregiving contexts.

Considering Safety

Including design features that would ensure caregivers feel safe using an e-MH intervention was expressed by caregivers in relation to 2 dimensions of safety, that is, psychological safety and data security. Psychological safety related to e-MH interventions that include online discussion forums, where anyone can respond to questions or comments posted by caregivers. Caregivers emphasized the importance of ensuring questions were answered respectfully and the potential need for monitoring in case incorrect information was shared or responses were disrespectful, judgmental, or negative.

> *I've seen things [forums] before where people would genuinely put something there, and you think they're crying for help, and somebody says, "What are you saying that for? Somebody's said that before." And I think that just straight away puts people right off, doesn't it? And people leave because of those sorts of things.... And if I put something on there and somebody said, "Oh, that's just stupid. What are you asking that question for?" That would make me think, "well, I'm just not going to bother anymore."* [Emily]

Data security related to caregivers' concerns regarding the security of information that would be shared within the intervention, and ensuring caregivers were informed about how their data were being handled.

> *You always want to know what's happening with the information that you give, who uses it, and how.... I think people are open-minded about that [sharing information] when they know.* [Olivia]

Engaging and User-Friendly Design Features

Ensuring e-MH interventions were engaging, not relying solely on written material, and incorporated opportunities for interaction was valued by caregivers. Opportunities for interaction that could be included within an e-MH intervention suggested by caregivers included creative activities, such as art-based activities and opportunities to interact with people, including other caregivers (eg, an online forum where caregivers could ask questions) and health care professionals (eg, a live session or talk with health care professionals, including time for caregivers to ask questions).

> *But I think you can't beat human contact. And if we've learned anything through the pandemic, it's that people need people.* [Olivia]

Ensuring the intervention was user-friendly was viewed as another important element to support caregiver engagement. Key design considerations suggested by caregivers to ensure the design of a user-friendly intervention included offering the intervention as an app to allow caregivers to access the

XSL•FO
RenderX

intervention quickly on their mobile phone and presenting information in an "easy to digest" (Freya) way using easy-to-understand language. Designing an intervention to meet the needs of caregivers with different levels of digital literacy was also emphasized as important to ensure the intervention is "straightforward" (Emily) to use and does not "presume that everybody's quite techy" (Emily).

Involving Caregivers and Other Interest-Holders in the Design Process

Involvement of people with lived experience, such as caregivers, people living with CKD, and other interest-holders with relevant expertise (eg, kidney care providers), during intervention development was recommended by caregivers as a key strategy to enhance their trust and positive views of an e-MH intervention.

> *I think when you're setting it [the e-MH intervention] up, when you're developing it, get people like me and people you've interviewed to test drive it for you. Because end users will tell you how it's working, [and if] it's meeting their need.* [Zainab]

Sustained involvement of people with lived experience and relevant expertise, such as having a project advisory group including public contributors and other interest-holders during initial testing and later intervention implementation, was also suggested as a strategy to ensure their perspectives continue to inform refinement of the intervention design. Such involvement was also perceived as important to demonstrate that the research and intervention development team is responsive to caregivers' preferences.

Supporting Flexible Usage

The online format was perceived as making e-MH interventions flexible and thus feasible for caregivers to access and use. Caregivers expressed the importance of the ability to choose when and where to access the intervention and how long to engage with it at one time. This flexibility was perceived as supporting caregivers' ability to balance their caregiving responsibilities and needs (eg, the need to limit contact with others due to COVID-19, with intervention use).

> *Also, if it's online, it means that we can do it whilst we are cooking, it means we can do it after work, or whatever.* [Priya]

Additionally, caregivers wanted to be able to access information in the intervention based on their own needs rather than needing to work through all the content in a set order. The intervention's online format was viewed as meeting this preference for flexible usage.

Tailoring to Cultural and CKD Caregiving Contexts

An e-MH intervention specifically for caregivers was valued as a way to provide a tailored support resource that would align with caregivers' needs and context. Tailoring the intervention to caregivers of people living with CKD was seen as important to enhance the perceived relevance of the intervention, which could encourage caregiver engagement. Caregivers expressed preferences for e-MH interventions tailored to recognize the caregiving experience. For example, addressing the "practical side and the emotional side" (Zainab) of caregiving, and including information and language relevant to caring for someone living with CKD.

> *I would want, as you mentioned, some intervention where it is tailored towards people that are caring for people with kidney disease and renal related issues. So, things like [including] useful terminology, using the language that kidney patients use, and carers use. I think that would be really helpful because it would set the tone, it would feel like the right environment.* [Priya]

Two caregivers had South Asian backgrounds, and they also mentioned the importance of cultural tailoring and cultural sensitivity when developing the e-MH intervention. For example, being aware of various religious holidays when scheduling live events or support sessions.

Content Preferences

Overview

This category describes the information and resources caregivers felt should be included within an e-MH intervention. This category has two subcategories: (1) providing information on CKD and how to support the care recipient, and (2) supporting emotional well-being.

Providing Information on CKD and How to Support the Care Recipient

Caregivers were interested in receiving information about CKD, including the stages, treatments (eg, dialysis, transplants, and side effects), diet, and information about living with someone who is living with a transplant and is immunosuppressed. Information was desired not only to understand the care recipient's current CKD stage but also to prepare for the progression of CKD to other stages and to understand future care and treatment needs.

> *I think for me, it [intervention content] would be what the future would be like, about dialysis, transplant, and what life would be like. Just so you can prepare yourself emotionally—this is what my life is going to be like.* [Freya]

Caregivers also wanted information that would help them to support the care recipient. This included information on how to provide them with emotional support so they "feel better in themselves as well" (Sarah), motivate them to do things to support their health and well-being (eg, attend medical appointments), and communicate effectively with the care recipient's care team to ensure they receive optimal care. Preferences for the intervention to include information about CKD were also connected to caregivers' desire for an intervention that would not only support them as caregivers, but also help them understand what the care recipient was experiencing and how to help monitor their health.

Supporting Emotional Well-Being

Caregivers expressed a need for resources offering practical tips and strategies they could use to practice self-care and manage the different emotions they had to cope with while

XSL•FO
RenderX

caring, such as coping with uncertainty and anxiety or feeling low:

> *I think ways of distracting yourself and ways of being kind to yourself really, suggestions of something you can do that's mindfulness, that takes your mind away from the whole caring situation.* [Sarah]

In addition to resources supporting their emotional well-being, caregivers were interested in strategies to help them balance different roles and responsibilities while identifying when to reach out for support. An e-MH intervention with practical, concrete activities caregivers could use in their daily routines, rather than just providing information, was viewed as something that would increase the perceived value of the intervention.

Support Preferences

Overview

This category describes characteristics of both the type of support that should be available within an e-MH intervention and the characteristics of individuals who would support the intervention. This category has the following four subcategories: (1) accommodating individual support preferences, (2) knowing support is available, (3) ensuring support providers have the right knowledge and skills, and (4) providing peer support.

Accommodating Individual Support Preferences

Support that could be customized to accommodate caregivers' individual preferences was preferred to ensure support would be accessible and acceptable to caregivers. Caregivers expressed mixed preferences regarding the support format, with in-person, written, telephone, and video-call support being mentioned. Flexibility to select the support format and change it based on needs and preferences was expressed, with Kate explaining that "if somebody doesn't want to physically talk, there is that option of just sending something [written]." Support should also be responsive to the type of support the caregiver wanted, for example, whether a caregiver wants emotional support or informational support (ie, to be directed to relevant resources and information). In-person support was viewed as an important way to connect with the support provider and facilitate relationship building and trust. However, in-person support sessions were not always viewed as feasible due to a lack of time and the potential burden of having to travel to the session. In addition to format preferences, the ability to select a support provider based on the provider's characteristics, such as gender or cultural background, was viewed as a way to further meet caregivers' preferences and help caregivers feel more comfortable seeking support:

> *I think having a mix of genders, sexualities [among support providers]—I think it's important because men might feel comfortable talking to men, women might feel comfortable [talking to women], or it might be the opposite. I think having access to both would really help.* [Priya]

Knowing Support Is Available

Caregivers expressed a preference for support to be available as part of an e-MH intervention, given it would be "nice to know that there is support there [in the intervention]" (Sarah). Caregivers felt that support providers should take active steps to support them by reaching out periodically rather than relying on the caregiver to initiate contact with the support provider. Support is needed to address caregivers' emotional support needs by building a relationship with the caregiver and providing encouragement:

> *And I think some, just some positive reinforcement along the way that you're doing the best that you can in this moment.* [Olivia]

Additionally, practical support to assist caregivers in using the intervention, such as technical support, understanding and applying intervention content in practice, and checking on caregivers' progress to motivate intervention usage, was important:

> *When I come across something I don't understand or I don't feel confident about, that's when I need support.* [Holly]

Ensuring Support Providers Have the Right Knowledge and Skills

Caregivers felt support providers would need to have a range of skills to meet caregivers' support needs, including cultural sensitivity, emotional support skills (eg, empathy and active listening), knowledge of CKD, knowledge of the intervention (eg, navigating intervention content), and an understanding of the caregiving experience:

> *Maybe somebody who's had some training on counselling or somebody who's empathetic. It [the support provider] needs to be somebody who can try and understand where you're at and where you are coming from.* [Rebecca]

It was acknowledged that a single support provider may not have the full range of knowledge and skills to meet all support needs. It was suggested that support providers could vary based on the type of support needed. For example, a support provider could be available for CKD medical information needs, and potentially a different provider for emotional support needs.

Providing Peer Support

Caregivers wanted an e-MH intervention to include opportunities to connect with other caregivers with shared characteristics, such as a similar age range or lived-experience (eg, caring for a young family and someone living with CKD). Shared lived experience was viewed as important to foster understanding and provide validation throughout the caregiving journey. Peer support was seen as a way to receive advice from other caregivers, including caregivers with more experience who may be able to provide insights on caring for people at different stages of CKD:

> *I think what I would really love is to meet somebody to say 'I was in that situation'.... It's all very well reading about it [CKD], but you still, you've got all those questions to ask. In terms of how much medicine is going to be in the house or how many hospital visits will there be and how will it impact on the whole family and things like that. So yes, first-hand experience, I think would be very helpful.* [Sarah]

XSL•FO
RenderX

However, depending on the format of peer support, guidelines and monitoring were perceived to be needed to ensure peer support provided is nonjudgmental and confidential.

Dissemination Preferences

Overview

This category describes key elements that should be considered when sharing information about the e-MH intervention with caregivers. This category includes 2 subcategories: (1) engaging communication strategies and (2) leveraging trusted and accessible sources.

Engaging Communication Strategies

Caregivers expressed that communication strategies used to promote the e-MH intervention would need to create interest and excitement in the intervention to motivate uptake. They suggested implementing communication strategies using short, easy-to-understand language that clearly expresses the purpose of the intervention so caregivers can quickly understand who should use the intervention and how it will meet their needs:

> *You can get bogged down, especially on our journey, with lots of words that you either don't understand or they're not in your day-to-day vocabulary. So, you would spend more time trying to Google what it meant. So, if something is bright, if it's clear, if it's short, if it's concise, those are the things that engage me.* [Kate]

Caregivers suggested that communication strategies should leverage factors they identified as motivating their uptake of an e-MH intervention, including an interest and desire to learn, the opportunity to try a new intervention, and evidence (eg, testimonials that other caregivers benefited from the intervention).

> *And knowing that you are part of a...pilot scheme, it's quite exciting, it's something new, it's something exciting, you know. And it's something that you want to be actively participating in.* [Claire]

Leveraging Trusted and Accessible Sources

Caregivers expressed that an e-MH intervention should be endorsed by a trusted source to enhance their confidence that the intervention and the information provided within it would be trustworthy. A variety of sources were considered trustworthy, including the kidney care unit, nonprofit CKD and caregiver organizations, and other caregivers:

> *I think using the kidney charities would be a really good way [to promote the intervention]. If they promote it, then you'd feel this is endorsed by someone I trust to have good information. I think if you just saw a random advert you'd think, 'is this actually legit?'* [Freya]

In addition to considering the trustworthiness of the intervention source, the accessibility and reach of the intervention source were other important considerations regarding who should disseminate information about the e-MH intervention. Not all potential intervention sources were considered accessible to all caregivers; for example, some caregivers had limited contact with the kidney care unit due to living far from the unit or not always attending appointments with the person they were caring for. Additionally, some caregivers felt that health care professionals can be overburdened and focused on the person living with CKD, and therefore, may not be the best source of information about interventions for caregivers.

Discussion

Principal Results

Overview

This study explored the preferences of caregivers of people living with CKD that require consideration to inform the development of an acceptable and relevant e-MH intervention for this group of caregivers. Study findings illustrated preferences for an e-MH intervention tailored to the context of caregivers in relation to intervention design, intervention content, support options, and dissemination approaches. Findings align with the Medical Research Council framework for the development and evaluation of complex health care interventions, which highlights the importance of considering context (eg, the caregivers' background and their caregiving situation) as a core component of the intervention development process [33].

e-MH Intervention Preferences

Many preferences identified in this study align with intervention preferences identified in other caregiving literature, such as the need for practical, disease-specific content, the provision of empathetic and knowledgeable support from a trained provider, and flexible options for how to use and engage with the intervention [7,42-44]. Although caregivers commonly report wanting information about the care recipient's illness [7,42], this study identified an interest in not only information related to the care recipient's current stage of disease, but also advanced stages as a way to prepare for the future. In contrast, a study focused on caregivers of people living with cancer found a preference for information specific to the care recipient's current stage of disease [42]. This difference may relate to the progressive nature of the CKD trajectory and the increase in care needs as the disease progresses to more advanced stages [45]. Additionally, other work suggests that seeking and obtaining information is important to support self-management of CKD by people living with CKD and their caregivers and that unmet information needs impact caregivers' mental health [46,47]. This highlights the importance of addressing caregiver information and education needs within an e-MH intervention.

Although the preferences identified in this study align with other research, it is important to recognize that this study only captured the preferences of women caregivers. Many e-MH intervention preferences reported by men align with the findings of this study, with men valuing easy-to-use e-MH interventions with flexible engagement options (eg, content available in multiple formats or the option to receive support from a trained provider) [48]. However, some e-MH intervention preferences may vary by gender; for example, one study found that men preferred e-MH interventions with a video-game format more than women [49]. Potential gender differences in e-MH

XSL•FO
RenderX

intervention preferences highlight the importance of including caregivers with diverse gender identities in the intervention development process to enhance intervention acceptability.

Contrasting Caregiver and Other Interest-Holder e-MH Intervention Preferences

To enhance the future implementation potential of an e-MH intervention for caregivers, the perspective of other interest-holders who would be involved in intervention delivery and dissemination is vital [33]. Our related research exploring potential implementers' (ie, professionals working in kidney care, mental health care, and nonprofit organizations) perspectives of an e-MH intervention for caregivers of people living with CKD [34] identified a number of similarities to the caregiver perspectives explored in this study. Potential implementers also viewed e-MH interventions as a flexible means of providing mental health support that could fit within caregivers' caring responsibilities, and that tailoring of intervention content and availability of support within the intervention were important design features [34]. However, they raised concerns regarding e-MH intervention access and digital exclusion [34]. Although caregivers in this study acknowledged designing an intervention to suit different digital literacy levels was important, they did not express similar concerns regarding digital exclusion. Since interest-holder views of e-MH intervention design and caregivers' ability to use the intervention are important implementation determinants [50], concerns regarding digital exclusion should be addressed as the intervention development process continues. Strategies to address these concerns and support intervention access for caregivers with lower digital literacy should include training to show caregivers how to use the intervention [41,42] and providing a nondigital version [34]. Continued engagement of caregivers and interest-holders in the co-design of the e-MH intervention will be needed to ensure the intervention is user-friendly and meets the preferences of relevant user groups [51].

Trust in e-MH Interventions

Trust was identified by caregivers as an important design element of e-MH interventions in relation to the credibility of the intervention and its content, trust in the organization disseminating or endorsing the intervention, and data security. Trust in e-MH interventions has only been minimally explored in the caregiving literature [29,34,52,53]; trust is an important element of eHealth intervention design [54]. For example, persuasive system design, an approach to designing digital interventions and technologies to change end users' attitudes or behaviors, highlights technology credibility as an important intervention feature that can be built through strategies such as highlighting the expertise of the intervention developers and the intervention's evidence base [55]. Another study suggests that aligning intervention features with user preferences is another way to build trust in e-MH interventions [54]. Applying this to the user preferences identified in this study, designing an e-MH intervention with multiple support format options that caregivers can choose from, such as written or in-person support, and having a gender and culturally diverse group of support providers such that caregivers can choose a support provider they feel most comfortable working with, could help foster trust of the e-MH intervention [54]. Additional strategies to enhance trust based on our findings and related research include leveraging trusted sources, such as health care providers and established nonprofit organizations, to disseminate information about the intervention, and involving caregivers and other interest-holders with relevant expertise in intervention development [34]. Incorporating strategies to build trust and credibility in the development of e-MH interventions will be important to support intervention adoption [54,56].

Implementation Considerations

An e-MH intervention for caregivers could fit well within a collaborative care model [57,58], whereby a central contact could link caregivers to health and social care professionals who can address their individual support needs. These could include facilitating a connection with the kidney health care team for support with medical information needs or a connection to a mental health professional for support with mental health needs. This approach to the provision of support aligns with the preference expressed in this study for support to be provided by providers with the appropriate competencies based on the caregivers' specific support needs. Collaborative care models have been shown to benefit caregivers, for example, improving caregivers' ability to cope and providing reassurance through the provision of accessible and acceptable support [59,60]. A collaborative care model to support caregivers of people living with CKD could be supported by the Assistant Wellbeing Practitioner (Kidney) role that has been proposed to be integrated within kidney units to provide mental health support to people living with CKD and their caregivers while working with multidisciplinary kidney care teams [61]. Competencies for the Assistant Wellbeing Practitioner (Kidney), including having knowledge related to mental health and CKD, and using psychologically informed approaches to support caregivers of people living with CKD, such as supporting caregiver use of digital interventions [61], align with the support preferences expressed by caregivers in this study. However, this role has not yet been implemented throughout the health care system.

Alternatively, nonprofit, community organizations have also been endorsed by caregivers [7] as an alternative implementation context for an e-MH intervention for caregivers of people living with CKD. Interest-holders working within community organizations also viewed an e-MH intervention for caregivers as aligning with the mission of their organization [34]. Implementation of e-MH interventions for caregivers within community organizations could align with the dissemination preferences expressed in this study, which highlighted that health care professionals can be viewed as less accessible to caregivers, given that not all interact with the care recipient's care team. Another factor that may facilitate implementation of an e-MH intervention for caregivers within community organizations is the preference for intervention support to be provided by peers (ie, people with lived experience of caring for someone living with CKD) and the high value caregivers place on the knowledge gained from lived experience [18,62]. Shared lived experience can support relationship building, which is an important common factor in mental health interventions [63]. There is also evidence that e-MH interventions supported

XSL•FO
RenderX

by peers are as effective as e-MH interventions supported by mental health care professionals [64]. Leveraging peers to provide support as part of an e-MH intervention for caregivers may also enhance the feasibility of implementing an e-MH intervention, given existing capacity challenges within the mental health care system [65] and the lack of psychosocial care professionals within the kidney care sector [66]. Therefore, community organizations should also be considered as a possible implementation setting for an e-MH intervention for caregivers.

Limitations

The perspectives of some potentially important subgroups of caregivers may not have been captured in this study, including the perspective of men caring for someone living with CKD, and caregivers from a wider range of cultural backgrounds. Caregiver mental health status was not assessed in this study; therefore, the preferences identified may not reflect the preferences of caregivers experiencing common mental health difficulties, such as anxiety or depression, who are the intended users of the e-MH intervention. However, the perspectives of caregivers who were coping well and not well were included in this work. Future studies may want to focus on recruiting caregivers reporting current or past experiences of common mental health difficulties to further inform e-MH intervention development. Caregivers were recruited using advertisements on various online platforms. Therefore, the views of caregivers with lower digital literacy may not have been captured in this study. As e-MH intervention development continues, strategies to engage caregivers with low digital literacy (eg, recruitment via newspaper or printed advertisements and in-person data collection opportunities) should be explored. Finally, caregivers' e-MH intervention preferences were obtained based on a text-based description of e-MH interventions, which could be interpreted differently based on caregivers' previous experiences and interactions with e-MH or other digital health interventions. Future work developing the e-MH intervention for caregivers of people living with CKD should continue to engage caregivers, leveraging recruitment strategies to enhance participant diversity [67], in the co-design process as tangible intervention prototypes are developed to ensure the intervention continues to align with caregivers' needs and preferences.

Conclusions

This study identified a number of preferences regarding e-MH interventions among caregivers of people living with CKD that can be used to inform future intervention development. Ensuring interventions are tailored toward caregivers' context, include content that meets caregivers' information needs and preferences, have flexible access and support options to accommodate caregivers' caring responsibilities and support needs, and are disseminated using engaging messaging via trusted sources were key design considerations. Future work should use the results of this study to codevelop e-MH intervention prototypes to continue the intervention development process, ensuring continued collaboration and feedback from caregivers and other interest-holders with relevant expertise.

Acknowledgments

We thank everyone who shared information about the study and all the caregivers who shared their experiences with us during interviews.

Funding

This study received funding from the European Union's Horizon 2020 research and innovation program under the Marie-Sklodowska Curie grant agreement number 814072, and was supported by U-CARE, a strategic research environment funded by the Swedish Research Council (dnr 2009-1093). The sponsors were not involved in the design, collection, analysis, and interpretation of data, or writing of the manuscript.

Data Availability

The datasets generated and/or analyzed during this study are not publicly available to maintain participants' privacy and confidentiality, but may be provided upon reasonable request from JW.

Abstract

Background: Approximately 19% of adults in Europe are affected by chronic pain, which reduces the quality of life. Pain-management mobile health (mHealth) apps offer a promising solution for self-management, but user engagement and adherence can limit their clinical impact. User experience design and research play a crucial role in optimizing usability and long-term adoption of digital health interventions.

Objective: This study aims to evaluate the user experience of Dolodoc, a mobile app for chronic pain self-management, using a mixed methods approach that assesses acceptability through a content quality survey and examines use by analyzing overall use patterns.

Methods: A cross-sectional acceptability study of the main content of Dolodoc was conducted among patients with chronic pain recruited from the Geneva University Hospitals pain center and through snowball sampling. Participants rated 84 evidence-based self-management strategies by using a 5-point Likert scale based on 5 acceptability criteria: understandability, motivation, feasibility, relevance, and alignment with the related quality-of-life dimension. To reduce participant fatigue and avoid random responses, the 84 strategies were randomly divided across survey versions. Use was assessed through metrics collected over 6 months with Piwik PRO Analytics to observe real-world use behaviors among Dolodoc users.

Results: In the acceptability study, 33 participants rated the self-management strategies positively across all dimensions. On a scale from –2 to 2, the strategies were well understood (mean 1.47, SD 0.76), motivational (mean 1.12, SD 0.96), feasible (mean 1.01, SD 1.05), relevant (mean 0.99, SD 1.09), and aligned with the dimensions (mean 1.33, SD 0.89). The use study demonstrated that 60% (486/802) of the patients used Dolodoc only once, indicating that long-term adherence remains a challenge. Within Dolodoc, pain tracking, useful links, and medication logging were the most actively used features.

Conclusions: This study highlights the gap between acceptability and long-term adherence to mHealth solutions. Improving personalization and accessibility could increase user engagement and long-term adherence. Future iterations of the app should incorporate tailored interventions and real-time feedback mechanisms. In addition, leveraging a digital navigation follow-up could facilitate user adoption and sustained engagement.

Introduction

Chronic pain is a major health care problem that affects about 19% of adults in Europe [1]. This pernicious symptom affects patients worldwide and across many dimensions of their quality of life [2], underscoring the need to develop new approaches to care. Chronic pain often forces individuals to explore multiple approaches to alleviate pain [3]. Managing chronic pain involves an integrative medicine approach based on pharmaceutical or nonpharmaceutical treatments, psychological support, and self-management strategies [4]. Optimizing self-management is paramount in the promotion of self-efficacy [5], which stands out as a powerful lever [6] to improve clinical outcomes related to chronic pain, such as disability, affective distress, and pain severity [7].

In this context, digital mobile health (mHealth) solutions represent a promising sector [8]. There is a growing number of smartphone apps that leverage these innovations to improve the care trajectories of patients with pain [9,10]. In fact, mobile apps for chronic pain management have demonstrated benefits, including improvements in quality of life and pain severity [11,12]. However, we postulate that their effectiveness depends on how well they address the needs and perceptions of the target users. Motivational factors are key to patient engagement in self-management [13] and multimodal treatment [14]. However, long-term engagement and adherence have emerged as key limiting factors for digital interventions in medicine [15,16]. One way to increase adherence and engagement of target users is user experience (UX) design, which aims to clarify the understanding of the human-product interaction, identifying key components and dimensions to improve design practices [17]. It serves as an essential framework at every stage of the design process, aiming to enhance the overall quality of the final product based on the needs of the target user [18]. UX design in health innovations aligns with the contemporary concept of person-centered medicine, which prioritizes patient engagement and individualized care [19,20]. Commonly used methods in UX studies include use metrics analysis, user interviews, usability testing, surveys, and behavioral analytics. These methods can be applied at various stages of the innovation process, ensuring adaptability to different research and design needs. Mixed methods studies facilitate understanding of UX, enabling better adoption and increased effectiveness of digital mHealth tools [21]. Globally, UX studies aim to understand 2 main characteristics of an mHealth solution: acceptability and usability [22].

Dolodoc is a mobile app designed to facilitate self-management of chronic pain. It features pain self-management strategies focusing on 7 quality-of-life dimensions, the ability to add information about the user's pain, and the ability to share a summary of pain-related activities and outcomes with health care professionals [23]. A recent study shows significant gaps between the functionality being developed and end-user expectations, highlighting the need for close collaboration among designers, developers, and users throughout the co-design process [24].

In this study, we describe users' perceptions of acceptability and study their perceptions of the information contained in Dolodoc using 5 selected acceptability criteria based on previous literature: understandability [25], motivation [26], feasibility [26], relevance [27], and alignment with the related quality-of-life dimension. Acceptability is a multifaceted construct reflecting the extent to which individuals delivering or receiving a health intervention consider it appropriate based on their anticipated or experienced cognitive and emotional responses [28]. Usability can be inferred from use studies that examine how systems are used in natural contexts. The aim is to observe and analyze how users interact with a product, service, or technology in their everyday or professional environments, paying particular attention to behaviors, routines, frequency of use, and changes in practice over time. It is mostly used in studies to understand the adoption and effective use of technologies, beyond mere usability performance [29]. In this study, we observe the use habits of real-world users. Overall, this work aims to describe key UX outcomes of an mHealth solution for chronic pain using a mixed methods approach.

Methods

Study Design

This mixed methods cross-sectional study assesses UX outcomes of a chronic pain self-management mobile app, including acceptability through content quality assessments by users and use through global use metrics.

Ethical Considerations

This study was submitted to the Geneva Cantonal Commission for Research Ethics and was deemed to fall outside the scope of the Swiss Federal Act on Research involving Human Beings (Human Research Act); therefore, formal ethics committee approval was not required. All participants were informed about the purpose of the study, and informed written consent was obtained prior to participation. Participation was voluntary, and participants could withdraw at any time without consequence. All data were collected and pseudonymized and handled in accordance with applicable data protection regulations. No personally identifiable information was collected, and confidentiality of participants was strictly maintained. No financial compensation was provided to participants for their participation in this study.

Mobile App Description

Dolodoc is a mobile app developed to assist patients in self-managing chronic pain. It provides self-management strategies and encourages users to maintain a digital journal to dynamically monitor their pain and related quality-of-life indicators. The development and implementation of this digital tool have been described elsewhere [30], and they follow UX design principles for optimization. The core content of the app consists of a library of 84 evidence-based self-management strategies that users can test in real life, tracking their effects within the app on various pain severity indicators, including quality-of-life measures. More details about the app, including illustrative examples, are available in Multimedia Appendix 1 and in previous publications [23,30]. The strategies were

XSL•FO
RenderX

developed through consultations with a focus group of patients with chronic pain and professionals specializing in chronic pain care. Participants first discussed the impact of pain on their daily life in various contexts. From these discussions, 7 quality-of-life dimensions emerged: mood, social support, sleep, work, intimacy, relaxation, and daily activities. Drawing on these dimensions and scientific evidence, a team of psychologists developed motivational pain-management strategies: each quality-of-life dimension corresponds to 4 to 20 strategies, totaling 84 self-management strategies. The self-management strategies were reviewed at the time by a pain specialist and a communication expert.

Participants

Acceptability Study

Participants in the content evaluation survey were eligible for inclusion if they were aged 18 years or older, had chronic pain, were fluent in French, and were able to provide informed consent. Participants were primarily recruited from the pain center at the University Hospital of Geneva, and additional patients meeting the inclusion criteria were recruited through snowball sampling.

There was no requirement to download or use the app to participate, as the study focuses on its content rather than the app itself. It allowed the study to include feedback from experienced users, novices, and nonusers alike. To ensure that each participant fully understood the framework within which the strategies were provided, a standardized contextual presentation of the mobile app was given before participants shared their opinions.

Use Study

As detailed in the following section, the use study included data from anonymous Dolodoc users. These data reflect the behavior of all Dolodoc users throughout the study period, not just the participants who took part in the evaluation interviews.

Setting, Recruitment, and Data Collection

Acceptability Study: Content Quality Assessment by Users

Recruitment took place from June to September 2024. Some participants were recruited passively through flyers in the waiting room, but most were recruited actively by members of the pain center team. All 84 strategies were randomly divided into 5 groups to reduce the total duration of the survey. On the basis of the time of their recruitment, participants were allocated to a random sample of 5 to 22 strategies. This methodological choice was made to reduce participants' burden. In this study, we evaluated the content of the app, not the app itself. Participants were asked to complete an online questionnaire covering demographics, pain characteristics (duration and impact on the 7 quality-of-life dimensions included in Dolodoc), and an evaluation of each sampled strategy. Each strategy was assessed by 5 to 10 participants against 5 acceptability criteria: understandability, motivational impact, feasibility, relevance, and alignment with the relevant quality-of-life dimension (refer to Multimedia Appendix 2 for an example). Responses were collected on a 5-point Likert scale ranging from "strongly disagree" to "strongly agree," allowing for a quantitative understanding of participants' perceptions of each strategy.

Use Study: Real-World Use Metrics

Use data were obtained from the Piwik PRO Analytics Suite (Piwik PRO GmbH), an online usage analytics platform that collects Dolodoc use metrics via anonymous tracking using cookies and session data. Data were collected over 6 months, from January to June 2024.

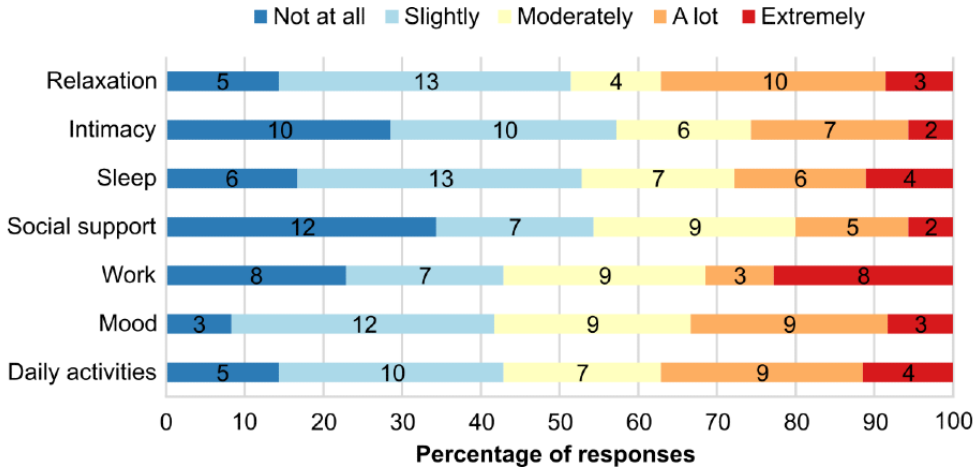
A cookie (named _pk_id) is collected to determine if a user is recurring and to calculate the number of visits and the duration of each session. Another cookie (named _pk_ses) is used to indicate whether a session is active. The information contained in these cookies is sent to Piwik with each event during the use of Dolodoc (eg, a page view).

The unique identifier from the _pk_id cookies is used as a proxy to identify unique visitors. At the same time, session data are extracted from _pk_ses, including operating system, session number, page title, time spent on the page, and session duration. Although most of our analyses included both iOS and Android users, the number of sessions per visitor could not be calculated for iOS users, likely because on iOS, _pk_id is deleted after 30 minutes of inactivity due to Apple's stricter cookie management. As a result, Piwik always identifies iOS users as unique visitors, preventing us from distinguishing between recurring and unique visitors.

Statistical Methods

Descriptive and inferential statistics were applied depending on the nature of the data. Microsoft Excel, Jupyter Notebook [31], and Orange Data Mining (University of Ljubljana) [32] were used for data analysis and visualization.

Results



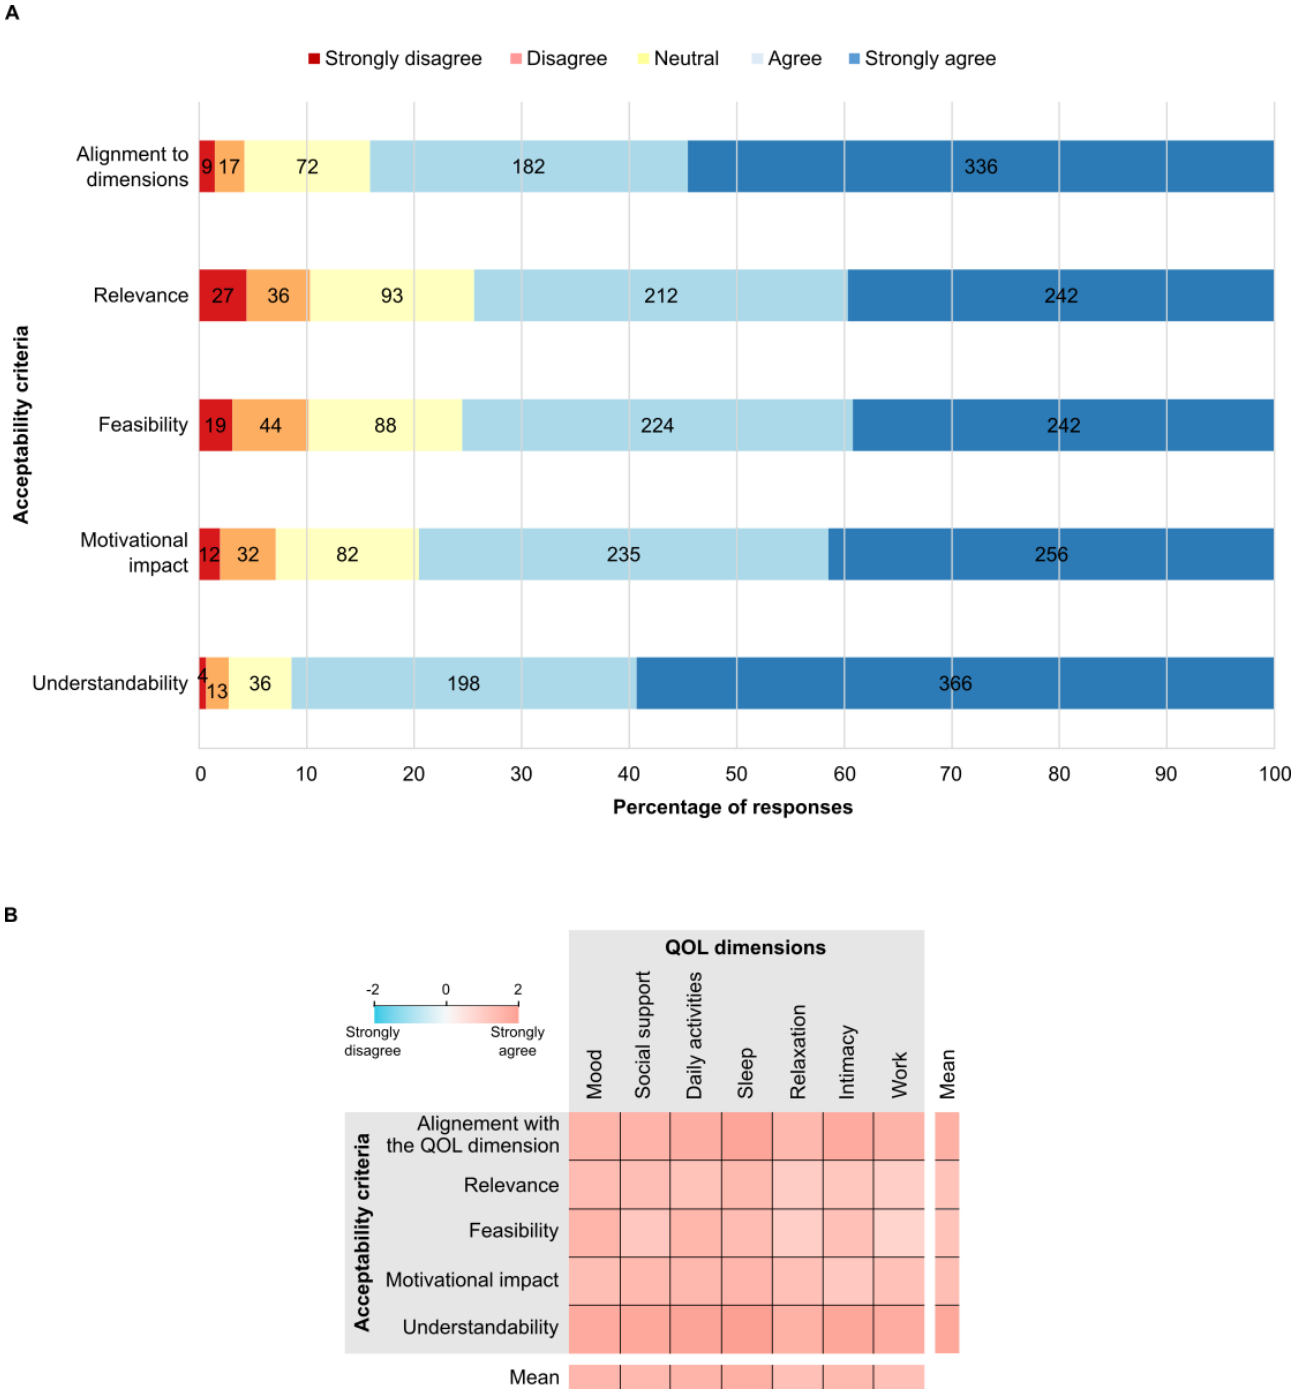
Acceptability Study

Demographics and Pain-Related Characteristics

A total of 33 participants (n=20, 60.6% female and n=13, 39.4% male individuals) were enrolled in the study. A total of 3 (9.1%) participants evaluated 2 different subsamples of strategies; therefore, the total number of assessments per question in the survey is up to 36. For these 3 (9.1%) recurrent participants, we minimized intraindividual variability using only their most recent responses for demographic variables. The participants' ages ranged from 23 to 79 years, with a mean age of 38.1 (SD 15.63) years. Most participants reported chronic pain for more than 1 year (n=24, 72.7%), while 9 (27.3%) participants reported chronic pain for less than 1 year. Each quality-of-life dimension was affected to varying degrees, but overall, quality-of-life dimensions were not homogeneously affected by chronic pain in our sample (χ^2_{24}=21.4; P<.001; Figure 1). These results support the idea of an individual profile in the impact of pain on quality of life.

XSL•FO
RenderX

Figure 1. Impact of pain on the 7 quality-of-life dimensions targeted in the self-management strategies incorporated in the Dolodoc mobile app, as reported by the 33 participants. The number of assessments in each subfraction (35-36 in total) is indicated within the bars; 5 missing values were excluded.



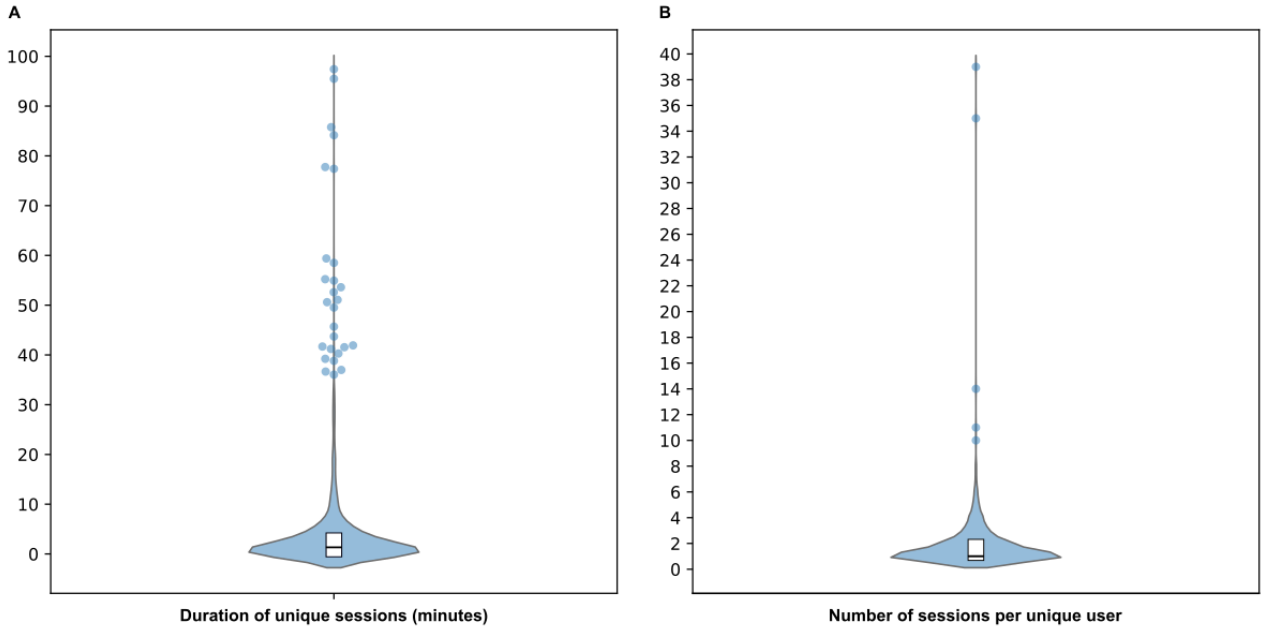
Content Evaluation Survey

Overall, the content of Dolodoc was well perceived by participants: on a Likert scale from –2 to 2 (from strongly disagree to strongly agree), the average rating across all acceptability criteria was 1.18. Moreover, of the 84 strategies, 62 (73.8%) received strong agreement (mean >1), whereas 22 (26.2%) were agreed upon (mean >0), demonstrating that acceptability criteria were globally fulfilled according to our user sample. More specifically, understandability was the highest-rated acceptability criterion (mean 1.47) while relevance (mean 0.99) and feasibility (mean 1.01) received the lowest ratings. The strategies were also perceived as motivational (mean 1.12) and aligned with the specific dimensions (mean 1.33; Figure 2A). Each acceptability criterion received between 610 and 617 ratings. In this study, missing values accounted for 0.26% (8/3085) of the data because the online questionnaire did not require respondents to answer all questions before submitting the survey.

To precisely assess perceptions of the strategies in the context of well-being, we calculated a mean rating for each of the 7 previously described quality-of-life dimensions, based on each acceptability criterion (Figure 2B). The mean scores range between 1 (agree) and 2 (strongly agree), with values from 1.08 for the “relaxation” dimension and 1.40 for the “sleep” dimension. The detailed, numbered results are provided in Multimedia Appendix 3. These results suggest a positive consensus among participants regarding Dolodoc self-management strategies within all quality-of-life dimensions.

XSL•FO
RenderX

Figure 2. Pain-management strategies in Dolodoc are well perceived by users across 5 acceptability criteria and 7 quality-of-life (QOL) dimensions. (A) Bar plot showing the distribution of ratings across 5 acceptability criteria. The number of assessments in each subfraction is indicated within the bars (B) Heat map displaying the average rating score for acceptability criteria and QOL dimensions (n=3077 ratings in total).



Use Study

Over a 6-month period, from January to June 2024, a total of 3589 unique sessions were recorded, with 59% (2116/3589) on iOS and 41% (1473/3589) on Android. The mean duration of each session was 3 minutes and 21 seconds (201 s; Figure 3A and Multimedia Appendix 4 for percentile distribution). On average, 10.39 page views occurred per session. We observed 0.07% (25/37,255) missing values in the page titles data because these events were not counted as page views. Unique sessions containing only missing values were excluded from analysis (n=7) The bounce rate (ie, the percentage of sessions where only 1 page view occurred) was 23.34% (836/3582).

XSL•FO
RenderX

Figure 3. Analysis of user interaction with the Dolodoc mobile app based on the number of sessions and duration. Violin plots (box plots represent the IQR and the median) show (A) the distribution of the number of sessions per unique user and (B) the duration of each unique session. (A) 1473 sessions from Android users; (B) 3589 sessions from Android and iOS users. Outliers (above 95th percentile) are displayed as individual points. Underlying data are presented in Multimedia Appendix 4.

Among Android users, 1473 sessions were observed among 802 unique visitors. A total of 60.6% (486/802) of these visitors visited the app only once, and the mean number of sessions per visitor was 1.84, although a few outliers displayed more than 10 sessions during this period (Figure 3B and Multimedia Appendix 4 for percentile distribution). As mentioned in the methods section, iOS data were not available for this analysis.

Table 1 shows the top 10 most visited pages for all users. When navigating the app, the most visited page was the "first launch page," showing that a substantial proportion of users used Dolodoc only once. Next, visitors most often viewed the home page and the page where they could monitor quality-of-life dimensions through a 4-point visual scale. Interestingly, the page where the strategies are compiled was the first action users took in the mobile app, because the 3 previous pages are automatically displayed upon connection. These results are consistent with the architecture and purpose of Dolodoc, guiding users toward self-observation and exploration of the included strategies for self-managing chronic pain.

Table 1. Top 10 most visited pages in Dolodoc over 6 months.

Page	Fraction of total views (n=37,230), n (%)	Functionality	Type of user interaction
First launch	9830 (26.4)	Welcome	Passive
Home	5737 (15.41)	Welcome and monitoring	Passive
Quality-of-life dimension evaluation	4333 (11.64)	Monitoring	Passive
Strategies	4312 (11.58)	Management	Active
Report export	2860 (7.68)	Monitoring	Active
Details of activities	2509 (6.74)	Management	Active
User profile	1479 (3.97)	Personalization	Active
Graphical view of collected data	843 (2.26)	Monitoring	Active
History of pain	789 (2.12)	Monitoring	Active
Dashboard	661 (1.78)	Monitoring	Active

Interestingly, the time spent on each page of the app does not follow the same architectural logic as the most visited pages (Table 2). Users spent the most time on less accessible pages (ie, pages that required more clicks to be accessed) of the app, such as a page where they could describe and add characteristics to their pain named "add your pain," a page containing useful links, and a page where they could add their current medication named "add medication." These results showed what users actively sought as they navigated the app, providing valuable feedback and insight into their expectations and needs.

XSL•FO
RenderX

Table 2. Top 10 most engaging pages in the Dolodoc mobile app based on average visit duration over 6 months.

Page	Time spent (s), mean (SD)	App content functionality	Type of user interaction
Add your pain	78.97 (107.23)	Personalization	Active
Useful links	59.70 (209.62)	Education	Active
Add medication	48.15 (62.67)	Personalization	Active
Association	39.65 (147.96)	Social support	Active
Home	39.08 (108.24)	Welcome and monitoring	Passive
Graphical view of collected data	28.89 (102.56)	Monitoring	Active
Create an activity	28.64 (69.30)	Management	Active
Report	23.71 (96.94)	Monitoring	Active
Print report	21.31 (59.46)	Monitoring	Active
Personal information	20.32 (27.91)	Monitoring	Active

Discussion

Key Results

This study provides a detailed evaluation of specific dimensions of UX, focusing on content acceptability and real-world use patterns, rather than on interaction design or interface usability. The population that evaluated the app's content was unevenly affected by pain when assessing its impact on 7 quality-of-life dimensions, highlighting the variability in the experience of chronic pain and the need for personalized approaches to pain management. Self-management strategies included in Dolodoc were perceived as engaging by users, based on 5 acceptability criteria: understandability, motivational aspect, feasibility, relevance, and alignment with quality-of-life dimensions. This result was not straightforward, because although the app was developed using a user-centered design, end users were not involved in developing this content [23]. Although participants in the acceptability study perceived the content as acceptable and engaging, real-world use data showed that 60% (486/802) of users discontinued the app after a single visit. This suggests a potential discrepancy between perceived acceptability in an experimental context and actual acceptability in real-life conditions. However, users were actively engaged with less accessible features that required deeper navigation and/or active data entry, which may explain the longer visit durations. Personal pain and medication descriptions underscore the importance of being active with the app, and the need for personalization to enhance engagement and motivation [27]. Pages offering educational and social support were also among the most visited in the app, underscoring their relevance. Overall, this mixed methods pilot study provides preliminary insights into UX parameters of a mobile app for the self-management of chronic pain, highlighting directions for future research rather than serving as a comprehensive review of the topic.

Limitations

The main limitation of the acceptability study is the relatively small number of patients (N=33), which limits generalizability; therefore, the results must be interpreted as preliminary. Additionally, patients were recruited primarily by health care professionals, which may lead to selection bias, with the most motivated patients participating. Further exploration of the difference between active and passive approaches would have brought valuable information to the study. However, our sample was diverse for demographics and pain-related characteristics.

A major limitation of this study is the lack of qualitative feedback from users who discontinued the app early. While the use analytics indicate that approximately 60% (486/802) of users accessed the app only once, the reasons underlying this early dropout remain unknown. Without direct user feedback, it is not possible to determine whether the discontinuation was due to usability issues, a lack of perceived relevance, insufficient onboarding, or unmet expectations. This limits our ability to fully interpret acceptability in real-world conditions, particularly for users who did not engage beyond an initial session. Taken together, these findings indicate that good content acceptability alone is not sufficient to ensure sustained use or even initial adoption, highlighting the multifaceted nature of UX in mHealth interventions.

Another limitation of the acceptability study is the assessment of tailored acceptability criteria, instead of a standard measurement instrument, such as the user version of the Mobile Application Rating Scale (uMARS) [33]. However, our study focuses on a French-speaking population, and at the time of the study's conception, the uMARS had not been translated into French. As mentioned in the methods section, the main limitation of the use study was excluding iOS users from the number of sessions per visitor calculation. Furthermore, interpreting bounce rate and session data requires caution, as these metrics do not directly reflect user satisfaction or use.

Interpretation

This study highlights the challenges of adopting a pain self-management app and identifies an important gap between acceptability and long-term engagement. This rare combination of real-world and experimental UX observations in the context of chronic pain provides useful, patient-centered insights that could help improve Dolodoc and inspire similar mHealth innovations. Indeed, postproduction UX studies in the context of mHealth solutions for chronic pain are sparse and usually based on small user samples, lacking real-world use data [24,34-36]. Using both ecological and survey-based data helps

XSL•FO
RenderX

mitigate the "trial bias," which has been previously described as an important confounder in user engagement studies of unguided eHealth interventions [34].

Users were satisfied with the content of this mHealth solution, suggesting that the user-centered design that guided its development [23] led to good acceptability of Dolodoc, similar to other mHealth interventions for chronic pain. In comparison, other therapeutic modalities, such as cognitive behavioral therapy [37], mindfulness-based interventions [38], physical activity [39], and multimodal group therapy [40], are also generally well accepted by patients experiencing chronic pain. However, real-world use habits in our study demonstrate the need to enhance long-term engagement further. This study does not identify specific barriers to adoption and sustained use; however, poor long-term engagement has already been described for other mHealth interventions in chronic disorders [16] and chronic pain [41], highlighting important barriers to use, such as the lack of reminders [26,42].

The diversity of pain profiles among our sample of users in the acceptability study, and the fact that global users actively spent most of their time on pages that were dedicated to personalization features, reveal the importance of personalizing pain-management mHealth solutions, in accordance with previous reports [25,26]. The personalization of mHealth apps positively influences users' trust, thereby increasing the likelihood of their adoption [43].

Generalizability

Despite the limitations mentioned, the study provides a strong initial assessment of the acceptability and use of Dolodoc. Although these UX results are specific to this mHealth solution, they align with reports on similar interventions regarding use [44,45] and acceptability [46].

Perspectives

On the basis of the results of this study, it seems relevant to add features to improve engagement over time, such as a reward system and additional features [26]. Additionally, it would be useful to revise the app navigation logic to facilitate access to the most frequently used pages. Future improvements could also help us collect UX data longitudinally by letting users rate content within the app using like or dislike buttons.

Future research should prioritize qualitative investigations to understand the reasons for early discontinuation. Semistructured interviews or focus groups involving users who abandoned the app after initial use could provide valuable insights into barriers related to usability, perceived value, emotional experience, or contextual factors. Such qualitative feedback would complement use analytics and content acceptability measures, enabling a more comprehensive understanding of UX and informing more targeted design improvements.

However, optimizing digital therapeutic alliance [47] remains a key challenge for the future of mHealth. In this regard, digital navigation follow-ups have emerged as a potential solution, grounded in human interactions, to maximize patient engagement with mHealth solutions [48] and increase their clinical impact [49].

Acknowledgments

The authors want to thank Myriam Perrier for her help in navigating the use study results.

Funding

The development of Dolodoc was funded by a grant from the Private Foundation of the Geneva University Hospitals (grant QSP2-03).

Abstract

Background: Uptake of mild cognitive impairment (MCI) and dementia screening among community-dwelling older adults remains suboptimal globally and is shaped by limited dementia literacy, fear, stigma, and difficulties navigating services. Virtual reality (VR)–assisted education may enhance engagement, but older adults' experiences of such education and the contextual conditions shaping screening intentions require further understanding.

Objective: This study aims to explore community-dwelling older adults' understanding, concerns, and attitudes regarding MCI and screening after exposure to a community-based VR-assisted cognitive health education intervention and to examine their perceived information, motivation, and behavioral skills related to screening using the information-motivation-behavioral skills (IMB) model.

Methods: Twenty-two community-dwelling older adults were recruited from participating communities between August 23 and September 17, 2025, using purposive sampling with attention to variation in age and educational attainment, supplemented by snowball sampling. All participants completed a 40-minute VR-assisted cognitive health education session comprising a 10-minute immersive 360° video delivered through a Meta Quest 3 head-mounted display followed by 30 minutes of nurse-led face-to-face education. Four researchers coded the original Mandarin transcripts; themes and subthemes were derived inductively from the data and subsequently mapped to the IMB model.

Results: Sixteen data-derived subthemes were subsequently mapped to the 3 domains of the IMB model. Information-related accounts encompassed misunderstanding and lack of knowledge about MCI, the relationship between MCI and dementia, knowledge acquisition and clarification, timing and psychological readiness, information overload, attention to peripheral details, and uncertain awareness of cognitive health status. Motivation-related accounts included fear and stigma associated with screening, perceived reduction in stigma and greater screening acceptability, reconciliation with aging, low self-prioritization, and a pessimistic outlook on treatment. Behavioral-skills accounts included low confidence in self-management, knowledge to action, community-based referral and navigation, and difficulty changing established habits. Across domains, participants' accounts suggested that greater understanding and screening acceptability did not necessarily translate into action when practical navigation and referral support were lacking.

Conclusions: Participants perceived VR-assisted cognitive health education as engaging and helpful for making MCI-related information more concrete, but their accounts also indicated that screening intentions may not translate into action without clear, trusted navigation and referral support. These findings describe participants' experiences and perceived barriers and facilitators rather than estimating intervention effectiveness.

Introduction

Dementia is a leading cause of disability and dependency in older adults and poses growing challenges for health systems worldwide as populations age [1,2]. In China, rapid demographic aging, large absolute numbers of older people, and uneven access to specialist services make cognitive impairment a major public health and nursing priority [3]. Mild cognitive impairment (MCI) represents an intermediate clinical state between normal aging and dementia, characterized by objective cognitive decline with relatively preserved functional independence, and it is widely regarded as an important window for early identification, risk reduction, and timely support [4,5]. Although disease-modifying treatment development has faced substantial setbacks and methodological challenges [6-8], prevention and risk reduction remain central components of dementia care [4,9]. Timely recognition may enable individuals and families to plan ahead, access services, and consider appropriate interventions and support [10]. However, the potential benefits of early detection depend on whether older adults are willing and able to engage with screening and follow-up services [10,11].

Despite increasing attention to cognitive health, dementia screening hesitancy remains common [11], and dementia may remain undetected in primary care [12]. Prior studies have identified multiple barriers, including limited dementia literacy [13,14], uncertainty about dementia risk reduction and assessment [13], fear of receiving a diagnosis and the psychological consequences of a high-risk result [15], and shame or anticipated stigma associated with dementia [15,16]. In addition, many older adults interpret memory lapses as a normal part of aging and therefore not warranting assessment [17]. These barriers involve not only information but also motivation, identity, family considerations, and social norms; system-level constraints and communication problems can further delay recognition and diagnosis [18].

Community-based primary care has a pivotal role in addressing these barriers. In China, community health centers are a core component of the primary health care system, with responsibilities for prevention and chronic disease management [19,20]. Primary care is also increasingly recognized as an important setting for early detection of cognitive impairment in older adults [21]. Strengthening coordination between primary care institutions and hospitals is a recognized priority in China [20], providing a structural basis for referral and navigation support when further cognitive assessment is needed.

Immersive virtual reality (VR) has been applied to cognitive assessment [22], dementia-related nursing interventions [23], and rehabilitation research [24], while systematic reviews have examined its health applications among community-dwelling older adults [25]. In dementia education specifically, a randomized trial in Japan evaluated a multielement VR program combining simulation and VR films with short films, lectures, and discussion; the intervention improved intention to help people with dementia, although the primary attitude outcome did not differ significantly between groups [26]. More recent work in older adults with MCI has also reported improvements in dementia knowledge, critical health literacy, and self-efficacy following a VR-based dementia prevention program [27]. These findings support the potential of VR as an educational format, but they do not explain how older adults experience VR-assisted cognitive health education in community settings or how such experiences intersect with screening decisions. The literature on immersive VR in community-dwelling older adults has also highlighted the need for further study of usability and acceptability [25]. In the Chinese context, qualitative evidence remains limited regarding how older adults perceive VR-assisted cognitive health education, how fear or stigma shape screening readiness, and what practical service-navigation barriers may persist after education. Clarifying these perceived processes and contextual conditions may help inform screening-promotion interventions that can be integrated with routine community care.

Behavior change theory provides a useful lens for understanding how educational interventions translate into health actions. The information-motivation-behavioral skills (IMB) model [28] proposes that people are more likely to adopt a health behavior when they (1) possess relevant and usable information, (2) are sufficiently motivated at personal and social levels, and (3) have the behavioral skills and self-efficacy to act, including the practical ability to navigate services. This model has been applied to a range of preventive and self-management behaviors [29-31] and is particularly relevant to screening contexts, where knowledge and willingness may be present but follow-through fails because the “next step” is unclear or difficult. Applying IMB to cognitive screening in community settings can clarify which components of an intervention are most salient for older adults and what additional nursing or system supports are needed to reduce the gap between intention and action.

Against this background, this study explored a community-based VR-assisted cognitive health education intervention. The aims of this qualitative study were to (1) describe community-dwelling older adults’ understanding, concerns, and attitudes regarding MCI and screening after exposure to VR-assisted education; (2) examine participants’ perceived information, motivation, and behavioral skills relevant to screening, guided by the IMB model; and (3) identify implications for community nursing practice and service processes that may support screening uptake.

Methods

Study Design

This study used a descriptive qualitative design to explore community-dwelling older adults’ experiences and perceptions of VR-assisted cognitive health education in relation to MCI screening. The qualitative component was initiated during the recruitment and health education phase of a broader

XSL•FO
RenderX

community-based cluster-randomized study after the research team observed that some older adults were hesitant to participate in cognitive screening. It focused on participants' accounts, meanings, and contextual factors and was not designed to test intervention effectiveness or estimate causal effects on screening uptake [32,33]. Reporting was guided by the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist [34] (Multimedia Appendix 1).

Broader Cluster-Randomized Study and VR-Assisted Cognitive Health Education

The broader community-based cluster-randomized study comprised 3 study arms: VR-based adaptive-difficulty cognitive training, VR-based fixed-difficulty cognitive training, and a control condition without additional cognitive training. The community was the unit of randomization, and the 9 participating communities were allocated to the 3 study arms using a random-number-table method. A total of 178 older adults who met the parent-trial eligibility criteria, including confirmation of MCI, were formally enrolled in the 3 randomized trial groups. The shared VR-assisted cognitive health education component was provided across the study conditions, whereas the groups differed in the subsequent cognitive training component. The present qualitative sample was recruited earlier, during the common recruitment and health education phase, and participation in the qualitative interviews did not require a confirmed MCI diagnosis or depend on subsequent randomized-group allocation.

The shared VR-assisted cognitive health education session lasted approximately 40 minutes and comprised 2 components. First, participants viewed a 10-minute Chinese-language immersive 360° video using a Meta Quest 3 head-mounted display. Viewing was individual and seated. The experience was observational rather than interactive: participants could explore the 360° visual environment through head movements but did not manipulate virtual objects. The video presented first-person scenarios intended to depict cognitive change, including a familiar living room transforming into a floating island and the intermittent appearance of relatives' faces in a "memory maze." A local person living with dementia and a family member also described experiences of early screening, result notification, diagnosis, and treatment. Chinese subtitles were provided. Immediately after the VR session, participants received a 30-minute face-to-face educational session delivered by a nurse, who provided additional information about MCI and dementia and explained cognitive screening and the screening process.

Semistructured interviews were conducted with 22 older adults who had completed the shared VR-assisted cognitive health education session. The qualitative study specifically examined participants' experiences of this common educational component and was not designed to compare experiences or outcomes across the randomized cognitive training groups. The interviews explored participants' prior experiences of cognitive health education, reactions to the VR format, understanding and concerns regarding MCI and dementia, and views about screening and follow-through. The interview guide (Table 1) was informed by the IMB model and covered information-related understanding and misconceptions, motivational factors such as fear and stigma, and behavioral skills such as confidence and service navigation.

XSL•FO
RenderX

Table 1. Semistructured interview guide questions informed by the information-motivation-behavioral skills (IMB) model.

Number	Interview question	Core IMB constructs	Relevance to screening uptake or intervention experience
1	Before viewing the VR[a] session, what did "MCI"[b] and "dementia" mean to you? How did you interpret memory changes as "normal aging" versus "a problem"?	MCI or dementia literacy; symptom appraisal	Probing baseline misconceptions that shape perceived need for screening
2	Before today, what did you know about cognitive screening (what it involves, where it happens, and what results mean)?	Screening process knowledge; perceived consequences	Identifying knowledge gaps that create uncertainty and avoidance of screening
3	How do you usually experience community health talks or printed materials about cognitive health (eg, terminology, pace, and amount of information)?	Information accessibility; cognitive load	Examining barriers in conventional education that limit comprehension and engagement
4	After viewing the VR session, what information became clearer for you, and what (if anything) remained confusing?	Information acquisition; message clarity	Exploring whether participants perceived the VR session as clarifying information for decision-making
5	How acceptable was the VR format for you (eg, comfort, attention, and distraction by novelty or details)?	Information processing conditions; intervention acceptability	Clarifying delivery-related conditions that may strengthen or dilute key messages
6	When you think about cognitive screening, what feelings or concerns arise (eg, fear, being labeled, stigma, and "loss of face")?	Stigma; anticipated social judgment; affective motivation	Exploring how stigma-related emotions may influence willingness to initiate screening
7	How do you view the value of screening and early action (eg, "knowing is useful" vs "nothing can be done," treatment pessimism, fatalism)?	Outcome expectations; response efficacy; fatalism	Exploring how participants described the perceived value and manageability of screening and early action
8	Do responsibilities and self- prioritization influence your decision (eg, "not worth spending time or money on myself," caregiving duties, and reconciliation with aging)?	Self-worth; aging narratives; competing priorities	Uncovering identity- and values-based barriers that persist despite improved knowledge
9	If you decided to be screened, what would you do first (where to go, which department, how to register), and what would be the hardest step?	Service navigation skills; self-efficacy	Mapping the intention-action gap into concrete capability and system-friction points
10	What support would make it easier to complete screening (eg, community referral, appointment help, reminders, and accompaniment)?	Social support; action planning; enabling resources	Identifying implementation supports participants considered helpful for translating readiness into screening action

[a]VR: virtual reality.

[b]MCI: mild cognitive impairment.

Participants and Recruitment

Participants were recruited from 9 participating communities in Nanjing, Jiangsu Province, China, between August 23 and September 17, 2025, using purposive sampling supplemented by snowball sampling. Community staff posted standardized recruitment notices in community WeChat (Tencent Holdings Limited) group chats (WeChat is a widely used messaging and social media platform in China), including brief information about the study and the research team's contact details. Interested older adults contacted the researchers directly and voluntarily. Among eligible individuals who expressed interest, the research team purposively selected participants with attention to variation in age and educational attainment to capture a range of perspectives. Snowball sampling was used as a supplementary strategy, whereby some participants learned about the study through older adults who had already participated. Eligibility criteria for the qualitative study differed from those of the parent trial because the qualitative study focused on experiences of cognitive health education and screening rather than cognitive-training outcomes among people with confirmed MCI. Eligibility criteria for the qualitative study were an age of 60-85 years, completion of the shared VR-assisted cognitive health education session, the ability to communicate sufficiently to participate in an in-depth interview, and willingness to discuss perceptions and experiences concerning MCI, dementia, and cognitive screening. A confirmed MCI diagnosis was not required. Individuals who had previously undergone MCI or other cognitive impairment screening at another institution and medical professionals were excluded. Participants provided written informed consent before the interview and received a small gift worth approximately CNY 10 (US $1.50) after participation.

XSL•FO
RenderX

Data Collection and Analysis

Before each interview, the researcher collected participant characteristics including age, retirement status, marital status, educational level, family history of dementia, and prior MCI screening. The semistructured interview guide was developed in Mandarin Chinese and pilot-tested with 3 older adults, who were included in the final sample of 22. No substantive changes were made to the interview guide after pilot testing; therefore, the 3 pilot interviews were retained in the final analytic sample. During the pilot stage, interview notes were reviewed with the 3 pilot participants to confirm that the recorded content accurately reflected their intended meaning. Interviews were conducted in Mandarin by TY, a researcher trained in qualitative methods who was involved in volunteer recruitment and intervention delivery in the broader study. Before the qualitative interviews, TY had prior study-related contact with 7 of the 22 participants; she had no prior relationship with the remaining 15. All interviews were conducted face-to-face in private, quiet indoor rooms provided by the participating communities, with only the interviewer and participant present. Interviews lasted 39-152 minutes. The variation reflected differences in the depth and richness of participants' responses; some participants provided particularly detailed and reflective accounts, leading to additional probing and clarification and consequently longer interviews. With participants' consent, interviews were audio-recorded and transcribed verbatim in Mandarin within 24 hours after each interview. Field notes were recorded during and immediately after the interviews to document contextual observations, relevant nonverbal responses, and issues requiring clarification; these notes were considered alongside the transcripts during coding and interpretation. Thematic saturation was initially judged to have been reached after the 19th interview. Three additional interviews were conducted to confirm saturation, and no new themes emerged in interviews 20-22. Full verbatim transcripts from the 22 formal interviews were not returned to participants for checking.

Coding, theme development, and interpretation were conducted using the original Mandarin transcripts. All 4 researchers (TY, BY, JY, and YW) coded the full set of 22 transcripts using Microsoft Word and NVivo (version 15; Lumivero). Codes, subthemes, and themes were developed iteratively from the interview data. Coding decisions and emerging interpretations were compared regularly among the 4 researchers; disagreements regarding coding, code definitions, theme boundaries, or interpretation were discussed until consensus was reached. Related codes were grouped into candidate subthemes, which were reviewed against the coded extracts and original transcripts and refined until the research team agreed on the final thematic structure. After the subthemes had been developed from the data, they were mapped to the IMB model domains according to their predominant conceptual meaning. Thus, the IMB model served as a theoretical framework for organizing and interpreting the final thematic structure rather than as a rigid set of predetermined themes. English translations were prepared for the participant quotations selected for reporting after the qualitative analysis had been completed.

Patient and Public Involvement

Patient and public involvement occurred at different stages of the broader research program and was separate from the 22 semistructured interviews reported in this study. First, formative qualitative work was conducted before this interview study to characterize community perceptions and stigma related to MCI and dementia; findings informed development of the VR-assisted cognitive health education content. During intervention development, community-dwelling older adults and community staff viewed the VR educational materials and provided feedback on the content and presentation. Their comments were considered by the research team when refining the materials before implementation. During recruitment for the present qualitative study, community health coordinators supported logistical organization and dissemination of recruitment information.

Ethical Considerations

This study was approved by the Ethics Committee of the First Affiliated Hospital of Nanjing Medical University (number 2025-SR-015) and conducted in accordance with the Declaration of Helsinki [35]. Participants provided written informed consent before the semistructured interviews and received the stated compensation after participation.

Results

Characteristics of Participants

Twenty-two community-dwelling older adults from participating communities participated in the interviews. Their mean age was 73.27 (SD 4.95) years, and 15 (68.18%) were women. Most participants had completed secondary education or higher (Table 2). The relationship between the qualitative interview sample and the formally enrolled parent cluster-randomized trial sample is summarized in Table S1 in Multimedia Appendix 2. The two samples were recruited at different stages and under different eligibility criteria and were not statistically compared.

XSL•FO

No	19 (86.36)
Yes	3 (13.64)

Themes, Subthemes, and Codes

Participants described varied prior understanding of MCI and dementia, concerns about screening, and experiences of the VR-assisted education session. Several participants perceived the VR content as making concepts easier to understand or less threatening, whereas others described information overload, distraction by delivery details, or persistent uncertainty. Across interviews, participants also emphasized practical barriers to acting on screening intentions, particularly uncertainty about where to go and how to obtain referral support. Sixteen subthemes were developed from the interview data and subsequently mapped to the 3 IMB domains (Figure 1).

Figure 1. Subthemes mapped to the information-motivation-behavioral skills (IMB) model across 22 semistructured interviews. MCI: mild cognitive impairment.

XSL•FO
RenderX

Information

Misunderstanding and Lack of Knowledge About MCI

Participants commonly described limited prior understanding of MCI, often equating memory problems with "dementia" or "mental problems." Their accounts indicated that these misconceptions shaped how they interpreted the value and possible consequences of screening:

> *I always thought poor memory was senile dementia and there's no cure for it, so I didn't want to get screened.* [N14, female, 68 years old]

Participants' accounts also reflected uncertainty about the nature of MCI and what, if anything, could be done after early identification. Some participants linked screening to additional worry or family burden:

> *In our village, they all say it's the "confused disease," and getting screened won't help anyway; it just makes the children worried.* [N21, female, 76 years old]

The Relationship Between MCI and Dementia

Participants frequently described uncertainty about the distinction and relationship between MCI and dementia, and some interpreted MCI as inevitably progressing to dementia:

> *The VR said it's not dementia, but it's the early stage of dementia. So wouldn't that just be a matter of time? Hearing this made me even more scared.* [N12, male, 68 years old]

> *Now I understand. It's like the relationship between high blood pressure and cerebral infarction. If it's managed early, it might not progress to that stage.* [N15, male, 71 years old]

Knowledge Acquisition and Clarification

Several participants perceived the visual and immersive presentation as easier to understand than professional terminology or dense written materials and described the session as helping them clarify previously confusing concepts about MCI and dementia:

> *Before, just listening to the terms, I couldn't understand. The animation in the VR clearly demonstrated "aging of brain circuits" and "complete disconnection." Now I really understand.* [N5, male, 67 years old]

Some participants also valued the individually delivered format and described it as allowing them to engage with the information at a more comfortable pace, without the social discomfort they associated with asking questions during face-to-face health education:

> *When the doctor was explaining, I was too embarrassed to ask. With this VR, I can watch it slowly and even go back to review it. Finally, I understood that "forgetfulness" and "pathological forgetfulness" are different.* [N22, male, 71 years old]

Timing and Psychological Readiness

Participants described timing and psychological readiness as important to how cognitive-health messages were received. When education occurred during periods of anxiety or poor physical health, some participants interpreted screening suggestions defensively or negatively:

> *During that time, I wasn't feeling well physically either. Anyone who suggested I have my brain checked, I thought it was cursing me.* [N4, female, 79 years old]

Participants also described greater receptiveness at certain life transitions, such as retirement, suggesting that readiness to engage with prevention messages varied by personal context:

> *Before retirement, I never thought about these things. When I just retired, I was nervous. At this time, when someone told me about prevention, I could listen to them.* [N20, female, 65 years old]

Information Overload

Participants described conventional health-education materials and expert talks as difficult to follow when information was dense, highly technical, or delivered too quickly. These experiences were especially salient in accounts of frustration or disengagement:

> *With this VR, it feels like there's a patient teacher guiding me step by step. Today, I'll understand how the heart beats, and tomorrow I'll learn about the blood vessels. This way of learning is not tiring, and I have a clear understanding. As a result, everything is firmly imprinted in my mind.* [N8, female, 75 years old]

Participants' accounts suggested a preference for information delivered in smaller, layered segments rather than large amounts of technical content presented at once:

> *They gave me a booklet with densely packed text and many English abbreviations. After reading it for a while, I got a headache and threw it aside directly.* [N1, female, 77 years old]

> *The experts spoke too fast, with one professional term after another. I didn't even have time to take notes and after listening, I became even more confused.* [N10, male, 79 years old]

Attention to Peripheral Details

Some participants reported that the novelty of VR or peripheral visual and operational details initially drew attention away from the core educational message. Questions about image accuracy or the realism of examples sometimes became a focus of discussion:

> *Why is the color of the brain model in the VR program pink? I heard it should be gray. Could this be unscientific?* [N7, female, 69 years old]

For these participants, attention to non–core details appeared to compete with attention to the intended message about MCI and screening:

XSL•FO
RenderX

> *The example given is that buying vegetables and making a mistake with the money. I think this example is not good. Our generation's mental arithmetic is not as good as that of the young people.* [N6, female, 79 years old]

Uncertain Awareness of Cognitive Health Status

Participants often described uncertainty in appraising their own cognitive health, moving between interpretations of memory change as "normal aging" and as a possible problem. Some accounts combined worry with avoidance, including a preference not to know whether a problem was present:

> *I just occasionally forget things. Everyone does this. There's no need to specifically check; finding out would only add to my worries.* [N16, female, 75 years old]

> *Sometimes I feel my reaction is slower, but I'm afraid it's really a problem. It's better not to know.* [N13, female, 71 years old]

Motivation

Fear and Stigma Associated With Screening

Participants described screening as carrying negative social meanings, including being labeled, diagnosed, or viewed as "abnormal." These anticipated consequences contributed to fear and reluctance in some accounts:

> *I don't want to be screened. What if something goes wrong during the test, will others think I'm "abnormal"? Even my grandson might not let me do it.* [N2, female, 71 years old]

Some participants described avoiding cognitive screening because they feared discovering a problem or being judged by family, peers, or the wider community. Their accounts positioned stigma as a social and emotional barrier to screening:

> *I don't go for this screening test even when my unit organizes it. I'm afraid it will affect my reputation and be said that "his mind is not good."* [N3, male, 82 years old]

Perceived Reduction in Stigma and Greater Screening Acceptability

Some participants reported that the VR session made cognitive decline feel less shameful and screening more acceptable, particularly when the content framed cognitive change as a health issue that could be discussed and managed.

A man who had previously refused screening said after the session:

> *Previously, I thought being diagnosed meant being "mentally retarded." Now I understand that it's just a risk condition like high blood pressure, and early detection can also be controlled. I don't fear being laughed at by others anymore.* [N18, male, 81 years old]

Participants who identified with the community-based cases described less embarrassment and greater openness to considering screening. These accounts suggest a perceived reduction in stigma rather than a measured change in screening behavior:

> *The cases in the VR were all normal. They were like neighbors to me, making me feel that having such a condition is not embarrassing. I should get checked if there's a need.* [N11, female, 69 years old]

Reconciliation With Aging

Participants sometimes normalized cognitive decline as an inevitable part of aging. For some, this interpretation functioned as an adaptive way of maintaining calm and self-identity, but it also reduced the perceived need to seek assessment for memory changes:

> *As one gets older, the machine becomes old and the parts don't work properly. This is normal. Why bother?* [N3, male, 82 years old]

Participants' accounts indicated that acceptance of aging could coexist with reduced motivation to pursue screening, particularly when memory changes were interpreted as universal and unavoidable:

> *Having a poor memory also has its advantages. Not being able to remember the troubles, life becomes simpler.* [N9, female, 73 years old]

Low Self-Prioritization

Some participants placed their own health needs behind family responsibilities and described screening as not worth the time or expense. These accounts reflected low self-prioritization rather than lack of awareness alone.

A rural woman whispered:

> *It's not easy for the children to earn money. I won't bother to have my health checked. It's a waste of money.* [N1, female, 77 years old]

Another man who had been caring for his ill spouse for a long time said:

> *My job is to take good care of my wife. I don't care about my own situation.* [N10, male, 79 years old]

These accounts suggest that prioritizing family responsibilities over personal health could reduce motivation to seek screening.

Pessimistic Outlook on Treatment

Several participants expressed pessimistic expectations about the value of early identification or treatment for MCI and dementia. For some, the belief that progression was inevitable reduced the perceived benefit of screening:

> *I've seen what dementia is like in its advanced stage. Currently, there is simply no cure. Once diagnosed, there's only waiting.* [N20, female, 65 years old]

> *Even with early intervention, it's only a delay. Eventually, it will still progress. This awareness is actually a burden.* [N14, female, 68 years old]

XSL•FO
RenderX

Behavioral Skills

Low Confidence in Self-Management

Some participants doubted that self-management or lifestyle changes could meaningfully protect cognitive health. These accounts reflected low self-efficacy and limited confidence in their ability to act on prevention advice:

> *Memory is determined by nature. What you eat and what you practice are all psychological effects.* [N16, female, 75 years old]

> *I can't even manage my diabetes well. How can I manage my brain? Let it be as it is.* [N19, female, 77 years old]

Knowledge to Action

Participants described a gap between understanding screening recommendations and knowing how to act on them. Even when they considered screening worthwhile, some reported low confidence in making appointments, choosing a department, or initiating the process.

A retired teacher who was aware of the benefits of early intervention confessed:

> *I know I should get checked, but I'm completely confused about how to make an appointment, where to go, and what tests to take. It's so confusing that I just put it off and forget about it eventually.* [N9, female, 73 years old]

Participants' accounts repeatedly returned to the question of "what to do next," highlighting the need for practical instructions, prompts, and support to initiate screening:

> *After the lecture, I thought it made sense, but when I got home and was busy with daily chores, I forgot all about it. There was no reminder, no one to guide me through the first step, and it was very difficult for me to start.* [N21, female, 76 years old]

Community-Based Referral and Navigation

Participants described familiar community health services as a preferred first point of contact for cognitive screening and referral. They emphasized the value of clear, convenient, and trusted guidance about where to go and how to access the appropriate service:

> *If the community hospital can conduct simple initial screenings, or if the doctor can refer me to the right department, I will definitely be willing to go. I myself would go to the hospital for registration, but I couldn't even figure out whether to go to the neurology department or the geriatrics department.* [N17, female, 69 years old]

Participants' accounts portrayed community staff and local networks as sources of practical guidance, trust, and reassurance. These relationships appeared important when older adults felt uncertain about navigating hospital departments or registration processes:

> *Our building's group leader organized everyone to go to the community health center for assessment. With companions and familiar doctors, I felt at ease and I participated.* [N12, male, 68 years old]

Difficulty Changing Established Habits

Participants also described difficulty changing long-established lifestyle and social routines, even when they understood health recommendations. These accounts reflected challenges with self-regulation and translating advice into sustained behavior:

> *The doctor told me to go out more and play cards with others, but I'm used to staying at home alone. I don't know who to go to when I go out. Thinking about it, it's more comfortable to stay at home.* [N3, male, 82 years old]

> *I know eating lightly is good for the brain, but I've been eating salty food all my life and the dishes have lost their flavor. I just can't eat them. My willpower is not strong enough.* [N5, male, 67 years old]

Participants' accounts suggested that established habits could make both preventive lifestyle change and participation in screening activities more difficult. They described these routines as obstacles to acting on health advice and attending screening:

> *I usually enjoy going fishing and playing cards. These are all static activities. I just don't like going out for activities, let alone participating in screening events in the community or at the hospital. I don't like it at all and I can't change that.* [N5, male, 67 years old]

Discussion

Principal Findings

This qualitative study explored how community-dwelling older adults experienced VR-assisted cognitive health education and how their accounts related to the IMB model. Participants described the immersive educational content as making some information about MCI and screening more concrete and understandable, and some reported feeling less fearful or embarrassed about cognitive screening after the session. However, participants also described persistent uncertainty about how to proceed with screening, including where to go, how to register, and whom to approach for assistance. Taken together, these accounts suggest potential information-related, motivation-related, and behavioral skill–related processes through which VR-assisted cognitive health education may support screening readiness, while also highlighting practical conditions that may prevent willingness from translating into action. These findings represent participants' experiences and perceived processes and should not be interpreted as evidence that VR caused an increase in screening uptake.

Information: Dementia Literacy and Cognitive Load

Participants described substantial gaps in basic knowledge about MCI, commonly conflating MCI with dementia or mental illness, and equating screening with being diagnosed and socially labeled. These accounts are consistent with studies documenting limited dementia knowledge in diverse community populations [13,14,36] and qualitative work showing that biomedical terminology, shame, and negative social meanings can shape how people understand dementia [16]. Help-seeking research

XSL•FO
RenderX

further suggests that early cognitive changes are often discounted as normal aging, left uncertain, or misattributed, which can delay recognition of the need for assessment [17]. In our study, misconceptions were not only about disease concepts but also about the purpose and consequences of screening, with some participants anticipating social harm (loss of reputation) or family disruption (worrying adult children), which reduced perceived benefit.

Compared with their prior experiences of conventional health education, participants often described the VR session as easier to understand because it provided concrete visual explanations and could be followed at an individual pace. This perceived benefit is consistent with emerging intervention evidence showing that VR-based dementia education can support dementia-related knowledge, health literacy, or behavioral intentions in some settings [26,27]. In this study, however, participants' descriptions of the immersive presentation should be interpreted as perceived clarity rather than evidence that knowledge objectively improved.

At the same time, participants described limitations related to novelty, peripheral details, and dense information. These concerns are consistent with systematic review evidence emphasizing the need to consider usability and acceptability when applying immersive VR with older adults [25]. Participants' accounts in this study also suggested a preference for information that is paced and layered rather than densely presented. A practical implication is therefore to keep VR education brief and focused on a small set of core messages: what MCI is and is not, why screening may be considered, what screening involves, and what the next steps are in local services.

Motivation: Stigma, Avoidance, Fatalism, and Reconciling With Aging

In the motivation domain, participants' accounts highlighted fear of being labeled, anticipated discrimination, and concerns about face and reputation. This pattern is consistent with prior research identifying stigma, fear, and social consequences of a cognitive label as barriers to screening, diagnostic assessment, or dementia-service use [11,15,37]. Some participants described the community-based cases in the VR session as relatable and less stigmatizing, suggesting that familiar narratives may make screening feel more acceptable. Because these are retrospective qualitative accounts, however, the data do not establish the magnitude or durability of any change in stigma.

Several participants also expressed low perceived self-efficacy and fatalism, including skepticism that lifestyle changes or early identification could help. Pessimism about treatment and low self-prioritization were also evident in some accounts. These themes are consistent with prior research showing that reluctance toward cognitive screening or follow-up can be shaped by perceived limited benefits, psychological burden, stigma, and concerns about the consequences of diagnosis for patients and families [11,13,37]. Some participants described MCI as feeling more manageable after the session, particularly when it was framed as a risk state for which early management may still be meaningful; this should be interpreted as a perceived shift in understanding rather than a measured intervention effect.

A contribution of this study is the detailed description of reconciliation with aging as an adaptive psychological stance. Many participants normalized cognitive decline as part of aging and described acceptance as a way to maintain calm and identity. Similar narratives appear in help-seeking research, where memory changes are often discounted as normal aging or their significance is left uncertain [17]. In our data, this stance was double-edged: it protected well-being but reduced intrinsic motivation to pursue screening. Participants' accounts suggest that the educational content did not necessarily require directly challenging acceptance of aging. For some participants, framing screening in relation to self-care, maintaining independence, and reducing potential family burden appeared to provide an alternative way of considering screening. For nursing practice, motivational work may therefore benefit from culturally sensitive and values-based communication rather than emphasizing disease threat alone.

Women accounted for 15 of the 22 interview participants. Although several female participants discussed health education in relation to family roles and caregiving, the study was not designed to compare women and men, and the overrepresentation of women may reflect self-selection into health education or interview participation. These accounts therefore should not be interpreted as evidence of a sex or gender difference in interest in the intervention.

Behavioral Skills: The Intention-Action Gap and the Centrality of Community Referral

A practice-relevant pattern in the behavioral-skills domain was the gap participants described between considering screening worthwhile and knowing how to complete it. Participants frequently reported uncertainty about where to go, how to register, which department to choose, what screening would involve, and how to take the first step. In their accounts, this intention-action gap was closely tied to complex service navigation and low confidence in navigating hospital systems.

Consistent with research on primary care and community-based models of care, participants emphasized the value of a trusted and convenient referral route. Prior studies have highlighted the role of primary care in cognitive detection [21], the importance of coordination with specialist services in dementia diagnosis [38], and the value of integrated teams and navigation support for older adults [39,40]. In this sample, participants' accounts suggest that education alone may be insufficient when there is no immediate, low-barrier next step; this is an implementation hypothesis that requires prospective evaluation.

For practice, the findings suggest a potential role for community nurses and primary care teams in linking education to action. Future VR-assisted education could be kept brief and structured, followed by facilitated discussion to check understanding and address concerns; multielement VR dementia education has previously combined immersive content with lectures and discussion [26]. It could also end with concrete service information: where screening is available, how to book, what to expect, and who can assist. Nurse-led navigation strategies such as appointment assistance, reminders, or accompaniment should be evaluated rather than assumed to improve uptake.

XSL•FO
RenderX

For education, nursing curricula and continuing professional development should strengthen skills in stigma-sensitive communication, motivational interviewing with older adults, and age-friendly digital health facilitation. Training should also cover how to recognize and respond to reconciliation-with-aging narratives in a way that respects values while supporting preventive action. For policy and service planning, investing in technology alone is unlikely to be sufficient. This emphasis is consistent with evidence supporting stronger coordination between primary care institutions and hospitals in China [20], navigation support for older adults using community-based primary care [39], and interdisciplinary team support in dementia primary care [40]. Future implementation strategies could evaluate standardized community-to-hospital referral processes, clear responsibility for follow-up, and protected staff time for navigation support. Program evaluation could consider not only knowledge-related outcomes but also screening completion and appropriate follow-up care.

Strengths, Limitations, and Future Research

A strength of this study is its theory-informed qualitative design conducted within a community intervention context, which allowed exploration of experiences and contextual factors that quantitative outcomes may not capture. Developing themes from the interview data and subsequently mapping the subthemes to the IMB model provided a structured way to distinguish information, motivation, and behavioral-skill issues while retaining patterns grounded in participants' accounts.

Several limitations should be considered. The sample was drawn from communities in one province and included many participants with secondary education or higher, which may limit transferability to rural or lower-literacy populations who could face different barriers to VR use and screening access. Participants initially volunteered in response to community recruitment information and were then purposively selected with attention to age and educational variation; this process may still have favored older adults who were more willing to engage with cognitive health education or research. Women were overrepresented (15/22), and interview participation may therefore have been subject to self-selection; apparent gender-related patterns should be interpreted cautiously. Future research should prospectively evaluate integrated approaches that combine VR-assisted education with structured nurse-led clarification, referral, reminders, and follow-up and should assess equity, feasibility, and screening completion in underserved settings.

Conclusion

This qualitative study suggests that VR-assisted cognitive health education may be experienced as engaging and understandable by some community-dwelling older adults, while fear, stigma, uncertain self-appraisal, and practical service-navigation barriers can persist. Participants' accounts particularly emphasized the value of trusted community-based guidance when considering what to do after receiving screening information. These findings support further evaluation of models that pair age-friendly digital education with clear referral and navigation support, but they do not establish that VR itself increases screening uptake.

Acknowledgments

We sincerely thank the older adults who generously dedicated their time to participate in this study. We also express our appreciation to the staff at the home-based older adult care service centers for their assistance in facilitating data collection.

Abstract

Background: Surgical telementoring enables a remote expert surgeon (mentor) to guide an operating surgeon (mentee) during surgery and facilitates the transfer of surgical skills. However, commonly used audio and static visual cues are inadequate to demonstrate complex tool-tissue interactions. To overcome this limitation, dynamic augmented reality (AR)–based visual cues are overlayed on the operative field to demonstrate precise instrument movements.

Objective: The objective of this work was to evaluate dynamic AR cues and identify the most suitable cue that effectively demonstrates the required motions of surgical instruments during laparoscopy.

Methods: A user study was conducted in a simulated environment among mentor-mentee pairs using 3 dynamic AR cues (hand gestures, a 3D pointer, and a virtual tool). The task assessed how closely the mentee was able to follow the mentor. The outcomes measured were (1) dynamic time warping distance, representing the closeness of the paths followed; (2) angular error in tooltip orientation; and (3) the NASA Task Load Index, assessing cognitive workload during telementoring.

Results: Telementoring using the virtual tool resulted in a reduced dynamic time warping distance compared with hand gestures (P<.01 for 12/13, 92.3% of the trials) and the 3D pointer (P<.05 for 11/13, 84.6% of the trials). Lower orientation error was also noted while using the virtual tool as compared with hand gestures (P<.05 for 5 of 6 poses). There were no substantial differences in the NASA Task Load Index scores.

Conclusions: Use of a virtual tool (as a dynamic AR cue) enabled the mentee to follow the mentor's instructions with fewer errors than both hand gestures and a 3D pointer without increasing cognitive workload. Further research is needed to assess the clinical effectiveness of the virtual tool during live surgery.

laparoscopy; minimally invasive surgical procedure; telementoring; augmented reality; dynamic visual cues

Introduction

A growing need for expert surgeons' guidance during laparoscopic surgery necessitates the adoption of telementoring technologies [1]. During telementoring, an expert surgeon (mentor) can guide an operating surgeon (mentee) in real time even if they are continents apart. Operating room footage is sent to the remote mentor, who then provides instructions to the mentee using audio cues. Further enhancing the mode of instruction, the telementoring system may also integrate augmented reality (AR) technologies, whereby computer-simulated virtual objects are superimposed on the user's field of view [2]. This includes the use of static AR-based visual cues such as annotations or *telestrations* (ie, sketches or illustrations drawn over a video feed by the mentor in real time) overlaid on the mentee's operative view displayed on a screen. This is useful during in-person guidance as well, as the mentor can point at anatomical structures instead of describing them verbally [3]. However, static AR cues remain stationary within the operating field, and the mentor may not be able to communicate the required tool positions, orientations, and movements. To overcome this limitation, the use of dynamic AR cues, including but not limited to the mentor's hand gestures, a 3D pointer, and a virtual tool, has been proposed [4]. The remotely located expert surgeon can communicate with the mentee by controlling these cues in real time, thereby

XSL•FO
RenderX

demonstrating complex tool-tissue interactions required during laparoscopic surgery. This can also be used to enhance in-person guidance, thereby eliminating the need for the mentor surgeon to take control of the instruments to demonstrate specific tool movements.

Advancements in dynamic AR cues for telementoring during minimally invasive surgery (laparoscopic and robot assisted) have been tested extensively (Table 1). They include procedures such as cholecystectomy, prostatectomy, and suturing in various clinical settings such as virtual simulator, synthetic phantom, animals (cadavers), and humans (live). The dynamic AR cues frequently used for guiding mentees during minimally invasive surgeries can be categorized as hand gestures, pointers, or surgical tools [5]. While some of the studies have provided a description of the technologies used, others have compared dynamic AR cues with different modes of mentoring. They include assessment of hand gestures with audio cues [3,6,7] or in-person guidance [8], 3D pointers with audio cues [9,10], and virtual tools with in-person guidance [11-15]. A comparison of dynamic AR cues against static 2D telestrations has also been conducted [16]. As shown in Table 2, previous articles have already reported favorable results while using dynamic AR cues when compared with standard practices such as audio cues, in-person guidance, and static 2D telestrations. Both hand gestures and 3D pointers have shown improved performance compared with audio cues. Virtual tools have resulted in comparable performance to and lower operating time than that with in-person guidance. In these studies, all 3 dynamic AR cues were preferred over static 2D telestrations. While some of the related studies have introduced these telementoring technologies in cadaveric and live surgical settings, they have not objectively compared the 3 dynamic AR cues, namely, hand gestures, 3D pointers, and virtual tools, against each other. To the best of our knowledge, there are no existing studies that have performed a comparative analysis of the different dynamic AR cues. To enhance telementoring and improve the learning experience for the mentee, there is a need to standardize and optimize the use of dynamic AR cues. This requires comparing different types of dynamic AR cues among themselves to identify the most effective modality for the mentor to render the information to the mentee during surgical telementoring.

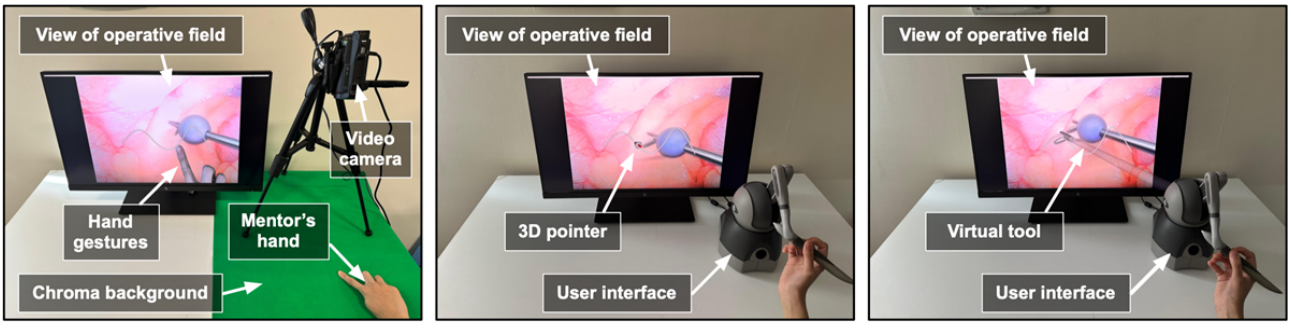
Virtual tool	—	Similar performance [11-14,19,20], shorter operating time, and fewer failed attempts [15]	Preferred over static visual cues by the participants [16,24]

[a]Not available.

In this study, we aimed to quantitatively assess the dynamic AR cues during telementoring and compare the mentee's performance while receiving instructions in each mode, namely, hand gestures, a 3D pointer, or a virtual tool. In the following sections, we present the experimental setting used for this study, the results obtained during the trial, and a discussion of the major implications of using dynamic AR cues for telementoring during laparoscopic surgery.

Methods



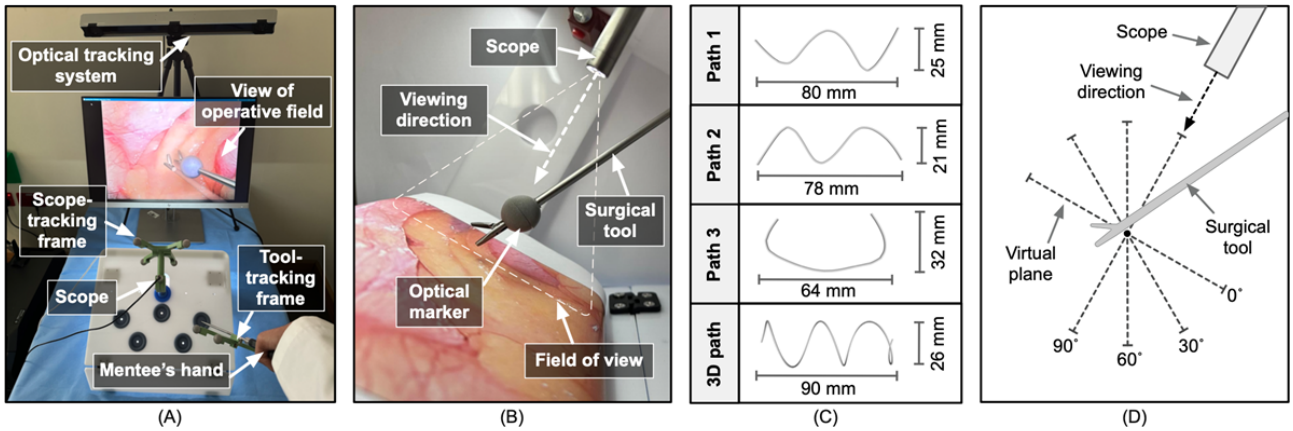
Participant Enrollment

A user study was conducted among mentor-mentee pairs as participants to evaluate the dynamic AR cues for telementoring. Participants were recruited from the Department of Surgery at Hamad General Hospital in Qatar. They were researchers working on the development of surgical technologies. None of them had prior experience performing real surgeries; however, they had experience using surgical simulators and were familiar with the hand-eye coordination required for maneuvering laparoscopic tools. Hand-eye coordination is crucial for laparoscopic tasks, especially when the operative field is displayed to the user on a 2D screen [26]. A total of 10 participants as mentees were included in the user study. One participant, a senior researcher from the Department of Surgery who was familiar with the telementoring system, was recruited as the mentor to demonstrate the required laparoscopic instrument motions to the mentees. The mentor was well versed in using user interfaces at the mentor's site to demonstrate the required motion of a laparoscopic tool using different dynamic AR cues.

Setup at the Mentor and Mentee Sites

The mentor used 3 different dynamic AR cues, namely, *hand gestures*, a *3D pointer*, and a *virtual tool*, to guide the mentees. The setup at the mentor's site for generating each of the dynamic AR cues is shown in Figure 1. To capture hand gestures (Figure 1A), the mentor moved the hand over a chroma background, and a camera was used to acquire the movements. The background was then removed from the acquired video, and the hand gestures were overlaid onto the live view of the operative field. In the case of the 3D pointer (Figure 1B), the mentor controlled the position and orientation (pose) of a stylus (Geomagic Touch; 3D Systems). The relative motion of the stylus was mapped to the 3D pointer rendered onto the live view of the operative field. Finally, the same stylus was also used to control the movements of the virtual tool (Figure 1C) based on our previous work [27].

Figure 1. The setup at the mentor's site to generate the 3 types of dynamic augmented reality cues: (A) hand gestures, (B) a 3D pointer, and (C) a virtual tool.

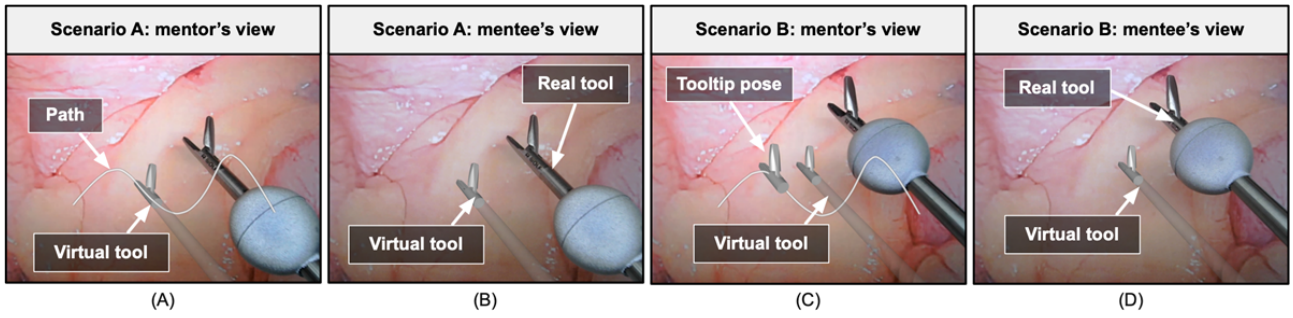


At the mentee's site, the study was performed on a low-fidelity synthetic phantom setup using a laparoscopic box trainer (Figure 2). The setup is shown in Figure 2A. A one-to-one comparison of the 3 dynamic AR cues requires a controlled environment that remains constant throughout the trials to eliminate confounding variables related to anatomical variability, tissue deformation, and procedural differences. For this reason, we designed this study using a phantom setup, which provides a stable and reproducible environment. This approach allowed for the isolation and objective assessment of the effect of each

XSL•FO
RenderX

dynamic AR cue on tooltip movement and spatial guidance independent of the surgical procedure itself. Second, it avoided patient-related surgical risk and ethical concerns while still providing meaningful insights on the use of dynamic AR cues. The type of task that was selected was surgical tool maneuvering. It was chosen as it is an essential skill for laparoscopy requiring hand-eye coordination and precise instrument control [28]. Improvements in instrument control and spatial guidance are broadly transferable to more complex surgical tasks.

Figure 2. (A) Setup at mentee's site comprising an optical tracking system, a screen rendering the view of the operative field, a box trainer, a surgical scope, and a laparoscopic instrument. (B) Setup inside the box trainer. (C) Three virtual 2D paths and one 3D path used in scenario A. (D) The orientation at which the 2D paths were rendered in front of the scope on a virtual plane.



The dynamic AR visual cues were overlaid on the mentees' view of the operative field in real time. The dynamic AR cues assisted the mentees in comprehending the required pose of the laparoscopic instrument and maneuvering it accordingly. To record the movements of the laparoscopic instrument with respect to the scope, tracking frames were used. An optical tracking system (V120-Trio; NaturalPoint) was used to track the motion of the laparoscopic instrument and the scope. In addition, the distal end of the laparoscopic instrument was fitted with an optical marker (Figure 2B). This assisted in capturing accurate positions of the laparoscopic instrument tip during the study. As the setup required placing an optical marker on the laparoscopic instrument, the user study was conducted in a simulated environment instead of on humans.

Telementoring Scenarios

Two scenarios, scenario A and scenario B, were simulated to assess the dynamic AR cues. Scenario A evaluated dynamic AR cues to facilitate continuous tool movements. The movements of the laparoscopic instrument were characterized by 4 different paths (Figure 2C). They consisted of 2D paths, each positioned at 0°, 30°, 60°, and 90° orientations (Figure 2D), and one 3D path. The paths were rendered onto the mentor's screen (Figure 3A), whereas the mentees were able to see the dynamic AR cue generated by the mentor (Figure 3B). The mentor was asked to generate dynamic AR cues that would guide the mentees to follow the paths using the laparoscopic instrument. The mentees observed the dynamic AR cues in real time and performed the movements of the laparoscopic instrument to follow the mentor.

Figure 3. (A) Mentor's view in scenario A. (B) Mentee's view in scenario A. (C) Mentor's view in scenario B. (D) Mentee's view in scenario B.

Scenario B evaluated dynamic AR cues to facilitate precise orientation of the laparoscopic instrument's jaw. Six different feasible poses for orienting the jaw of the laparoscopic instrument were rendered to the mentor (Figure 3C). The mentor observed these poses and generated dynamic AR cues. The dynamic AR cues were rendered to the mentees (Figure 3D), and the mentees maneuvered the laparoscopic instrument to orient the jaw. As it was impossible to indicate this using 3D pointers, only hand gestures and virtual tools were used for guidance in scenario B.

In both scenarios, verbal instructions from the mentor were not provided. No verbal instructions were given to assess the dynamic AR cues independently as feedback in the form of audio cues can assist the mentees and alter the performance during the task. After completion of both scenarios, the mentees were required to complete the NASA Task Load Index (NASA-TLX) questionnaire [29] for each dynamic AR cue.

XSL•FO
RenderX

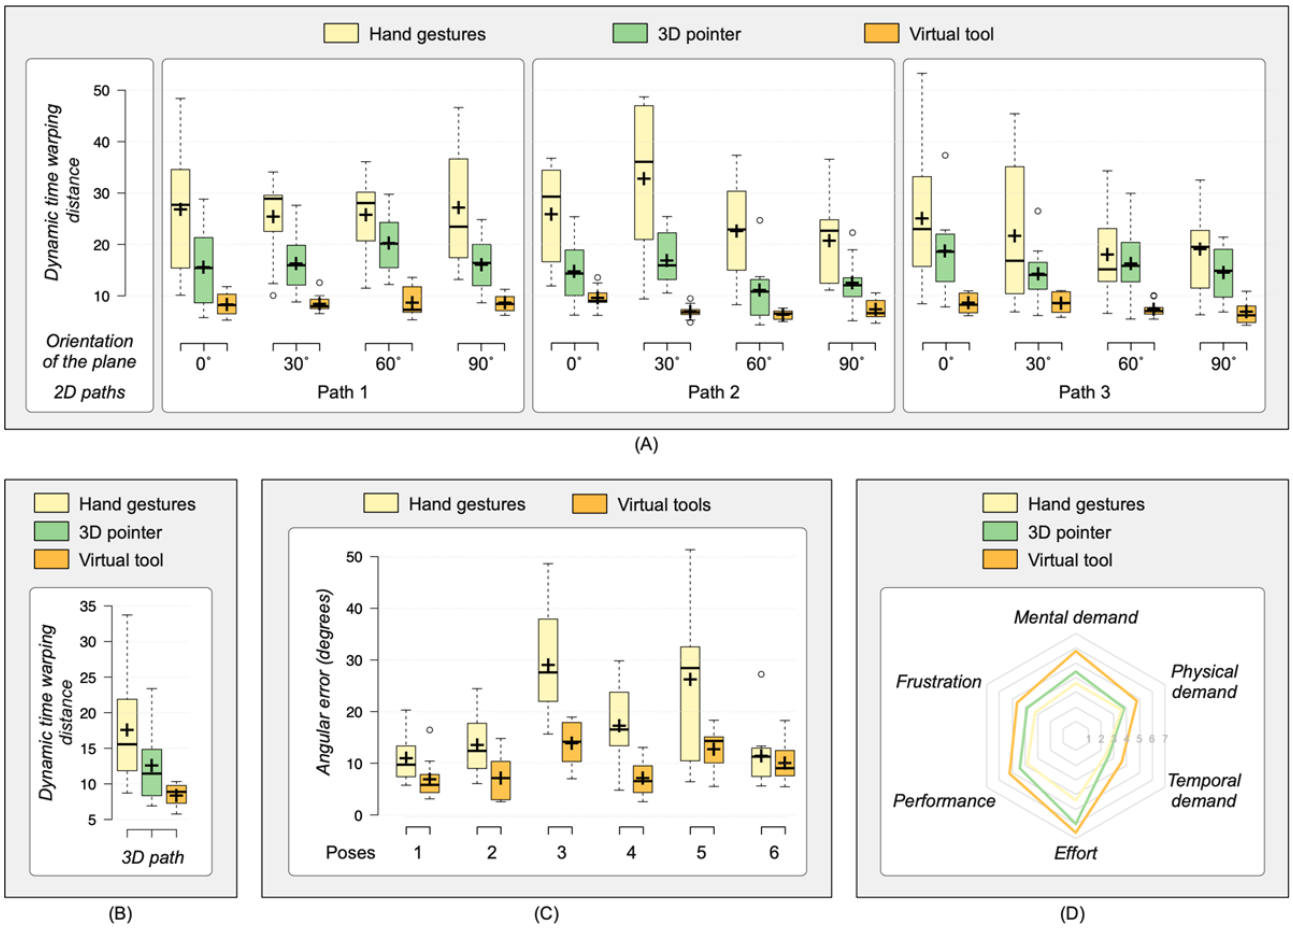
Study Design and Outcomes Measured

We chose to study within-subject factors by having the same individuals participate in all 3 dynamic AR cues. In this way, the participants acted as their own controls, and we eliminated any variation in task performance arising from individual differences. Additionally, to eliminate bias arising from the learning effect, we randomized the order in which the AR cues were allocated to the participants, as well as the order of the different tasks performed using each AR cue. Before the start of the study, each mentee went through a preparatory step to familiarize themselves with the telementoring setup and dynamic AR cues. Each mentee performed both scenarios with all 3 dynamic AR cues. The sequence in which the dynamic AR cues were used by the mentor-mentee pair was randomized. Furthermore, in scenario A, the sequence in which the 2D and 3D paths were rendered to the mentor and the orientations in the case of the 2D path were also randomized. The primary outcomes measured as part of this study included objective assessments in the form of (1) the average dynamic time warping (DTW) distance between the paths followed by the mentees and the required paths shown by the mentor during scenario A and (2) angular errors (measured in degrees) in orienting the laparoscopic instrument jaw during scenario B. DTW is a technique for measuring similarity between time-series data using temporal alignment [30]. Unlike the Euclidean distance, which relies on point-to-point comparison, DTW allows for one-to-many and many-to-one comparison, which is useful for paths that vary in time and speed. DTW has been applied for surgical performance and instrument motion demonstrations [19,26,27,31]. A lower value of DTW indicates a greater similarity and better alignment between the mentees' path and the reference path. The secondary outcome consisted of subjective assessment scores rated by the mentees using the NASA-TLX. These measured mental, physical, and temporal demands; effort; performance; and frustration on a scale from 1 to 10, with a lower score indicating a more positive rating.

Statistical Analysis

In scenario A for paths 1 to 3, an ANOVA was performed to determine whether there were significant mean values over the 3 dynamic AR cues and the 4 orientations of the virtual plane. The dynamic AR cue model variable was highly statistically significant ($P<.01$) in all cases, whereas the orientation of the virtual plane was significant only in path 2. It was then decided to study all pairwise comparisons of the 3 dynamic AR cues for a path and a specified orientation, and as the same mentee participated in all 3 AR cues, we used the 2-tailed paired *t* test. For path 4, ANOVA established significant differences among the 3 AR cues. Therefore, a paired *t* test was used to examine statistically significant mean differences over all 3 pairs. Finally, in scenario B, a paired *t* test was used to determine the statistical significance between the 2 dynamic AR cues (hand gestures and virtual tool). In all the above models, the standard model assumptions were violated, and so the response variable was transformed using the natural logarithmic transformation to alleviate the problem. All relevant descriptive statistics and *P* values are reported in the Results section.

Ethical Considerations



Institutional review board approval (MRC-03-23-786) was obtained from the Medical Research Center at Hamad Medical Corporation, Qatar. A research information sheet was used to obtain consent from the participants taking part in the study. All data collected was anonymized and stored securely. The participants enrolled in the study on a voluntary basis and were not provided any financial or other forms of compensation.

Results

All participants successfully completed the tasks in both scenarios. Figure 4 presents the observed results when the mentees received guidance from the mentor in the form of dynamic AR cues. During scenario A, the paths followed by the mentees had improved DTW distances when they were guided by a virtual tool as opposed to hand gestures and a 3D pointer. As shown in Table 3, the reduction was statistically significant when the virtual tool was used by the mentor compared with hand gestures ($P<.01$ in 12/13, 92.3% of the trials) and the 3D pointer ($P<.05$ in 11/13, 84.6% of the trials). This improvement in performance was consistently observed across the three 2D paths in each plane orientation (Figure 4A), as well as the 3D path (Figure 4B).

90°	20.7 (8.0)	12.6 (5.0)	7.4 (2.1)	.03	.03	<.001
Path 3						
0°	25.1 (13.6)	18.8 (8.1)	8.7 (1.9)	.65	.004	.001
30°	21.7 (13.0)	14.3 (5.7)	8.6 (2.2)	.03	.001	<.001
60°	18.0 (8.6)	16.3 (7.0)	7.4 (1.5)	.04	.02	.001
90°	19.2 (8.8)	14.5 (5.4)	6.9 (2.3)	.17	.002	.03
3D path	17.6 (7.3)	12.6 (5.1)	8.4 (1.6)	.08	.03	<.001
Scenario B—angular error (degrees)						
Pose 1	11.0 (4.4)	—[a]	6.9 (4.0)	—	—	.03
Pose 2	13.5 (6.1)	—	7.2 (4.2)	—	—	.01
Pose 3	29.0 (10.4)	—	13.9 (4.3)	—	—	<.001
Pose 4	17.3 (8.1)	—	7.1 (3.4)	—	—	<.001
Pose 5	26.2 (15.0)	—	12.8 (4.5)	—	—	.03
Pose 6	11.5 (6.2)	—	10.1 (3.7)	—	—	.66

[a]Not applicable.

In scenario B, a substantial decrease in angular error was noted when the mentees were guided by the virtual tool as compared with hand gestures ($P<.05$ for 5 out of 6 poses). Pose 6, located toward the edge of the screen, did not have a statistically significant difference in angular error (Figure 4C).

The scores from the NASA-TLX (Figure 4D) suggest that the use of the 3D pointer and the virtual tool was relatively demanding for the mentees compared with hand gestures. However, the overall differences in NASA-TLX scores were not substantial (Table 4).

RenderX

Table . Scores from the NASA Task Load Index questionnaire.

Item	Question	Scale	Hand gestures, mean (SD)	3D pointer, mean (SD)	Virtual tool, mean (SD)
Mental demand	"How mentally demanding were the tasks in both the scenarios?"	1 - 10 (low-high)	3.6 (1.7)	4.4 (1.9)	5.8 (2.4)
Physical demand	"How physically demanding were the tasks in both the scenarios?"	1 - 10 (low-high)	3.6 (2.3)	3.8 (2.0)	4.8 (2.8)
Temporal demand	"How hurried or rushed was the pace of the tasks in both the scenarios?"	1 - 10 (low-high)	2.4 (1.5)	2.6 (1.3)	3.6 (1.5)
Performance	"How successful were you in accomplishing what you were asked to do?"	1 - 10 (perfect-failure)	5.6 (2.3)	4 (1.2)	3.4 (2.1)
Effort	"How hard did you have to work to accomplish your level of performance?"	1 - 10 (low-high)	3.8 (2.2)	4.4 (1.5)	5.2 (2.4)
Frustration	"How insecure, discouraged, irritated, stressed, and annoyed were you?"	1 - 10 (low-high)	3.2 (1.8)	3.8 (1.3)	4.6 (1.8)

Discussion

This study presents an assessment of 3 different dynamic AR cues, namely, hand gestures, a 3D pointer, and a virtual tool, used in telementoring during laparoscopic surgery. Integrating dynamic AR cues is necessary as static AR cues (telestrations) alone cannot fully reproduce the instructions conveyed during in-person guidance. The aim of this user study was to identify the most suitable dynamic AR cue for surgical telementoring. Overall, our results showed that the mentees were able to replicate the motions indicated by the mentor and follow the required path, demonstrating the feasibility of using dynamic AR cues. An important result of this study is that there was an improvement in performance when the mentor used the virtual tool to guide the mentees (as opposed to hand gestures or the 3D pointer). This was depicted in Figures 4A and B, where the nonoverlapping box plots across different plane orientations indicate a significant decrease in the DTW distance during scenario A. This indicates that the mentees could follow the required paths accurately in not only the 2D space but also the 3D space. As a result, it can be inferred that virtual tools would be useful during laparoscopic surgery. Such surgeries are performed in the insufflated body cavity with multiple tissue structures that vary in distance from the laparoscope's distal end. Therefore, having cues that allow for depth perception has the potential to improve accuracy while reducing procedure time and incidence of errors [32]. Similarly, in scenario B, lower angular errors were noted for the poses guided by the virtual tool than for those guided by hand gestures. This is a valuable observation as the ability to communicate and reproduce the precise jaw orientation of a laparoscopic tool is essential for avoiding damage to vital anatomical structures during live surgery [4]. Examples of such surgical steps include placing the initial snip on tissue structure, cutting a vessel, or placing staples for incision closure. Virtual tools would be more efficient compared with hand gestures while guiding the mentee to easily communicate the optimal position and orientation of the sharp scissors used for cystic duct or artery dissection during cholecystectomy. The direction of the curved side of the sharp scissors with respect to anatomical landmarks can be conveyed effortlessly [4]. Similarly, the appropriate orientation of a harmonic scalpel (consisting of an active blade and inactive jaw) can also be conveyed while separating the gallbladder from the liver. Conveying such information is critical as incorrect handling can result in damage to organs and bleeding, compromising patient safety [33].

The proposed work is not intended to replace the use of static 2D cues such as annotations or telestrations during laparoscopic surgical telementoring. The optimal cue for a particular surgical telementoring session can vary with type and frequency of instructions that a mentor (expert surgeon) must convey to a mentee (operating surgeon). This is dependent upon the complexity of the surgical procedure as well as the difference in expertise level between the mentor and mentee. When the mentor and mentee are of comparable expertise, telementoring using audio or static AR cues would be sufficient. Dynamic AR cues can assist in gaining microskills particular to an unfamiliar surgical technique when the mentee already possesses sufficient macroskills such as anatomical expertise [19]. Additionally, a prior review of dynamic AR cues used in minimally invasive surgeries has noted extensive use of surgical tools for telementoring during suturing among medical students and the use of pointers during cholecystectomy procedures among surgical trainees [5]. Further studies with surgeons will help assess the impact of dynamic AR cues in various surgical scenarios in which significant differences in expertise exist

XSL•FO
RenderX

between the mentor (expert surgeon) and mentee (operating surgeon).

Previous studies have shown that mentees report lower workload while receiving instructions using dynamic AR cues than using audio cues alone [3,7]. However, when assessing the workload perceived by the mentees for each of the dynamic AR cues in this study, there was no statistically significant difference between the NASA-TLX scores for hand gestures, the 3D pointer, or the virtual tool. Some of the mentees noted higher mental and physical demand while being guided by the virtual tool than by the other cues. This was attributed to the extra care taken by the mentee to align exactly with the mentor's virtual tool. Although virtual tools might have resulted in a perceived higher demand, the results indicate that the mentees were able to understand the required position and orientation of the tool (which was not conveyed by the other cues). It is important to bear in mind that the use of the NASA-TLX as an outcome measure would receive a relatively lower rating according to the Medical Education Research Study Quality Instrument, indicating a weaker methodological quality, as it measures subjective user perceptions [34]. A reasonable approach would be to conduct multiple trials and observe the difference in perceived workload for each dynamic AR cue over the course of the trials.

Laparoscopic surgery is considered the standard approach for many procedures (such as cholecystectomy and colectomy) due to its advantage for the patient in terms of lower risk of complications and shorter recovery period [6]. Nevertheless, adoption of laparoscopic surgery continues to be limited worldwide due to its steep learning curve and the complex instrument-handling skills required. Given its clear advantage over the open approach, laparoscopic surgery might be initiated without in-person supervision in some countries [35,36]. However, nonmentored laparoscopic surgeries are associated with higher rates of conversion to open surgery and complications and longer hospital stays than mentored ones [36,37]. This is due to the challenges faced by inexperienced surgeons working with an operative view that is drastically different from that in open surgery, resulting in dissection of incorrect layers or improper placement of the initial incision [36]. Telementoring overcomes this challenge by connecting experienced surgeons with the operating surgeon. However, the amount of information that can be transferred between the experienced and operating surgeons is dependent upon the quality of the cues rendered. Dynamic AR cues enhance the information by depicting the exact tool-tissue interaction required during the surgery.

In this study, the dynamic AR cues used by the mentor were displayed to the mentees on a 2D screen. However, a typical surgical field consists of anatomical structures located at varying depth levels. With limited depth perception, it is challenging to accurately convey instructions, especially when the target anatomy is located deep within the operative field. For future work, it would be useful to incorporate multiple cameras to capture and render a 3D model of the mentor's hand. In this way, the mentee will be able to perceive depth while being guided by hand gestures (which is lacking in the current setup). Furthermore, low-cost immersive head-mounted display (HMD) devices (such as the mixed reality–based Meta Quest 3 headset or Apple Vision Pro) could be used by the remote mentor to perceive a stereoscopic view of the surgical field obtained from a 3D laparoscopic camera used at the mentee's side. This would also allow the expert surgeon to convey the dynamic AR cues in a 3D space and better demonstrate the required motions to the operating surgeon. In addition, instead of using a traditional bulky workstation, such as a laptop or desktop connected to external input devices to manipulate dynamic AR cues, these HMD devices incorporate built-in sensors that can directly track hand gestures. The captured hand movements can then be translated into dynamic AR cues in real time, eliminating the need for intermediary input devices. Furthermore, these HMD devices are portable and just need an internet connection to link to the operating room.

Several limitations and future directions should be considered when interpreting the findings of this study. First, this study was limited to 10 participants as mentees due to budget constraints. The primary aim of this study was exploratory in nature, and despite the small sample size, the findings provide preliminary evidence that may help inform and guide future large-scale studies. Second, while previously published articles have already established favorable results while using dynamic AR cues when compared with audio cues alone [6,9,23], it would be nevertheless useful to incorporate audio cues to simulate a real surgical training setting. The audio cues are useful when both mentor and mentee possess comparable surgical macroskills, such as anatomical knowledge, instrument maneuvering, and identification of critical structures. However, when a mentor remotely guides a less experienced mentee through a newly acquired surgical technique, the mentee may not yet have mastered technique-specific microskills, including visual tactility, economy of movement, and tissue handling. In such cases, the overlaid dynamic AR cues are expected to expedite skill acquisition by providing clear, unambiguous visual guidance independent of verbal instruction (audio cue). Third, implementing dynamic AR cues in a live surgical setting where objective clinical outcomes (such as operating time, error rate, or incidence of intraoperative complications) are measured will be required to fully evaluate the effectiveness of using the AR cues. While this study focused on laparoscopic surgery, it would be interesting to explore the application of AR cues for robot-assisted procedures where the surgical instruments have additional degrees of freedom.

In conclusion, this work has indicated that the use of virtual tools as dynamic AR cues results in improved performance compared with hand gestures and 3D pointers. However, there was no significant difference in the perceived workload among the 3 AR cues. Moving forward, further exploration on a multi-institutional scale is recommended. Studies integrating various dynamic AR cues during real-world surgery would also be essential to fully assess the AR cues' clinical value during surgical telementoring.

Abstract

Background: Virtual reality (VR) systems offer promising potential as a controlled platform to investigate human behaviors specifically related to food choices. Yet, little is known about its viability for conducting food choice studies with children, thus limiting the development of public health research.

Objective: This study aimed to investigate the viability of VR technology for understanding children's food choices, focusing specifically on perceptual differences between VR and real-life (RL) settings. We examined how children perceive and interact with food portion sizes and container sizes in VR as compared with an equivalent RL scenario.

Methods: A within-subject, mixed methods study was conducted with 437 children aged 5 - 12 years at a science museum. Participants engaged in a standardized food selection task for a simulated breakfast scenario, choosing portions of cereal and milk in 2 conditions: a head-mounted VR environment and a corresponding RL physical setup. Children's food selection behaviors were quantitatively compared across 3 independent variables: condition (VR vs RL), food healthiness (healthy vs unhealthy options), and container size (small, medium, and large). Qualitative and quantitative data were collected via postsession questionnaires assessing presence, embodiment, and simulator sickness, alongside detailed interaction logs from the VR environment. Data analysis used statistical comparisons and thematic analysis.

Results: The findings revealed both behavioral consistency and significant perceptual differences between the VR and RL conditions. A behavioral similarity was identified, as children served significantly larger portions of unhealthy food compared with healthy food in both conditions. Crucially, a difference was observed in size perception: children struggled to accurately match the size of bowls and glasses between the VR and RL conditions. Furthermore, while children reported low feelings of presence and embodiment within the VR scenario, they demonstrated a high degree of control and engagement in the virtual task.

Conclusions: Our findings suggest that current state-of-the-art VR technology presents limitations in its viability for conducting food choice studies with children, particularly concerning accurate size and volume perception. Based on the findings, we provide 4 practical recommendations to guide the future development of immersive food environments, thereby supporting more reliable and ecologically valid food choice research with young populations.

Introduction

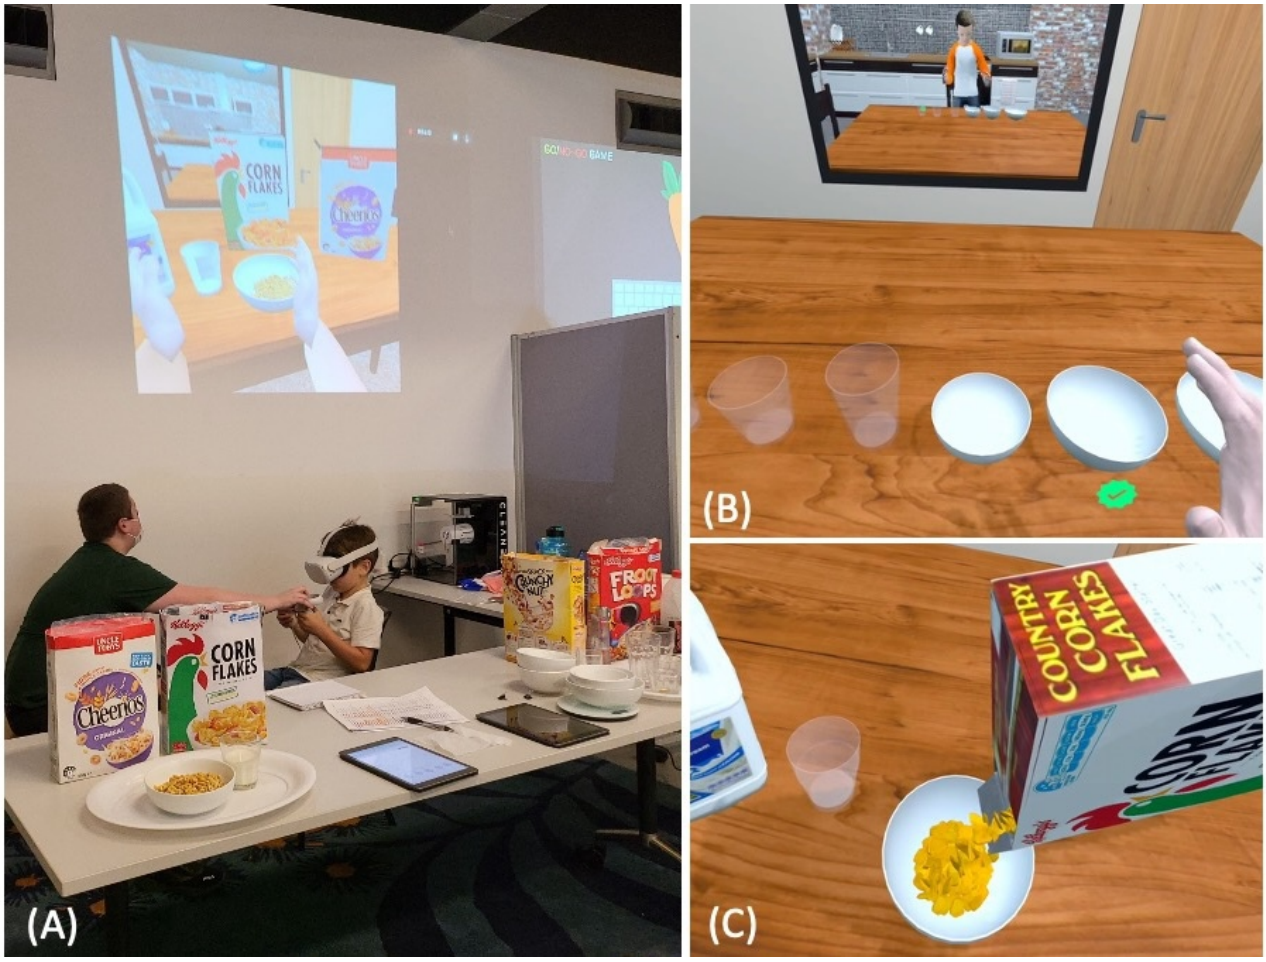
Background

Within the field of human-computer interaction (HCI), there is a growing interest in designing for and around food practices [1-3], underlined by research in dietary-monitoring systems [4,5], technologies for supporting rich conversations during mealtimes [6,7], and awareness about our food ecosystems such as food waste and carbon emission [8]. Recent works further blend food research with interactive experiences, such as combining real-life (RL) eating with virtual reality (VR) gaming experiences [9], encouraging healthy eating practices through tangible systems [10,11], and creating novel food experiences using emerging technologies such as 3D printers [12]. Recently, Covaci and colleagues [13] presented multiple design illustrations, through several co-design workshops, speculating the design of VR-based food experiences for the everyday context. As such, existing research collectively suggests that it

XSL•FO
RenderX

is feasible to enhance eating experiences with interactive technologies for different contexts. In this work, we take a step further and explore the viability of using VR technology as a tool to conduct food choice studies. Unlike existing works that focus on the adult population, we investigate the use of VR technology for younger children (aged 5 - 12 years).

On the other hand, existing literature in the nutrition science domain suggests the viability of using VR systems to conduct food choice studies, due to its capability to simulate realistic environments and food-related cues [14-18]. For instance, studies with adults using VR have highlighted key insights into their personal eating practices and the ways they feed their children [14,15,19]. There is, however, a notable gap in understanding the firsthand experience of children about their food choices. This is a crucial area to explore, as a rich understanding of how children make food choices can guide the development of effective programs that promote positive eating practices from an early age [20,21]. Given the rising rates of childhood obesity in many countries [22,23] and the serious health risks it poses later in life [20,22], this research addresses a timely and important topic.



Engaging children in research can, however, be challenging, as the scientific tasks may seem repetitive or boring to them [24]. Researchers have emphasized the need to employ developmentally appropriate procedures and measures for robust data collection [25] as well as to modernize study procedures to increase participation of children in research [26,27]. VR systems offer an engaging environment for children to learn and explore, and their popularity among children and teenagers is increasing [28,29]. A recent survey suggests that 1 in 5 families with children younger than 17 years has a VR headset [30] and that around 70% of 2 - to 15-year-old children in the United States and United Kingdom reported being fairly or extremely interested in VR [29]. Previous works have investigated the potential of VR to help children deal with painful clinical procedures [31,32], as well as to teach them a wide variety of topics in school settings such as learning to cook [33], Swedish language [34], and science simulations [35]. This research further extends the applications of VR with children by investigating how children interact with simulated food environments in VR and how their interactions differ from RL settings.

This paper investigates the viability of using VR technology to understand children's food choices. We investigated how children perceive food portion sizes and container sizes in VR and how these perceptions differ from RL scenarios. We specifically focused on only 2 tasks—food portioning (ie, how much can the individual serve themselves) and container selection (ie, which container the individual should select)—as these are the basic tasks required to conduct food choice studies. We conducted a controlled trial with 437 children aged 5-12 years at a science museum (as shown in Figure 1). Not all participants completed the same set of tasks; hence, the sample size for each research question (RQ) varied. Employing a within-subjects study design and mixed methods data collection approach, we present a comparative account of participants' interactions in a virtual food environment (ie, a virtual kitchen) with an RL museum setting.

This work makes the following contributions: First, our study investigates the firsthand experience of children in making food decisions related to food portion sizes and container sizes. Our findings showed that children served larger portions of unhealthy food than healthy food in both the VR and RL conditions. Second, we discovered that children struggled to accurately match the size of bowls and glasses between the VR and RL conditions. Both findings raise concerns on the viability of using VR technology for food choice studies. Moreover, our study also revealed that children found the VR experience so engaging and fun that it could potentially compromise the scientific rigor needed for data collection. In response, we present 4 recommendations to guide future development of playful VR experiences for children that can still maintain high scientific standards and data quality. Finally, this work extends HCI practices into nutrition science by exploring a novel application of VR technology as a research tool for conducting food choice studies. By introducing methods for testing concepts such as food portion sizes, container size mapping, and health factors related to food items, we have opened new avenues for HCI researchers and nutrition scientists to create robust and impactful VR systems in the future.

Prior Work

We discuss the related literature around 3 topics: VR as a tool for food research, VR as an engagement tool for children, and children's embodiment in VR.

VR as a Tool for Food Research

Researchers in health and nutrition are just beginning to explore the use of VR technology to study eating habits and food choices [14,16]. This field is still new [36], but initial studies have already shown that VR can create realistic food environments that produce convergent results with RL settings [14,36-38]. In food research, participants often perform the same tasks in VR and real-world settings, allowing researchers to directly compare their choices. These studies use a range of virtual environments, such as virtual buffets [14,15], cafeterias or food courts [39,40], and supermarkets [17,37,38,41], to offer participants a wide range of food options. On the other hand, VR systems also allowed researchers to easily change factors such as food color and texture, food venues (bar or restaurant), and social settings, as per the study requirements. It also provided a way to collect objective data related to food selection such as the order in which items are chosen, portion sizes of different food items, and the total weight of the selected food.

As such, prior research suggests the viability of using VR to conduct food studies [14-18]. Researchers have argued that the realism offered by VR technology addresses the existing issues with traditional measures to record personal food choices [25,42,43]. For instance, assessing food choices through real food is challenging due to the associated high cost of buying real food while also managing food safety (such as food handling) and food preferences (eg, allergies, vegan or vegetarian, etc). Limiting food choices to overcome the cost issues is not a viable solution as it can impact the generalizability of the study findings [43]. On the other hand, conducting studies with fake foods is another potential solution, which allows researchers to include a wide variety of food items for greater experimental control. However, fake foods lack in simulating realistic environments that significantly influence the food choices, hence limiting generalizability and ecological validity of the study findings [42].

To understand the food practices of children, several studies have employed proxy measures and investigated parents' feeding practices [14-16]. Persky and colleagues [15] compared parents' pasta selection for their children in VR versus RL conditions and reported a high correlation. Parents in the study also felt that the VR environment was realistic and that their virtual food choices accurately reflected their RL habits, both in terms of portion size and healthiness. Similarly, another study [44,45] used a VR buffet to raise awareness about childhood obesity among mothers whose children were genetically vulnerable to

XSL•FO
RenderX

being obese in childhood and later. The study was conducted with overweight and obese mothers, where they were required to select food they believed their child would eat through pointing-based interaction in VR. The researchers observed the mothers' decisions and measured the portion sizes they chose and accordingly educated them on appropriate food portion sizes for their children.

There is a limited understanding of the firsthand experiences of children's food selection in a virtual food environment, which this research aims to address. Our work builds upon the recent HCI research [13] that has explored the potential applications of VR for food-related environments. The authors described 18 themes to develop "food metaverse" that can help people connect with food and adopt sustainable practices. To design similar food metaverse experiences for children, it is important to understand their perceptions of food portion sizes and container size mapping, as these are fundamental tasks in any food choice study. Furthermore, by comparing how children perceive and interact with food in both VR and RL, we can determine whether VR is a valid tool for studying this age group. Our goal is to address these gaps by providing a detailed comparison of children's interactions in a virtual food environment versus an RL setting, focusing on portion sizes and container size estimation.

VR as an Engagement Tool for Children

VR has mainly been used as an educational tool to engage children in topics that are otherwise complex to teach in real-world settings. For instance, Gorman and colleagues [33] used VR with 360-degree images and videos to teach middle schoolers about food hygiene and safe cooking practices. The VR setup successfully overcame challenges related to the shortage of cooking facilities and teaching staff and created an engaging classroom where children were highly motivated to learn. In another study, researchers [46] designed a virtual kitchen where 7‐ to 9-year-old children could prepare their breakfast and get relevant feedback on their food choices. The study revealed that VR offered a promising environment, as children enjoyed learning about the nutritional value of various breakfast items. Another work [45] used a VR supermarket to teach 6- to 13-year-olds about the environmental impact of their food choices. The study found that all participants could recall the information presented in text and images format, but only those children older than 10 years were able to fully understand the messages. Interestingly, those who understood the information reported feeling sorry about the negative environmental impact of their food habits and expressed a desire to change their habits for the better. We extend the applications of VR for children beyond education and investigate their interactions with food and containers in a food choice study.

Children's Interactions in VR

A significant amount of works have explored how adults and older adults embody themselves in VR environments for different contexts, such as for physiotherapy training [47], combating social isolation in aged care facilities [48], and for gaming purposes [9]. However, there is a notable gap in understanding how children interact and embody themselves in VR (as also emphasized by a recent review paper) [49]. Among the few studies, Keenaghan and colleagues [50] compared how adults and 5-year-old children perceive different-sized avatars and objects in VR. Participants were asked to estimate sizes of their body and objects in a virtual "tea party" environment. The virtual avatar was manipulated relative to the participant's actual height. The study revealed that the reported degrees of embodiment across adults and children were comparable. Participants' perception of the virtual objects was influenced by their virtual body size, that is, they felt that the virtual objects were bigger when they embodied a smaller body and vice versa in a larger body. The notable finding was that unlike adults, children also felt that their (actual) body size increased in the large body condition; however, they did not report getting smaller in the small body size condition. The authors hypothesized that since children are more familiar with their growing body, they are more likely to notice a change in body size than adults. Also, children mainly reported feeling bigger and not smaller because shrinking of bodies is not a natural phenomenon. Previous research also suggests that children are more sensitive to their own-body representation as they must keep track of a constantly changing and growing body along with other sensory developments [51].

Weijs and colleagues [52] similarly compared a full-body embodiment of adults and 8- to 12-year-old children. The authors investigated participants' responses to synchrony of the avatar's movements (ie, avatar moving with the same or different speed as that of the participants) and appearance of the avatar as human and skeleton. Their study highlighted that both children and adults showed highest ownership for the virtual avatar for the synchronous condition, and that the ownership reduced with increased asynchrony. Also, higher ownership and agency were reported for human avatars than the skeleton avatars by children and adults. The notable difference was that children demonstrated a stronger sense of agency than adults, both with increasing temporal mismatches and with skeleton avatars. The difference in agency (ie, the sense of being in control) suggests the developmental differences in children and adults. Prior research [53] revealed that children aged up to 8 years move from relying solely on visual information to integrating multiple senses to develop a better sense of their own bodies.

In a recent study [54], researchers compared children's perception of human, animal, and anthropomorphized creatures in VR and revealed that the animal avatars received the most positive descriptions from children aged 5-9 years. Since animal creatures are farther away from human-likeness, realistic behaviors were not expected from them. On the other hand, human and anthropomorphized creatures were expected to have highly realistic behaviors. The virtual character's movements, blinking of eyes, and facial features such as head size or hair color were found strange and unreal by children. Similarly, another study [55] investigated the perception of 6- to 8-year-old children related to presence and realism in VR. Through a qualitative study of the VR experience where children swam in a pool with dinosaurs, the study highlighted how VR challenged children's understanding of reality when dinosaurs were treated as real. Children also tested the reality of VR by doing certain activities such as holding breaths and comparing the number of

XSL•FO
RenderX

fish the dinosaurs consumed in VR as opposed to their actual diet. While some children verbally described the VR experience as fake, they still reported physiological and emotional responses to VR exposure. The study concluded that although children knew that dinosaurs were extinct, VR was still able to create alternate perceptions of what is real for them. We take inspiration from these works and further extend the literature on VR by investigating children's perceptions of food and containers in a food choice study. Next, we describe our study design.

Methods

Ethical Considerations

The project was approved by the Deakin University ethics committee (ethics number 2019 - 393), including approval for the use of commercial VR headsets with children younger than the minimum recommended age of 13 years. Consent from parents and assent from children were obtained prior to the study. Once consent was obtained, parents provided the demographic details of the participants at the entry point through a questionnaire. The study was conducted exclusively with child participants. Upon recruitment at the study's entry point, each participant was assigned a unique alphanumeric ID code. This ID was utilized across all data collection platforms—including VR system logs and Qualtrics survey responses—to ensure seamless data integration. All subsequent statistical analyses were conducted using these IDs to maintain participant confidentiality.

Study Design

Our study was a part of a larger children's eating and weight project, which was conducted at a science museum in a metropolitan city in Australia. The museum is popular for featuring interactive installations and exhibitions related to science and technology and aims to expose children to innovation and its societal impact. The project was set up with multiple activities within a dedicated room within the museum, with a single entry and exit point. Our study was one of the activities within the room. Interested families approached the room at the museum, where banners were placed to invite participants. The volunteers introduced the families to the project and the associated activities. All participants, including children and parents, were recruited at the entrance. Parents were informed that VR activity may cause motion sickness, so children with motion sickness history should not participate. However, no parent mentioned any motion sickness history for their children.

To mitigate the risk for this age group, we ensured that the participants used the VR headset in a seated position. Additionally, to help prevent simulation sickness in children, we limited the duration of the VR experience to less than 5 minutes. We used Oculus Quest 2, as the study occurred before the rebranding of Oculus Quest 2 to Meta Quest 2. The study was conducted over 5 consecutive weekends (Saturdays and Sundays) for a total of 10 days over a school holiday period. In total, 437 children aged 5 - 12 (mean 8.2, SD 2.0) years participated in the study. Out of the 437 participants, 175 were female and 190 were male. Gender information for the remaining 72 participants was unavailable, which was attributed to either unstable internet connection at the museum or incomplete demographic information provided by the parents. Since the study was conducted at the museum, we had no control over the gender distribution and allowed all eligible participants to participate in the study. Participants did not receive any monetary compensation for their participation. We also noted that children younger than 16 years had free access to the museum; however, the accompanying parents were required to buy a ticket.

Research Questions

Building upon existing works that highlight the potential of VR technology for conducting food choice research [15,18,46], we designed a VR experience to investigate children's interactions in the virtual food environment. The main RQ we explored in our study was *what factors affect the use of VR as a medium for food choice research with children?* We compared the participants' interactions within a simulated food environment in VR with that of RL setting at the museum.

The main RQ is broken down into different aspects.

1. RQ1: How does VR influence the measurement of key variables in food choice studies (food portion size, container size, and additional characteristics of healthy and unhealthy)?
2. RQ2: How does the children's experience (presence, embodiment, simulator sickness, and repeatability) of being in VR affect its usage as a medium for food choice research?
3. RQ3: How do children's demographic characteristics (gender and age) affect the VR usage as a medium for food choice research?

Study Parameters

The study was designed around the everyday activity of breakfast, as this is when children are most likely to serve themselves food. Participants were asked to imagine that it was breakfast time, and they needed to serve themselves cereal and milk. The 2 main conditions for the study were VR and RL. The setting for the VR condition was a virtual kitchen environment, and the setting for the RL condition was the museum. The independent variables were (1) food healthiness with 2 levels: healthy and unhealthy, and (2) container size with 3 levels: small, medium, and large. Table 1 provides a summary of the study design. These 2 independent variables were applied to 2 food options: cereals and milk. Figure 2 provides a snapshot of the study station.

XSL•FO
RenderX

Table . Summary of our 2×2×3 study design. Food options included breakfast cereal and milk, and container options included bowl and milk.

Independent variable	Levels
Condition	Real life and virtual reality
Food healthiness	Healthy and unhealthy
Container size	Small, medium, and large

Figure 2. A snapshot of the study station for the real-life condition: 3 sizes of bowls and glasses (small, medium, and large), a large plate to prevent milk spillage, a tablet to fill out the questionnaire, and a scale to weigh the results afterward.

Our choice of cereal and milk was guided by their health star rating and sugar content information available on the package: health star rating is a standard method to define the healthiness of a product in our country [56,57]. A large amount of sugar is not desirable in young children, as sugar intake has been associated with potentially adverse consequences, such as dental caries, obesity, and coronary heart diseases, in the long run [58]. Two healthy cereals in the study included Uncle Toby's Cheerios (Health Star Rating of 4 [59] and sugar content as 14.6 g/100 g) and Kellogg's corn flakes (Health Star Rating of 3.5 and sugar content as 10 g/100 g). Two unhealthy cereals included Kellogg's Froot Loops (Health Star Rating of 2 and sugar content as 38.8 g/100 g) and Kellogg's crunchy nuts (Health Star Rating of 2 and sugar content as 35 g/100 g).

For cereals, we also maintained the consistency in shape to avoid any other potential influence on the findings [60]. For example, using dinosaur-shaped cereal can influence children's choice as opposed to using flat-shaped cereals (ibid.). Hence, we selected breakfast cereals of similar shapes for both healthy and unhealthy options. For instance, Uncle Toby's Cheerios (healthy option) and Kellogg's Froot Loops (unhealthy option) both are ring-shaped. Similarly, Kellogg's corn flakes (healthy option) and Kellogg's crunchy nuts (unhealthy option) both are flat.

XSL•FO
RenderX

On the other hand, options for milk included plain milk as a healthy option (with sugar content as 4 g/100 g) and chocolate milk as unhealthy (with sugar content as 10.6 g/100 g). For cereal bowls and milk glasses as containers, we purchased crockery sets (bowls and glasses) with 3 sizes: small, medium, and large from the local department store. Participants were instructed not to consume any food during the RL trial to prevent potential risks related to food allergies and food hygiene.

In the study, we did not ask nor expect participants to distinguish between healthy and unhealthy foods. Instead, the research team randomly assigned children with different food options. The healthiness variable was used mainly to investigate food portion size in RQ1. Consequently, no visual labels were added on the boxes to categorize them as healthy or unhealthy. In previous research, factors such as taste, health, and social settings have all been shown to affect how much food people serve themselves [3,61]. While we did not investigate taste or social influence in our study, we specifically investigated how the health factor impacts food portion size. Some studies suggest that foods with high sugar content are often perceived as tastier than those with less sugar [62], thus making the health-taste-portion size connection relevant for our study.

In the RL condition, products were replenished as needed to maintain consistency across participants. To preserve the structural integrity of the cereal, items were never handled directly; instead, they were poured into and out of the containers, preventing physical breakdown. In contrast, milk was replenished on a daily basis due to its shorter shelf life.

Due to the challenges of letting children handle real food in a public museum, our study adopted a different approach for the RL and VR conditions (more details under “Methodological Challenges” section). In the VR condition, children served the food themselves. In the RL condition, however, a researcher served the food based on the child’s verbal instructions. We made this choice to maintain a level of agency for the child in both conditions. This difference, particularly in how the stop pouring” action was executed (verbally in RL vs by hand movements in VR), does create a confounding variable. However, we expect that it will not impact our results, as RQ1 aims to investigate children’s decision-making process about food portion sizes as a cognitive task and not as a motor skill task of serving food. Therefore, we expect the final portion sizes to be comparable in both conditions.

VR Experience

We designed a virtual environment of a typical home kitchen with a range of food products, crockery, and cutlery along with other typical everyday objects (eg, vase and microwave) to create a realistic environment (Figure 1 provides a summary of the study). Participants appeared as an avatar seated at a kitchen table, with virtual cereal boxes and milk cans within their reach. We used the same cereal and milk brands for both the VR and RL conditions. A virtual bowl and glass were placed in front of the participants on the kitchen table. Participants were required to press the controller buttons to grab an object (bowl, glass, cereal box, and milk can) from the table and tilt the controller to pour cereals and milk into the containers (Figure 1C). We placed a virtual mirror in front of the participant, on the other side of the kitchen table, to induce ownership of the self-avatars [63] (Figure 1B). Using Unity meter units, virtual bowls and glasses were matched with the dimensions of store-bought physical containers for all sizes: small, medium, and large (default scale of 1 unit equals 1 meter).

To calculate the cereal weight in VR, we applied a particle system that provided an estimate weight of each cereal type. We measured the average weight of cereal for each of the 4 types, performed a sample test by measuring the real weight of full and half-full bowls for all sizes, and finally calibrated the measurement values in VR. To calculate the volume of milk, we applied the rate of pouring based on the tilt angle of the milk container to increase the visual content within the virtual glass. We measured the capacity of the physical glasses for full and half-filled and adjusted the visualization of the virtual glasses to match accordingly. The weight of the RL containers (bowls and glasses) was measured prior to the study.

Study Procedure

Before starting the study, we conducted a pilot study with 10 children (4 boys and 6 girls; mean age 8.1, SD 1.9 years) recruited through the researchers’ network. The pilot study was conducted 4 weeks before the final study in a VR laboratory at the university campus to check whether the study tasks were age appropriate and whether the children were able to finish the entire study within 10 minutes. Given that the study took place in a crowded science museum, it was essential for each child to complete the tasks quickly to manage the flow of participants within the large room with multiple study stations. The pilot study confirmed the risk of food spillage as some of the younger pilot participants could not comfortably handle the milk can. Thus, we adopted the procedure for a researcher pouring the milk in the RL condition instead of the children. On the other hand, the data collection questionnaire was revised to minimize the time spent at the VR station. Specifically, we simplified the Likert scales by reducing the number of response categories and reduced the number of questions to ensure that they were developmentally appropriate and easily interpretable for children aged 5 - 12 years (more about questionnaires is discussed under “Data Collection” section).

We employed a within-subjects study design, where all participants were asked to complete the main task of making the breakfast cereal in 2 conditions: VR and RL. For the first condition, participants were given the following instructions:

> *Imagine that you are in your kitchen. It’s a normal school day, and you are preparing breakfast for yourself before you head to school. You will not get to eat again for another 3 hours or so, so prepare yourself a sufficient breakfast. Serve yourself a breakfast cereal and pour yourself a glass of milk to drink.*

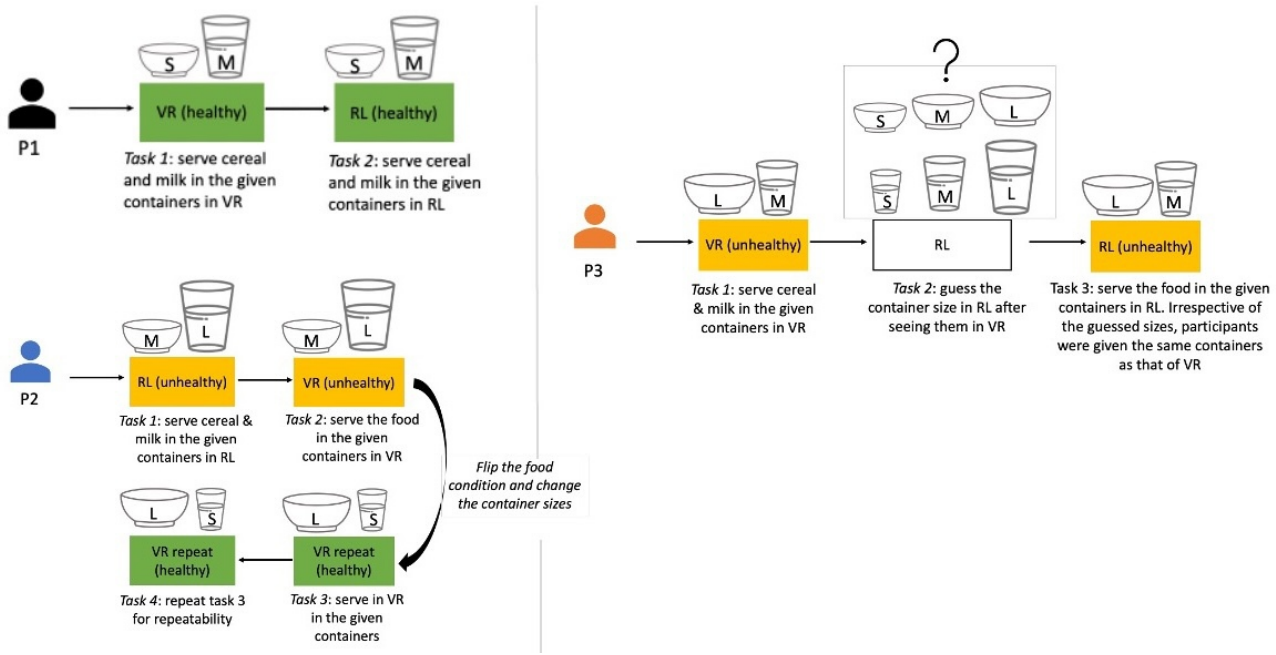
Participants were asked to pour milk and cereal into separate containers, so that we could accurately measure the portion sizes of each item individually. For the second condition, participants received the same instruction to serve the portion size that they would like to eat or drink, with the assumption that it would not have changed from the first condition. The first condition and

XSL•FO
RenderX

the second condition were alternated between VR first–RL second and RL first–VR second.

For the RL condition, participants were asked to sit on the provided chair, accompanied by a researcher. Each participant was assigned to either the healthy or unhealthy food option. The order was alternated to ensure a balanced number of participants in both groups. A bowl and a glass were placed directly in front of them. Participants did not handle the food directly in RL; rather, the researcher poured the food, following their instructions. The researcher first provided the task instructions to the participants and then picked up the selected cereal and started pouring it into the bowl. Participants were asked to say "Stop" when the desired amount was reached. A similar process was repeated for the drink. The researcher slowly poured the food and constantly checked with the children whether the amount was appropriate. After that, the bowl and glass with the food were weighed on a table scale and the data were recorded in Qualtrics. The actual weight of the corresponding container was later subtracted to retain the weight of the poured food content. Milk was measured by weight rather than volume for consistency. All food contents were poured back into their respective containers for reuse. Figure 2 shows the arrangement of the study station for the RL condition.

For the VR condition, participants were first asked to sit comfortably in the provided chair. A researcher assisted the participants in wearing the VR headset (Oculus Quest 2) and 2 handheld controllers. The interpupillary distance of the headset was adjusted for each participant for the best visual clarity, but the adjustment values were not recorded as data. The researcher ensured that the participant remained seated throughout the session for safety purposes, with a protocol in place to stop the session immediately if a child experienced any VR-related discomfort. However, no adverse effects were observed, and all participants successfully finished the session. The researcher explained to the participants how to operate the handheld controllers and interact with the virtual environment. A practice task was completed before starting the study tasks to avoid novelty. In the virtual kitchen, participants were represented as a virtual avatar seated against a table, with gender and skin tone matched according to the researcher's observations. The researcher confirmed whether the participant agreed to the chosen gender and skin tone of the virtual avatar before starting the study procedures.



In the virtual kitchen, participants were asked to wave at themselves (virtual avatar) in the mirror and explore how their movements matched the avatar before beginning with the study tasks. The participants then proceeded to grab the desired cereal box and pour it into the virtual bowl placed in front of them to the desired amount or to match with the previous RL condition. The participants then completed the task of pouring milk (plain or chocolate) into the virtual glass (refer P1 case in Figure 3). Figure 1B and C show the point of view of a participant for the bowl size selection task and cereal-serving task.

A subset of participants was asked to perform additional tasks related to RQ2 (repeatability) and RQ1 (container size estimation). For instance (refer to P2 case in Figure 3), within the same VR session, participants were first instructed to serve the food in RL and VR. Then they were instructed to serve again by imagining that they were serving breakfast for a subsequent day—with the goal of matching the exact portion of the food items as performed in steps 1 and 2. This task contributed data collection for RQ2 (repeatability). To avoid learning effects, they were presented with a different set of cereal and milk, and container sizes.

To answer RQ1 about container size estimation (refer P3 case in Figure 3), participants in the first condition were presented with a specific-sized bowl and glass. In the second condition (VR or RL), they were presented with 3 different sizes of bowls and glasses and were asked to identify the sizes they had seen in the first condition. "VR first" refers to the condition when participants were initially shown the bowl or glass in VR condition and then were asked to guess the container size in RL condition and vice versa for "RL first." The sizes selected by participants were recorded. Regardless of their answer, the correct-sized bowl and glass were presented to them to help them complete the tasks for the second condition. In total, participants spent less than 5 minutes in VR and less than 10 minutes in total.

XSL•FO
RenderX

Figure 3. Sample order of tasks for 3 participants completing VR and RL conditions. P1 completed only the main task related to RQ1 portion size for healthy condition. P2 first performed the portion size task and then completed additional tasks to serve the same amount of food in VR for tasks 3 and 4 for repeatability testing (RQ2). P3 was asked to guess the glass and bowl sizes (RQ1) before performing the portion size task (RQ1). Sizes of bowls and glasses were randomized and counterbalanced. RL: real-life; L: large; M: medium; RQ: research question; S: small; VR: virtual reality.

Data collection procedures varied across RQs to accommodate the high volume of museum visitors. While the P1 case was conducted during peak hours, the P2 and P3 cases (Figure 3) were restricted to off-peak periods (such as late afternoons) as they required additional time and physical setup. This scheduling was essential to manage the long queues for the popular VR exhibit and ensure a steady participant flow. Consequently, these variations in study design resulted in distinct participant pools for each RQ, as detailed in Table 2.

XSL•FO
RenderX

Table . Summary of data points for each research question (RQ).

Research questions and subtasks	Participants, n	Final data points after cleaning
RQ 1		
Food portion size	317	• 317 data points for cereal (both VR[a] and RL[b] conditions) • 305 data points for milk (both VR and RL conditions)
Food healthiness	284	• 284 data points for cereal in RL condition • 264 data points for cereal in VR condition • 276 data points for milk in both VR and RL conditions
Container size	195	• 195 data points for bowl size guesses (72 RL first and 123 VR first) • 193 data points for glass size guesses (70 RL first and 123 VR first)
RQ 2		
Presence, embodiment, and simulator sickness	411	• 411 total responses: 240 responses from age group of 5-8 years, and 171 responses from age group of 9 - 12 years.
Repeatability	140	• 134 data points for cereal and 140 data points for milk—all data points were only in the VR conditions
RQ 3		
Demographics	420	• 180 male and 169 female participants; gender data not recorded for 71 participants • 245 participants in age group of 5 - 8 years; 175 participants in age group of 9 - 12 years • 195 data points for glass size estimation; 193 data points for bowl size estimation

[a]VR: virtual reality.

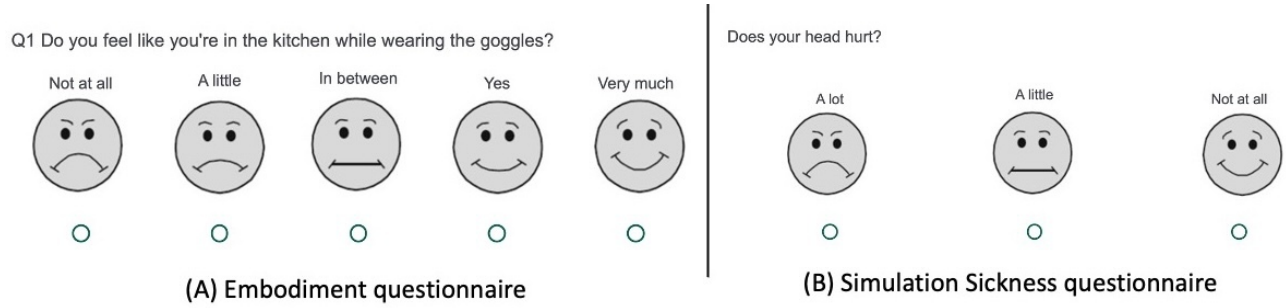
[b]RL: real-life.

Methodological Challenges

Our study procedures were guided by the challenges of conducting a controlled study in a real-world setting with children. Challenges of testing prototypes in real-world settings and the need to adapt study design have been highlighted for field studies [64], which also guided our study design. First, we aimed at reducing the VR exposure time for children to manage potential simulation sickness. Hence, we developed short VR activities for children and simpler and shorter questionnaires for data collection.

Second, to ensure a smooth and safe experience in the busy science museum, we made a few adjustments to the study tasks for RL and VR conditions that were guided by the pilot testing. Unlike in VR, participants in the RL setting were not allowed to handle the food directly. This approach not only safeguarded our electronic equipment from food spillage but also aligns with how parents typically serve food to young children to avoid spillage. By having a researcher serve the food, we were also able to mitigate risks related to food allergies and hygiene.

Finally, due to the different affordances of virtual and real worlds, we used a mirror in VR as it is a common strategy [63] to induce ownership of a virtual body. Participants can connect to the virtual avatar by seeing their mirror reflection and associating their bodily movements with the avatar. However, in RL, it was not natural to see yourself in a mirror in a public setting (ie, amidst the crowd) when participants could directly see their body movements without any interruption. Hence, a mirror was not included in RL.



Data Collection

A researcher carried a tablet with Qualtrics questionnaires for data collection. Demographics information was noted based on the researcher's observations of the participant's gender, skin tone, and hair color, which were used to match the VR avatar. Participants' demographic details (age and gender) were collected from their parents during recruitment. After completing the study tasks, participants sat down with a researcher to complete a questionnaire with 17 questions structured in the following way: (1) 1 question on previous experience with VR; (2) 8 combined presence and embodiment questions, including 3 questions (Q1-Q3) about presence adopted from the iGroup Presence Questionnaire [65] and 5 questions (Q4-Q8) about embodiment adopted from Gonzalez-Franco [66]; (3) 7 questions on discomfort felt in completing the activity through an adopted

XSL•FO
RenderX

sickness questionnaire [67,68]; and finally, (4) 1 question on subjective experience with VR. We combined the presence and embodiment questionnaires and reduced the number of questions to simplify data collection from our participants and to keep the study length manageable for children. The researcher read each question to the participants while showing the tablet with the visual Likert scales, as shown in Figure 4, and asked the participants to touch the desired option. The researcher also asked the participant to verbally explain their reasoning wherever relevant, which were noted down as a response to the last question. Researchers' observations were also noted through a separate Qualtrics form.

Figure 4. Snapshots of visual scales for (A) embodiment questionnaire and (B) Simulator Sickness questionnaire.

Presence, embodiment, and sickness questions followed a visual scale as shown in Figure 4A. For the presence and embodiment questionnaire, the Likert scale was coded as not at all=1, a little=2, in between=3, yes=4, and very much=5, while the Likert scale for the Simulator Sickness questionnaire was coded as not at all=1, a little=2, and a lot=3. The Likert scale for presence and embodiment was reduced from a 7-point scale to a 5-point scale, while the sickness questionnaire was reduced from a 4-point scale to a 3-point scale. These changes were guided by our pilot testing with children, where children naturally used the descriptors—not at all, a little, and a lot—to respond to presence-, embodiment-, and sickness-related questions. These changes are aligned with a previous study [69], which emphasizes the importance of using simple and visual scales when designing questionnaires for children.

Study variables related to the virtual kitchen were recorded in the VR headset as a csv file. The csv files were transferred from the headset to a safe storage at the end of the day. The csv included data related to study condition (VR or RL), food type (healthy or unhealthy), given cereal type (Froot Loops and crunchy nuts as unhealthy cereals; Cheerios and cornflakes as healthy cereals), given milk type (chocolate milk as unhealthy option and plain milk as healthy option), and size of the given bowl or glass (small, medium, and large). These data also included the cereal weight (in g) poured in the virtual bowl, milk weight (in g) poured in the virtual glass, guess made by the participant about the container size (as small, medium, and large), and time taken to pour cereal or milk. For the RL condition, the researcher manually maintained an Excel sheet to record participants' selection such as cereal weight poured in the bowl, milk weight poured in the glass, and guess made by the participant about the container size.

Data Analysis

To answer our RQs, we conducted statistical tests using STATA (version 17; StataCorp LLC) on the data collected through the VR headset. We conducted chi-square tests, correlations, 2-tailed *t* tests, and kappa analysis to compare the level of agreement between study parameters. Kappa statistics [70] is more suitable for assessing agreement when multiple categorical factors are involved. Agreement cannot be measured through a chi-square test or a regression test, as they can only suggest correlation between the outcome and independent variables. All significant results are reported in the "Results" section. Descriptive analysis was conducted to analyze presence, embodiment, and simulator sickness collected through Qualtrics. Finally, we conducted deductive thematic analysis [71] on the subjective data collected through the researcher's notes in Qualtrics, and participants' responses on the last question in the poststudy questionnaire. Thematic analysis was conducted to mainly complement the findings gathered from the quantitative analysis, as per the mixed methods approach [72]. Initially, the first author (DA) created a separate Excel workbook with participants' quotes and researchers' notes, which had a total of 63 entries. She then coded the 63 entries deductively around the RQs, with code names as kitchen characteristics, avatar characteristics, presence, sickness, VR experience, VR issues, study tasks, and other issues. After finalizing the quantitative analysis, the first (DA) and second authors (TH) worked together to select the best representing quotes for the generated quantitative insights.

Table 2 presents a summary of the data points that guided all 4 RQs. Data were cleaned by excluding incomplete records and identifying outliers based on physical plausibility. Data points were discarded if the poured volume exceeded the maximum capacity of the assigned container (small, medium, or large). These logical bounds ensured that the final dataset included only realistic serving behaviors. To establish a baseline for outlier detection, the maximum capacity for each of the 3 container sizes (small, medium, and large) was determined by measuring the physical weight of the bowls and glasses when filled to capacity with cereal and milk. Consequently, the total number of valid data points (column 3 in Table 2) differs from the initial number of recruited participants. Because each child performed tasks in both VR and RL environments, they contributed multiple data points to the final dataset. In total, 437 participants contributed data to this study, with each participant contributing to 1 or multiple research data points. Hence, Table 2 distinguishes between the participant count and the valid data points used for analysis in each condition.

To address RQ1 related to food portion size, a paired 2-sample *t* test was conducted to find relations between the amount of

XSL•FO
RenderX

food (milk or cereal) poured by the participants in VR and RL conditions. A total of 317 data points were used for cereal and 305 data points were used for milk.

To address RQ1 regarding food healthiness, we conducted a 2-sample *t* test assuming equal variances to compare the weight of unhealthy and healthy cereal and milk in both conditions. Healthy and unhealthy portion sizes were compared separately for RL and VR conditions. We had 284 data points for cereal in the RL condition, 264 data points for cereal in the VR condition, and 276 data points for milk in both VR and RL conditions.

In response to RQ1 regarding the container size, we analyzed how close participants' guesses were to the correct container size. We first performed a weighted kappa analysis on the study conditions (VR or RL) and participants' guesses to the container (bowl and glass) size. For weighted kappa analysis, we used weighted metrics for calculating agreement in a way that a perfect agreement was assigned a 100% weight, while the next closest option received a 75% score, and the third option received zero weight. We also conducted a chi-square test to supplement the results of weighted kappa analysis. There were 195 data points for bowl size guesses, and 193 data points for glass size guesses.

To analyze RQ2 regarding presence, embodiment, and sickness, we excluded incomplete responses, which led to a total of 411 responses. We analyzed these responses for 2 age groups: those aged 5 - 8 years (240 responses) and 9 - 12 years (171 responses). We split our analysis into 2 groups, as previous research suggests that children undergo different motor skill development at different ages [53,73,74], which may influence their interactions within VR.

The Likert responses were coded as numeric values from 1 to 5 for "Not at all" to "Very much," and from 1 to 3 for "Not at all" to "A lot." We calculated the mean of the responses for all questions under the same category. For instance, the average of Q1, Q2, and Q3 scores formulated the score for "Sense of Presence." Finally, an embodiment score was calculated by taking an average of the responses for 3 categories: body ownership, self-location, and control.

To investigate the repeatability of tasks in VR (RQ2), we had 134 data points for cereal and 140 data points for milk. A paired 2-sample *t* test was performed to compare the amount of cereal and milk poured by participants in VR.

Finally, for RQ3 regarding the effect of demographics, we again conducted kappa analysis to find the influence of age and gender on the amount of food (milk or cereal) served in VR and RL conditions, as well as in guessing the container sizes. The analysis was done separately for boys and girls, younger than and older than 8 years, that is, aged 5 - 8 and 9 - 12 years. There were 306 data points for cereal and 295 data points for milk.

Results

We structure our findings around the 3 RQs. A total of 437 children participated in our VR study. Out of 437 participants, 328 children had no experience with VR and 109 children had used VR at least once.

RQ1: Food Portion Size (Being Served in RL Versus Serving Themselves in VR)

As per the paired 2-sample *t* test, the mean value of milk poured in VR is 242.5 (SD 8623.6) g and in RL is 215.9 (SD 9073.9) g. For both conditions, the SDs for the mean value of milk poured are high. The high SDs are due to the high variability of milk content poured by the participants. The mean value of milk poured in VR was significantly higher than in RL (t_{304}=3.87; P<.001).

We also conducted the paired 2-sample *t* test to understand the order effects (VR first vs RL first) on milk portion sizes. There was a significant difference for participants who completed VR first (t_{147}=6.37; P<.001). Children poured more milk in VR (mean 258.9, SD 9153.2 g) than in RL (mean 212.5, SD 9827 g) when they completed the VR condition first. However, if the participants completed the RL condition first, there was no significant difference in milk weight between the 2 conditions.

We conducted a paired 2-sample *t* test, which shows that the mean value of cereal weight in VR (mean 54.1, SD 796.3 g) was significantly higher than the mean value of cereal weight in RL (mean 41, SD 388.6 g; t_{316}=8.16; P<.001). This shows that children served themselves more cereal in VR than what they were served by the researcher in RL. The SD for the mean value of cereal poured is much higher in the VR condition than in RL.

We conducted the paired 2-sample *t* test to understand the order effects (VR first vs RL first) for cereal. Regardless of which condition was completed first, there was a significant difference that participants served more cereal in VR than in RL. For participants who completed the VR condition first, cereal weight in VR (mean 57.2, SD 826.7 g) was significantly higher than in RL (mean 43, SD 454.7 g; t_{147}=5.71; P<.001). For participants who completed the RL condition first, cereal weight in VR (mean 51.3, SD 758 g) was significantly higher than in RL (mean 39.1, SD 323.7 g; t_{165}=5.83; P<.001).

RQ1: Food Healthiness

As per a 2-sample *t* test, the mean value of unhealthy cereal poured in RL (mean 48.4, SD 461.1 g) was significantly higher than the mean value of healthy cereal weight in RL (mean 34.2, SD 258.8 g; t_{284}=6.31; P<.001). This shows that participants served themselves more portions of unhealthy cereal in RL than the healthy cereals. Similarly, the mean value of unhealthy cereal poured in VR (mean 63.1, SD 934.1 g) was significantly higher than the mean value of healthy cereal poured in VR (mean 41.1, SD 225.2 g; t_{264}=−7.47; P<.001). This shows that participants served themselves more portions of unhealthy cereals in VR than the healthy cereals. High values of SD are due to the large variability of the food selection made by children. The healthiness of the milk had no significant effect on the serving sizes chosen by the participants in either the VR or RL conditions. These findings confirm that children's attitude toward food healthiness is similar in both VR and RL.

XSL•FO
RenderX

RQ1: Container Sizes

The weighted kappa statistics showed no agreement (κ=0.34) between the given and guessed size of bowls between VR and RL conditions. This shows that children cannot accurately match the size of the serving bowl between VR and RL. Participants made more incorrect guesses in VR first than in RL first, with a correct to incorrect distribution ratio of 59:64 and 46:26, respectively, as shown in Table 3. Chi-square test showed significant differences for small-sized bowls ($\chi^2_{1,\ 53}$=12.0; *P*=.001). This suggests that children cannot match the small-sized containers in RL correctly if the bowl is first shown in VR. No significant differences were found for medium-sized and large-sized bowls. These results suggest that children are better at matching the medium-sized containers, regardless of whether they saw them in VR or RL first.

Table . Guesses for bowl and glass based on conditions. VR[a] first means that participants were shown the bowl or glass in the VR condition first and then were asked to guess the size in the RL[b] condition.

Conditions	Small (correct/incorrect)	Medium (correct/incorrect)	Large (correct/incorrect)	Total (correct/incorrect)
Bowl VR first	9/29	37/9	13/26	59/64
Bowl RL first	12/3	21/10	13/13	46/26
Glass VR first	10/32	17/26	20/18	47/76
Glass RL first	11/10	19/9	13/8	43/27

[a]VR: virtual reality.

[b]RL: real-life.

For glass size guesses, we similarly performed weighted kappa analysis and found no agreements (κ=0.20) between the given and guessed size for the VR and RL conditions. This shows that children cannot accurately match the size of the serving glass between VR and RL. Similar to the bowl size condition, participants made more errors in guessing glass sizes in the VR-first condition than in the RL-first condition, with distribution between correct and incorrect guesses as 47:76 and 43:27, respectively. Chi-square test showed nonsignificant differences for all sizes of the glass. The results (correct-to-incorrect ratio for different sizes) in Table 3 suggest that children are better at matching different-sized glasses in VR after first seeing them in RL.

RQ2: Presence, Embodiment, and Simulator Sickness

Table 4 presents the presence and embodiment scores for 2 age groups: those aged 5 - 8 years (n=240) and 9 - 12 years (n=171). The overall scores for each factor are similar for both groups. The mean embodiment score of 3.1 suggests that participants felt a moderate or ambiguous sense of ownership and control regarding their virtual body and its location in VR. Similarly, Presence received the mean score value of 2.9 for both groups, suggesting that participants partially felt that they were present in VR. On the other hand, control received a relatively higher mean score for both groups: 3.5 for those aged 5 - 8 years and 3.6 for those aged 9 - 12 years.

We also analyzed the simulator sickness score for the 2 age groups: those aged 5 - 8 years and 9 - 12 years and found similar results. Table 5 presents a cumulative mean score of 1.10 (SD 0.32) and 1.12 (SD 0.33) for younger and older children, respectively. The low sickness scores suggest that participants did not feel any simulation sickness in VR. Some participants, however, mentioned feeling eye fatigue after the study.

XSL•FO
RenderX

Table . Presence (denoted as P) and embodiment (denoted as E) scores on the Likert scale (1 being "Not at all" to 5 being "Very much") for age groups of 5 - 8 and 9 - 12 years.

Factors	Questions	Age group (5 - 8 years), mean (SD)	Age group (9 - 12 years), mean (SD)
P: Presence	• Q1. Do you feel like you're in a kitchen while wearing the goggles? • Q2: Do you feel like you're still in the museum? • Q3: Does the kitchen feel real?	2.9 (1.1)	2.9 (1.1)
E: Body ownership	• Q4: Does the virtual hand feel like your hand? • Q5: Does the virtual body feel like your body?	2.6 (1.4)	2.5 (1.2)
E: Self-location	• Q6: Do the virtual hands appear where your hands are? • Q7: Does the virtual body appear where your body is?	3.2 (1.1)	3.4 (1.0)
E: Control	• Q8: Do the virtual hands move like you want them to?	3.5 (1.0)	3.6 (0.95)
Embodiment score (Inclusive of Q4-Q8)		3.1 (1.2)	3.2 (1.0)

Table . Sickness score on the Likert scale (1 being "Not at all" to 3 being "A lot") for the age group of 5 - 8 and 9 - 12 years.

Question ID	Question	Age group (5 - 8 years), mean (SD)	Age group (9 - 12 years), mean (SD)
S1	Do you feel sick?	1.1 (0.4)	1.1 (0.2)
S2	Does your head hurt?	1.1 (0.4)	1.1 (0.3)
S3	Do your eyes hurt?	1.1 (0.3)	1.2 (0.4)
S4	Is your stomach upset?	1.1 (0.3)	1.1 (0.3)
S5	Are you dizzy with your eyes open?	1.2 (0.4)	1.2 (0.4)
S6	Are you dizzy with your eyes closed?	1.1 (0.3)	1.1 (0.3)
S7	Do you feel like burping at all?	1.1 (0.2)	1.1 (0.4)
Sickness score (Inclusive of S1-S7)		1.1 (0.3)	1.1 (0.3)

RQ2: Repeatability

A paired 2-sample *t* test did not show any significant difference between the first and second trials for pouring milk (t_{139}=0.19; *P*=.84) and cereals (t_{133}=0.77; *P*=.44). These values could suggest that VR offers a reliable test-retest mechanism for food and drink with respect to portion size.

RQ3: Demographics

Kappa statistics were used to assess the level of agreement between VR and RL container size estimations across different demographic subgroups. The results indicated no significant agreement between the 2 conditions when analyzed by age or gender (see Table 6 for details). Similarly, no significant agreement was found between VR and RL food portion sizes across these age and gender groups.

Table . Summary of kappa statistics for container size estimation.[a]

	κ values for glass size estimation	κ values for bowl size estimation
Male	0.15 (n=108)	0.39 (n=107)
Female	0.28 (n=87)	0.26 (n=86)
5 - to 8-year-olds	0.18 (n=120)	0.33 (n=118)
9 - to 12-year-olds	0.24 (n=75)	0.35 (n=75)

[a]All κ values are less than 0.40 and hence considered small.

Qualitative Results

To better understand the quantitative findings presented in the previous section, now we present the qualitative findings that were generated from participants' responses and researchers' notes.

Higher Food Portion Sizes in VR

We found multiple reasons for higher food portion sizes in VR than in RL (RQ1). First, there is no sense of weight in VR, such as the weight of a milk can or serving bowl. The lack of weight in VR led to a "mismatch" in motor expectations. For instance, when lifting the virtual 2-liter milk can, participants often overcompensated for its expected weight, leading to exaggerated movements and accidental spilling. We included any food that landed in the bowl or glass in our final measurements because these spills were not technical errors or outliers; rather, they were a fundamental result of the participant's interactions with the VR interface. Removing them would have artificially inflated the accuracy of the VR condition.

Second, the VR food environment was found fun by participants, where they were intrigued by the novelty of the VR and/or the task presented. Participants turned the simple task of pouring food into a playful activity, where they continued pouring to overflow the containers. This is evident by high SD values for cereal and milk portion sizes in VR as compared with the RL condition (as discussed under section "RQ1: Food Portion Size"). As such, children enjoyed the freedom to interact with food in VR and tried different activities to test the virtual environment (eg, throwing containers, turning containers over to check gravity, etc). Although participants received identical instructions to serve themselves food in both conditions (VR and RL), significant variations in portion size were observed. These discrepancies likely reflect differences in how the younger cohort interpreted or retained instructions across environments.

Finally, since the children did not handle real food in RL, this pseudopouring could have created a difference. For example, participants might not want to be judged by the researcher on their intake and hence agreed on smaller portions of food in RL. Interestingly, we identified an *order effect* specifically for milk portions: participants who completed the RL condition first were more likely to replicate similar volumes in VR. This suggests that the visual transparency of the RL glassware provided a sensory anchor that guided subsequent actions in VR. In contrast, when the VR condition was performed first, the lack of haptic weight, the playful nature of the environment, and different perception of size in VR [75] might have led to significantly larger milk portions that did not align with subsequent RL servings. The RL bowl, on the other hand, was opaque; hence, the visual guidance was limited to influence participants' behaviors in VR.

Lower Presence and Embodiment in VR

In our study, presence in the VR experience and embodiment of the VR avatar received lower scores from the participants (RQ2). In the poststudy questionnaire, many participants commented that the virtual kitchen did not resemble the kitchen at their home. As said by one of the participants, "It's not my own kitchen!." Another mentioned, "The table wasn't like a kitchen table." Participants looked at how realistic the kitchen and the surroundings were, and the limitations with real-world resemblance reduced their sense of presence in the virtual kitchen. The participants strongly felt that they were in the museum while doing the VR activity. The concept of the virtual world was new to them, and they could not imagine being at 2 places—both in the real and virtual worlds simultaneously.

The low score for the control factor for 5- to 8-year-olds is in line with our observations, as younger children could not use the controllers effectively. They found it challenging to navigate the VR tasks through controller buttons and movements. On the other hand, presence received the same scores from both age groups, and self-location was found higher in older children than in the younger age group (5-8 years).

Low scores for body ownership suggest that participants did not feel embodied with the VR avatar. Participants provided comments on avatar resemblance, physicality, and fidelity. One participant mentioned in the poststudy questionnaire, "Hands do not feel real because real hands can't go through the table." Another participant commented on the nonhuman characteristics of the avatar: "The boy [avatar] did not blink. It looked like a ghost." One participant noted in the questionnaire: "The body feels like a cartoon. You can't feel the hands; you can't move the fingers." Participants were looking for sensory sensations in their hands while doing actions in VR, and perfect matching of the virtual avatar with their body characteristics (eg, skin color, hand size, body size, etc)—the absence of which reduced their ownership of the virtual body.

Discussion

Principal Findings

Our study investigated the potential of using VR to conduct food choice studies with children. We examined their perception of food characteristics (portion size and container size) and their experience of being in VR (embodiment, presence, and repeatability) and compared them with the RL interactions at a museum. We found key differences in terms of food portion sizes (RQ1) as children served themselves more food in VR than in RL settings, along with some similarities as children served themselves more portions of unhealthy food in both VR and RL. For container size mapping (RQ1), we found that children were good at matching the medium-sized bowls more accurately, regardless of whether they saw them in VR or RL first, and they are better at matching different-sized glasses in VR after first seeing them in RL. On the other hand, presence and embodiment scores (RQ2) were found low, whereas control was higher for both age groups of 5 - 8 and 9 - 12 years. Additionally, VR qualified the test-retest mechanism (RQ2) for both food and drink, as children were able to repeat the same tasks in VR. Finally, we found no influence of demographics on container size estimation or food portion size (RQ3).

Our study revealed that the effectiveness of a virtual food environment is influenced by factors related to both VR's affordances and the study's setting. These factors include the differences in handling food in VR and RL conditions, level of engagement in VR versus RL, and the limitations of VR in

XSL•FO
RenderX

supporting tactile and sensorial interactions. These differences highlight how VR, as a novel interaction medium, offers a distinct experience from RL surroundings, due to which a direct mimicry of RL interactions is neither feasible nor should be expected. The study also highlighted challenges related to ensuring data accuracy with VR and inquiring about the real and virtual worlds in the questionnaire. Consequently, our study suggests that the current form of VR is not suitable for conducting food choice studies with children. Next, we discuss our findings into 2 themes and present 4 design recommendations to guide effective VR experiences for this research context in future.

Playfulness Versus Science

Overview

Our results showed that children served themselves more food (both cereals and milk) in VR than in RL (RQ1). The SD was also much higher for VR than for RL, likely because children found the VR environment engaging and playful, wherein they dismissed the study instructions to explore the VR space (such as testing how food would overflow). Conversely, in RL, children were assisted by a researcher during the pouring tasks, which limited their opportunities for play. Despite the playful behavior in VR, we found that participants in both conditions served themselves more unhealthy food. This suggests that the differences in food-handling methods did not influence the children's overall food choices.

While extending the familiarization phase to mitigate the novelty effect may seem beneficial, it presents significant risks regarding participant fatigue and disengagement, particularly within the 5 - 12 years age demographic. Prolonged exposure to VR environments can be cognitively taxing for younger children. Consequently, we used a brief orientation to ensure that participants were proficient with the mechanics while maintaining the focus required for reliable data collection. This approach allowed us to capture more authentic behavior before the onset of boredom or cognitive exhaustion.

Prior work has shown that VR can put children in a positive mindset, even during uncomfortable medical therapy [32]. Another study [76] explored the balance between playfulness and learning, in which playfulness is a conceptualization of intrinsic motivation, suspension of reality, and internal locus of control. In our study, the lack of consequences for actions in VR amplified 2 of these aspects of playfulness: suspension of reality and internal locus of control. Children enjoyed the VR environment and the freedom of controlling their food serving without supervision increased their excitement. Research on ethical practices of involving children with VR [77] highlighted that children are easily excitable within VR worlds; hence, their exposure should be limited. We observed this effect firsthand, although our virtual environment was a kitchen and not designed to be explicitly playful. The excitement for the VR experiences was also evident by the fact that our study station was the most popular among all other stations in the study room and still children were happy to wait for their turn.

While playfulness increased the likability of VR among children, it raised challenges for using it as a scientific tool. Engagement came at the cost of accuracy and precision, diminishing the quality of the data we collected on food selection. These insights raise important questions about how to use VR for scientific studies with children, for which we provide 2 guidelines next.

Recommendation 1: Design Supervised VR Food Experiences

To achieve greater validity in food choice studies with children, we suggest developing supervised VR food experiences that include a moderator in the virtual environment. The moderator, who could be a member of the research team, could guide children through the required activities such as selecting food or containers. While some attempts have been made to develop supervised VR experiences, for example, to encourage equal participation in moderated online meetings [78], engaging children in supervised VR experiences for scientific activities has not received any attention yet.

The role of the moderator and their interactions within the environment must be carefully considered, as they should not overshadow the children's interactions in the virtual food environment. Additionally, it is also important to explore how a moderator could be embodied as an avatar (eg, humanoid or nonhumanoid) to encourage greater engagement from children of different ages. Having a moderator might lead to altered behavior, which aligns with the existing literature on the Hawthorne effect [79,80]. However, as per Slater [81], there are always a multitude of variables that could potentially influence the results, and he recommended using data triangulation—which could be employed when designing and testing supervised VR food experiences for children.

Recommendation 2: Design Gamified VR Food Experiences for Children

Building on the insights from our study that VR was a fun experience for children, we suggest developing gamified VR experiences. Recent research has used gamified VR to prepare adolescents (aged 10 - 16 years) for the rigors of magnetic resonance imaging scans [82]. By engaging in a "statue game" with a virtual panda, children practiced physical movements that mirrored the scan procedure, such as reclining on a bed in synchronization with the virtual character. This study demonstrated that interactive VR environments, combined with real-time feedback, effectively increase task compliance and minimize the involuntary motion that often compromises medical imaging. Gamified VR experiences could support children's intrinsic motivation to find play in everyday activities [76,83]. However, such experiences must be carefully designed so that the game elements encourage children to perform the required tasks more accurately and discourage behaviors that go against the study goals. Points and award systems can be used to positively reinforce children within the game. For instance, players could receive points based on how cleanly (ie, without any spillage) they perform a pouring task in VR. Consequently, gamification would not only increase children's willingness to perform the task but also enable researchers to use the virtual medium more appropriately.

"It's Not My Own Kitchen!": Presence and Embodiment

Overview

Our study revealed that children have a high threshold for realism with both their virtual avatars and the VR environment. The lack of realism created issues, as children struggled to embody the virtual avatar and did not feel present in the virtual kitchen (RQ2, Table 4). The participants' behavior in our study is typical of the Goldilocks problem [84]. In the popular children's story, Goldilocks seeks a chair and porridge that are "just right"—not too big or too small, not too hot or too cold. Similarly, our participants desired a virtual body avatar and kitchen setting that felt "just right" to them. This is an age-appropriate behavior, as children (unlike adults) engage in an internal dialogue to identify objects based on their prior knowledge (ibid.).

For embodiment, Slater [81] explained the differences in embodiment levels across age groups by looking at the biases we develop as we get older. The authors argued that as adults, our concept of "real" in VR is biased. Since adults already know the limitations of the technology, we are more likely to accept certain nonrealistic aspects of a virtual world as being "realistic" enough. Likewise, adults understand that the behavior of virtual objects may deviate from the real world, and they would still find it an acceptable interactive experience.

Our findings are in line with prior works [52,54,55], as they all highlight the importance of human-like avatars for children to feel embodied in VR. For example, Liao and colleagues [55] also reported low embodiment in a study with 6 - to 8-year-old children, as the VR experience was described as not real. However, physiological and emotional responses collected during that study suggested the children were immersed in the virtual environment. Research on the cognitive development of children [85] suggests that younger children decipher between "real" and "unreal" based on their prior perception and reasoning of their surrounding world. Our study confirmed this observation, as participants still found the VR experience very engaging despite providing low presence scores. Further studies are required to understand if and how low embodiment in VR influences the food portion sizes children serve.

In our study, control was found to be slightly higher for older children (aged 9 - 12 years) with a mean score of 3.6 (SD 0.95) as compared with the younger group (aged 5 - 8 years) with a mean score of 3.5 (SD 1.0). Control is correlated with their sense of self-location, and older children therefore also had a better sense of self-location than younger children. We found that younger children found it challenging to maneuver the VR controllers for the required tasks, whereas older children demonstrated better motor skills. We also observed that younger children were losing their balance while performing the task of pouring and tilting in VR (it is important to note that no accidents were reported, as children were seated and were in constant supervision). These findings are consistent with prior literature on movement skill development [86], which suggests that control skills are still developing in children aged 1 - 7 years, and therefore they require greater coordination to perform such tasks.

Presence was also found low in our study, potentially because of the language used in the instructions. By asking children to imagine being in their own kitchen and serving breakfast (as described under section "Study Procedure"), we unintentionally led them to compare the virtual environment with their actual home kitchen in terms of layout and food items. Moreover, participants also commented that the virtual hands did not feel real, thus contributing to low scores. Despite the low scores, children enjoyed the overall activity.

These insights raise important questions that require further investigation. For instance, is it possible for children to enjoy VR activities without being "present" in the virtual world? How important is high embodiment for children in VR? Finally, how can we design efficient tools to measure children's presence in VR? Next, we discuss 2 guidelines on how to enhance children's immersion in VR.

Recommendation 3: Design Virtual Food Selection Tasks Around Children's Motor and Perceptual Abilities

In our study, the VR experience primarily involved 2 interactions: grabbing an object (a cereal box and milk can) and tilting it onto a bowl or glass, respectively. We found that younger children (aged 5 - 8 years) struggled with these tasks because they required complex control through the VR controllers. Owing to the developing motor skills in children of various age groups, we suggest that designers should carefully develop the virtual tasks around the motor capabilities of the target age group. Additionally, designers should not try to exactly mimic the real-world interactions with food in VR as they may not be feasible. For instance, the pouring task in our study was problematic, as there is reduced weight perception in VR, which led to accidental spillage. Hence, we suggest mapping the real-world tasks to simpler actions within VR such as grabbing or moving.

Our study also indicated that children are more likely to perceive food container sizes correctly for the "medium" size (RQ1). As per Piaget's discussion [87], children younger than 11 years are known to have difficulty in estimating the object volume. For instance, such children focus only on 1 dimension of an object and tend to ignore others. Hence, they find it difficult to understand that a quantity does not change if it has been altered (eg, by stretching, shrinking, spread out, etc). Similarly, another study [75] suggests that adult participants perceived sizes very differently between VR and RL, and that in VR, they were more reliant on the familiar sizes to perceive the size of unfamiliar objects. In our study, when we asked children to pick the same bowl in VR as they had picked in RL and vice versa, children could make correct estimations only for medium size. They were able to identify all 3 sizes of glasses in VR if they had seen them first in RL. With the VR first condition, more incorrect guesses were observed. Our study suggests that apart from the cognitive inabilities and abilities of our target group, we anticipate that the virtual environment adds another layer of complexity that makes the size estimation challenging for children.

XSL•FO
RenderX

Participants guessing the "medium" size containers more accurately than other sizes could also be understood through the Goldilocks problem [84], where children selected "just the right kind" of containers for themselves. For instance, children aged 5 - 12 years are typically served in small- to medium-sized containers at home to prevent food wastage. Participants may have selected medium-sized containers due to their everyday exposure to that size. Moreover, previous works in object size perception [50,88] also indicate that object sizes in VR have an inverse correlation with virtual hand sizes, under all degrees of avatar realism. In our study, we used a single size avatar for all participants, without scaling to participants' bodies. Hence, further studies are required to understand the connection between avatar size and container size selection for children.

Our findings related to container sizes also suggest that it is more efficient for future studies to have a single size. Additionally, it was challenging to replicate the continuous variation in food amount while being poured into virtual containers in VR. Therefore, for future studies on food selection in VR, we suggest that researchers should focus on using discrete portion sizes, such as different slices of pizzas or a bowl of soup instead of involving actions such as pouring or serving food through spoons.

Recommendation 4: Design Visual Embodiment and Presence Questionnaires for Children

Our final recommendation relates to how to measure children's embodiment and presence. In our study, we found that children were unable to understand the questions related to the real and virtual world. For instance, questions related to embodying an avatar were difficult for children to interpret, as the virtual body and hands were neither their own nor very realistic. As such, children were very focused on their RL experiences and were unable to connect to an unfamiliar kitchen and unknown avatar. Our concerns with the existing questionnaires resonate with the concerns raised by other researchers [49,89], as they also noted the methodological challenges of using questionnaires and emphasized the importance of using other measures to better understand participants' perceptions of the virtual world.

Slater [81] argued that presence is not a natural phenomenon, as we do not think about it in our everyday life. Also, unlike other feelings such as anxiety, presence cannot be easily compared with our previous life experiences. Since children have fewer RL experiences than adults, their familiarity with different concepts in VR may differ. Hence, researchers should inquire about embodiment on parameters that children can easily compare with. Additionally, presence should be inquired against familiarity. For instance, questions related to familiarity with the designed experience should be asked to understand children's perspective. Designers should also build VR experiences that children are likely to be familiar with to help them develop valid connections in the virtual environment.

New tools are, therefore, required to inquire about measures of embodiment and presence of children in VR. Prior work [90] developed a visual questionnaire to understand the perceived physical literacy of children. The questionnaire shows a "bunny" character performing different physical activities. Children interpret the bunny's activities and indicate their literacy level around physical activities. Using an animal-based visual questionnaire helped children to focus on the question being asked without focusing on the finer details of the bunny character. Similarly, using animal avatars with children in VR has also received positive responses in previous research as realistic behaviors were not expected from animal characters [54]. Visual questionnaires coupled with animal characters thus present a promising direction toward measuring children's embodiment and presence within VR.

Limitations

This study has certain limitations, which might influence the generalizability of the study findings. First, there was a difference in how the VR and RL tasks were managed in our study. In the VR condition, children poured their own food, but in the RL condition, they did not. This was a necessary limitation due to the study's setting in a public museum, where the risk of spillage could impact other visitors and damage the VR equipment. Although we anticipated that the food portion sizes would be similar between both conditions, they varied. We found that this variation was not only due to the difference in pouring mechanisms but also because the novelty of VR combined with a lack of supervision within VR—which led children to treat it more as a playful activity. This highlights why our recommendation to design supervised experiences is an important consideration for future studies.

Second, children were not allowed to eat the food they served themselves due to food safety reasons such as allergies. Since the amount of food served may differ from the amount consumed, further research is needed to understand the relationship between these 2 variables. Moreover, we used an average avatar size and did not adjust the VR kitchen or its features such as container sizes to account for each child's hand size or age, which may have influenced our findings. Moreover, since eating practices vary across cultures, some may not consider cereals as a healthy option. While it is infeasible to choose a food item that satisfies every culture, our choice of food items was driven by the health star rating and sugar content mentioned on the package.

Third, due to the complexity of multiple tasks for each RQ, as well as the context of conducting research in an active public setting of a popular museum with multiple data collection stations, data loss across different tasks was an issue, causing imbalance of participant numbers across each RQ. Additionally, the playful behaviors of the participants of continuously pouring food in VR caused significant data loss for VR conditions.

Another limitation of our study is that it was conducted with an age group younger than the VR industry's recommended demographic. Although we received ethics approval and implemented safety protocols, such as limiting VR exposure and ensuring that children remained seated, the design of the headsets may have influenced the children's experience and our findings. The implication of the study could be limited to the specific hardware setup that was used, which was the Oculus Quest 2. Moreover, our participant sample may not be representative of all socioeconomic groups. Because the study was conducted at a museum with an entry fee for accompanying

XSL•FO
RenderX

adults and free access to children, the findings may not generalize to children from other socioeconomic backgrounds.

Finally, we acknowledge that the modified embodiment and simulator sickness questionnaires may have impacted the results. These changes were necessary to simplify the questions and make them suitable for child participants.

Conclusions

This paper presents insights from a controlled study conducted with 437 children (aged 5 - 12 years) at a science museum. We investigated the potential of using VR as a tool for food choice research by measuring how children perceive food portion size and container size, and how their experience in VR compares with an RL setting. Our study raised important questions about how to collect accurate data with children using VR, how to design immersive experiences for them, and how to create a valid questionnaire to measure their experience in VR. In response, we present 4 recommendations around designing supervised virtual food experiences, applying gamification to ensure data accuracy, developing virtual tasks around children's motor abilities, and designing visual questionnaires to inquire about children's immersion in VR. Despite certain limitations, our study presents the first understanding of how children perceive food in VR, how they behave in a simulated food environment, and finally how VR could serve as a potential measuring tool for measuring their eating behaviors. These insights offer foundational knowledge for future VR research with children in the domains of HCI and health, while also opening new avenues for researchers at the intersection of VR and food science.

Abstract

Background: Behavioral health concerns are common in pediatric practice, with pediatricians reporting a lack of skills related to providing effective behavioral management strategies to parents. A prior human-facilitated, screen-based virtual reality training curriculum proved effective in enhancing behavioral health communication skills among pediatric residents. However, barriers to spread and scale of the curriculum included the need for human facilitation.

Objective: This study explored the usability of an automated virtual reality–based behavioral health anticipatory guidance curriculum for pediatric residents.

Methods: Through a partnership with BreakAway Ltd, an automated prototype was developed that required verbalization by users to support progress through simulated scenarios and included the receipt of personalized feedback to enable deliberate practice of communication skills. Usability of the prototype was assessed using mixed methods that included in-person completion of the prototype, a semistructured interview, and completion of survey instruments including the System Usability Scale and the Measurement, Effects, Conditions: Spatial Presence Questionnaire.

Results: Nine individuals completed usability testing. Qualitatively, users indicated that the system was easy to use, realistic, gamified, and likely most helpful for novice learners. Quantitatively, the ease of system usability was rated highly with some limitations related to spatial presence noted.

Conclusions: Usability testing of an automated curriculum to support behavioral health counseling skills in pediatric residents was completed, providing data to support adaptations in preparation for implementation.

Introduction

Background

Although pediatricians frequently discuss behavioral health concerns with families [1], they report a lack of training on how to effectively address these concerns using evidence-based approaches and collaborative communication [2,3]. This represents a critical training gap, as the implementation of effective behavioral management strategies by parents to address typical childhood behaviors (eg, tantrums) can mitigate the development of future behavioral health disorders [4]. With approximately 20% of children currently having a diagnosis of a behavioral health disorder [5], identification of training strategies to support future pediatricians' skills in delivering behavioral health anticipatory guidance (BHAG) is needed [6].

Recent curricula aiming to support BHAG skills in pediatric residents have primarily relied upon experts to deliver content via didactic or case-based discussions, limiting the opportunity for spread and scale of effective interventions [7,8]. Simulation-based medical education in the form of patient actors has been incorporated into training pediatric residents on BHAG; however, limitations related to accessibility, realism, and psychological safety have been reported [9]. Advances in technology offer an opportunity for broad dissemination of theory-based education. Screen-based virtual reality (VR) is one technology that can be leveraged to support BHAG skill development in pediatric residents to optimize pediatric health outcomes.

XSL•FO
RenderX

Prior Work

We previously developed a novel screen-based VR curriculum to enhance BHAG competencies among pediatric residents through deliberate practice of skills [10-12]. A human facilitator drove both the VR responses of graphical characters in scenarios and provided personalized performance feedback following each simulated scenario. The VR curriculum proved highly acceptable and efficacious in enhancing BHAG and health care communication skills [10,12-14]. During usability testing of the human-facilitated curriculum, residents reported the curriculum as realistic, engaging, practical, appropriately scaffolded, and psychologically safe. They indicated the curriculum was easy to use and reported high levels of immersion and spatial presence within the virtual environment [10]. The spread and scale of this education was limited due to the need for highly trained human facilitators. Artificial intelligence (AI) offers an opportunity to explore how automation may support maintenance and scale of such VR-based educational interventions.

AI allows users to interact with computer systems that use data sources to interpret user inputs and deliver curated responses [15]. The use of AI in medical education and simulation has been limited; prior research indicates limitations related to realism and accuracy [16,17]. Thus, we sought to assess the feasibility and acceptability of an automated curriculum to support BHAG and communication skills in pediatric residents.

Methods

Ethical Considerations

This study was reviewed and determined to be exempt by the Cincinnati Children's Hospital Medical Center Institutional Review Board (2023-0314). A waiver of documentation of informed consent was granted; therefore, prior to data collection, participants reviewed a study information sheet, and participation in study procedures indicated their consent. All study team members adhered to institutional procedures governing data access and privacy. Compensation was provided to all participants.

Curriculum Development

To develop the automated intervention, we partnered with BreakAway Ltd, a game developer that created a conversational interaction system titled Standard Patient Studio (SPS) [18]. SPS uses a cloud-based AI platform in which progression through a simulated scenario is driven by a user's verbalizations. A multidisciplinary team that included 2 pediatricians, 1 pediatric psychologist, 3 software developers with expertise in AI, and 2 research assistants adapted the human-facilitated VR curriculum to the SPS platform. Procedures included scenario storyboarding with branching logic using the prior human-facilitated VR scenarios as a guide, with iterative scenario development testing by study team members. The final curricular prototype yielded 2 scenarios that replicated the human-facilitated VR curriculum's learning objectives and used identical verbal statements by the graphical parent. Potential answer options for the learner were displayed on the screen during each scenario to support scaffolded learning and to inform a learner's spontaneous verbalizations, thereby ensuring progression through a scenario. The answer option most closely aligned with the user's verbalizations was selected by the natural language understanding system. This system categorizes user input via a medical taxonomy reference that assigns an appropriate patient action. In prior trials, this system has demonstrated a 92% appropriate response rate [19]. On the basis of the selected answer option, the user received immediate feedback (ie, excellent, acceptable, or poor response) via color-coded emojis that were previously embedded in the SPS platform. Upon scenario completion, users received feedback indicating why an answer selection was preferred or not preferred. The feedback mirrored the human-facilitated feedback by identifying the specific BHAG and motivational interviewing skills demonstrated during a scenario and where there were missed opportunities to demonstrate such skills. A low performance score required users to repeat the scenario, which mirrored the deliberate practice approach used for the human-facilitated VR training.

Usability Testing

Usability testing, a critical component of intervention development, which seeks to systematically evaluate the extent to which an intervention achieves its intended purpose by engaging experts to identify weaknesses, occurred using mixed methods [20,21]. Health care team members, including senior faculty, psychologists, simulation educators, and pediatric residents, were purposefully sampled to pilot the curriculum. Usability testing occurred in person, where users were asked to "think aloud," verbalizing their perspectives as they navigated the automated curriculum [22]. Following completion, participants underwent a semistructured interview to explore their overall impressions (Textbox 1). Interviews were recorded, transcribed, and analyzed by 2 raters (AM and FR) using the rigorous and accelerated data reduction (RADAR) technique, a rapid qualitative analysis approach [23]. RADAR uses a 5-step approach to data reduction through the iterative refinement of data tables and is well suited for studies with narrow research questions. The raters ensured consensus on reduction decisions at each step. Trustworthiness of the qualitative data was also supported through the use of an interview guide that generated descriptive responses (credibility), multiple analyzers and peer debriefing (dependability), and recording of detailed procedures (confirmability) [24]. Participants also completed the System Usability Scale (SUS) [25] to examine the platform's ease of use and a subset of items from the Measurement, Effects, Conditions: Spatial Presence Questionnaire (MEC-SPQ) [26] to assess for immersion in the virtual environment.

Textbox 1. Interview guide.

Usability interview guide items

- What are your overall impressions of the automated curriculum?
- How easy or difficult was the curriculum to use? Tell me more.
- How was your interaction with the avatar characters?
  - What would you change?
- What were your impressions of the feedback you received after the simulation?
  - Did it seem to accurately reflect your performance?
  - How easy or difficult was it to interpret?
- What one change would you make to the automated curriculum?
- Would you recommend the automated curriculum for learners? Why or why not?

Results

A total of 9 individuals, including 2 pediatric psychologists, 3 senior pediatric faculty, 2 pediatric residents, and 2 simulation educators, underwent testing during a 1-week period in August 2024. Participants had a mean age of 36 (SD 7.9) years and were mostly women (n=8, 89%), White (n=8, 89%), and non-Hispanic (n=9, 100%).

Qualitative

Of the 9 participants, 8 (89%) provided qualitative data. Participants described the scenarios as relevant and realistic. Overall, they reported that the system was easy to use and correctly coded their verbalizations. The study team observed, and participants reported, that there was a learning curve associated with using the online microphone. Participants indicated appreciation for the nuanced answer options and level of difficulty, although some participants desired decreased scaffolding and increased free agency. Some participants described a game-based experience, attributed to the immediate feedback in the form of color-differentiated emojis. Some viewed the game mechanics integration positively, while others felt it detracted from realism. All participants (n=8) indicated that they would recommend the curriculum for learners. Due to the inclusion of game-based elements and the select option format, some participants believed the curriculum was best suited for novice learners (eg, medical students and residents) rather than practicing pediatricians. All participants indicated that the feedback accurately reflected their performance. When asked what one change participants would make to the automated curriculum, 3 (38%) requested more free agency and less scaffolding during the simulations, 2 (25%) wanted shorter answer options, 2 (25%) wanted more variability in terms of graphical character responses, and 1 (13%) wanted more specific feedback regarding incorrect answer selections.

Table 1 includes exemplar quotes informing these data interpretations.

XSL•FO
RenderX

Table . Principal themes and supporting quotes.

Theme	Supporting quotes
Easy to use	• "I thought it was very easy. I had no problems using the system and getting through the scenario." [ID 26] • "It's very self-explanatory, and you just have to like push a button. It's not super high, not high-tech in a way that I'm like I have no clue what to do with this." [ID 21]
Realistic scenarios	• "I think it's a practical way, some of the things that the parents said are very realistic and real life that we hear all the time, so I thought that was realistic." [ID 24] • "I felt the situation was very realistic, and it felt like the, it just, it felt accurate. That's my biggest reaction. These things come up all the time, and kids do have tantrums in the office all the time, so this is very relevant." [ID 26]
Accurate character responses	• "I feel like she responded appropriately to what I said." [ID 22] • "I think I would say it feels representative in some ways of what like parents might say." [ID 27]
Game-based design	• "I felt more like it was like a game to find the best answer than an actual interaction with the person. It felt more like a trivia game." [ID 26] • "It [the feedback] felt like a score, like a game and a score." [ID 27]
Potential for more realistic characters	• "I would like the room to look more realistic, and I'd like Phyllis [the graphical parent] to look more realistic, and I'd like Alex [the graphical child] to actually be with Phyllis and not a pop-out video." [ID 30] • "I mean, if it looked more realistic, obviously, that would be nice. And her voice sounds a little bit monotone. Like if it could sound a little bit more natural, then I think I would feel more bought in that it feels like a more realistic patient interaction." [ID 22]
Accurate and clear feedback	• "I like this [feedback] page, especially because it breaks it up, and it gives specific feedback. I guess sometimes I didn't pick the most egregious answers, so I didn't always get like the bad feedback. But I do like that you could see kind of what the other choices are, and you could kind of see what the scale is." [ID 29] • "I like that it's relatively clear [the feedback]. Obviously, you know, there's the green, yellow, red. Green is good. Yellow is kind of that middle of the road. Red is bad." [ID 23]
Most helpful for novice learners	• "I can see how it could have a lot of value for resident training and definitely helping residents get more experience." [ID 27] • "I think I would, especially for like interns or early learners because, I mean, it's low stakes with the avatar. And I also like the microphone aspect of it, because I think speaking the words instead of just where you've been clicking goes a long way." [ID 29]

Quantitative

The overall SUS mean score among participants was 78 (SD 9.8; range 65.0-92.5), indicating good to excellent usability of the system [27]. On the MEC-SPQ, 44% (4/9) of participants agreed or strongly agreed that it felt like they actually participated in the action of the simulation. Only 11% (1/9) agreed or strongly agreed that they felt as though they were physically present in the environment. (Table 2)

XSL•FO
RenderX

Table . Quantitative outcome metrics assessing system usability (System Usability Scale [25]) and spatial presence (adapted Measurement, Effects, Conditions: Spatial Presence Questionnaire [MEC-SPQ] [26]), which both use a 5-point Likert scale from strongly disagree (score=1) to strongly agree (score=5).

Items	Score, mean (SD)
System Usability Scale	
I think that I would like to use this system frequently	3.6 (0.9)
I found the system unnecessarily complex	1.9 (1.1)
I thought the system was easy to use	4.1 (0.6)
I think that I would need the support of a technical person to be able to use this system	1.4 (0.5)
I found the various functions in this system were well integrated	3.8 (0.8)
I thought there was too much inconsistency in this system	1.9 (0.9)
I would imagine that most people would learn to use this system very quickly	4.3 (0.5)
I found the system very cumbersome to use	1.6 (0.5)
I felt very confident using the system	4.0 (0.7)
I needed to learn a lot of things before I could get going with this system	1.7 (0.5)
Total	78.3 (9.8)
MEC-SPQ (subset)	
The virtual reality experience captured my senses (ie, it held my attention)	3.3 (1.0)
I dedicated myself completely to the virtual reality experience. (ie, I was not distracted)	3.4 (1.0)
I was able to make a good estimate of the size of the presented space	3.2 (0.8)
I felt as though I was physically present in the environment of the simulation	2.6 (1.0)
It seemed as though I actually took part in the action of the simulation	3.1 (0.9)
The objects in the simulation gave me the feeling that I could do things with them	2.4 (1.0)
Even now, I still have a concrete mental image of the spatial environment	3.6 (1.0)

Discussion

Principal Results

Adaptation of a human-facilitated VR curriculum on BHAG was successfully automated through the use of the SPS platform developed by BreakAway Ltd. Qualitative and quantitative data indicated that users could easily navigate the platform and interact with its components. Compared with the human-facilitated VR curriculum [10], users reported less spatial presence in the virtual environment. However, users still described the automated training as realistic and relevant. Users also endorsed a game-based aspect to the training experience, which was not reported with the prior human-facilitated VR curriculum [10]. Overall, users indicated that the current automated training might be most appropriate for novice learners. Our decision to scaffold the learning experience by displaying answer options supported reliable progression through the scenarios and safeguarded against misclassification of verbalizations, which can occur when using generative AI models [17,28-30]. However, more advanced learners may benefit from removing scaffolded answer options at a limited number of interaction points.

Limitations

This study had several limitations. First, our small, purposeful sample, ideal for usability testing [31-33] and intervention development, limited generalizability. However, recent literature by Guest et al [31,32] indicates that 6 to 7 interviews are likely sufficient to support theme generation for homogenous samples such as ours. Second, the rapid qualitative analysis method may have limited exploration of interview data. However, the RADAR technique is well suited for research questions that are narrow in scope [23].

Comparison with Prior Work

Behavioral health medical education lacks effective, innovative training curricula necessary to develop practice competencies [3]. By removing the need for a human facilitator or patient actors, AI-based communication training provides an opportunity for spread and scale [16,34]. Additional research is needed on how to best incorporate AI into education interventions to optimize learning outcomes that support

XSL•FO
RenderX

behavior change. We specifically sought to align the automated curriculum with deliberate practice principles, as this served as the theoretical foundation for the prior human-facilitated VR curriculum [11]. Deliberate practice is a personal, goal-oriented approach to training that focuses on attempting a behavior (eg, providing BHAG), receiving immediate feedback, and then repeating it until demonstrating skill mastery. Consistent with this theoretical framework, the automated curriculum provided a platform for rehearsal of specific verbiage, feedback based on each interaction point, repetition of skills over the two scenarios, and the opportunity to repeat scenarios. Aligning AI-based educational interventions with evidence-based adult learning theories will allow us to establish a literature base on how AI might most effectively support learning. This is particularly important for the topic of behavioral health, as recent studies describing curricular interventions often do not specifically indicate a theoretical foundation for the work [8,35,36]. As AI becomes integrated routinely into training, we should consider how we might best facilitate trust for learners interacting with AI systems as well as provide transparency regarding AI algorithms and source data [37].

Conclusions

Our study demonstrated the feasibility of developing an automated curriculum to support BHAG skills in pediatric residents through collaboration with an experienced industry partner. Automation of training curricula adds value by enhancing the capacity for scalability by reducing dependence on human facilitation. As such, automation also decreases the costs for participation, supporting equity among learners in accessing novel, evidence-based education. Next steps include updating the curriculum based on usability testing and implementing it among pediatric residents to assess its acceptability and effectiveness among that population and to explore how its outcomes compare to other training modalities, such as human-facilitated VR interventions. An evaluation of implementation strategies will also be critical to understand how such novel education can be integrated into resident curricula. Moreover, given the varying perceptions related to the game-based elements incorporated into the intervention, further exploration of how such game-based features impact attitudes and learning outcomes is warranted. We also plan to add an orientation regarding learning goals prior to intervention completion to align with best practices for promoting a constructive digital feedback environment [38]. In the future, we aim to refine the automated curriculum, including adjusting the level of free agency and gamified elements, to support learning across the continuum of health care providers.

Funding

This work was supported through the Cincinnati Children's Hospital Medical Innovation Fund award. Funders played no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; and preparation, review, or approval of the manuscript.

Abstract

Background: Stroke often leads to persistent impairments that limit daily functioning and psychosocial well-being. Virtual reality (VR) has emerged as a promising adjunct in stroke rehabilitation, although research has largely focused on clinical outcomes, with limited attention to user involvement and the experiences of multiple stakeholders in the design process.

Objective: This study aimed to explore the challenges and benefits of co-designing and using VR to support home-based poststroke rehabilitation.

Methods: A qualitative co-design case study was applied to gain an in-depth understanding of the challenges and benefits. Rapid co-design principles were used in developing VR prototypes delivered via head-mounted displays through 3 workshops with participants with stroke, health care professionals, and VR developers from November 2023 to May 2024. A design prototype revision was done based on feedback from the workshops. Data were collected via audio-taped co-design workshops with all participants and 10 successive semistructured interviews with health care professionals and VR developers conducted in a rehabilitation hospital. A thematic analysis was performed on transcribed recordings.

Results: In total, five main themes emerged: (1) adaptability for stroke-related impairments in home rehabilitation, (2) safety and ease of use, (3) goal orientation, (4) motivation, and (5) VR as a complementary tool. One of the primary challenges identified lies in the adaptability of VR systems for individuals with hemiparesis. Additionally, customization and safety concerns remain a complex barrier, as VR solutions must be capable of addressing a wide range of stroke-related impairments and aligning specific rehabilitation goals. VR demonstrated potential to enhance rehabilitation by simulating real-life tasks that encourage goal-oriented and motivating therapy. As a complementary tool, VR can enhance traditional rehabilitation by increasing the intensity and volume of therapy.

Conclusions: This study offers insight into how VR can be effectively integrated into rehabilitation practices. Its integration into rehabilitation requires alignment with established therapeutic principles within VR applications, such as adjustable task-specific training and meaningful outcomes tailored to individual needs, to ensure clinical relevance and user engagement. VR should complement, rather than replace, conventional therapy by increasing training intensity, reducing therapist workload, and extending rehabilitation into the home. Thoughtful co-design with stakeholders is key to creating VR tools that bridge the gap between structured clinical care and independent recovery, offering continuous support throughout the rehabilitation process.

KEYWORDS

virtual reality; rehabilitation; people after stroke; co-design; stroke

Introduction

Stroke ranks as the second leading cause of death globally and is a major contributor to adults' neurological and neuropsychological persistent impairments [1], impacting 17 million individuals annually [2]. This is a cause for concern as the demand for poststroke rehabilitation is expected to rise significantly [3], imposing considerable strains on both the quality of life of people after stroke and health care resources. Rehabilitation for people after stroke often requires a long period of rehabilitation and motor relearning [4]. Artificial intelligence (AI)–driven virtual reality (VR) solutions are expected to support individuals' self-managed rehabilitation and have the potential to effectively engage individuals in intensive, repetitive, and task-oriented activities [5]. They can serve as useful tools for monitoring progress and enhancing decision-making in the rehabilitation process for people after stroke and health care professionals [6].

Stroke can affect individuals to varying degrees, with motor impairments being the most frequent disability. These impairments can limit motor mobility and have a negative impact on individuals' physical activity levels and psychosocial well-being [7]. A European multicenter cohort study demonstrated that after 5 years, people after stroke experienced a decline in functional and motor outcomes, reverting to the levels observed at 2 months post stroke, highlighting that many individuals experience residual impairments [8]. Motor disabilities can vary from slight weakness to severe paralysis, impacting one's ability to perform everyday activities like eating, cooking, and dressing independently. It is estimated that about 75% of people after stroke initially face arm impairment, with only about 50% regaining arm function within 6 months after their stroke [9,10]. Although there are several studies on the effectiveness and use of VR, with some targeting specifically upper limb rehabilitation [11-13], they are mostly systematic reviews. The empirical studies on this topic are mainly based on the evaluation of the effects of VR in the rehabilitation process and not individual experiences [14-18]. While both the systematic reviews and evaluations on the effect of VR have enhanced our understanding of the benefits of these interventions, there is a paucity of knowledge on how these positive outcomes are achieved.

Experiencing a stroke often affects more than just physical activities and functions; it also impacts cognition and personal factors. The impact on life after stroke often leaves individuals feeling vulnerable and anxious about what lies ahead [19,20]. Cognitive challenges, including difficulties with memory, attention, and problem-solving, are common, as are emotional effects, such as mood swings, depression, and anxiety [21]. VR technologies targeting cognitive function and stress management have also been found to be effective [22]; however, a recognized gap in the literature exists regarding the effect that VR has on psychological well-being, which potentially affects cognitive rehabilitation. Therefore, greater attention is needed regarding how individuals recovering from stroke engage with VR solutions. This paper seeks to contribute to the growing body of knowledge in this area. Stroke rehabilitation is often a prolonged and challenging process, requiring long-term therapeutic intervention. A study by Johansen et al [23] examining the use of VR equipment in home settings for individuals with brain injuries highlighted the ongoing need for cognitive rehabilitation following hospital discharge. Participants in the study emphasized the importance of individualized VR interventions and noted that initial training typically occurred within hospital environments. These findings suggest that exploring the early implementation of VR in controlled clinical settings, facilitated through close collaboration with health care professionals, may offer valuable insights into the feasibility and effectiveness of VR-based rehabilitation post stroke.

The gaps identified above underscore the importance of understanding how VR technology can be both designed for and experienced by users within a safe and supportive environment, one that allows for a comprehensive exploration of its potential benefits as well as its inherent challenges. This demands a focus on the process of engaging the users rather than merely evaluating the effects. Focusing on the effects without elaborating on the development process poses the danger of oversimplifying the mechanisms through which VR contributes to recovery. Without a clear understanding of the underlying processes, it becomes challenging to optimize and innovate VR interventions to maximize their rehabilitation potential. Given the limited research on the use of immersive VR for stroke rehabilitation involving clinicians, people after stroke, and VR developers, it is crucial to integrate a multidisciplinary co-design approach to ensure that clinical VR solutions are both effective and user-centered [24-26]. By involving individuals with stroke, developers, and multidisciplinary health care professionals early in the design process, we can balance desired features with evidence-based design recommendations, enhancing the relevance and usability of these digital technologies. This approach also helps prevent the development of solutions that fail to meet actual treatment needs or pose safety risks to people after stroke when using VR solutions independently at home.

Even though VR systems promise more engaging experiences, especially when it comes to repetitive movements in poststroke rehabilitation, it is still not a go-to practice for many people after stroke and therapists. This study, therefore, aims to address the identified research gaps by exploring the challenges and benefits of co-designing and using VR to support home-based poststroke rehabilitation.

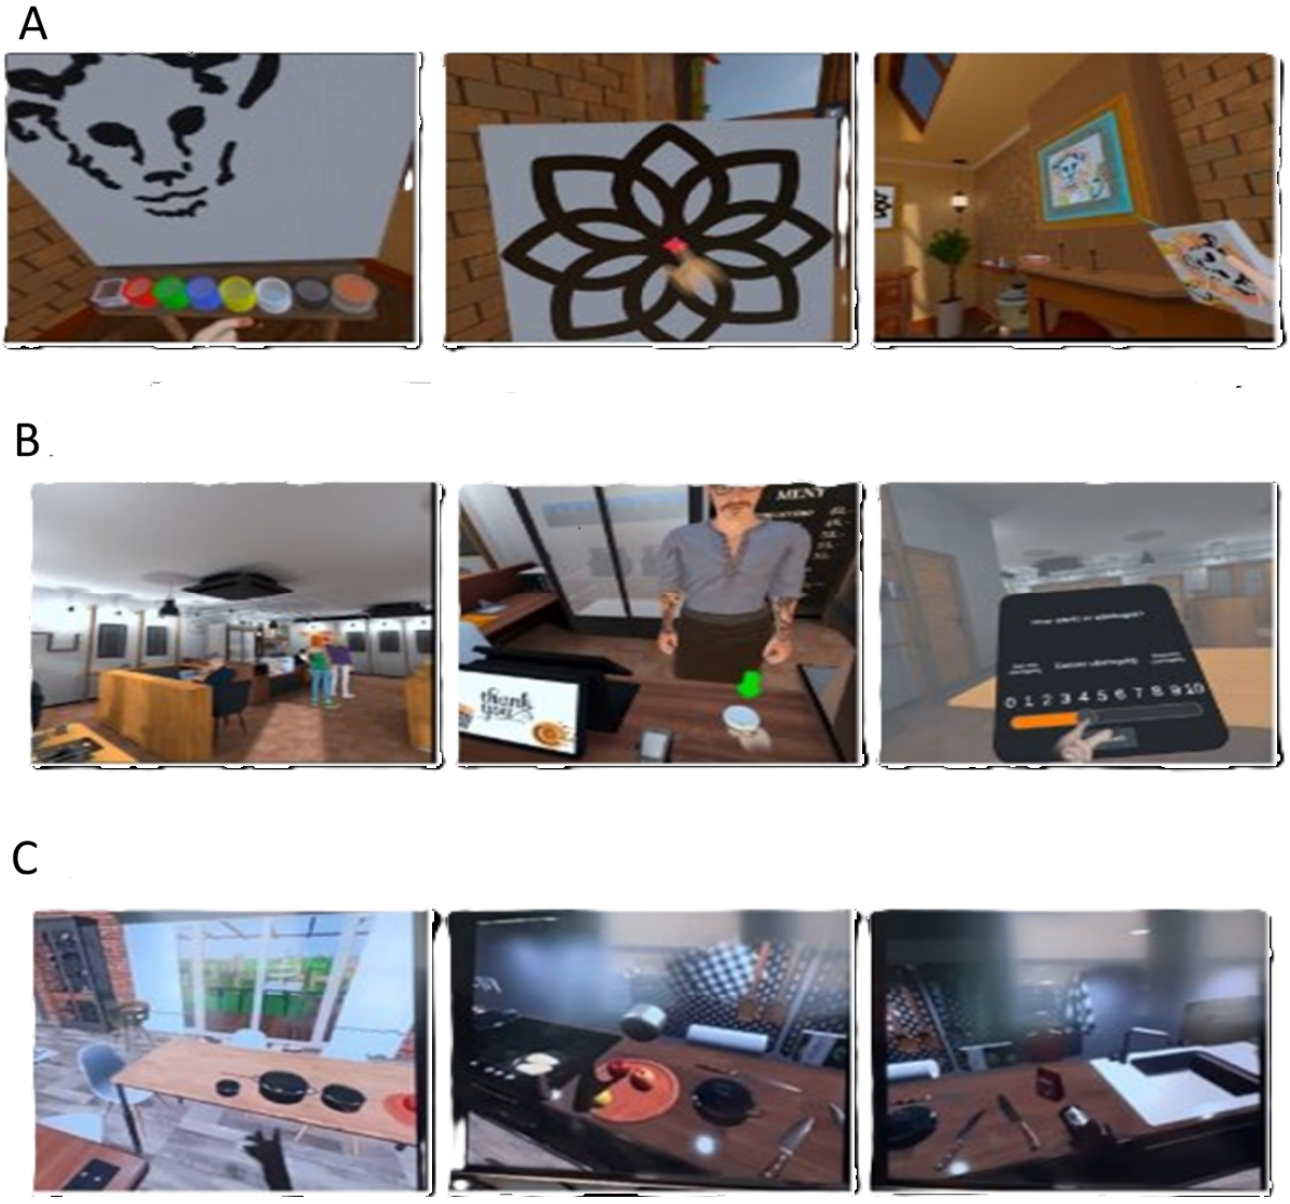
Methods

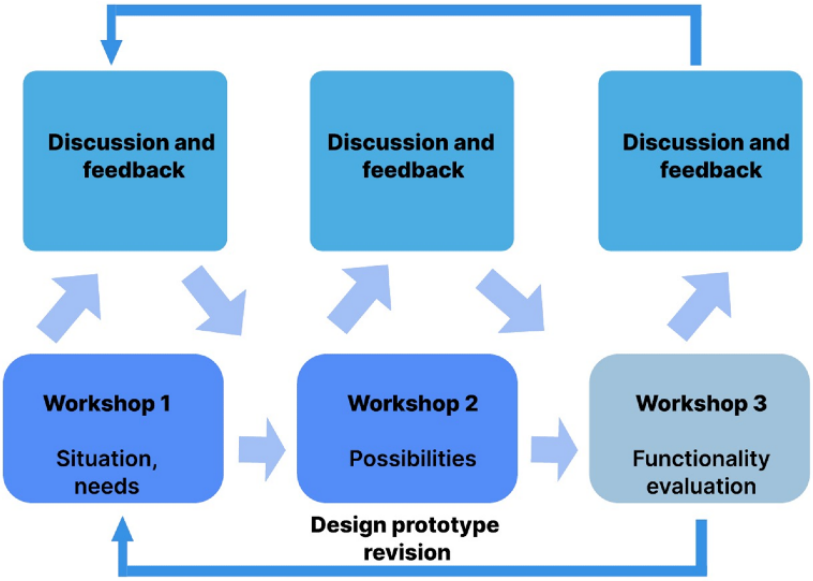
Overview



A qualitative co-design case study was conducted to gain an in-depth understanding of the real-life phenomenon within its environmental context [27]. A single case study approach was selected as it provided a robust means to explore "how" and "why" questions within a specific context, which gave the opportunity to investigate deeper causes of the phenomenon [28]. The data were collected through different sources of semistructured interviews and workshops.

Design Process Using Rapid Prototyping

We applied design principles and rapid prototyping [29] to develop VR prototypes (Figure 1) through 3 workshops with a mixture of participants held between November 2023 to May 2024 with the goal of (1) understanding the challenges and map the needs of people after stroke using an existing VR café scenario; (2) discuss possibilities and evaluate features in kitchen and a painting scenarios; and (3) test, evaluate, and refine the modified prototypes of the kitchen and painting scenarios through discussions and user feedback. The prototypes were immersive VR environments delivered via head-mounted displays (Oculus Quest 3 [Reality Labs]), featuring AI-driven interactive virtual characters, while other scenarios used scripted or noninteractive virtual elements with hand tracking.



To explore the potential of immersive environments in stroke rehabilitation, 3 VR scenarios, that is, a painting studio, a café, and a kitchen (Figure 2), were designed to simulate familiar and meaningful everyday settings. These environments were purposefully developed to promote creative engagement and functional interaction, allowing participants to practice activities reflecting real-life contexts in a safe and controlled virtual space. The 3 scenarios are illustrated in Figure 1.

Figure 1. Virtual reality scenarios presented to people after stroke (n=4) during stakeholder workshops. (A) Scenario 1: Painting, (B) Scenario 2: Café, and (C) Scenario 3: Kitchen.

XSL•FO
RenderX

Figure 2. Flowchart illustrating the design workshops involving people after stroke, health care professionals, virtual reality developers, and researchers (n=16) to iteratively develop and refine a virtual reality prototype for poststroke rehabilitation.

The first scenario illustrates the painting environment, where the participants entered a living room and moved toward the drawing board, where equipment and colors were located. The participants could choose between freehand painting and tracing a preset illustration or figure. Guidelines for each activity were provided in all scenarios. The second scenario placed participants in a large café environment. They moved toward the cashier's desk, ordered their food, and paid using a tablet. Participants also had the opportunity to interact with other VR avatars in the café. The third scenario illustrates a kitchen environment, where the participants could move between the kitchen counter and the dining table. They could do different activities like setting the table, placing kitchen utensils in drawers, or putting apples in a bucket.

In the first workshop, painting and café scenarios were presented to people after stroke and health care professionals. For the subsequent workshops, only painting and kitchen scenarios were further developed, as these were identified as most relevant and useful for people after stroke undergoing home rehabilitation, particularly for enhancing physical and cognitive functions. The co-design process was led by 2 researchers (MAP and NP)—a professor and an associate professor—who brought insider knowledge about the co-designing and feature-adjusting phenomena. Furthermore, 2 additional researchers (TS and AMHM), a postdoctoral and doctoral candidate, provided an outsider view to challenge assumptions. This single case approach allowed researchers to follow the co-design development process and adaptation of VR systems to the needs and demands of people after stroke, health care professionals, and VR developers.

Each workshop began with a short introduction to the aim of the VR scenarios, followed by people after stroke testing the solutions, and finally followed by 2 discussion sessions with all stakeholders and 1 exclusively with health care professionals. Feedback from the workshops informed iterative revisions of the prototype, as illustrated in Figure 2.

Recruitment of Participants

The study was conducted in a rehabilitation hospital where participants were recruited to participate in the workshops from three distinct groups where the number of unique participants was: (1) health care professionals (n=10), (2) people after stroke (n=4), and (3) VR developers (n=2). All participants received previous written information and were invited to participate in both the workshops and follow-up interviews via phone or email. Health care professionals were recruited by the unit leader, while people after stroke were selected based on their involvement in ongoing rehabilitation programs within the hospital. The VR developers were already involved in organizing the workshops as part of their collaboration with the research team. They agreed to participate in interviews after the workshops were concluded. During the workshops, all 3 groups were asked if they were willing to participate in follow-up interviews. A total of 10 participants agreed, including health care professionals and VR developers. Additionally, 3 out of 4 participants with stroke agreed to engage in short conversations and provided feedback during VR testing. The 4 participants were recruited from a community-funded rehabilitation hospital in Norway based on the following inclusion and exclusion criteria: adults with a confirmed stroke diagnosis, speaking either English or Norwegian, and living at home in the subacute or chronic phase (more than 3 months since the last stroke) as defined by a stroke trajectory framework [30]. In addition, the participants needed to have a score of 18 or above on the Montreal Cognitive Assessment (MoCA) [31] and the ability to complete specific tasks from the Action Research Arm Test [32,33], such as pouring water from one glass to another and placing a hand on top of the head. Exclusion criteria included individuals younger than 18 years, pregnant women, and people with receptive or expressive aphasia or memory and communication impairments that hindered them from using the prototypes. The 4 participants with stroke had a balanced gender distribution and ranged in age from 53 to 64 years. The participants experienced different types of strokes; 2 experienced

XSL•FO
RenderX

ischemic strokes, while the other 2 experienced hemorrhages (1 subarachnoid and 1 brainstem). None of the participants with stroke had previous experience with VR. Additionally, several health care professionals with expertise in stroke rehabilitation (ie, physiotherapists, occupational therapists, nurses, and medical doctors) and VR developers participated. The stakeholders, consisting of people after stroke, health care professionals, and VR developers, were involved in all 3 workshops as illustrated in Table 1.

Table 1. Overview of the participants excluding the researchers involved in the workshops (n=16) and interviews (n=10).

Stakeholder	Workshop attendance	Individual interviews
Researchers	• Workshop 1: n=3 • Workshop 2: n=3 • Workshop 3: n=4 • Total number of unique participants: n=4	—[a]
People after stroke	• Workshop 1: n=3 • Workshop 2: n=3 • Workshop 3: n=3 • Total number of unique participants: n=4	—
Health care professionals	• Workshop 1: n=8 • Workshop 2: n=5 • Workshop 3: n=10 • Total number of unique participants: n=10	Number of interviewees=8 (4 occupational therapists, 2 physiotherapists, 1 medical doctor, and 1 nurse)
VR[b] technology developers	• Workshop 1: n=2 • Workshop 2: n=2 • Workshop 3: n=2 • Total number of unique participants: n=2	Number of interviewees=2 (VR developers)

Data Collection

Audio recordings from each of the 3- to 4-hour co-design workshops [34] and collaboratively developed individual interviews conducted at a rehabilitation hospital served as the primary data sources for this case study. A total of 10 semistructured interviews, lasting 60-90 minutes each, were conducted and audio-recorded. Open-ended questions were used in both workshops and interviews (refer to interview guide in Multimedia Appendix 1). All meetings were conducted face-to-face. Workshop 3, being both comprehensive and advanced, built upon the outcomes of Workshops 1 and 2 and served as the primary data source for this study. Both workshops and interviews were transcribed and anonymized, with no real names or personal information retained from participants, to ensure confidentiality and adhere to ethical research standards. Researchers from Oslo Metropolitan University, led by designers with experience in design-driven innovation, user experience design, and digital prototyping (MAP and NP), mediated the workshops, while clinicians provided support to participants with stroke during the testing. Interviews and initial analysis were conducted by 3 experienced qualitative researchers (AMHM, TS, and NP) from Oslo Metropolitan University, with backgrounds in physiotherapy, science and technology studies, and computer and design science. Tasks were assigned based on relevant expertise; for instance, Norwegian-language interviews were conducted by fluent researchers, while interviews with VR developers were handled by a researcher specializing in the science, technology, and society interface.

The decision to conclude data collection after 10 interviews was guided by the concept of information power [35], which asserts that sample adequacy in qualitative research depends on the relevance and richness of the data in relation to the study's aim. Given the focused objective of gathering actionable feedback for iterative refinement of VR prototypes rather than achieving full thematic saturation, a small, purposefully selected sample was appropriate. This approach aligns with rapid prototyping methodology, which prioritizes targeted insights to inform design decisions over exhaustive theme development [36]. The study also followed participatory research principles, prioritizing a representative sample of end users to ensure relevance and applicability. The sample size (n=10) also aligns with Creswell's [37] recommended range of 5-25 participants for phenomenological studies. Finally, triangulation [38] using audio recordings from stakeholder workshops and individual interviews enhanced the credibility and depth of the findings.

Data Analysis

The data were transcribed verbatim using the transcription software Whisper (OpenAI) and manually checked for accuracy. Thematic analysis (TA) [39] was used to generate in-depth insights from participants' discussions. A codebook-based TA approach, involving multiple coders (AMHM, TS, and NP), was used to enhance the credibility and consistency of the findings [40]. The primary analysis was conducted by 3 researchers, all of whom were experienced in conducting qualitative research and applying TA as an analytical method. Further analysis was conducted collaboratively by all authors of the study and validated by health care professionals to ensure

XSL•FO
RenderX

the study addressed both theoretical and clinical aspects. The analysis followed Braun and Clarke's 6-phase framework, beginning with familiarization through repeated readings of the data to gain a comprehensive understanding. Subsequently, inductive and descriptive codes were applied, which were then grouped into preliminary themes. These initial themes were collaboratively reviewed and refined by the research team to ensure consensus about their accuracy and reliability. The processes of defining, naming the themes, and reporting the findings were conducted collectively.

To illustrate the development of the theme "safety and ease of use" using Braun and Clarke's 6-phase framework, we present an example from the analysis process. In the familiarization phase, repeated readings of transcripts revealed frequent concerns about physical safety, navigation, and psychological comfort in VR. Initial coding grouped statements about uncertainty, environmental awareness, and support needs under relevant codes, which were later collated into the broader theme. In the reviewing phase, we ensured this theme was coherent and differentiated from other related themes like "adaptability for stroke-related impairments," which focused more on task customization. "Safety and ease of use" emphasized risk minimization and user confidence. During theme definition and naming, we finalized it to reflect participants' emphasis on secure, intuitive, and supportive VR environments. Final reporting included selecting illustrative quotes to demonstrate how safety concerns informed both design recommendations and user engagement.

Rigor

Rigor was obtained through frequent debriefing and discussions among coders during data analysis and collaborative theme development within the research team. The qualitative data obtained from audio recordings of the workshops and individual interviews enabled triangulation and cross-references between findings [40], which strengthened the credibility of the results. The theoretical flexibility that TA offers was well-suited to accommodate the diverse perspectives and knowledge production of the multidisciplinary research team [41], which in this study included specialists in allied health, computer science, and design.

Ethical Considerations

The Norwegian National Research Ethics Committee for Medical and Health Research assessed the study and determined the need for ethical approval. They declared that this study's focus on health service research fell outside the scope of the Health Research Act § 2 and therefore did not require approval (ref 651236). Instead, this study was approved by the Norwegian Agency for Shared Services in Education and Research (ref 857865) to ensure compliance with privacy protection regulations. Participants received both oral and written information, and informed consent was obtained before the workshops and individual interviews. To protect the privacy of the participants, the study data were deidentified by using pseudonyms for all participants. Participants did not receive any financial or material compensation for their participation.

Results

Overview

Different participants with stroke, multidisciplinary health care professionals, VR developers, and researchers were present and participated in all workshops. There was a variety among the stroke individuals who were engaging in their first, second, or third workshop with the VR scenarios. Although engaging with avatars and objects in the café scenario was engaging, the stakeholders believed it did not target the rehabilitation principles. In the second workshop, this was amended by engaging in the kitchen and painting scenario. In the third workshop, these 2 prototypes were further developed by gamifying certain arm movements, targeting the affected arm in particular. The following results are based on the participants' needs and key challenges and benefits that were generated in workshops 1 and 2, and applied in workshop 3, which form the bases of this study, together with retrospective individual interviews with health care professionals. The findings generated five themes: (1) adaptability to accommodate stroke-related impairments in home rehabilitation, (2) safety and ease of use as fundamental in VR stroke rehabilitation, (3) goal orientation, (4) motivation, and (5) VR as a complementary tool.

Adaptability to Accommodate Stroke-Related Impairments in Home Rehabilitation

Participants viewed VR as a promising tool for poststroke home rehabilitation, offering interactive environments to aid motor recovery. However, they stressed that its usability depended on adapting to stroke-related impairments, such as accommodating both right- and left-handed hemiparetic users, as the first workshop primarily targeted right-hand users.

Customization was highlighted as crucial to address diverse needs, including issues like putting on VR glasses, gripping tasks, and aligning activities with rehabilitation principles. Participants stressed the importance of personalizing rehabilitation, as each person after a stroke faces unique challenges. Effective poststroke rehabilitation requires balancing engagement and endurance, as cognitive load and fatigue often limit people after a stroke. VR therapy demands motor and mental skills, making it vital to tailor intensity and duration to each individual's ability. It was noted that VR could overwhelm people after stroke, limiting its effectiveness.

> *When it comes to effectiveness, dosage and repetitions, VR will take more mental capacity because you use cognitive functions alongside motor function. Many people with stroke have fatigue; some can only do it for 10 minutes before their battery is low.* [Karla]

The potential for AI-powered VR solutions to enhance customization was discussed, with many participants emphasizing the rehabilitation goal of fostering independence and regaining agency. However, participants cautioned that VR was not suitable for everyone. Discrepancies between VR command techniques of gripping and actual abilities for people after stroke emerged during testing:

XSL•FO
RenderX

Therapist: You can also try to lift the kettle and the red bag there.

Person after stroke, first-time user: I try with the left hand first.

Person after stroke, first-time user: Just press through, sort of?

VR developer: Yes. Use the whole thing. I had to practice a bit with gripping, because I thought I could grip with my fingers.

VR developer: You have to use your whole hand, sort of, to grip.

Therapist: Then you try to open your hand, and then... Like that, yes!

Person after stroke, first-time user: Incredible.

Participants also noted errors between VR scenarios and real-world tasks. One participant described challenges with gripping:

> *You can pick up things and put them in a drawer, but it's hard to grip them. Then it kind of falls and suddenly pops up again...You haven't managed to do what you intended...Maybe the tasks are too difficult or not well adapted.* [Jane]

Additional challenges included the difficulty of putting on heavy headsets for those with reduced arm function or configuring the VR system. One participant emphasized the need for customized adjustments to accommodate for stroke-related individual differences and goals:

> *I believe that those with severe cognitive impairments or difficulties with visual mapping might find VR too difficult initially. If we could personalize this, because one person's goal could be the opposite to others.* [Sue]

Participants recognized that VR required a certain level of cognitive function. Practicing new strategies in advanced tasks like kitchen training posed greater challenges than simpler tasks focused on errorless learning, such as dressing. Familiar settings were suggested to enhance engagement and skill transfer from virtual practice to real-world tasks. While cognitive impairments such as visual mapping and adjusting to new surroundings could cause difficulties, VR's potential to shift focus away from disability and reduce learned nonuse was noted. One participant explained:

> *When you enter that room, you slightly forget what is affected. And when you don't see that the arm isn't working, perhaps it will engage a bit more.* [Betty]

Kitchen training was widely regarded as a familiar and widely used element in rehabilitation. Participants noted that a VR kitchen could provide additional practice opportunities, as kitchens are a universally relevant and accessible setting for most people after stroke. A participant emphasized the importance of adjustable environments to accommodate individual needs.

"*You can put things high and low. You have the ability to increase or decrease the height of your entire kitchen, the cabinet, bench, whatever, so you can lower it or increase it for adjusting the difficulty level for your needs but also making it easier to use or potentially putting it to the exact same height as you have everything at home.* [John]

He also stressed the need for customizable difficulty levels, such as easy, medium, and hard, while acknowledging that further customizations were necessary to address individual differences. Many participants agreed that a one-size-fits-all approach would not work, but segmenting recovery stages into acute, subacute, and chronic phases, or tailoring tasks based on gripping ability, was proposed as a viable strategy.

Safety and Ease of Use as Fundamentals in VR Stroke Rehabilitation

Ensuring safety was a fundamental consideration in VR-based stroke rehabilitation. Many people after stroke face mobility impairments, balance issues, and cognitive challenges, increasing the risk of falls or disorientation in virtual environments. During the workshops, one health care professional highlighted their obligation to people after stroke:

> *We cannot tell them they can do it alone if we are not sure that it is safe.* [Jane]

Participants noted that a secure VR environment could encourage engagement and push physical limits, enhancing rehabilitation progress. However, some participants warned that VR might create a false sense of safety. As one participant with stroke explained:

> *Now I can't see where my legs are or anything. It's an uncertainty. I feel like going over to hold onto the table, but that won't work. Now I'm trying to do as I do at home and park the walker next to the kitchen door.* [Person after stroke, second-time user]

The transition from institutional rehabilitation to home-based therapy was identified as a critical phase, often accompanied by anxiety and uncertainty. One participant noted that VR could reduce anxiety and prevent early readmission to health care facilities:

> *We have to make sure they go home without as much anxiety, because when they do, they might just return early to the healthcare system due to a fall or stress from something minor. With the help of virtual reality, we could avoid this because we've tested it already at "home", but at the institution.* [Tom]

Participants emphasized the need to carefully consider the difference between VR tasks and real-world activities. He further explained:

> *That's going to be challenging, since there is a clear difference between how difficult something will be in VR versus in the real world, like cutting vegetables with a knife.* [Tom]

Some participants noted that successfully completing tasks in VR but failing in real life could lead to disappointment, especially when tasks required a higher degree of task complexity.

One highlighted the importance of minimizing unnecessary movement in home-based VR rehabilitation:

XSL•FO
RenderX

> *If someone is going to use it alone, I would limit tasks where you have to walk far, because I wouldn't consider that safe.* [Jane]

Similarly, Kate pointed out that while real-life practice is ideal, VR enables people after stroke to safely train in everyday activities like walking, empowering them to actively engage in their recovery.

Beyond physical safety, participants also discussed the psychological benefits of VR, particularly its ability to reduce the fear of failure, which often prevents people after stroke from participating in rehabilitation activities. Ben underscored the importance of structured support for VR in both institutional and home settings:

> *Using it in our hospital department would be great because they can use it in their rooms with instructions to be seated during activities. And it can be used in the later afternoon when they're done with daily [therapy-assisted] rehabilitation training. At home, they would be instructed to sit in a chair or a sofa with a space around them in case they get excited and get up.* [Ben]

The focus on sitting exercises typically placed occupational therapists in charge of VR rehabilitation due to traditional task distribution. However, health care professionals raised concerns about the safety and feasibility of using the VR system without therapist assistance, questioning whether users could operate and administer the system without assistance. Technological advancement, such as developing hybrid and mixed reality VR rooms, were proposed as potential solutions to address safety concerns. One participant with stroke explained:

> *I would need the ability to sense the outline of it [the walker], because it is safer when I know where it is. Otherwise, I could have practiced in the real kitchen, so it was fairly similar.* [Person after stroke, second-time user]

Furthermore, the presence of a caregiver or therapist was seen as essential for building user confidence in using VR, as indicated by Maud:

> *It's very important to have someone who watches what you and [make sure] you do it carefully. If you fall, there's someone with you, and you feel secure. Our people with stroke have belts on, and the physio holds the belts from the back. Maybe these people with stroke can't walk without a stick, but with that support, they feel very secure.* [Maud]

One proposed solution, which came up during workshops, was to differentiate between safer, low-scale tasks for home use and more challenging tasks, such as standing or increased reaching activities, to be conducted during follow-up sessions at the hospital.

Goal Orientation

The participants highlighted that a goal-oriented approach was essential in poststroke rehabilitation, as it helped people stay motivated and engaged after stroke. VR was perceived as a platform to structure rehabilitation programs around individualized goals, allowing people after stroke to track progress and experience achievement. The participants found that incorporating meaningful, measurable objectives encouraged consistent participation and reinforced the benefits of repetitive practice. Observing progress and perceiving tangible improvements increased commitment to rehabilitation exercises. Several participants stressed the importance of person-centered VR rehabilitation, where goals align with daily needs and personal aspirations. Karla noted:

> *The person with stroke's goal is everything in the rehabilitation. If someone wants to dress independently, we have to focus on that. The person with stroke is in the driver's seat.* [Karla]

Participants emphasized that VR technology should focus on customization in goal setting to enable people after stroke to work on relevant activities, like regaining independence in dressing, cooking, or mobility. To maximize effectiveness, VR interventions needed a clear focus.

> *I think it's really important if you use this in a rehabilitation program, you need to specify your target. Is it cognition, arm movement, or balance?* [Tom]

However, limitations were noted where VR could not adapt to all needs. During the workshops, a health care professional explained:

> *Some patients can only use this movement—just this—but others need to grip something. Then, the patients need resistance, and this [VR] won't improve their function like the real activity. If they are going to move the paint, there is some weight in the paint, and you dont get transferability. To see improvement at home, they must do it similarly.* [Physiotherapist, Workshop 3]

Participants suggested that providing multiple training options would enhance adherence and long-term commitment to therapy. Effective VR rehabilitation required targeting more tasks that mirror real-life activities to develop skills essential for independent living after discharge, such as putting up a painting, washing the dishes, or putting on clothes. It was important that the chores or activities used in rehabilitation served a specific therapeutic purpose. Kate pointed out:

> *An activity like painting, you don't want to be a better painter, but you want your arm to get better. That's the method.* [Kate]

From a therapist's perspective, this highlights how everyday tasks can be repurposed as meaningful rehabilitation goals, where the focus is on physical recovery rather than mastering the activity itself. A blended approach, where people after stroke first practiced activities in VR and then transferred skills to real-life settings, was suggested to reinforce motor learning and recovery. Repeating engagement in virtual tasks before real-life performance helped internalize movements, build confidence, and strengthen neural connections essential for motor function.

However, not all participants' goals were covered by VR prototypes. One participant with stroke noted:

XSL•FO
RenderX

> *There is no gait training, at least not intentionally. I would have to be on a treadmill, walking into the woods. This is for the arm, though.* [Person after stroke, second-time user]

Tracking progress in VR was seen as a powerful motivator for people after stroke. Participants explained that observing measurable improvements encouraged continued training and inspired confidence to tackle more demanding tasks. They emphasized that VR should serve as a stepping stone, bridging the gap between virtual practice and real-life application. However, there was a need for a clear focus on whether VR training aimed for improvement or sustainability. Gamification elements, like points or rewards, were considered ineffective unless the real-world relevance of the tasks was clear for people after stroke:

> *It's not necessarily the case that you get motivated by getting extra points, if you don't quite understand why you're doing this.* [Jane]

Ensuring VR-based rehabilitation included familiar, everyday tasks enabled explicit goals in a more engaging, functional, and transferable home environment. Therefore, a variety of VR rehabilitation activities, such as hanging clothes in the laundry room or other meaningful daily activities, were considered valuable.

Motivation

The participants emphasized that motivation played a crucial role in the effectiveness of VR rehabilitation for people post stroke, ensuring long-term engagement with their rehabilitation program. Tom noted the importance of regular follow-up sessions for maintaining motivation.

> *We can see when they were very motivated here. They go home, and there are only challenges, no solutions. But when they return for follow-up sessions, they're extremely motivated.* [Tom]

Motivated individuals were more likely to push themselves and put in the effort required to achieve their rehabilitation goals, potentially leading to better motor outcomes and quality of life. People with stroke noted that the VR scenarios stimulated learning and movement, enabling them to train without being consciously aware of it.

> *Person after stroke, third-time user: Now I have used the entire room, I see.*
>
> *Therapist: Now we have followed you around the entire room.*
>
> *Person after stroke, third-time user: Today's workout.*
>
> *VR developer: Shall we see how many points there have been. It sounded like it was beeping a lot.*

Karla highlighted how competition could drive people after stroke to improve their performance.

> *It's motivating when it's like a competition. You did this last time, now try to reach this one for the progression of function.* [Karla]

Setting and achieving progressively challenging goals allowed people after stroke to experience significant functional gains, reinforcing their overall commitment to recovery and reaching rehabilitation outcomes. One participant noted the extrinsic motivation provided by VR and its effects on the brain.

> *Because when you do that, your brain tells you it's very useful, because you get points.* [Person after stroke, second-time user]

While the rehabilitation process could be challenging and frustrating, motivation was seen as a driver to overcome the physical and emotional barriers, persisting through difficulties, and maintaining a positive attitude toward recovery. Many participants emphasized the role of human support in maintaining motivation, as Ben explained:

> *If you're not motivated or very depressed, your life is over. We won't do anything with you. You need humans to train with you.* [Ben]

Health care professionals' emotional and psychological encouragement was regarded as crucial in helping people after stroke stay engaged. Motivated individuals were more likely to communicate their preferences and needs, allowing for a more personalized and active rehabilitation experience.

In addition, motivation was closely linked to psychological well-being. Engaging in meaningful and enjoyable activities improved mood, reduced anxiety, and enhanced overall mental health, which was crucial for recovery. Sue underscored the role of curiosity in maintaining motivation.

> *It's more like an opportunity to explore and be curious. If you manage to get curious, you have less capability to be afraid or be sceptical.* [Sue]

Building confidence was another key factor in motivating people after stroke to embrace new challenges and persist with VR. One suggested strategy to foster confidence was visual progress tracking.

> *If you could implement that, for example, in painting stations, storing your paintings so you could see at the beginning I was able to make a line that was so big, but after two weeks I'm able to make a line that's this big, could be a motivational tool.* [Sue]

Seeing tangible improvements over time reinforced the belief of people after stroke in their abilities, motivating continued rehabilitation efforts. Jane emphasized the importance of simplicity and ease of use for maintaining motivation.

> *For people with stroke to use it themselves, they must have high motivation. It must be simple enough to master quickly, not something they struggle with and give up in the end. It must be meaningful and beneficial for them.* [Jane]

Others suggested integrating VR with existing digital training programs, such as Exorlive, to offer a self-training option to therapy-assisted activity training. Ben highlighted the difference in outcomes between motivated and unmotivated individuals.

> *If you're a person who wants to do better, you have a very clear goal. You just do that with the help of others or sometime without any help. But if you're a person like, oh, now this is my life, I'm going to live*

XSL•FO
RenderX

> *with it, and you're not motivated to do anything, you might just sit there and let it go day by day.* [Ben]

Those with clear goals and motivation were likely to strive for improvement, while those without motivation might become complacent.

Finally, John emphasized the importance of creating varied and personalized scenarios to maintain motivation, stating:

> *To motivate people, it would be more interesting to create different environments, such as a bedroom where you can dress yourself or a garage where you can tinker and build with your hands.* [John]

By providing scenarios aligned with the specific goals and interests of people after strokes, the rehabilitation process becomes more rewarding and engaging, fostering long-term motivation.

VR as a Complementary Tool

VR was seen as a valuable complement to stroke rehabilitation, enhancing training intensity and offering structured exercises in both clinical and home settings. While not a replacement for traditional therapy, it effectively supported recovery by supplementing existing approaches. Given the limited window for optimal recovery, its role in maximizing progress was emphasized. Mary highlighted VR's contribution to intensive training.

> *Our institution specializes in giving intensive training. I don't think VR could match that, but as an additional supplement it would be amazing. Together we could help people with stroke recover more quickly. Especially for people with stroke, there is a time period to get as good as they can get.* [Mary]

This highlights that VR should complement, not replace, therapist-led rehabilitation by enhancing therapy intensity during the critical recovery phase. Additionally, participants proposed implementing validated clinical measurements, goal assessment scales, or kinematic data to monitor outcomes and progress within the VR system during the workshops. Betty noted the alignment between the painting scenario and existing cognitive tests, such as MoCA, suggesting VR's potential for cognitive diagnostics in addition to general executive functions:

> *Because we have a test where we follow a line with a pen from number to number, or from numbers to letters. That kind of cognitive test. So, both for cognition and physical aspects, it [VR] is, if I may say so, very useful.* [Betty]

Individuals with stroke face unique challenges, requiring personalized rehabilitation plans tailored to their specific needs. VR adaptability offers a promising tool for delivering customized training that complements traditional therapy, ensuring alignment with each person's circumstances. VR was seen as a tool to bridge this gap by providing structured exercises that encourage movement and engagement.

> *It's another intervention in addition to what we do. I think it would increase the activity for the people with stroke to use their arm more than they otherwise would, if they have such an aid in addition to a therapist.* [Jane]

During workshops, VR was seen as a controlled environment where people after stroke could practice real-life tasks safely before transitioning to real-world applications. Jane highlighted this advantage:

> *We've discussed it being a supplement to training and in a safer setting for the people with stroke. It will not be instead of, but it may increase the activity between each session. Someone has concrete things to practice until next time, then practice in a real kitchen situation when someone is present to secure the situation.* [Jane]

Combining home-based VR training with in-person therapy was considered an ideal model for stroke rehabilitation. Participants, like Kate, emphasized that while VR enabled frequent, self-paced training at home, regular sessions with a therapist were essential to maintain motivation. This hybrid approach demonstrated VR's potential to extend rehabilitation beyond clinical settings while preserving professional oversight. Balancing self-practice with therapist support was considered crucial. However, as Betty noted, the attitude and behavior of staff introducing VR could significantly influence patient engagement.

> *Let's say the therapist has zero interest in VR. That could easily rub off on the patient. (..) I think it makes a big difference who introduces it to the patients.* [Betty]

As stroke rehabilitation requires extensive repetition to regain lost motor functions, VR was seen as an efficient way to deliver high-volume training, ensuring people after stroke get the practice needed for meaningful improvement. One participant explicitly noted they lacked solutions targeting volume training:

> *The advantage of VR is that you can do high-volume training efficiently. In rehabilitation of people with stroke, you need to spend hundreds of training hours to achieve some really big goals.* [John]

VR was seen as a possible way to make repetitive training more accessible and help people commit to the long-term rehabilitation process necessary for significant recovery. While VR was valuable, it was perceived as a stepping stone for real-life training. During the second workshop, an occupational therapist participant emphasized the limitations of VR in meeting diverse patient needs, noting that some individuals require functional resistance and weight-bearing activities to achieve transferability to real-life tasks:

> *Most people understand that VR is a supplementary tool along the way that bridges the gap, making it easier, but they know they need real life [activities] because that's where they are anyway.*

These results show that VR should not replace traditional therapy but serve as a tool to facilitate a smoother transition to functional activities.

XSL•FO
RenderX

Summary of the Key Findings

The integration of VR into stroke home rehabilitation presents both significant challenges and promising benefits. One of the primary challenges lies in the adaptability of VR systems for individuals with hemiparesis, as these systems must accommodate both right- and left-handed users. This requires considerable technical resources and expertise to ensure that the technology can be effectively tailored to the diverse needs of people after stroke. Additionally, customization remains a complex barrier, as VR solutions must be capable of addressing a wide range of stroke-related impairments and aligning with specific rehabilitation goals, which can vary greatly from person to person. Another critical concern is the balance between engagement and endurance. While VR has the potential to make rehabilitation more stimulating, it is essential to calibrate the intensity and duration of exercises to prevent cognitive overload and fatigue, which are common among individuals with stroke. Usability also poses a significant hurdle; many people after stroke experience limited motor function, which can make it difficult to interact with VR headsets and systems. Furthermore, challenges in visual mapping and task comprehension can hinder the effectiveness of VR-based interventions.

Despite these challenges, VR offers several compelling benefits for enhancing stroke rehabilitation at home. The integration of AI into VR platforms can enable highly personalized rehabilitation experiences, adapting in real time to the user's progress and specific needs. This level of customization can significantly enhance the efficacy of home-based therapy. Moreover, VR has the potential to increase motivation and engagement through gamification, progress tracking, and the simulation of meaningful, real-life tasks that resonate with users. VR also provides a controlled and safe environment for practicing daily activities, which can help reduce anxiety and better prepare people after stroke for real-world challenges. As a supplementary tool, VR can enhance traditional rehabilitation by increasing the intensity and volume of therapy. This aligns with 10 key principles of experience-dependent neuroplasticity, where factors such as specificity, high-repetition, intensity of stimulation, timing, task-specific training, auditory stimuli, and behavioral experience are essential for optimizing recovery outcomes after brain damage [42]. Textbox 1 provides an overview of the main challenges and potential benefits associated with using virtual reality in poststroke rehabilitation. It highlights critical considerations for implementation and the opportunities VR offers to enhance recovery outcomes.

Textbox 1. Summary of the key challenges and benefits in the use of VR for rehabilitation of people after stroke.

Key challenges in virtual reality (VR) usage for people after stroke rehabilitation

- Adaptability for hemiparesis
- VR systems need to accommodate both right- and left-handed users, which requires significant resources and skill to adapt to various people after stroke needs.
- Customization barriers
- VR technology must address individual stroke-related impairments and specific rehabilitation goals, which can be complex and demanding.
- Balance between engagement and endurance
- Tailoring the intensity and duration of VR exercises to avoid overwhelming people after strokes is crucial, especially considering cognitive load and fatigue.
- Usability concerns
- VR headsets and systems can be challenging for people after strokes with limited motor function, and difficulties in visual mapping and understanding tasks.

Key benefits in VR usage for people after stroke rehabilitation

- Enhanced customization with artificial intelligence
- Artificial intelligence–powered VR solutions can provide personalized rehabilitation experiences, address individual needs, and enhance home-based therapy.
- Motivation and engagement
- VR can make rehabilitation more engaging through gamification, tracking progress, and providing meaningful, real-life tasks that motivate people after strokes.
- Controlled and safe environment
- VR offers a controlled environment for practicing real-life tasks safely, reducing anxiety and preparing people with strokes for real-world challenges.
- Supplement to intensive training
- As a complementary tool, VR can increase therapy intensity, providing high-volume, repetitive training efficiently to maximize recovery outcomes.

XSL•FO
RenderX

Discussion

Principal Findings

This study explored the challenges and benefits of co-designing and using VR to support home-based poststroke rehabilitation, with a particular emphasis on user involvement and experience. The TA revealed 5 key themes that offer insight into how VR can be effectively integrated into rehabilitation practices. Adaptability emerged as a central concern, highlighting the need for VR systems to accommodate a wide range of stroke-related impairments, including motor, cognitive, and sensory limitations. Participants emphasized the importance of customizable interfaces and adjustable task difficulty to ensure accessibility and relevance. Safety and ease of use were also critical, with users expressing a preference for intuitive designs that minimize physical strain and cognitive overload, especially in unsupervised home settings. The theme of goal orientation underscored the value of VR in facilitating task-specific training that aligns with personal rehabilitation goals, thereby enhancing the perceived relevance and purpose of exercises. Motivation was closely linked to the immersive and interactive nature of VR, which participants found to be more engaging than traditional methods, potentially supporting persistent participation over time. Finally, the role of VR as a complementary tool reflected a shared understanding that VR should not replace conventional therapy, but rather augment it, offering additional benefits for practice and reinforcement in a flexible, home-based format.

The study has revealed that one of the primary benefits lies in the adaptability and individualization of VR environments to meet the diverse needs of people after stroke. As noted in the study, many people after stroke experience hemiparesis, necessitating VR systems that accommodate both right- and left-affected users. It was noted that the final prototype involving the kitchen scenario factored this in by rewarding participants for using their affected arm. The ability to individualize VR experiences to address specific activities impaired by stroke, such as initially setting up the VR system and further conducting activities, such as reaching and gripping objects, is critical for effective rehabilitation. With appropriate individualization, VR systems have demonstrated significant effectiveness in improving various aspects of stroke rehabilitation, including upper limb function, cognitive abilities, and balance [25,43,44].

However, to bridge the gaps between the recovery process in stroke rehabilitation, technology, and clinical practice, an awareness, exploration, experimentation, and evaluation framework ensuring the solutions are engaging, accessible, accountable, and adaptable is advocated [45]. A common challenge with commercially available gaming technology, such as VR, is that even though it provides immersive, engaging, and tailored therapy (accessibility and engagement), it is not easily adapted for people after stroke, especially those experiencing limited movement or cognition. Based on our assessment, we argue that the complexity of the devices makes them difficult to adjust, posing a challenge for people after stroke to secure them properly and customize them to their individual needs. Although customization was frequently proposed to meet the individual needs of users, this highlights a critical tension. In practice, effective customization demands considerable resources to adequately and efficiently respond to the diverse and complex needs of individuals living with stroke. As indicated by one study, reducing the complexity to one working application on the goggles can limit potential errors [23]. In this study, some individuals required additional assistance in adjusting the headset or coping with cognitive impairments. There is a paradox between the ideal of customization and the reality of implementing it effectively. Achieving this may involve a balance between providing customized opportunities and still making it feasible to implement and ensure its ease of use by categorizing similar users into groups.

VR has the benefit of providing multiple training environments that target individuals by engaging them in meaningful and enjoyable activities, as particularly found in the kitchen scenario. Functional exercises, such as washing dishes, dressing, and brushing teeth, allow people after stroke to develop skills essential for independent living after discharge [46]. This aligns with one study [47], in which people after stroke found different activities in everyday life easier to perform since starting their VR training, such as opening a drawer or applying toothpaste to a toothbrush. Enriched environments are essential in leveraging VR for stroke rehabilitation, as they offer diverse and stimulating approaches to problem-solving and skill development [48]. Some overarching principles that guide an enriched environment approach are complexity, variety, and novelty of the environment as well as targeting underlying needs [49]. In our study, the VR scenarios targeted all principles, but ideas for scaffolding complexity and variety tailored for each individual were proposed.

By simulating real-life scenarios and interactive challenges, VR provides people after stroke with engaging and repetitive practice, which is crucial for neuroplasticity and motor recovery [50]. Additionally, the adaptability of VR allows therapists to modify the learning environment to match individual needs, for example, by adjusting the levels of difficulty, thereby fostering a more immersive and intensive experience that enhances engagement and accelerates rehabilitation progress. This flexibility not only improves functional recovery but also increases motivation and adherence to therapy, making VR a promising tool in modern rehabilitation strategies [51]. In a study by Gustavsson et al [47], VR provided a feeling of being in a different world where users felt they were reaching higher and moving faster. However, VR environments can deceive the mind into believing they are a real-life environment. This illusion is a cause for concern, as the immersive nature of VR can make the brain perceive the simulated surroundings as authentic, thereby inducing a false sense of safety and achievement [52].

Given the challenging nature of rehabilitation for individuals who have experienced a stroke, VR plays a critical role in motivating them by ensuring their active participation and long-term effort in the recovery process. Engaged people after stroke are more likely to adhere to their therapy schedules and participate actively in their rehabilitation exercises. Rehabilitation can be challenging and frustrating, and motivation

XSL•FO
RenderX

helps people after stroke overcome these barriers, persist through difficulties, and maintain a positive attitude toward their recovery [25]. It drives users to push through the physical and emotional challenges of rehabilitation, helping them to stay committed to their therapy even when progress seems slow or when they encounter setbacks. By fostering a sense of achievement and progress, motivation can transform the rehabilitation experience from a daunting task into a rewarding journey.

However, maintaining motivation can be difficult, especially for people after stroke facing mental health challenges, such as depression or anxiety. These conditions can significantly impact their willingness to engage in rehabilitation activities. While we saw that the use of gamification elements, such as points and rewards, served as incentives to motivate people after stroke, they work only if people after stroke understand the real-world relevance of their tasks. Without this understanding, the motivational impact of these gamification elements may be significantly diminished. This highlights the need to design VR programs that closely mimic real-world scenarios to maximize their effectiveness.

Another benefit of VR is that it creates a controlled and secure environment that encourages people after stroke to engage more actively in rehabilitation by reducing the fear of injury, thereby promoting better recovery outcomes when they feel safe enough to push their physical limits. However, this is contingent on structured supervision and support, which are essential to mitigating risks and enhancing user confidence, particularly given the mobility impairments, balance issues, and cognitive challenges faced by people after stroke, which increase the risk of falls or disorientation [25,44]. The importance of therapist involvement in tutorials and adjusting difficulty levels when engaging with VR is highlighted in multiple studies [23,47]. This is particularly important for individuals recovering from stroke, as prolonged exposure to VR may induce motion sickness or dizziness. Additionally, those with impairments in executive functioning and problem-solving challenges observed during our workshops may find it especially difficult to navigate and adapt to such technologies. To maximize the benefits of VR therapy, careful system design, real-time monitoring, and gradual progression in exercise intensity are essential to ensuring a safe and effective rehabilitation experience [53].

While support and guidance in the use of VR emerged as indispensable, this could present challenges in terms of manpower due to the decreasing number of health care professionals. The presence of therapists significantly motivated many individuals with stroke to continue engaging with VR activities. However, this reliance on external motivation could become problematic once they are discharged home, where self-motivation is essential for ongoing rehabilitation [54]. It is not feasible to maintain this level of support when individuals with stroke transition to their home setting. Many people with brain injuries are dependent on help from their families when using digital technologies, such as VR, at home [23,54].

The use of VR presented an advantage in facilitating a goal-oriented approach by enhancing consistent participation and reinforcing the benefits of repetitive practice. The application of motor learning principles in VR design is advocated to enhance rehabilitation outcomes [25]. This includes progressively challenging tasks, real-time performance feedback, and multimodal feedback [25,43]. The development process through the workshops led to improvements in VR content in line with standardized stroke guidelines, such as goal- and task-specific activities and quantifying activities. However, it emerged from the study that the challenge lies in ensuring that VR interventions are carefully designed with clear and specific goals, whether to improve cognitive function, enhance arm movement, or restore balance. It is important that the rehabilitation goals are aligned with the daily needs and personal aspirations of the people after stroke. This requires a deep understanding of each person's lifestyle, preferences, and long-term objectives. Achieving this alignment is challenging, as the goals can change over time, requiring continuous assessment and adjustment of the VR activities to ensure they remain relevant and motivating.

Despite the positive effects associated with measuring progress in VR, the process can be difficult [55]. This difficulty arises from the need to ensure that the metrics used in VR accurately reflect real-world abilities and improvements. While many VR games are primarily designed for entertainment rather than rehabilitation, the importance of involving users in the co-design of VR applications is increasingly recognized [25].

The use of VR in this study revealed that it is beneficial as a complementary tool in stroke rehabilitation, enhancing user engagement, increasing training intensity, and providing structured exercises in both clinical and home environments. While VR cannot replace traditional rehabilitation methods, it can serve as a powerful addition that supplements existing therapy approaches. Previous studies suggest that integrating specific VR technologies with traditional rehabilitation approaches can lead to greater improvements in motor function and activity levels in people after stroke compared with using conventional rehabilitation methods alone [56-58]. For example, VR can provide repetitive and varied exercises that target specific motor skills, helping people after stroke to practice and refine their movements in a controlled environment, thereby freeing therapists from the mundane tasks of high-volume training.

A potential benefit could also be, as found in a study [59], that VR demonstrated significantly greater therapeutic effects than conventional training in improving upper limb function, as assessed by the Fugl-Meyer and Action Arm Research Tests [32]. Following the stroke trajectory, VR could be implemented during the hospital stay, as a prepractice and supplement to real-life activities. In the home setting, it would need to be scaled down to accommodate safety precautions, but has the possibility to be further scaffolded when returning for follow-up at the hospital in cooperation with health care professionals. A significant challenge in using VR for rehabilitation is ensuring its effective integration with traditional therapy while maintaining professional oversight as rehabilitation extends beyond clinical settings.

Successful integration is essential, as it necessitates a seamless combination of VR-based and conventional approaches to

XSL•FO
RenderX

optimize therapeutic outcomes. Professional oversight remains crucial for monitoring patient progress, adjusting interventions, and providing ongoing support tasks that become increasingly difficult to maintain once people transition to home-based rehabilitation after stroke.

Implications for Practice

Our findings suggest that VR could be a valuable supplement to traditional rehabilitation for specific stroke groups, but it cannot replace the essential contact with the therapist, clinical reasoning, or the assessment of activity limitations and opportunities. We propose that VR could be particularly beneficial for a younger population with stroke who lack sufficient access to home-based rehabilitation and struggle with motivation for self-training. Additionally, VR may help maintain function in individuals in the chronic phase after a stroke, where repetition and high-quality training are crucial to prevent functional decline. However, it is important to acknowledge that VR cannot fully replicate training in real-life, everyday activities. For VR solutions to be effective, they must be carefully tailored to the individual's functional level and ease of use. This tailoring process, however, can be resource-intensive in an already strained health care system.

In light of this, we raise important questions about who will truly benefit from VR, given the wide range of outcomes following a stroke, and whether, in some cases, it may be more appropriate to prioritize traditional therapy. Finally, we emphasize the importance of training for relatives and caregivers, as their role may be critical to the successful use of VR at home.

Limitations and Future Work

The limitations of this study primarily stem from the use of a qualitative single case study design [27], which provides an in-depth understanding of the real-life phenomenon but may limit the generalizability of the findings across broader contexts. The reliance on rapid prototyping and TA, while effective for capturing detailed insights into VR usage in poststroke rehabilitation, may not fully address the variability of experiences and needs among a wider population of people after stroke. Also, the rapid evolution of VR technology means that some of the results will soon be outdated, limiting the applicability of the findings to current and future developments in the field [55,60].

Future work should aim to expand the scope of research by incorporating multiple case studies across diverse settings to enhance the generalizability of the results. This could involve a larger and more varied participant pool to capture a broader range of experiences and needs. Future work should focus on developing integrated, individualized therapy solutions that seamlessly combine arm therapy, cognitive therapy, and mental support within a single solution, addressing the multifaceted rehabilitation needs, such as cognitive needs or physical therapy needs, of individuals with stroke as described in Gkintoni et al [61].

This requires implementing design methodologies that facilitate co-creation with diverse stakeholders, including health care professionals, VR developers, and people after stroke with varying needs, ensuring that the solutions are both inclusive and effective. Efforts should also be directed toward creating a smooth transition from hospital settings to home environments for people after stroke, as described by Pourliaka et al [62], using VR to extend rehabilitation beyond clinical settings while maintaining professional oversight.

Furthermore, the development of AI-powered solutions that account for the personalized goals, needs, and situations of people after stroke is crucial, enabling tailored interventions that adapt to individual progress and challenges. For instance, the system could select the most appropriate exercises based on how individuals perform each exercise [63]. One option is to incorporate validated assessments, such as the short-form of MoCA [31,64], to evaluate patient situations accurately and guide therapy adjustments.

Designing solutions that not only excite individuals with stroke, but also genuinely facilitate improvements in their therapy goals and daily life challenges is vital. This involves crafting engaging VR environments that motivate consistent participation while ensuring real-world relevance and measurable benefits in rehabilitation outcomes. Further exploration of potential scenarios that can adapt to the individual requirements of home rehabilitation over time is also essential.

Additionally, more validation studies, for example, pilot trials or feasibility studies to evaluate the preliminary effects and randomized controlled trials to evaluate actual VR solution outcomes, are urgently needed [54]. In addition, standardized usability and comfort measures, such as the System Usability Scale and the Virtual Reality Sickness Questionnaire, were not used. Their inclusion could have offered more structured and quantifiable assessments of user experience, particularly regarding interface usability and potential adverse effects like motion sickness. Future work should consider integrating these validated instruments to complement qualitative feedback and provide a more comprehensive evaluation of user interaction and comfort.

Conclusion

This study underscores the transformative potential of VR in advancing stroke rehabilitation. VR provides a dynamic and interactive platform that can be customized to support the individualized trajectories of recovery, accommodating the physical limitations, cognitive profile, and personal goals of people after stroke. Its core strength lies in its adaptability by offering immersive simulations of real-world tasks that foster motivation and engagement through meaningful and goal-directed experiences. However, the successful application of VR in rehabilitation requires more than technological advancement. It needs to be integrated thoughtfully with established rehabilitation principles, including task-specific training, measurable and ecologically valid outcomes, as well as alignment with the evolving needs of individuals. A critical insight from this study is the necessity of embedding clear therapeutic intent into VR interventions. Whether the objective is motor recovery, cognitive enhancement, or balance restoration, each activity should serve a purpose that is clinically relevant and meaningful to the user's daily life. This demands a comprehensive understanding of individual motivations,

XSL•FO
RenderX

challenges, and aspirations through involving people after stroke in the design process. It is through participatory co-design that developers can ensure that VR experiences are both engaging and clinically appropriate. As an emerging technology, VR should not be considered a replacement for traditional therapy, but rather a powerful adjunct that can increase training intensity, reduce the burden on therapists, and extend rehabilitation into home settings, making therapy more accessible and continuous. When thoughtfully designed and implemented, VR can bridge the gap between structured clinical care and independent recovery, providing consistent support throughout the rehabilitation journey.

Abstract

Background: Over the past 2 decades, virtual reality–based neuropsychological tasks have gained traction as tools for objectively assessing symptoms of attention-deficit/hyperactivity disorder (ADHD), offering enhanced ecological validity by simulating naturalistic environments. To complement realistic settings with an ecologically valid task, we recently developed the virtual email sorting task (VEST), which immerses participants into an office environment where they sort emails while being exposed to distractors.

Objective: This study examined for the first time the VEST's sensitivity to medication effects and its specificity in differentiating ADHD from other psychiatric disorders that share overlapping cognitive symptoms, such as major depressive disorder (MDD).

Methods: A total of 23 unmedicated individuals with ADHD, 23 medicated individuals with ADHD, and 16 unmedicated individuals with MDD completed the VEST. During alternating distractor phases (DP) and nondistractor phases (NDP), we recorded the participants' task performance; head, torso, and leg actigraphy; eye movements; and brain activity using functional near-infrared spectroscopy (fNIRS), and subjective symptom ratings. Correlational analyses of main objective and subjective task-related parameters were computed. Data were analyzed using mixed-design ANOVAs.

Results: Processing time variability increased over time in participants with MDD and unmedicated ADHD as indicated by a group × block interaction (P=.04; η^2_p=0.10), while a group × phase interaction (P=.009; η^2_p=0.15) revealed that medicated participants with ADHD showed an increase during DP compared to NDP. Moreover, both ADHD groups exhibited increased head movements during DP compared to NDP (trend group × phase interaction: P=.09; η^2_p=0.08), an effect not observed in the MDD group, and higher rotation during DP in unmedicated individuals with ADHD (P<.001; η^2_p=0.23). Also, scores in 3 out of 4 subjective symptom intensity ratings of inattention, impulsivity, and emotional dysregulation were higher in at least 1 of the ADHD groups compared to the MDD group. No significant group differences were found in actigraphy measures of the arm and torso, fNIRS brain activity, or eye-tracking data. Regarding correlational analyses, inattention was correlated to off-task gaze (r=0.28; P=.03), hyperactivity with mean processing time (r=0.33; P=.01) and head movement (r=0.35; P=.006), and impulsivity with error rate (r=0.35; P=.006), and various significant correlations between objective parameters were found.

Conclusions: Our findings highlight the potential of the VEST to differentiate between ADHD and MDD, as well as to detect medication-related effects within ADHD. The results underscore the value of multimodal and ecological assessment approaches with distractors in the evaluation of attentional and behavioral symptoms. The VEST may offer a standardized way to investigate

XSL•FO
RenderX

complex behavior in mental disorders in research settings and, potentially, in clinical practice. However, further studies with greater statistical power are needed to confirm these findings.

Introduction

For attention-deficit/hyperactivity disorder (ADHD), a neurodevelopmental disorder with an estimated prevalence of 5% in children and 2.58% in adulthood [1,2], the search for assessment tools to objectively assess its core symptoms of inattention, impulsivity, and hyperactivity [3] has been ongoing. At present, to assess adult ADHD, clinical interviews and self-report questionnaires are primarily used [4,5]. While these methods provide the highest diagnostic accuracy to date, they are influenced by various confounding factors, such as varying introspective skills and recall bias [6,7]. To overcome these limitations, researchers have explored various measures such as neuropsychological tests [8] and biomarkers [9]. Although such measures have successfully distinguished individuals with ADHD from healthy controls (HC) at the group level, they still lack sufficient clinical precision for accurate diagnoses at the individual level [8,10,11]. Moreover, studies often focus only on one or two domains such as performance or brain activity [12,13], and therefore may fail to encompass the full complexity of the disorder. Hence, to further increase the accuracy of the objective assessment of symptoms of ADHD and to fully depict the disorder, the search for suitable tools has been ongoing.

In recent years, virtual reality (VR)–based assessments have gained increasing popularity in the assessment of mental disorders in general [14], and especially in ADHD [15]. As outlined in more detail in previous works [16], VR-based assessments offer several advantages over traditional neuropsychological tasks. First, VR setups provide immersive features, such as the presentation of complex 3D environments that participants can interact with in a highly standardized manner [17]. Second, VR environments, such as virtual classrooms, are considered to be more ecologically valid than the experimental setups typically used in conventional neuropsychological tests [17]. Third, to examine the ADHD symptom of increased distractibility [3], realistic auditory and/or visual distractors can be incorporated into VR scenarios, allowing researchers to study their impact on various outcome measures. Fourth, VR can be integrated with a variety of physiological measures, including brain imaging, eye tracking, and actigraphy, enabling a multimodal assessment covering both behavioral and physiological indicators of ADHD [18,19].

One of the first VR-based assessment paradigms making use of these advantages for adults with ADHD was the virtual seminar room (VSR) [16,20], which was developed by our research group and inspired by a similar paradigm for children with ADHD, the virtual classroom [21]. In both paradigms, participants have to perform a continuous performance task (CPT) projected to the front of the virtual environment on a whiteboard or chalkboard, while the surrounding level of distraction is systematically varied by phases of high distraction (distractor phases [DP]) and low distraction (nondistractor phases [NDP]). Using the CPT, a neuropsychologically validated task for measuring sustained attention and impulsivity, in which participants are required to respond to target stimuli (eg, letters) and suppress responses to nontarget stimuli [22], was integrated into an ecologically valid classroom setting [21].

The multimodal VSR allowed for the measurement of task performance, brain activity via electroencephalography and functional near-infrared spectroscopy (fNIRS), head actigraphy, eye movements, and subjective symptom intensity. Differences were found, for instance, in CPT performance and actigraphy between individuals with ADHD and HC [20]. Based on separate training and test sets generated across multiple VSR studies [20,23], participants could be classified as ADHD or HC with 81% accuracy [18]. However, while the VSR represents a successful first step toward a more ecologically valid VR-based assessment of adult ADHD, within this scenario, it continues to rely on the highly abstract CPT.

To address this, we developed the virtual office room [24]. In this paradigm, the virtual environment is displayed in an open space office room in which the participants sit at a desk in front of a virtual desktop and perform a virtual email sorting task (VEST). In contrast to the CPT applied in the VSR, the VEST follows a more function-led than construct-driven approach, as the task is designed to simulate everyday goal-directed behavior within a realistic work context to increase its generalizability to real-world behavior [17]. Hence, more realistic stimuli material and task design are used than in the CPT. Moreover, as in the VSR, participants are exposed to alternating DP and NDP. In a first study using the VEST [24], we found a higher PTV in the ADHD group than in the HC, and a higher increase in head movement from NDP to DP in ADHD.

Beyond the differentiation between adults with and without ADHD, VR-based neuropsychological tests may also assist in assessing the effects of pharmacological treatments or other therapeutic interventions. This could, for instance, help in determining whether a treatment should be continued or adjusted, and which specific symptoms are being positively or insufficiently impacted. Up to now, the effect of medication has been investigated in 3 studies in children/adolescents using VR-based neuropsychological tests. All studies applied a virtual classroom scenario and reported lower reaction time variability [25-27], lower omission errors [25,27], as well as lower reaction times, commission errors, and decreased head movements [25] in medicated participants compared to unmedicated participants. In adults, we found a trend effect between medicated and

XSL•FO
RenderX

unmedicated participants on omission errors in the VSR [20]. In summary, while VR-based neuropsychological tests have shown promising initial results in detecting medication effects, further research is needed, especially in adult populations.

To evaluate the potential of the VEST for ADHD in adulthood, it is crucial to also examine its capacity to differentiate individuals with ADHD from individuals with other psychiatric disorders that can involve similar cognitive impairments. As a first step in this approach, we decided to test a sample with major depressive disorder (MDD) in comparison to ADHD. In addition to the generally high comorbidity of the two disorders, they overlap in some cognitive domains [4,28], which is why it is of interest to see whether the multimodal procedure can be used to find parameter characteristics that are specific to ADHD. As of now, there have only been VR-unrelated studies investigating differences in neurocognitive function between individuals with ADHD and individuals with MDD. Potvin et al [29], for example, report similar cognitive performances of both groups in various measures of subjective and objective cognitive function, including working memory and processing speed, with lower performances than HC. Moreover, in a study by Paucke et al [30], individuals with MDD, with ADHD, and with both disorders, showed impairments in sustained attention compared to HC. In a study adopting the group design of Paucke et al [30] with a notably higher sample size, Van Hal et al [31] found impairments in attention and other executive functions in all clinical groups. With regard to actigraphy, while a plethora of studies have investigated movement in daily life in individuals with MDD [32], to the best of our knowledge, no studies have applied actigraphy measures during the performance of neuropsychological tasks. In general, MDD is associated with psychomotor disturbances such as psychomotor agitation and retardation [33], and individuals with MDD show lower activity than HC [32]. Considering differences in eye movement behavior in MDD compared to HC, studies have shown an increased maintenance of gaze on dysphoric and decreased maintenance of gaze on positive stimuli [34], in addition to slower reaction times in pro- and antisaccade tasks [35]. As of now, however, no studies have investigated the influence of distracting stimuli on task performance in MDD. When examining brain activity using fNIRS, the dorsolateral prefrontal cortex (dlPFC) appears to be of particular interest in ADHD, where reduced oxyhemoglobin (oxy-Hb) concentrations have been observed during inhibition tasks [36]. Similarly, studies in individuals with depression have also reported differences in activation levels in this brain region compared to HC during verbal fluency tasks [37]. Although both clinical groups show dlPFC hypoactivation across different cognitive tasks, it remains of interest to explore whether, particularly the component of distractor inhibition, reveals a pattern that is specific to ADHD compared to MDD and if so, how it is altered through medication.

The aim of this study was to investigate the VEST's sensitivity to medication effects and its potential to differentiate individuals with ADHD from those with other psychiatric disorders. To this end, we compared 3 groups: unmedicated individuals with ADHD, medicated individuals with ADHD, and unmedicated individuals with MDD. Specifically, we examined performance on the VEST, eye movement behavior, brain activity measured via fNIRS, motor activity assessed through actigraphy (head, torso, nondominant arm, and opposite leg to nondominant arm), and self-reported symptom intensity. In addition to group comparisons, we investigated distractibility and time-on-task effects.

Based on the existing literature, we hypothesized that both ADHD groups would exhibit greater head and body movement than the MDD group.

Based on the heterogeneity and limited number of prior studies, we also formulated two research questions:

1. Can the VEST differentiate on any outcome parameter between medicated and unmedicated individuals with ADHD?
2. Can the VEST differentiate on any outcome parameter between unmedicated individuals with ADHD and unmedicated individuals with MDD?

Methods

Ethical Considerations

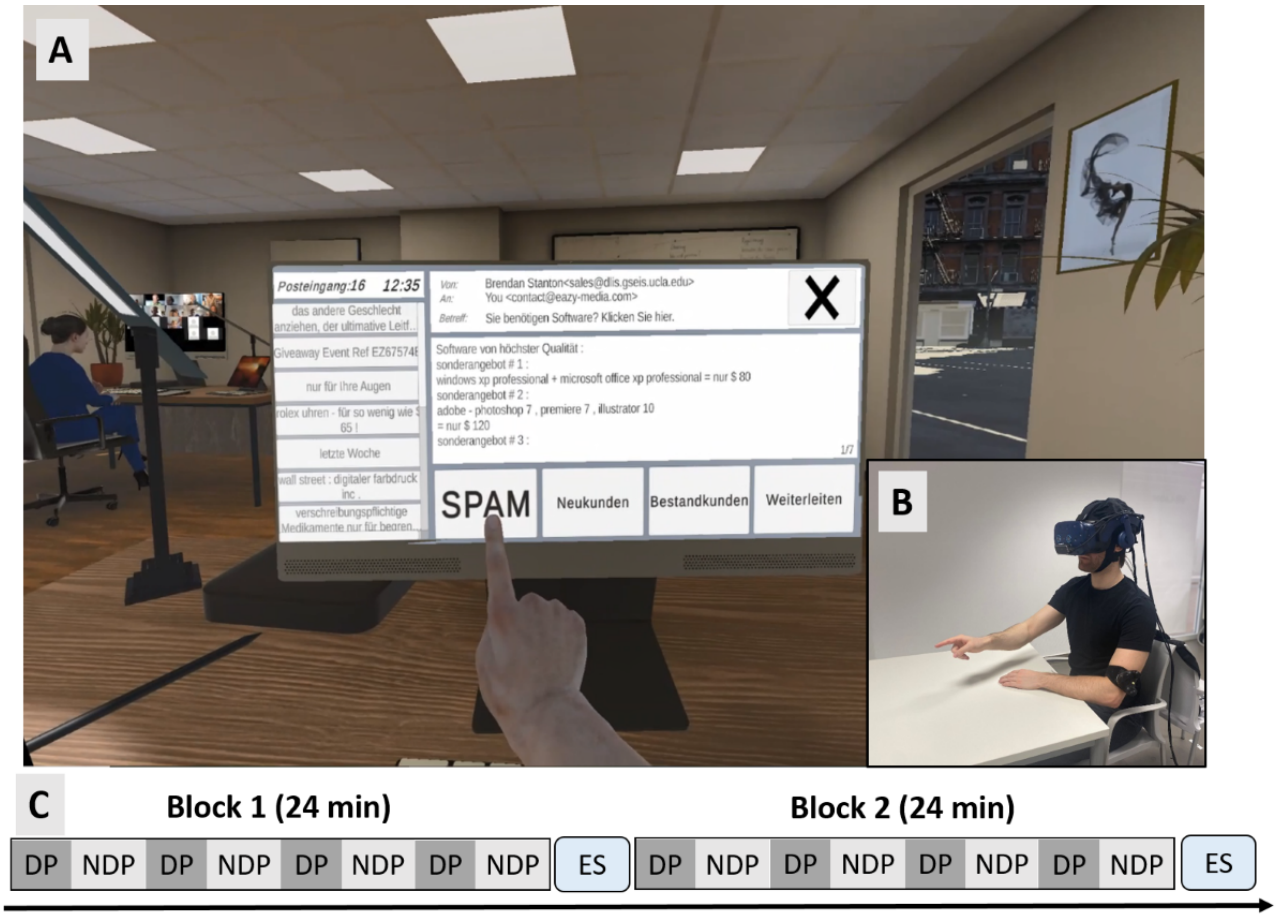
The study received approval from the ethics committee of the Faculty of Medicine at the University of Bonn (protocol number 105/23) and was preregistered on July 20, 2023, in the German Clinical Trials Register (DRKS00031259). All participants were informed in advance about the study's objective and procedures, the use of technical equipment, and possible risks of participation such as motion sickness, and they provided written consent before taking part. Personal data such as names and addresses were recorded only on paper documents, including the consent form and the reimbursement form. A study ID was used for all data collection. Participants received a compensation of €40 (US $47.5) for full participation. Individuals who had to be excluded after the first session or who dropped out received prorated compensation.

Participants

A total of 63 individuals participated in the study, including 24 medicated adults with ADHD, 23 currently unmedicated adults with ADHD, and 16 unmedicated adults with MDD. The participants were recruited in various ways: direct approach of suitable individuals at the ADHD outpatient clinic of the University Hospital Bonn, advertisements on the internal website, posting flyers in outpatient clinics, writing to self-help groups, and a press release followed by a radio report. Participants could take part in the study if they fulfilled either ADHD or MDD criteria but no other severe psychiatric disorder, such as psychosis or severe addiction disorder. Participants were not screened for comorbid autism spectrum disorder, as autism spectrum disorder did not constitute an exclusion criterion and its prevalence in the population with ADHD is markedly lower in adults compared to children and adolescents [38]. Furthermore, participants had to be aged between 18 and 50 years, have normal or corrected-to-normal vision, and no history of epilepsy or other severe neurological disorders, pregnancy, or skin irritation on the head.

XSL•FO
RenderX

General Procedure



The study consisted of 2 separate appointments. During the first appointment, participants underwent a clinical assessment after providing informed consent. The assessment had 2 main objectives. First, to confirm the diagnoses of ADHD or MDD, depending on which group the participant should be assigned to, and to rule out the respective other condition. Second, to identify potential comorbidities that signified as an exclusion criterion. The assessment lasted approximately 1-2 hours and was conducted either in person at the psychiatry department of the University Hospital of Bonn or via a video call using the online platform Red Connect [39]. Two clinical interviews were administered: the Diagnostic Brief Interview for Mental Disorders (Mini-DIPS) [40] to screen for 17 mental disorders and the Integrated Diagnosis of ADHD in Adulthood [41] to confirm or rule out the diagnosis of ADHD. Both interviews are based on the criteria of the *DSM-5* (*Diagnostic and Statistical Manual of Mental Disorders* [Fifth Edition]) and *ICD-10* (*International Statistical Classification of Diseases, 10th Revision*) and were conducted in German. After the clinical interviews, participants completed various self-rating scales via the online survey tool SoSci Survey [42], including the Patient Health Questionnaire-9 (PHQ-9) [43], and ADHD Self-Rating Scale (ADHS-SB) [44]. Additionally, a self-constructed questionnaire was administered to collect various sociodemographic data and the medication status. If no exclusion criteria applied during the initial assessment, participants were invited to the second appointment. During this session, the actual VR experiment took place in the VR laboratory of the University Hospital of Bonn. Once prepared, 3 motion trackers were affixed to the participants. Next, they were seated, and preparations for fNIRS recording commenced. Prior to the start of data acquisition, participants were fitted with the head-mounted display (HMD), and the VR environment was launched. Within the VR, a brief eye-tracking calibration was conducted, followed by a 30-second acclimation period to allow participants to familiarize themselves with the virtual setting. After that, participants received task instructions and completed a short practice block, before the actual experiment started. This consisted of 2 blocks, each lasting 24 minutes. Symptom assessments were conducted following both blocks, and the Virtual Reality Sickness Questionnaire (VRSQ) [45] was administered at the conclusion of the session. Throughout the experiment, the software Lab Streaming Layer (Christian Kothe) [46] was used to record and synchronize all data streams, including task performance, fNIRS, actigraphy, and eye-tracking data. Following completion of the experiment, all measurement devices were removed, and participants were debriefed and dismissed. Since the same study supervisor conducted both the diagnostic assessment and the VR session, the study did not include experimenter blinding.

Apparatus and Virtual Environment

The VR scenario was presented via the HTC VIVE Pro Eye HMD (HTC Corporation). The VR scenario (Figure 1) was created using Unity 3D (version 2019.4.11f1; Unity Technologies) and coded in C# [24]. To enable controller-free interaction with the virtual environment, a Leap Motion Controller (Ultraleap) was used to track participants' hand movements and online transfer them to a virtual 3D hand model ("Leap Motion Realistic Hands," Unity Asset Store). The VR environment, entered via the HMD, depicted an open-plan office equipped with typical office supplies, furniture, and virtual colleagues (Figure 1; for further specifications of hardware and software, see Multimedia Appendix 1 [47,48]). In front of the participant, the VEST was displayed on a virtual computer screen.

(B) Participant during the experimental session taking place in the virtual reality laboratory of the University Hospital Bonn. (C) Experimental timeline. DP: distractor phase; ES: experience sampling; NDP: nondistractor phase.

VEST

During the experiment, participants had to perform the VEST, a task that we developed and piloted in a previous study [24]). Compared to conventional CPTs, which often involve abstract stimuli, the VEST uses stimuli that mirror real-world office activities. In this task, participants assumed the role of a secretary in a marketing agency, where they were required to categorize incoming emails into 1/4 predefined categories: "spam," "new customer," "existing customer," and "forward." To ensure comparability with classical CPT paradigms, the task was structured such that 65% (389/599) of emails belonged to the spam category, making it the default response. Emails classified as "new customer" and "existing customer" each comprised 15% (90/599) of the total emails, while 5% (30/599) of emails fell into the "forward" category. Emails classified as "spam" were sourced from the Enron Spam Dataset ("Enron Spam Dataset," 2015) but translated into German before usage. Emails for the remaining categories were composed by members of our research group and written from the perspective of a fictitious company or private individual and included both a subject line and a request relevant to a marketing agency. The emails contained clear identifying features corresponding to their respective categories, ensuring that each email had only one correct classification. In total, 599 mails were used in the VEST and presented in a randomized order.

The emails were displayed on a virtual computer screen in front of the participants (Figure 1). The screen simulated a touch interface, allowing participants to interact with it by using their virtual hands to select the appropriate category for each email (Figure 1). Emails did not expire after a certain time limit, so participants performed the task at their own pace—once an email was categorized, the next email would automatically open. Each block consisted of 4 DP and 4 NDP, each lasting 3 minutes and alternating. Consequently, over the course of the entire experiment, participants experienced 8 DP and 8 NDP. During each DP, 6 visual, auditory, or audiovisual distractors were presented in succession, each lasting 30 seconds. These distractors were randomly selected from a pool of 48 potential distractors. The order of the first phase in each block (ie, whether it was a DP or NDP) was counterbalanced across participants.

To assess the participants' performance on the VEST, 3 distinct parameters were separately extracted for each DP and NDP: the average processing time and PTV (calculated by using the coefficient of variation) per email as measures of vigilance, and the error rate of misclassified emails as an indicator of inattention and impulsivity. For the statistical analysis, the mean values of each parameter were calculated across all DP and NDP per block.

Experience Sampling

To evaluate participants' subjective symptom experience, a VR-embedded user interface controlled via gesture input was

XSL•FO
RenderX

presented immediately before block 1, between the 2 blocks, and at the end of block 2. For each block, participants were asked to rate their momentary levels of inattention, impulsivity, and hyperactivity [18,20,24], as well as their emotional dysregulation. The items were rated on a 7-point Likert scale, ranging from –3 to +3. For statistical analysis, only the subjective symptom reports collected after block 1 and block 2 were used. Following the final subjective symptom report, the VRSQ was presented on the same interface and Likert scale. The VRSQ includes 8 items assessing potential physical discomfort from VR exposure, from which a total score is calculated [45].

Actigraphy Recording and Analyses

During task execution in the VR environment, the movements of the participant's head, torso, arm, and leg were recorded. Head movement data were acquired via the HMD, with its position and rotation continuously tracked in the 3D space defined by the base stations. The movements and rotation of the torso, arm, and leg were captured using HTC Vive trackers (HTC Corporation), each of which was also tracked in the 3D space relative to its own dedicated base station. The placement of the trackers depended on the participants' handedness, that is, for right-handed participants, 1 tracker was attached to the left upper arm, 1 around the torso, and 1 to the right ankle. For left-handed participants, the position of the ankle and upper arm were reversed. In line with our previous studies [16,20,24], all motion data were processed using a uniform analytical approach. First, the data were down sampled to ~10 Hz. Subsequently, the Euclidean distance between successive data points was calculated to quantify the change in position and rotation over time. The mean changes per task phase were then computed to summarize movement dynamics.

Eye Tracking Recording and Analyses

To track the participant's horizontal and vertical eye movements, the Tobii eye tracker (Tobii Technology) built into the HTC Vive Pro Eye was used (for further specifications of hardware and software, see Multimedia Appendix 1). Here, we tracked the participant's duration of momentary gaze focus on the canvas on which the task was displayed on and the duration spent looking away from the canvas (off-task gaze) [24]. The momentary gaze focus time spent off-task was calculated for each NDP and DP.

fNIRS Recording and Analyses

As in previous studies [16,20,24], the participants' fNIRS brain activity was recorded during task performance by the NIRSport 2 system (NIRx Medical Technologies) and acquisition software Aurora fNIRS (NIRx Medical Technologies). We focused on oxy-HB in the dlPFC tracked by 2 channels (Fc1-Fc3, Fc2-Fc4; see also [20]), taking previous studies on ADHD using fNIRS [36] and spatial constraints into consideration (for further specifications of hardware and software used for recording and preprocessing, see Multimedia Appendix 1). For following statistical analyses, DP and NDP were first split into six 30-second units, equivalent to the length of distractor intervals in DP. Next, block averages across all units per phase were determined, and mean concentration of oxy-Hb was calculated for each phase. Lastly, each NDP was subtracted from its corresponding DP, and mean DP-NDP contrasts across all DP-NDP pairs were determined for each participant.

Missing Data Handling

One participant was not able to conclude the experiment due to motion sickness in the second block and was excluded from analysis. For the VEST performance and head actigraphy, all remaining 62 datasets were complete and included; for eye tracking analysis, the sample was reduced to 61 datasets. Due to intermittent data transfer issues with the body trackers, some datasets were incomplete. If at least 3 out of 4 phases were successfully recorded, the phase average for each block was calculated using the 3 available values. However, datasets with more than 1 missing phase were excluded from the analysis. Using this approach, 58 datasets were included in the analysis of arm movements and 45 datasets in the analysis of torso movements. For leg movements, only 35 datasets remained, which led to the exclusion of this parameter from the analysis. Regarding the fNIRS data, 33 datasets were excluded for the left dlPFC and 39 for the right dlPFC due to insufficient data quality, leading to a reduced sample of n=29 and n=23, respectively. Since fNIRS was the only method used for analyzing brain activity in this study, the remaining datasets were still analyzed despite the decreased sample size. Multimedia Appendix 2 [49] presents descriptive summaries of missing data by modality and binary logistic regression analyses assessing whether missingness was associated with group, gender, and age.

Statistical Analysis

For the majority of parameters of interest (eg, error rate; processing time; PTV; head, torso, and arm rotation and position; and off-task gaze), separate 3×2×2 mixed-design ANOVAs were conducted, with group as a between-subjects factor and block and phase as within-subject factors. For the experience sampling data, a 3×2 mixed-design ANOVA was performed with group and block as factors. Analyses of fNIRS and VRSQ data were conducted using 1-way ANOVAs with group as the factor. Furthermore, we conducted an exploratory correlational analysis of the objective parameters and subjective, task-related symptom intensity. For this purpose, we used aggregated values across phases and blocks. Because of the exploratory nature of the correlational analysis, we decided not to correct for multiple testing. Statistical significance was set at $\alpha<.05$ and α between .05 and .10 was considered as a statistical trend level for all calculations.

Due to right-skewed distributions, several variables (eg, error rate, off-task gaze, and actigraphy measures for arm and torso) were subjected to square root transformations prior to analysis. Inattention scores exhibited left skewness; thus, these data were first mirrored and then square root transformed. Homogeneity of variances was assessed using Levene test, with $P>.05$ indicating acceptable homogeneity for all variables except inattention, for which homogeneity was not achieved despite transformation.

To control type I error inflation due to multiple testing, Bonferroni corrections were applied to the main effect of the

XSL•FO
RenderX

3-level group factor in the ANOVA, to interaction terms, and to all post hoc group comparisons. Effect sizes were interpreted according to Cohen [50] with partial eta squared (η^2_p) values of 0.01, 0.06, and 0.14 representing small, medium, and large effects, respectively for ANOVA results and Cohen *d* with values of 0.2, 0.5, and 0.8 representing small, medium, and large effects for post hoc comparisons.

Results

All key ANOVA results are summarized in Multimedia Appendix 3.

Sample

The sample consisted of 46 participants with ADHD, equally divided between the medicated and unmedicated groups, and 16 individuals with MDD. The 3 groups did not significantly differ in terms of gender, age, handedness, or level of education. Regarding self-reported clinical measures, the groups only differed on those that were specific to ADHD. Further demographic details can be found in Table 1.

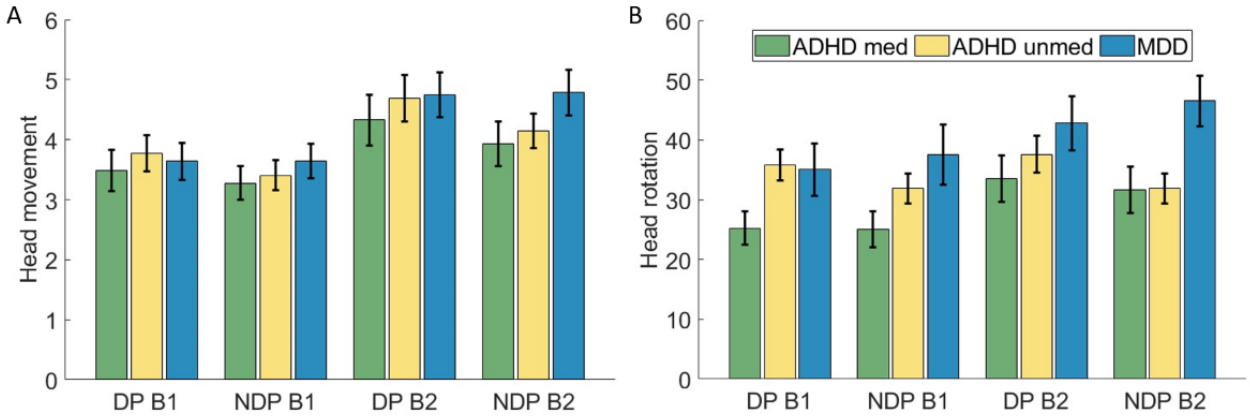
VEST Performance

Performance data of the VEST are presented in Figure 2. The analysis of mean processing time revealed significant main effects of block ($F_{1,59}$=68.22; P<.001; η^2_p=0.54) and phase ($F_{1,59}$=23.99; P<.001; η^2_p=0.29), but not of group ($F_{2,59}$=1.49; P=.24). Mean processing time was higher in block 1 than block 2 (mean difference [MDiff]=4.48, 95% CI 3.40-5.57) and higher in DP than NDP (MDiff=1.86, 95% CI 1.10-2.61). In addition, there was a significant interaction of block × phase ($F_{1,59}$=4.00; P=.05; η^2_p=0.06), which was not further interpreted.

Figure 2. Results of the virtual email sorting task. (A) Mean processing time in seconds. (B) Processing time variability. (C) Error rate. Error bars indicate the standard error of the mean. ADHD: attention-deficit/hyperactivity disorder; B1: block 1; B2: block 2; DP: distractor phase; MDD: major depressive disorder; med: medicated; NDP: nondistractor phase; unmed: unmedicated.

For PTV, the analysis yielded a significant main effect of block ($F_{1,59}$=8.39; P=.005; η^2_p=0.12), indicating a higher PTV in block 2 than block 1 (MDiff=–0.05, 95% CI –0.09 to –0.02). There were no significant main effects of phase ($F_{1,59}$=0.46; P=.50) and group ($F_{2,59}$=1.18; P=.32). However, the analysis revealed significant interactions of block × group ($F_{2,59}$=3.35; P=.04; η^2_p=0.10), phase × group ($F_{2,59}$=5.09; P=.009; η^2_p=0.15) and a trend for block × phase ($F_{1,59}$=3.79; P=.06; η^2_p=0.06), which was not further interpreted. In the pairwise comparisons, we found a significantly higher PTV in block 2 than 1 in the unmedicated ADHD group (P=.03; d=0.39; MDiff=–0.07, 95% CI –0.13 to –0.01) and in the MDD group (P=.005; d=0.95; MDiff=–0.11, 95% CI –0.18 to –0.03), but not in the medicated ADHD population (P=.73). For phase × group, pairwise comparisons revealed a significant difference between DP and NDP in the medicated ADHD group (P=.02; d=0.78) with higher PTV in DP than NDP (MDiff=0.07, 95% CI 0.02-0.12), while for the unmedicated ADHD group (P=.09) and the MDD group (P=.88) there was no significant difference.

The analysis of square root–transformed error rates yielded a significant main effect of phase ($F_{1,59}$=41.12; P<.001; η^2_p=0.41), indicating a higher error rate in DP than NDP (MDiff=0.02, 95% CI 0.01-0.02). Apart from that, no significant main effects of block ($F_{1,59}$=1.79; P=.19) or group ($F_{2,59}$=0.04; P=.96) or significant interactions were found.



Actigraphy Results

Head

Results of head actigraphy analyses are depicted in Figure 3. The ANOVA for head movement revealed significant effects of block ($F_{1,59}$=60.12; P<.001; η^2_p=0.51) and phase ($F_{1,59}$=23.99; P=.005; η^2_p=0.13), but not of group ($F_{2,59}$=0.48; P=.62). Movement was greater in block 2 compared to block 1 (MDiff=–0.90, 95% CI –1.13 to –0.67), and higher in the DP condition than in NDP (MDiff=0.25, 95% CI 0.08-0.42). A trend toward a phase × group interaction was also observed ($F_{2,59}$=2.56; P=.09; η^2_p=0.08). Pairwise comparisons indicated significantly increased movement in DP compared to NDP for both ADHD groups (medicated: P=.03; d=0.42; MDiff=0.30, 95% CI 0.03-0.59; unmedicated: P=.001; d=0.66; MDiff=0.46, 95% CI 0.19-0.73), whereas no significant difference was found in the MDD group (P=.89).

XSL•FO
RenderX

Figure 3. Results of head actigraphy analysis. (A) Head movement. (B) Head rotation. Error bars indicate the standard error of the mean. ADHD: attention-deficit/hyperactivity disorder; B1: block 1; B2: block 2; DP: distractor phase; MDD: major depressive disorder; med: medicated; NDP: nondistractor phase; unmed: unmedicated.

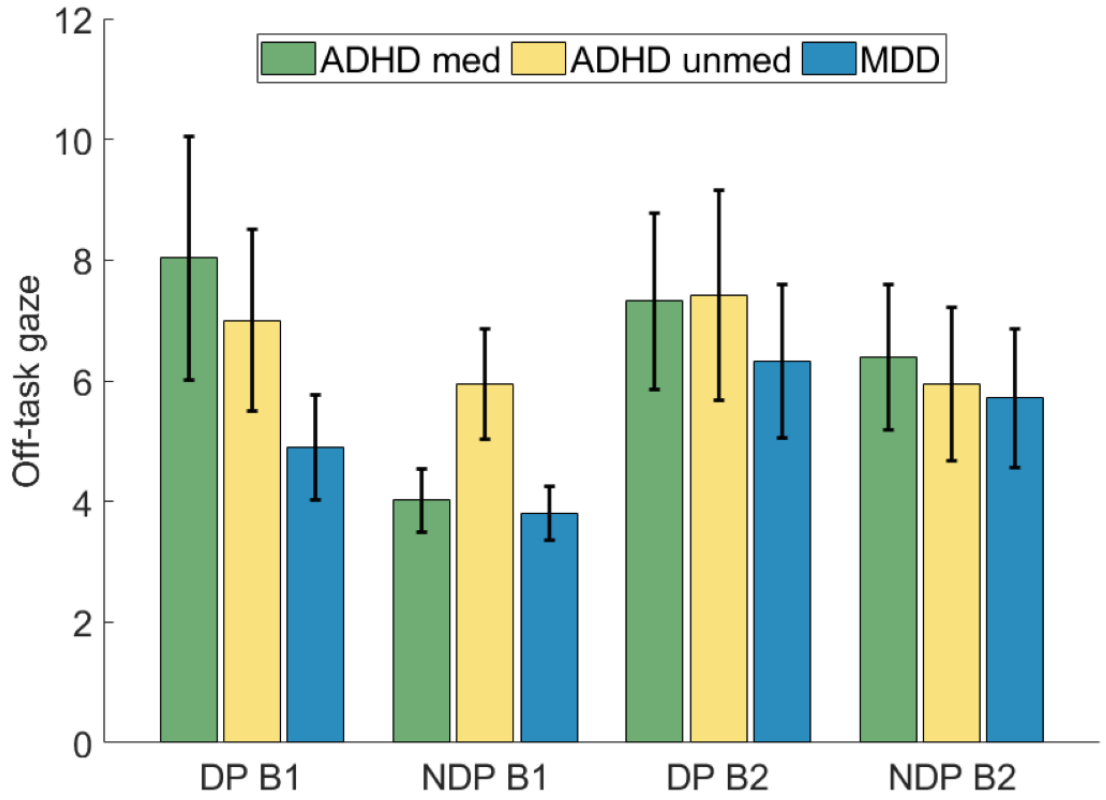
For head rotation, a significant main effect of block emerged ($F_{1,59}$=17.33; P<.001; η^2_p=0.23), with greater rotation in block 2 than block 1 (MDiff=–6.25, 95% CI –9.25 to –3.25). Also, there was a trend toward a group effect ($F_{2,59}$=3.08; P=.05; η^2_p=0.10), though no significant effect of phase ($F_{1,59}$=0.20; P=.66). Pairwise comparisons showed a trend for a difference between medicated individuals with ADHD and those with MDD (P=.05; d=0.72; MDiff=11.63, 95% CI –0.08 to 23.34). Additionally, a significant phase × group interaction was detected ($F_{2,59}$=8.81; P<.001; η^2_p=0.23). Here, pairwise comparisons revealed significantly higher rotation in DP than NDP for the unmedicated ADHD group (P=.003; d=0.56; MDiff=2.83, 95% CI 1.00-4.65). By contrast, the reverse was observed for the MDD group (P=.006; d=0.65; MDiff=–3.10, 95% CI –5.29 to –0.91), and no significant difference was observed for the medicated ADHD group (P=.27).

Arms

Analysis of the square root-transformed arm movement and rotation data showed a significant block effect for both, arm movements ($F_{1,55}$=38.93; P<.001; η^2_p=0.41) and arm rotations ($F_{1,55}$=13.29; P<.001; η^2_p=0.20), with greater activity levels in block 2 than 1 (movement: MDiff=–0.30, 95% CI –0.40 to –0.21; rotation: MDiff=–0.30, 95% CI –0.46 to –0.13). No significant main effects were found for phase or group in either case (movement: phase with $F_{1,55}$=0.02; P=.90, group with $F_{1,55}$=0.53; P=.59; rotation: phase with $F_{1,55}$=0.31; P=.58, group with $F_{1,55}$=1.73; P=.19). For arm rotation, an additional interaction between block and phase was observed ($F_{1,55}$=5.41; P=.02; η^2_p=0.09), but not further explored.

Torso

For square root–transformed torso movement, the ANOVA revealed a significant main effect of block ($F_{1,42}$=14.73; P<.001; η^2_p=0.26) indicating increased movement in block 2 compared to block 1 (MDiff=–0.15, 95% CI –0.24 to –0.07). No significant main effects of phase ($F_{1,42}$=0.01; P=.91) or group ($F_{1,42}$=0.32; P=.73) were observed.



For rotation, the ANOVA revealed a significant main effect of phase ($F_{1,42}$=4.30; P=.04; η^2_p=0.09), with greater rotation observed during the DP than NDP (MDiff=0.10, 95% CI 0.00-2.00). No significant effects of block ($F_{1,42}$=0.56; P=.46), group ($F_{1,42}$=0.68; P=.51), or their interactions were found.

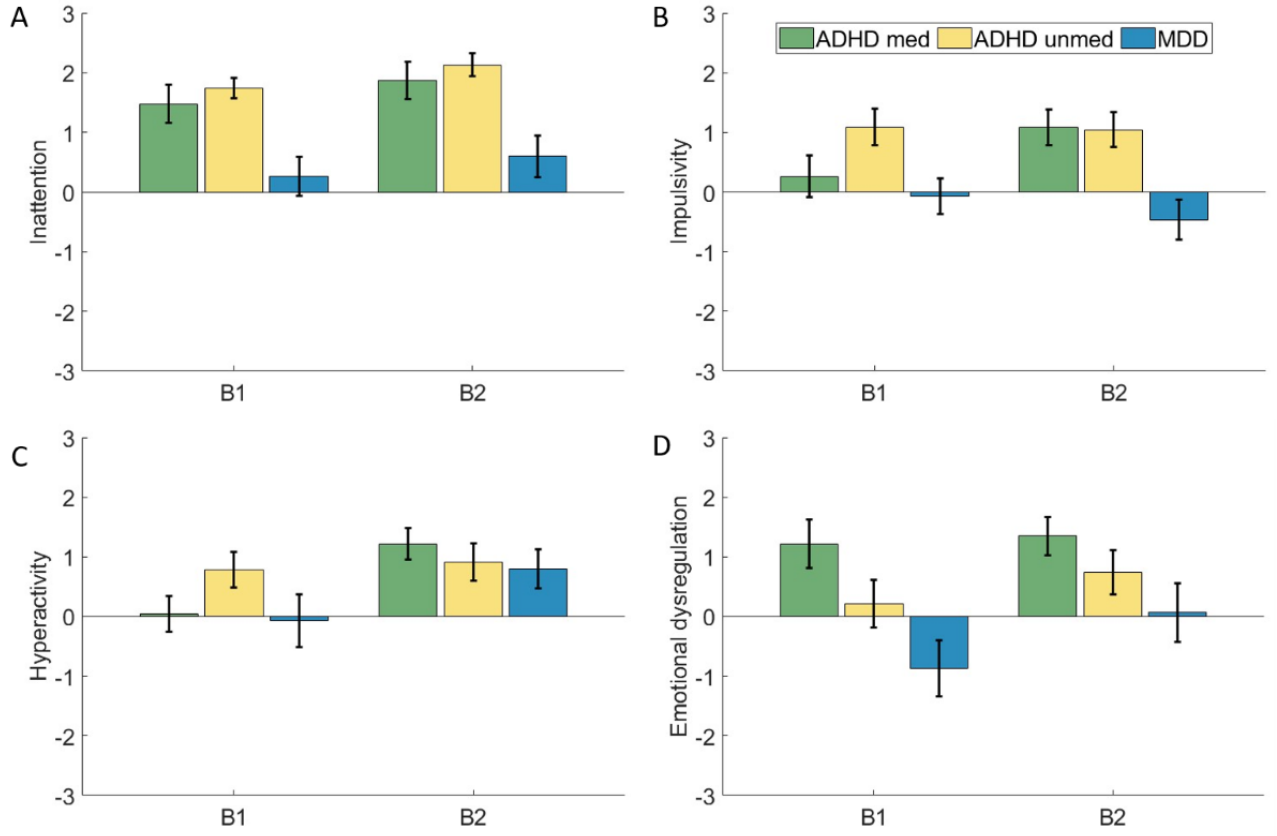
Eye Tracking

Eye tracking data are depicted in Figure 4. The ANOVA for square root–transformed off task gaze data revealed a significant main effect of phase ($F_{1,58}$=4.72; P=.03; η^2_p=0.075), in that across groups, there was a higher off task gaze in DP than NDP (MDiff=0.31, 95% CI 0.02-0.59). Apart from that, no main effect of block ($F_{1,58}$=0.50; P=.48) or group ($F_{1,58}$=1.16; P=.32) and no significant interactions were observed.

XSL•FO
RenderX

Figure 4. Results of the eye tracking analysis (off-task gaze time). Bar plot depicts logarithmically transformed data. Error bars indicate the standard error of the mean. ADHD: attention-deficit/hyperactivity disorder; B1: block 1; B2: block 2; DP: distractor phase; MDD: major depressive disorder; med: medicated; NDP: nondistractor phase; unmed: unmedicated.

fNIRS



One-way ANOVAs revealed no significant group differences in DP-NDP oxy-Hb contrast on either channel of interest with $F_{1,28}$=0.29; P=.73; η^2_p=0.02 for the left dlPFC and $F_{1,22}$=0.06; P=.94; η^2_p=0.07 for the right dlPFC.

Experience Sampling

Results of the participants' reported ADHD symptom intensity during and after task performance are depicted in Figure 5. The ANOVA of self-reported square root–transformed inattention intensity revealed a significant main effect of block ($F_{1,58}$=9.52; P=.003; η^2_p=0.14), with higher scores in block 2 than 1 (MDiff=–0.09, 95% CI –0.03 to –0.15). A significant main effect of group also emerged ($F_{1,58}$=9.28; P<.001; η^2_p=0.24). Pairwise comparisons showed significantly higher inattention scores in both medicated (P=.007; d=0.91; MDiff=0.27, 95% CI 0.48-0.06) and unmedicated (P<.001; d=1.68; MDiff=0.36, 95% CI 0.57-0.15) participants with ADHD compared to those with MDD, while the ADHD groups did not differ significantly (P=.69). No significant block × group interaction was found.

XSL•FO
RenderX

Figure 5. Results of experience sampling. (A) Inattention rating after block 1 and block 2. (B) Impulsivity rating after block 1 (B1) and block 2 (B2). (C) Hyperactivity rating after B1 and B2. (D) Emotional dysregulation rating after B1 and B2. Error bars indicate the standard error of the mean. ADHD: attention-deficit/hyperactivity disorder; MDD: major depressive disorder; med: medicated; unmed: unmedicated.

Regarding subjective impulsivity, a significant main effect of group was found ($F_{2,58}$=6.16; P=.004; η^2_p=0.18). Post hoc comparisons indicated that unmedicated participants with ADHD reported significantly higher impulsivity than participants with MDD (P=.003; d=1.22; MDiff=1.40, 95% CI 0.42-2.38). Additionally, there was a trend (P=.10; d=0.73; MDiff=0.88, 95% CI –0.11 to 1.86) for higher impulsivity scores in medicated participants with ADHD than in participants with MDD, while the ADHD groups did not differ significantly (P=.44). No significant main effect of block was found ($F_{1,58}$=0.38; P=.54), nor was there a significant interaction between group and block.

For self-reported hyperactivity, a significant main effect of block was observed ($F_{1,58}$=16.87; P<.001; η^2_p=0.22), indicating higher hyperactivity levels in block 2 compared to block 1 (MDiff=–0.72, 95% CI –1.08 to –0.37). There was no significant main effect of group ($F_{2,58}$=0.54; P=.59). However, a trend-level interaction between block and group emerged ($F_{2,58}$=2.53; P=.09; η^2_p=0.08). Pairwise comparisons revealed significant increases in hyperactivity from block 1 to block 2 in the medicated ADHD group (P<.001; d=0.68; MDiff=–1.09, 95% CI –1.65 to –0.52) and MDD group (P=.02; d=0.70; MDiff=–0.87, 95% CI –1.56 to –0.17), whereas hyperactivity levels remained stable across blocks in the unmedicated ADHD group (P=.44).

For emotional dysregulation, ANOVA revealed a significant main effect of block ($F_{1,58}$=9.20; P=.004; η^2_p=0.14), with higher scores observed after block 2 compared to block 1 (MDiff=–0.53, 95% CI –0.88 to –0.18). A significant main effect of group also emerged ($F_{1,58}$=3.74; P=.03; η^2_p=0.11). Post hoc comparisons indicated that the medicated ADHD group reported significantly higher emotional dysregulation than the MDD group (P=.03; d=0.94; MDiff=1.55, 95% CI 0.15-2.96). No significant differences were found between the two ADHD groups (P=.86) or between the unmedicated ADHD and MDD groups (P=.24).

VR Sickness

Across groups, mean VRSQ scores were in a low positive range (mean 0.31, SD 1.23), indicating a low level of motion sickness during the experiment. The conducted 1-way ANOVA revealed no significant differences between groups ($F_{2,60}$=1.04; P=.36).

Correlation Analyses Between Modalities

Core findings of the correlational analysis are presented in Table 2, whereas results of all computed correlations with respective sample sizes are available in Multimedia Appendix 4. Regarding associations between task-related symptom intensity and psychophysiological markers, inattention was correlated with off-task gaze (r=0.28; P=.03). Hyperactivity correlated with both mean error rate (r=0.34; P=.008) and mean processing time (r=0.33; P=.01), as well as with head movement (r=0.35; P=.006) and head rotation (r=0.30; P=.02). Analyses further

XSL•FO
RenderX

showed a correlation between impulsivity and mean error rate (r=0.35; P=.006), and between emotional dysregulation and off-task gaze (r=0.29; P=.02). For the correlational analysis between the objective measures, we found, among other things, a significant correlation between off-task gaze and mean PTV (r=0.33; P=.01), head movement (r=0.43; P<.001), and arm movement (r=0.40; P=.002). Additionally, to its significant correlation to off-task gaze, mean PTV was also found to be correlated to head movement (r=0.35; P=.006) and rotation (r=0.26; P=.04). Furthermore, we also found a significant association between head rotation, mean processing time (r=0.30; P=.02), and head movement (r=0.51; P<.001).

Discussion

Principal Findings

In this study, we applied our virtual office room scenario with its VEST to a sample of medicated participants with ADHD, unmedicated participants with ADHD, and unmedicated participants with MDD. Using a multimodal approach, we explored the paradigm's potential to detect differences in various outcomes across the 3 groups, extending previous research on VR-based assessment methods [20,24]. While we expected more movement in the ADHD groups than in the MDD group, only partial evidence supported this hypothesis. Unmedicated individuals with ADHD showed a distraction-induced increase in head rotation, whereas those with MDD showed a decrease in rotation during distraction. A trend-level effect also indicated more head movement during distraction in both ADHD groups compared to the MDD group. Additionally, regarding our research questions, we found an increase in PTV in unmedicated individuals with ADHD and in those with MDD, but not in medicated individuals with ADHD. Furthermore, we found an increase in PTV during distraction in medicated individuals with ADHD. At least one of the ADHD groups also reported higher task-related levels of inattention, hyperactivity, and emotional dysregulation than the MDD group. No differences between groups were found in eye movement, brain activity in the dlPFC as measured via fNIRS, and movement of the arms and torso. These findings indicate differences between the investigated groups in some of the parameters measured, and distinct responses to distractors and time-on-task, which will be examined in more detail in the following discussion.

Investigating task performance, we found a significant increase in PTV over time in participants with unmedicated ADHD and participants with unmedicated MDD, but not in medicated participants with ADHD. This finding indicates a time-on-task decline of sustained attentional performance or vigilance in unmedicated ADHD and MDD. This result aligns partially with previous research using VR-based CPTs in children, reporting lower reaction time variability in medicated compared to unmedicated individuals with ADHD [25-27]. Moreover, a meta-analysis by Kofler et al [51] found significant effects of stimulant treatment on reaction time variability, whereas no consistent reaction time variability differences were found between adults with ADHD and other clinical populations, including MDD. Our results indicate that medication helps maintain attentional focus over time in ADHD and that unmedicated individuals with ADHD or MDD show a comparable decline in attentional performance.

Additionally, medicated participants with ADHD showed a significantly higher PTV in DP than NDP. Although the effect was observed only in the medicated ADHD group, this finding suggests that the task is sensitive to distractor-specific influences on performance variability. The absence of the effect in the unmedicated ADHD group remains unclear. One possible explanation concerns the measure of variability; while the coefficient of variation is a common metric for reaction time variability, some argue that controlling for mean reaction time may be inappropriate, particularly in ADHD populations [52]. In this study, while not significantly different, unmedicated individuals with ADHD showed descriptively higher mean processing time than the medicated ADHD and the MDD group. Additionally, it is unclear to what extent processing time for emails is comparable to reaction times measured in tasks such as CPTs, which may also suggest the need for an alternative measure of variability.

Of note, no group differences emerged in mean processing time and error rates. This means that we were unable to use the VEST to map the comparatively slower information processing of individuals with MDD that has been observed in other neuropsychological tasks [53]. The error rate, which can be considered a measure of impulsivity, also showed no group differences. This may be due to the task itself, as the stimulus remains visible until a response is made rather than disappearing after a brief interval. It is also possible that, alongside the well-established impulsivity in ADHD, individuals with MDD exhibit impulsivity problems that reduce group differences, which has previously been shown [54]. However, it should be noted that the previous study likewise found no differences in error rates between ADHD and HC [24].

In addition, we observed a longer processing time in DP compared to NDP across groups. While this finding suggests that the experimental induction of distractibility was generally effective in observing reduced attentional performance across all groups, the distractors did not appear to elicit symptom-specific patterns of distractibility that would differentiate between diagnostic groups or between medicated and unmedicated participants.

We hypothesized that both ADHD groups would exhibit increased movement compared to the MDD group. This hypothesis is based on prior research that suggested that the overall activity level of individuals with MDD is decreased compared to those with ADHD. In our task, we measured specific body movements while sitting during task performance, which participants with ADHD and MDD did not differ in. Hence, differences might be found in overall motoric activity but not necessarily in physical activity during cognitive tasks. Nonetheless, the hypothesis was partially supported by a trend-level increase of movement during DP in both ADHD groups, but not in the MDD group. Similarly, we previously found a more pronounced increase in head movements from NDP to DP in ADHD compared to HC [24]. This pattern may reflect core symptomatology of ADHD, particularly hyperactivity and distractibility. If replicated, this differential movement response to environmental distractors may serve as a clinically relevant marker to distinguish between ADHD and MDD populations. In line with this, unmedicated participants with ADHD also displayed a significantly greater head rotation in DP than NDP. This finding further supports the potential use of actigraphy-derived motion parameters as objective, ecologically valid markers for differential diagnosis. By following up the phase and group interaction, we also found a higher head rotation in NDP compared to DP in participants with MDD. While seemingly counterintuitive at first, this finding might be due to the paradoxical effects of distractors. Prior research has presented evidence that distractors can sometimes facilitate performance [55,56], depending on the

XSL•FO
RenderX

task characteristics and properties of the distractors, and the specific population explored, including MDD and ADHD [57,58]. Given the unclear directionality and inconsistency with baseline expectations, further research is needed to clarify the mechanisms behind this effect.

The increase in movement of the head, arms, and torso across groups is in line with our previously reported increase in head movement over time in the same paradigm in HC and individuals with ADHD [24]. Increased body movement during sustained attention tasks may reflect a compensatory mechanism to maintain attention [59,60] and can be viewed as an adaptation to the demands of prolonged sustained attention, such as decreasing arousal or accumulating fatigue.

As pertains eye tracking, we found a reduced focus on the task in phases with distractions compared to phases without distractions, but no group differences. Regarding ADHD medication effects, this null finding aligns with our previous study [20], which also revealed no significant differences in eye movement patterns between these 2 subgroups. We also did not find any differences between ADHD and MDD, indicating that all groups spent a similar amount of time looking at the task. Nonetheless, it remains possible that subtle effects exist but were not detected due to limited statistical power resulting from relatively small sample sizes.

In the fNIRS analysis, we did not observe any group differences in the DP-NDP contrast in the dlPFC. This may partly be due to the loss of data caused by technical issues, reducing the analyzable sample on both channels of interest to 29 and 23, respectively. In contrast to traditional inhibitory control tasks, where reduced activation in the dlPFC is consistently reported in individuals with ADHD compared to HC [36], we found no difference between medicated and unmedicated individuals with ADHD. It is also possible that the type of inhibitory control required in classical tasks is different from inhibiting distractors, or alternatively, that the distractors used in our study were not strong enough to elicit such effects [24].

Pertaining to self-reports of task-related symptom experience, both ADHD groups reported higher levels of task-related inattention and impulsivity compared to the MDD group. Assuming that our PTV measure partly captures inattention, this contrasts with our finding that unmedicated individuals with ADHD or MDD showed greater PTV increases than medicated individuals with ADHD. Hence, there appears to be a partial discrepancy between behavioral and self-reported measures, which could mean that they capture different aspects of attentional dysfunction or be attributed to a greater sensitivity of PTV as an index of inattention. For impulsivity, although elevated levels have also been reported in MDD [54], the higher scores observed in the unmedicated ADHD group and, at a trend level, in the medicated ADHD group are consistent with the classification of impulsivity as a core symptom of ADHD. In terms of emotional dysregulation, only the medicated ADHD group reported higher scores than the MDD group, whereas both ADHD groups showed comparable levels to each other. Difficulties in emotion regulation are frequently reported in association with ADHD [61], and in our sample, medication use does not appear to have exerted a beneficial effect, with descriptively higher scores in the medicated group. The MDD group showed the lowest scores, which differed significantly from those of the medicated ADHD group. Because participants in our MDD group were affected by mild to moderate depressive symptoms that did not currently require medication, it is conceivable that they were able to use emotion-regulation strategies such as acceptance. Nevertheless, previous research has shown that individuals with MDD, even when remitted, still tend to suppress emotions, which could also manifest in lower scores [62]. Importantly, emotional dysregulation is a construct that includes various dimensions such as emotional reactivity and intense experience of emotion, but also decreased emotional awareness [63]. Therefore, it is possible that the item used to assess task-related emotional dysregulation might have only encapsulated one facet of emotional dysregulation. Also, it should be noted that, irrespective of absolute levels, all 3 groups reported values in the positive range of emotional dysregulation after the second block.

No group differences emerged in self-reported hyperactivity, which contrasts with the distractor-induced differences detected via head actigraphy, but aligns with the null results from actigraphy-derived torso and nondominant arm movements as discussed above.

Lastly, we conducted an exploratory correlational analysis of the task-related symptom intensity and the objective parameters we measured. Two key points emerged: first, self-reported, task-related intensity of inattention, hyperactivity, impulsivity, and emotional dysregulation were each correlated with different objective measures. For instance, inattention and emotional dysregulation were associated with higher levels of off-task gaze; impulsivity was associated with a higher error rate; and hyperactivity was associated with increased head movement, higher error rate, and longer processing time. Although exploratory, this pattern might suggest that a multimodal assessment combining task performance, eye movements, and body movements (particularly head movement) may capture distinct symptom dimensions of ADHD. Second, off-task gaze and head movement and rotation showed a correlation with mean PTV, and, in the case of head rotation, with mean processing time. While these findings present a first glance into the potential relationships of different behavioral modalities during the VEST, the causal relationship of these parameters needs further investigation.

Limitations and Future Directions

While the VEST was specifically designed to increase ecological validity compared to traditional neuropsychological tasks by applying a function-led design approach, it would be of interest to investigate the specific cognitive domains it draws upon [24]. Therefore, future studies should examine its associations with established (neuropsychological) measures, for example, attention and reading comprehension. Additionally, although the VEST is designed to simulate a realistic setting and task, a systematic investigation of its ecological validity, meaning the correspondence between behaviors exhibited in the virtual environment and in real-world settings [64], is still needed. While it would be very challenging to assess eye movement behavior, brain activity, and performance measures during the

XSL•FO
RenderX

participants' work to evaluate the equivalency of behavior in the virtual office room to real-world behavior, several alternative approaches could be applied. For example, cognitive functioning at work could be assessed using questionnaires [65,66]. Moreover, office-based participants could be asked to wear a mobile eye tracker and an actigraph during work sessions, while ambient noise levels would be simultaneously measured to assess auditory distractions. This would allow investigation of the relationship between distractor-related shifts of attention and movements in the virtual office room and real life.

Further, although the total sample comprised 62 participants, the sizes of the diagnostic subgroups, particularly the MDD group, were limited. As indicated by a sensitivity analysis, our sample consisting of 63 participants provided 80% power to detect large main effects (η^2_p=0.14, as calculated via G*Power, Heinrich Heine University Düsseldorf [67], based on the harmonic mean group size). Consequently, small- to medium-sized differences between the investigated population may not have been detected. Future studies with larger and more balanced samples are necessary to replicate and extend these results. For example, to reliably detect medium main effects, at least 50 participants per group would be needed. Furthermore, while the MDD diagnosis of participants in the MDD group was confirmed using the structured clinical interview Mini-DIPS, some MDD participants only reported mild depressive symptoms in the PHQ-9 [43]. Therefore, it is unclear whether the results can be generalized to individuals with MDD with elevated symptom intensity.

While we provide an analysis across multiple levels of behaviors by group, examining the influence of time-on-task and distractors, and conduct an exploratory correlational analysis, more in-depth integrative approaches combining these measures could further enhance our understanding of behavior in ADHD. For example, a machine learning approach similar to our analysis in Wiebe et al [18] could integrate the various parameters to classify between medicated versus unmedicated individuals with ADHD, and individuals with ADHD versus HC if combined with the dataset reported in Pakos et al [24]. Additionally, a more thorough analysis of distractor-related movement and gaze behavior, and their interplay during task errors, could illuminate potential underlying causes of said errors.

Moreover, while assessing the VEST's discriminant validity in differentiating between ADHD and MDD represents an important step toward evaluating its potential use in a clinical context, future research might also explore the overlap and divergence of symptom profiles in individuals with comorbid ADHD and MDD. This could further inform the refinement and diagnostic use of VR-based assessments like the VEST. Consequently, although the actual clinical applicability of the VEST still requires further investigation, it is conceivable that it could be used, for example, as a complementary tool in differential diagnostics or for monitoring symptom severity or symptom changes associated with medication. Its administration is straightforward, and even if the space or financial resources for a fully equipped VR laboratory are not available, it would be possible to use the application on a smaller scale, for example, on a smartphone with an inexpensive VR headset alternative.

Conclusion

This study examined, for the first time, the potential of our recently developed multimodal VEST to distinguish individuals with ADHD and MDD, and to detect medication-related effects in ADHD. An increase in PTV over time was observed in unmedicated ADHD and MDD participants, but not in those with medicated ADHD, suggesting a stabilizing effect of medication on attentional capacities. Moreover, medicated individuals with ADHD showed an increase in head rotation during distractions, and, on a trend level, both medicated and unmedicated individuals with ADHD showed increased distractor-associated head movements, an effect not observed in the MDD group. This finding underscores the potential of actigraphy in combination with distracting events during task performance as a tool for differentiating ADHD from other clinical populations. Additionally, exploratory correlational analyses showed correlations between various subjective and objective, as well as psychophysiological markers. While we also observed higher scores in task-related inattention, impulsivity, and emotional dysregulation in at least 1 ADHD group compared to MDD, no differences were found in gaze behavior and brain activity measured by fNIRS. To solidify the results and be able to reliably detect potential small size differences between the groups, and verify the task's potential as an assessment tool with potential applications in research and a clinical context, higher-powered studies are needed.

Acknowledgments

We sincerely thank all participants for generously giving their time to this study. This work was funded by the iBehave Network and supported by the Open Access Publication Fund of the University of Bonn. OpenAI's GPT-4o was used solely for language editing (grammar, phrasing, clarity, and flow). It was not used for study design and conception, methodology, analysis, interpretation, or generation of scientific content. All scientific content and decisions were made exclusively by the authors.

Funding

This work was supported by the Open Access Publication Fund of the University of Bonn. LA, JP, and LJ received funding given to AP and NB by the iBehave Network, which is sponsored by the Ministry of Culture and Science of the State of North Rhine-Westphalia. Abstract

Background: Probability-based surveys remain essential to epidemiology, but expanding mixed-mode data collection, which combines web self-completion and interviewer-administered surveys, raises concerns that administration mode and interviewer presence may influence health reporting. These concerns warrant further investigation of interviewer-related biases and mode differences in health reporting.

Objective: This study assessed whether responses to the 12-item General Health Questionnaire (GHQ-12) and 12-item Short Form Health Survey (SF-12), both self-completed, differed by interviewer presence and role: online without an interviewer, during a social interviewer visit, or during a nurse visit. It also assessed mode effects on doctor-diagnosed conditions recorded by interviewers in computer-assisted personal interviewing (CAPI) and when self-completed online. We further examined possible variation by sex and age.

Methods: The analysis used randomized mode allocation embedded within wave 12 (2019) of the UK Household Longitudinal Study Innovation Panel. After applying relevant exclusions, the final analytic sample comprised 1111 households (1779 participants) across the 3 randomly assigned survey modes: web-based self-completion, interviewer-administered CAPI, or nurse-administered CAPI. The sample was predominantly White British, with a broadly balanced sex distribution and participants from diverse age, employment, education, and household income groups. Participants did not always complete the survey in their randomly assigned mode. Effects were estimated using a two-stage residual inclusion instrumental variable approach, with randomized mode as an instrument for actual mode, to address confounding arising from nonrandom selection into actual mode.

Results: No statistically significant differences were observed across self-completion contexts for the GHQ-12 or the SF-12 mental and physical component scores. We found no statistically significant evidence of mode effects on doctor-diagnosed conditions. For example, no statistically significant mode effects in psychiatric conditions were identified across the comparisons: nurse relative to social interviewer (odds ratio [OR] 0.72, 95% CI 0.40 - 1.29; *P*=.53), web relative to social interviewer (OR 0.45, 95% CI 0.17 - 1.18; *P*=.14), and web relative to nurse (OR 0.63, 95% CI 0.27 - 1.49; *P*=.59). There was little evidence overall that mode-related differences varied by age or sex.

Conclusions: Our findings may support embedding self-completion modules within interviewer-administered surveys for the collection of SF-12 and GHQ-12. Meanwhile, potential mode-related differences should be considered when designing mixed-mode surveys and interpreting self-reported health data.

Introduction

Probability-based surveys have been a cornerstone of epidemiology and public health, providing reliable population-based estimates that enable the monitoring of population health trends to inform evidence-based policy [1]. Even amid the rise of alternative data sources, they remain essential to ensuring representativeness [2,3] and to capturing the social, psychological, behavioral, and biological determinants that shape health. Increasing emphasis on cost-efficiency and biomarker integration is accelerating the diversification of health survey administration. These modes include face-to-face interviews conducted by trained social interviewers, web-based self-administered surveys [4], and, where health is a focus, interviews conducted by nurses who can undertake standardized biospecimen collection and physical

XSL•FO
RenderX

measurements [5]. The use of these different modes allows surveys to accommodate varying data-collection requirements.

However, the use of different data-collection modes within surveys may affect responses and introduce bias in health estimates [6]. Mode effects refer to systematic differences in survey responses that arise from the mode of data collection and its associated conditions [7]. Different mechanisms may underlie these effects. The presence of an interviewer may increase socially desirable responding, whereby respondents report in ways they perceive to be more socially acceptable [8], while interviewer probing, clarification, and feedback may also affect how respondents understand and report health conditions [9,10]. The former mechanism may be particularly relevant to sensitive or subjective scales. For example, previous studies with random assignment to survey mode found that interviewer-administered surveys yielded more favorable health ratings than self-administered surveys [11-15]. To reduce mode effects arising from social desirability bias, several national surveys embed self-completion within face-to-face computer-assisted personal interviewing (CAPI) for sensitive items [16-18]. However, the context in which self-completion responses are provided may differ across modes. Interviewer presence may shape reporting even when respondents complete items themselves by influencing perceived privacy, thereby contributing to differences between self-completion embedded within interviewer-present CAPI and web self-completion [10]. For example, one study found that respondents completing the 12-Item General Health Questionnaire (GHQ-12) in the presence of an interviewer reported better mental health than those completing it without an interviewer present [19]. Similarly, among self-administered modes, less interaction with interviewers was associated with higher reporting of common mental disorder symptoms [20]. However, these findings may reflect between-sample differences or evidence from specific populations, limiting their generalizability.

For the reporting of specific chronic conditions, however, studies have primarily compared interviewer-administered with self-administered reporting. Any observed differences in reporting may therefore reflect not only social desirability bias but also interviewer-specific features, such as probing and clarification. Several studies found higher prevalence estimates in self-administered surveys than in interviewer-administered surveys for a mental health problem [21], longstanding limiting illness, and current bodily pain lasting more than 6 months [22], possibly reflecting social desirability bias. One randomized study also found that most health problems were reported more frequently in a self-administered postal survey than in an interviewer-administered survey [23]. However, existing studies have been restricted to older adults or young people [21,23], with one of these studies additionally constrained by a small sample size [21], whereas one study was unable to separate mode differences from temporal differences [22]. Consequently, the extent to which survey mode independently affects the reporting of different individual health conditions in the broader adult population remains unclear. In contrast, interviewer probing and clarification may facilitate reporting of chronic conditions. For example, previous reports of higher prevalence of longstanding illness [9], bronchial asthma, and chronic bronchitis [24] in interviewer-administered surveys may reflect interviewer probing and clarification. However, other studies reported no mode differences in the number of chronic conditions, the prevalence of longstanding illness [19,25], or the prevalence of bronchial asthma and chronic bronchitis [9]. Differences in findings across studies may also reflect population selectivity, between-sample differences, or residual selection effects. Thus, evidence supporting interviewer facilitation as a mechanism underlying mode effects remains heterogeneous.

In addition, evidence suggests that interviewers' professional roles can influence self-reported health [10], although the direction of these effects is inconsistent. Respondents interviewed by physicians or nurses have been reported to disclose fewer psychiatric symptoms [26] and fewer health problems than those interviewed by lay interviewers or completing self-administered questionnaires [23]. Conversely, higher pain intensity has been reported in some nurse-administered interviews [27]. However, these findings derive largely from specific subgroups or highly selected populations, limiting their generalizability. Meanwhile, whether interviewer effects associated with the professional role of nurses spill over into the self-administered modules embedded within CAPI surveys remains unclear. Furthermore, sex and age may modify the effects of survey mode on health reporting, but these differences have received limited attention. Sex-specific patterns may partly reflect variation in concerns about mental health stigma and disclosure. The greater perceived privacy of self-administered web surveys may facilitate the reporting of sensitive health information, particularly among men [21,28]. Age differences may reflect older adults' stronger emphasis on socioemotional goals and greater reluctance to disclose negative states in interpersonal settings. Compared with less interpersonal modes, surveys involving greater interviewer contact have elicited fewer reports of adverse psychosocial functioning among older adults, with this difference becoming more pronounced with increasing age [29].

Therefore, this study aimed to examine whether health measures completed by respondents themselves are reported differently across contexts that differ in interviewer presence and roles, and whether the reporting of doctor-diagnosed chronic conditions differs between web self-completion, social interviewer-administered CAPI, and nurse-administered CAPI. We then examined whether these associations varied by sex and age groups in secondary analyses. Specifically, we asked the following questions:

- Although the GHQ-12 and SF-12 were self-completed in all 3 conditions, do participants report mental health and functioning differently across self-completion contexts involving no interviewer, a social interviewer, or a nurse?
- Does the reporting of diagnosed health conditions differ between web self-completion, social interviewer–administered CAPI, and nurse-administered CAPI?
- Do these associations differ by sex and age group?

Methods

Data

The UK Household Longitudinal Study Innovation Panel (UKHLS-IP) is a national probability sample that covers the household population of Great Britain, specifically designed to support methodological development and experimental research in longitudinal survey design [30]. The UKHLS-IP began in 2008, with a sampling design that used a stratified, geographically clustered probability approach yielding 2760 addresses [31], and was refreshed at waves 4 (2011), 7 (2014), 10 (2017), and 11 (2018) [32]

The Innovation Panel wave 12 (IP12) issued sample comprised 2401 households: 1957 households participated as recontacts from IP11, and 444 returning households from earlier waves. Before fieldwork, these 2401 households were randomly assigned to one of three modes: (1) web-based self-completion, (2) face-to-face CAPI by social interviewers, or (3) nurse-led in-home CAPI [33]. The sample flow is described in the *Results* section.

Outcomes

The following health outcomes were chosen. Mental health was assessed using the GHQ-12 and SF-12 Mental Component Summary (MCS) scores. In all modes, respondents self-completed the scales, either as computer-assisted self-interviewing (CASI) modules within social-interviewer or nurse CAPI visits, or independently online. During the CAPI interview, the script instructed the social interviewer or nurse to pass the laptop to the respondent at the CASI section, which the respondent then completed independently. The interviewer or nurse generally remained in the room but attended to their own tasks and did not administer the questions or interact with the respondent during CASI completion, except when assistance was needed because of sight, reading, or language difficulties.

Each item in the GHQ-12 was rated on a 4-point Likert scale, yielding a total GHQ-12 score ranging from 0 (“no psychological distress”) to 36 (“severe psychological distress”), with higher scores indicating greater levels of distress [34]. The Physical Component Summary (PCS) score from the SF-12 was used to assess physical health. SF-12 MCS and SF-12 PCS scores were computed using the norm-based scoring algorithm [35]. Both scores were derived by the UKHLS team. We reverse-coded the scores such that higher values represented poorer physical and mental functioning, which allowed for effective interpretation and comparability.

In addition, we derived 6 binary indicators to capture major categories of chronic conditions, based on self-reported doctor diagnoses at IP12. Respondents were shown a list of specific conditions, on a showcard in the face-to-face modes and on screen in the web mode, and asked whether a doctor or other health professional had ever told them that they had any of these conditions. The measures, therefore, reflected doctor-diagnosed conditions reported up to the IP12 interview. These questions were ordinarily asked at a respondent’s first full individual interview. At IP12, however, both new entrants to the survey and continuing respondents were asked these questions. To improve statistical reliability and mitigate data sparsity, chronic conditions were grouped into six categories: (1) cancer, defined as any malignant neoplasm; (2) cardiovascular conditions, including congestive heart failure, coronary heart disease, angina, myocardial infarction, stroke, or high blood pressure; (3) metabolic–endocrine disorders, comprising diabetes or hypothyroidism; (4) musculoskeletal disorders, including arthritis; (5) psychiatric conditions, indicating whether respondents reported any doctor-diagnosed psychiatric disorder; and (6) respiratory conditions, including asthma, emphysema, chronic bronchitis, or chronic obstructive pulmonary disease. For each category, a value of 1 was assigned if any relevant condition was reported, and zero otherwise. The specific component conditions included in each major category, along with the number of participants reporting each condition, were described in Table S1 in Multimedia Appendix 1.

Survey Mode

The primary exposure was the actual survey mode completed by each respondent, categorized as web-based self-completion, interviewer-administered, or nurse-administered interviews. For the GHQ-12 and SF-12, all items were self-completed by respondents, including within the CASI module of CAPI interviews; for these outcomes, the exposure therefore represents the context of self-completion, namely online without an interviewer present, during a social interviewer visit, or during a nurse visit, rather than interviewer administration of the items. For doctor-diagnosed chronic conditions, the exposure reflects both survey mode and item administration, as conditions were self-reported in the web questionnaire but were elicited using a condition list in the CAPI interviews.

Covariates

Based on prior studies, we adjusted for a comprehensive set of contextual, sociodemographic, and survey-related variables to account for potential confounding [36-38]. Sex was coded as male or female. Gender identity and intersex variations were not available in the analytic data. Age was categorized into 6 groups: 16 - 25, 26 - 35, 36 - 45, 46 - 55, 56 - 65, and ≥66 years. However, because the prevalence of chronic conditions was very low at younger ages and increased sharply from the mid-50s onward, we used a binary age indicator (<56 vs ≥56 y) in models with chronic disease as the outcome to avoid sparse-data bias and to ensure sufficient events within each category for stable estimation. Ethnicity was classified as White British and other ethnicities. Marital status was grouped into married, never married, and separated/divorced/widowed. Employment status was categorized as employed (including self-employed, unpaid family workers, and apprentices), unemployed and inactive (including students, individuals unable to work due to health conditions/disabilities, and family caregivers), and retired [39]. Education was grouped into degree or equivalent, General Certificate of Secondary Education (GCSE) and A-levels or equivalent, and no qualifications or other. Monthly household income was divided into quintiles: (0 - 1969.13], (1969.13 - 2956.40], (2956.40 - 4083.32], (4083.32 - 5756.04], and (5756.04 - 20,000]. Household child status was based on the number of children, coded as none and ≥1 child.

XSL•FO
RenderX

The first participation wave was indicated by the wave of entry into the study: original sample in 2008, and refreshment samples in 2011, 2014, 2017, and 2018. Interview mode in IP11 was classified into 3 categories: interviewer-administered, web self-completion, and absence or proxy. Due to the small number of proxy respondents (n=12), they were combined with the absence of respondents.

Geographic regions included England, Wales, and Scotland. Urban-rural classification was based on population density, categorized as urban or rural areas.

Statistical Analysis

For descriptive analyses, we summarized sample characteristics using survey-design–weighted means with 95% CIs for continuous variables and weighted proportions with 95% CIs for categorical variables, based on the imputed dataset. All summaries were stratified by survey mode.

For the main analyses, we used a two-stage residual inclusion (2SRI) approach within the instrumental variable framework, with the initial random assignment used as the instrument for the survey mode actually completed [40-42]. To be valid, instrumental variables must satisfy 4 identification assumptions: relevance, independence, exclusion restriction, and monotonicity (Table 1; more details can be found in Multimedia Appendix 1). We used this approach because some respondents did not complete the survey in their assigned mode; consequently, the mode actually completed was not entirely random and may have been subject to selection. Additionally, analyzing by initial assignment preserves randomization but can be diluted by mode switching, while analyses based on the completed mode could be confounded by differences between those who did and did not switch modes. The instrumental variable approach may reduce these concerns by using the difference in completed mode that was created by randomization. Because that difference originates from randomization rather than from participants' own choices, it provides a basis for estimating the effect of completing that mode. Noncompliance and crossover are therefore incorporated through the extent to which assignment actually changed mode completion.

Table . Summary of instrumental variable assumptions and assessment.

Assumption	Assumption description	Assumption assessment	Conclusion and handling
Instrument relevance	Random assignment should be strongly associated with the survey mode actually completed.	First-stage models showed strong associations between assigned mode and completed mode. Detailed estimates and tests are reported in the Multimedia Appendix 1.	This assumption was satisfied.
Conditional independence	Random assignment should be independent of factors that may affect the outcomes, after accounting for measured covariates.	Assignment was randomized before fieldwork. Moderate covariate imbalances were observed (Table S2 in Multimedia Appendix 1), but the asymmetric switching rules operated only postrandomization and therefore do not undermine the initial assignment mechanism.	We used a conditional version of this assumption and adjusted for all prespecified covariates in both stages of the model.
Exclusion restriction	Random assignment should affect outcomes only through the survey mode actually completed.	Random assignment occurred before respondents had any survey exposure, making a direct effect of assignment on self-reported health through pathways other than the exposure unlikely.	This assumption was considered plausible, although it cannot be directly tested. Covariate adjustment was used to reduce potential alternative pathways.
Monotonicity	Assignment to a given mode should not reduce the probability of completing the interview in that mode.	Observed asymmetric switching does not, by itself, violate monotonicity. Defier status depends on treatment uptake under both assignment states and therefore cannot be inferred from a one-sided switch. Moreover, nurse-to-web switching is not evidence of defiance when nurse administration was unavailable under the comparison assignments.	This assumption was considered plausible but is not directly testable at the individual level.

In the first stage, we fitted a multinomial logistic regression model to predict respondents' actual survey completion modes, using randomized mode assignment as the instrumental variable. The first-stage model estimated an allocation arm-specific vector of probabilities for the three actual completion modes. The model adjusted for a set of covariates, including demographic characteristics, household composition, socioeconomic position, first participation wave, interview mode in IP11, and geographic indicators. By design, nurse completion did not occur among participants allocated to the web or social interviewer arms, and social interviewer completion did not occur in the nurse arm. Consistent with these switching restrictions, the fitted probabilities for mode transitions that did not occur were effectively zero. For each respondent, we then calculated

XSL•FO
RenderX

mode-specific residuals as the difference between indicators of actual completion mode and the corresponding predicted probabilities from the first-stage model.

In the second stage, the residuals for the modes were included alongside the observed survey mode and covariates in regression models estimating the associations with key outcomes. These outcomes included the total score of GHQ-12, the PCS and MCS scores from the SF-12, and a set of binary indicators for health conditions (cancer, cardiovascular conditions, metabolic-endocrine conditions, musculoskeletal disorders, psychiatric conditions, and respiratory conditions). We fitted outcome‐specific regression models: Gaussian linear models for continuous outcomes (GHQ-12 score, SF-12 PCS, and MCS scores) and logistic regression models for each binary chronic condition. All previously described covariates were included in both stages of the 2SRI analysis [43]. To avoid overstating clinical relevance, we a priori adopted the lower bound of these ranges (PCS=1.8; MCS=1.5) as our threshold for clinical importance [44]. For the GHQ-12, where no consensus threshold exists, we adopted 0.58 points on the Likert-scored scale, based on prior work, as a conservative benchmark to distinguish trivial from nontrivial differences at the group level [45]. For the GHQ-12 and SF-12 outcomes, we additionally reported standardized effect sizes. For binary outcomes, we prespecified a minimum clinically important risk difference of 5 percentage points for each chronic condition.

To address missingness, we applied multiple imputation using a random forest approach. Compared to parametric approaches, random forests are capable of capturing complex nonlinear relationships and higher-order interactions, and exhibit greater robustness to outliers and model misspecification [46]. The imputation model included outcomes and all covariates used in both the main analysis and the instrumental variable model, ensuring congeniality [47]. In addition, given the complex multistage survey design, the sampling weights, primary sampling units and stratification variables were incorporated into the imputation to preserve the underlying survey structure and mitigate potential bias arising from neglecting design features [48]. In addition, we performed imputation separately within strata of the exposure, defined by the observed survey mode, allowing the covariate and outcome distributions and their associations to differ flexibly between exposure groups and reducing bias when exposure-confounder interactions are present [49]. A total of 50 iterations per imputation were run to facilitate convergence. Given that approximately 15% of the data were incomplete, we generated 15 imputed datasets (Table S3 in Multimedia Appendix 1).

In each dataset, a 2SRI model was independently estimated to quantify exposure effects. To account for the complex survey design, we specified a clustered and stratified design and incorporated survey weights. Design-based standard errors were used in all analyses. The weight compensates for unequal selection probabilities introduced at each sampling stage and for nonresponse in IP12, ensuring that the weighted respondent sample remains representative of the UK adult population living in households at the time of fieldwork [32]. The final estimates and SEs were pooled using Rubin's rules to obtain overall effect estimates and CIs.

All statistical analyses were performed in RStudio. Two‐sided P values <.05 with a Bonferroni correction applied were considered statistically significant. Pairwise contrasts for the primary exposure (survey modes) and all interaction tests were adjusted for multiple comparisons using the Bonferroni method. The corresponding 95% CIs were Bonferroni-adjusted.

Interaction analyses were performed using a similar 2SRI approach in the imputed data accounting for complex survey design. The first-stage multinomial model for mode assignment was estimated in the full sample, after which residuals were included in second-stage models with survey-mode-by-sex and survey-mode-by-age-group interaction terms, respectively. To account for multiple comparisons, Bonferroni correction was applied across the subgroup-specific pairwise contrasts for each outcome.

As a supplementary analysis, we examined the total number of chronic-condition categories reported by each participant, ranging from 0 to 6. Because this outcome was a count variable, we used Poisson regression to compare the number of chronic-condition categories across survey modes, otherwise following the same modeling approach as the main chronic-condition analyses. Results are presented as incidence rate ratios (IRRs) with 95% CIs. As a sensitivity analysis, we repeated the main analyses after excluding participants whose completed survey mode differed from their originally allocated mode.

Additionally, we conducted a post hoc power analysis to assess the ability of the mode-specific sample sizes to detect a benchmark mode effect reported in previous literature for long-standing illness [9].

Ethical Considerations

The UKHLS received ethical approval from the University of Essex Ethics Committee. For waves prior to IP12, ethical approval for the IP was granted as part of the approvals for the UKHLS main survey data collection. From IP12 onward, separate ethical approvals have been obtained for each wave of the IP. IP12 received approval from the National Health Service East of England-Essex Research Ethics Committee (reference 19/EE/0146). Additional ethical approval was not required for the secondary data analysis conducted in this study.

Results

Following the fieldwork process, households were excluded due to noncontact, refusal, or other reasons, resulting in 1408 responding households: 442, 495, and 471 households in the social interviewer, web, and nurse groups, respectively. Further individual-level exclusions were then applied for refusals, proxy or incomplete interviews, incapacity, and children/adolescents. A small number of telephone-mode respondents were excluded from the analysis to avoid potential auditory-mode effects. In addition, respondents with a sampling weight of zero were excluded because such cases do not contribute to population estimates under this survey design [50]. The final analytic sample included 438 households (652 individuals) in the social interviewer group, 330 households (587 individuals) in the web group, and 343 households (540 individuals) in the nurse group,

XSL•FO
RenderX

resulting in a sample of 1111 households and 1779 individuals. The sample flow diagram is provided in Figure 1.

Figure 1. Flow diagram for the study sample.

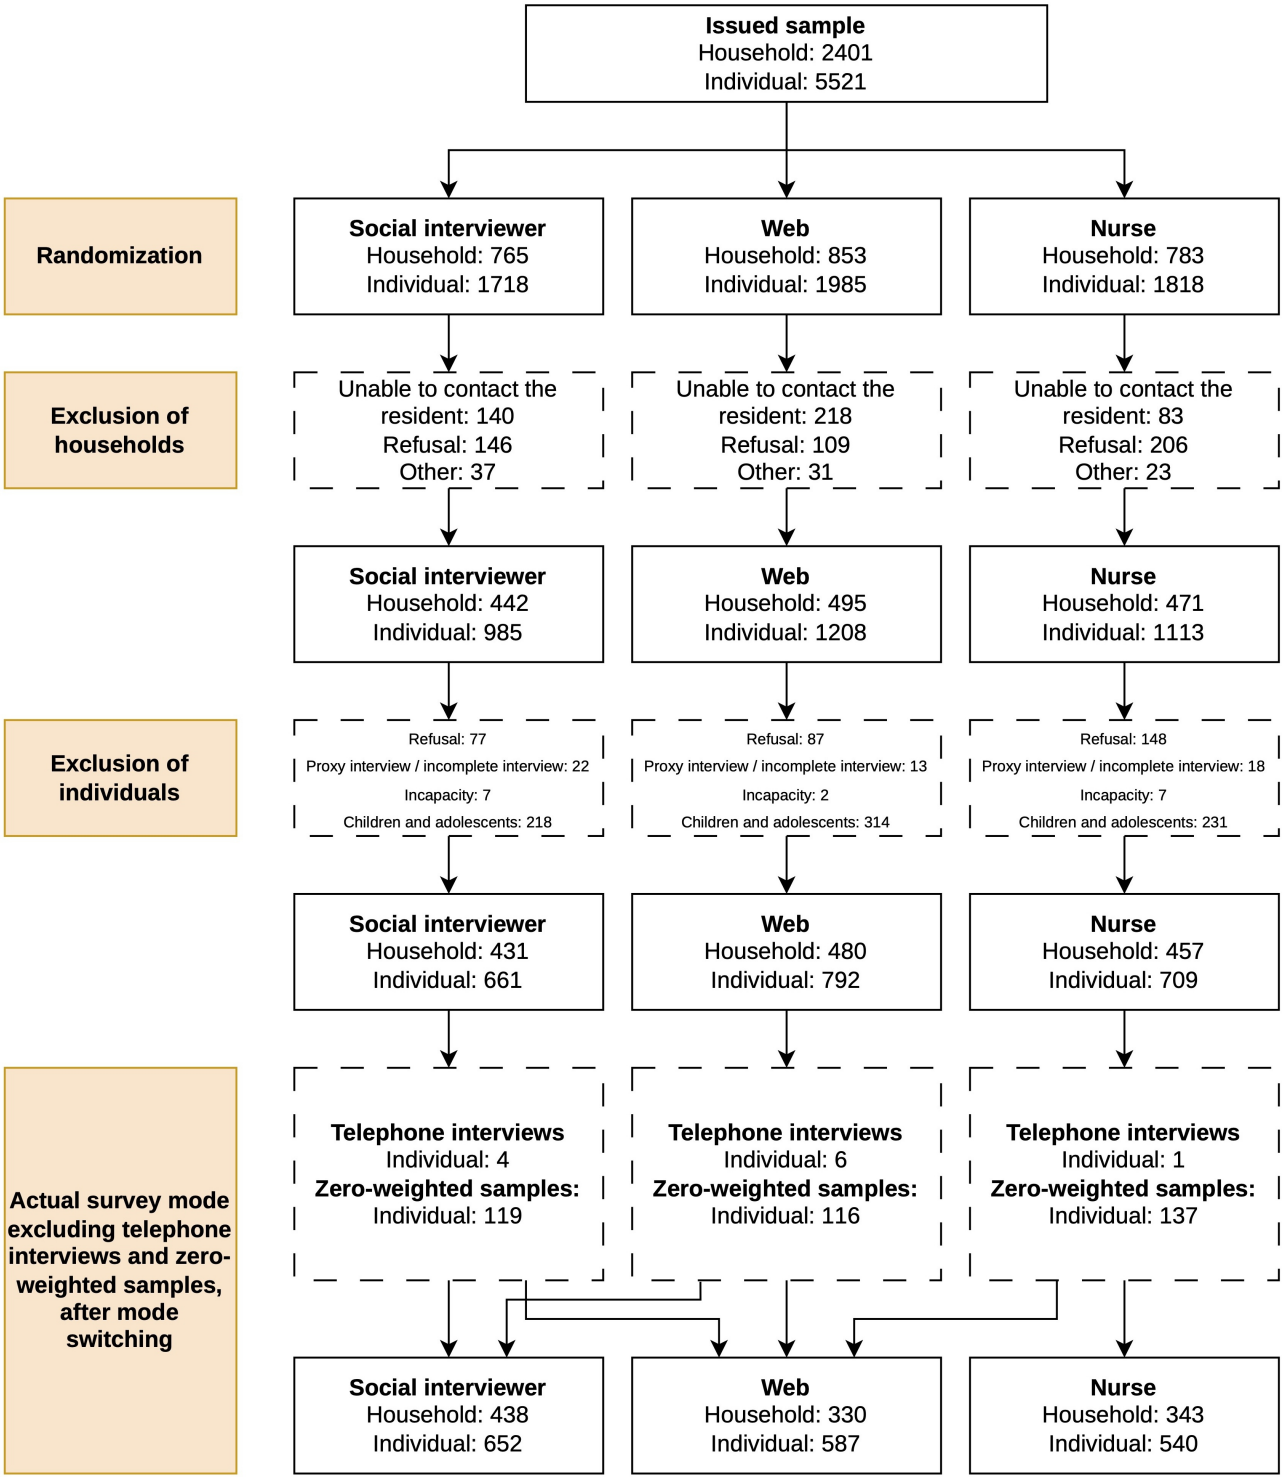

Table S4 in Multimedia Appendix 1 summarizes sample characteristics from weighted imputed datasets by actual survey mode (n=1779). In the imputed, survey-weighted sample, respondents in the web-based self-completion group were physically healthier (SF-12 PCS score 22.12, 95% CI 21.32 - 22.91) than those in either the interviewer-administered (SF-12 PCS score 26.54, 95% CI 25.44 - 27.64) or nurse-administered (SF-12 PCS score 24.71, 95% CI 23.50 - 25.91) CAPI groups. Web respondents also had a lower prevalence of cardiovascular conditions (unweighted 115/585; imputed, weighted 16.94%, 95% CI 13.21 - 20.68) and respiratory conditions (63/585, 11.46%, 95% CI 7.83 - 15.10) than did respondents in the social interviewer group (cardiovascular conditions: 187/651; 26.19%, 95% CI 22.41 - 29.96; respiratory conditions: 124/651; 19.47%, 95% CI 15.67 - 23.27), and fewer musculoskeletal disorders (74/585; 11.20%, 95% CI 8.37 - 14.04) than nurse-administered respondents (102/540; 17.77%, 95% CI 14.16 - 21.38).

XSL•FO
RenderX

Web respondents were younger, with more participants aged 16 to 25 years than in the social-interviewer group, and fewer aged 66 years or older. Compared with social-interviewer respondents, those in the web mode were generally more advantaged as they were less often separated, divorced, or widowed, less likely to have no formal qualifications, more likely to be employed, and less likely to be in the lowest income category. In addition, web respondents were significantly less likely to be separated, divorced, or widowed compared with respondents in the nurse mode. Web-mode respondents were less likely to have previously used interviewer-administered modes than respondents in the nurse mode or social-interviewer respondents, and were more likely to have previously used web self-completion.

Table 2 presents mode effect estimates for GHQ-12, the SF-12 MCS, and the SF-12 PCS, derived from a 2SRI approach that incorporates complex survey design features and multiple imputation for missingness. Across all mode comparisons, none of the estimated differences reached statistical significance. For GHQ-12, estimated differences ranged from −0.27 to 0.25 (effect sizes, −0.05 to 0.04; all *P*>.99); for SF-12 MCS, from −0.36 to 0.32 (effect sizes, −0.04 to 0.03; all *P*>.99); and for SF-12 PCS, from −1.02 to −0.36 (effect sizes, −0.10 to −0.03; *P*=.81 to >.99). Full pairwise estimates and 95% CIs are reported in Table 2. The findings of the complete case analyses were similar (Table S5 in Multimedia Appendix 1).

Table . Summary of results from the main analyses for 12-item General Health Questionnaire (GHQ-12), 12-item Short Form Mental Component Summary (SF-12 MCS), and 12-item Short Form Physical Component Summary (SF-12 PCS).

Outcomes	Estimate (95% CI)	Effect size	*P* value
GHQ-12			
Nurse (reference: social interviewer)	–0.27 (–1.38 to 0.84)	–0.05	>.99
Web (reference: nurse)	0.25 (–1.23 to 1.73)	0.04	>.99
Web (reference: social interviewer)	–0.02 (–1.97 to 1.94)	–0.01	>.99
SF-12 MCS			
Nurse (reference: social interviewer)	–0.36 (–2.14 to 1.42)	–0.04	>.99
Web (reference: nurse)	0.32 (–1.94 to 2.58)	0.03	>.99
Web (reference: social interviewer)	–0.04 (–2.99 to 2.91)	–0.01	>.99
SF-12 PCS			
Nurse (reference: social interviewer)	–0.36 (–2.25 to 1.53)	–0.03	>.99
Web (reference: nurse)	–0.66 (–2.20 to 0.88)	–0.06	.91
Web (reference: social interviewer)	–1.02 (–3.23 to 1.20)	–0.10	.81

Table 3 presents adjusted odds ratios (ORs; 95% CIs) from 2SRI logistic models that incorporate complex survey design and multiple imputation. For nurse vs social interviewer administration, ORs ranged from 0.72 to 1.56 across condition categories, with no consistent direction. In contrast, ORs for web vs nurse administration were consistently below 1, ranging from 0.54 to 0.90, corresponding to approximately 10% to 46% lower odds of reporting a doctor-diagnosed condition. Similarly, for web versus social interviewer administration, ORs were below 1 for 5 of the 6 condition categories (range 0.41 - 0.86), corresponding to approximately 14% to 59% lower odds. Musculoskeletal disorders were the only exception to this pattern for web vs social interviewer administration (OR 1.15, 95% CI 0.52 - 2.57). However, none of these pairwise comparisons reached statistical significance, and all 95% CIs included 1. The findings of the complete case analyses were similar (Table S6 in Multimedia Appendix 1), except for respiratory conditions when comparing respondents in the social interviewer (*P*=.005) mode with respondents in the web self-completion mode.

Web (reference: social interviewer)	0.41 (0.17-1.03)	.06

Tables S7-S10 in Multimedia Appendix 1 present the results of moderation analyses stratified by sex and age group. There were no statistically significant differences in SF-12 or GHQ-12 scores between male and female individuals (Table S7 in Multimedia Appendix 1; overall interaction *P*>.99, except for GHQ-12, *P*=.25). The overall interaction between age group and survey mode was statistically significant for the SF-12 PCS score (*P*=.04) but none of the individual interaction contrasts reached statistical significance. The corresponding interactions were not statistically significant for the GHQ-12 or SF-12 MCS scores (Table S8 in Multimedia Appendix 1; *P*>.99).

For chronic conditions, there was no evidence of an overall interaction between sex and survey mode (all *P*>.99, except for musculoskeletal disorders, *P*=.25). Nevertheless, among men, musculoskeletal conditions were reported more frequently in nurse interviews than in social interviewer CAPI (OR 2.43, 95% CI 1.14 - 5.20; *P*=.01) and in web self-completion mode (OR 0.43, 95% CI 0.19 - 0.97; *P*=.04; reference: nurse mode; Table S9 in Multimedia Appendix 1). The corresponding risk differences exceeded 5% (Figure S1 in Multimedia Appendix 1). In contrast, among women, the effect estimates were closer to the null, with ORs of 1.15 (95% CI 0.52 - 2.54) for nurse vs social interviewer, 1.10 (95% CI 0.51 - 2.35) for web vs nurse, and 1.26 (95% CI 0.47 - 3.41) for web vs social interviewer. For respiratory conditions, the direction of associations was consistent in men and women, with all pairwise ORs below 1, although the reductions were more pronounced among men. Among men, web self-completion was associated with lower odds than social interviewer CAPI (OR 0.32, 95% CI 0.10 - 1.00; *P*=.049) and nurse CAPI (OR 0.45, 95% CI 0.20 - 1.00; *P*=.05). Among women, the corresponding ORs were 0.53 and 0.64, respectively, with confidence intervals including 1. The overall interaction between age and survey modes was not statistically significant for any chronic condition (all *P*>.99, except for respiratory conditions, *P*=.86). Respiratory conditions were reported significantly less often via web-based self-completion among respondents aged 56 years and older compared to social interviewer CAPI (OR 0.25, 95% CI 0.09 - 0.71; *P*=.003) and nurse CAPI (OR 0.32, 95% CI 0.13 - 0.79; *P*=.005; Table S10 in Multimedia Appendix 1), with mode differences exceeding 5% (Figure S2 in Multimedia Appendix 1). However, the direction of associations was consistent across age groups; among respondents aged less than 56 years, the corresponding ORs for web versus social

XSL•FO
RenderX

interviewer and web versus nurse were 0.53 and 0.70, respectively, although their confidence intervals included 1.

The results of the supplementary analysis of the number of chronic-condition categories are shown in Table S11 in Multimedia Appendix 1. Participants completing the survey via the web reported fewer chronic conditions than those assessed by nurses (IRR 0.72, 95% CI, 0.54 - 0.96; *P*=.02). No significant differences were observed between nurse and social-interviewer modes (IRR 1.00, 95% CI, 0.83 - 1.20; *P*>.99) or between web and social-interviewer modes (IRR 0.72, 95% CI, 0.50 - 1.02; *P*=.07).

In sensitivity analyses excluding participants who completed a survey mode that differed from their originally allocated mode (Table S12 in Multimedia Appendix 1), findings were consistent with the main analyses. The only difference was that web mode (vs social interviewer) was associated with lower odds of respiratory conditions (OR 0.49; 95% CI, 0.26 - 0.94; *P*=.03), whereas this association was marginal (*P*=.06) in the main analysis.

Discussion

In this nationally representative study in Great Britain, we did not find clear evidence of differences in self-completed GHQ-12 or SF-12 scores across modes that varied in interviewer presence and role. We found no statistically significant evidence of mode-related differences in reports of doctor-diagnosed mental health and other conditions. However, the tendency for web self-completion to yield lower reporting of chronic conditions indicates that mode-related differences cannot be excluded. There was little evidence overall that mode-related differences varied by age or sex. Although some subgroup contrasts reached statistical significance, respiratory-disease estimates were broadly consistent across strata, while the musculoskeletal contrast within the male subgroup should be interpreted cautiously.

Although previous studies suggest that responses to self-completion instruments may vary according to the interview context [19,20], our study did not find clear evidence of differences in the self-completed GHQ-12 and the mental and physical components of the self-completed SF-12 across modes that varied in interviewer presence and role. Notably, a previous study found differences in GHQ-12 responses even though the GHQ-12 was self-completed by respondents in both interviewer-administered and self-completion survey modes, suggesting that contextual factors such as interviewer presence may still influence responses [19]. In contrast, the limited differences observed in our study may partly reflect the prior survey experience of the social interviewers and the study-specific briefing social interviewers and nurses received on fieldwork and interview procedures, together with CASI procedures that reduced direct interviewer involvement and protected the confidentiality of completed responses [51]. This interpretation is also consistent with recent evidence from a randomized study, which suggested that differences in the privacy and confidentiality afforded by self-completion modes may influence disclosure of mental health and other sensitive information [20]. Although our point estimates for GHQ-12 and SF-12 MCS were slightly more favorable in the nurse mode than in the social interviewer or web modes, the differences were negligible and not statistically significant. Differences between web and social interviewer modes were also minimal. These findings provide little evidence that either the presence of an interviewer during CAPI or the interviewer's professional role introduced systematic bias in responses to the self-completed GHQ-12 or SF-12 instruments. Furthermore, our findings may support the use of appropriately implemented CASI within CAPI to minimize the mode effects previously observed when health scales were administered directly by interviewers [11,13,15,19,24]. This approach is widely adopted in many national surveys; for example, the 2023-2024 Adult Psychiatric Morbidity Survey in England similarly adopted a self-completion section within CAPI interviews to mitigate social desirability bias in sensitive item responses [18]. Overall, these findings may support the use of self-administered approaches, whether web-based or embedded as CASI within interviewer-administered surveys, particularly for administering sensitive health-related scales.

We also did not find statistically significant evidence of mode effects for doctor-diagnosed psychiatric conditions, similar to findings from previous research based on diagnostic algorithm measures [24]. A possible explanation is that factual questions with simple categorical response options may be less susceptible to social desirability bias than multi-item or more subjective mental health measures [9,24]. For other doctor-diagnosed chronic conditions, the reporting was also broadly similar across web self-completion and interviewer-administered modes, with no statistically significant evidence of mode effects. No consistent pattern emerged when comparing outcomes between nurse interviewers and lay interviewers. However, descriptive prevalence estimates tended to be lower for web self-completion, and adjusted OR estimates were generally in the direction of lower reporting for web self-completion, although the 95% CIs were wide and included the null. A supplementary analysis of the number of chronic-condition categories also suggested that web respondents reported fewer condition categories than those interviewed by nurses. The estimate was similar but less precise when web respondents were compared with social-interviewer respondents. This pattern is broadly consistent with previous research suggesting a tendency toward lower reporting of physical health conditions in web self-completion than in interviewer-administered modes [24]. One possible explanation is that interviewer probing and clarification facilitate the elicitation of chronic conditions that might otherwise go unreported in self-administered questionnaires [9]. Overall, although no statistically significant evidence of mode effects was observed for individual doctor-diagnosed chronic-condition categories, our findings provide further context for ongoing discussion of this potential mechanism. Mode-related differences in the overall reporting of doctor-diagnosed chronic conditions therefore cannot be excluded.

When the analysis was restricted to participants who did not undergo a mode switch, the association between web self-completion and respiratory conditions, relative to interviewer administration, strengthened from marginal to statistically significant (*P*=.03, compared with *P*=.06 in the

XSL•FO
RenderX

main analysis), with respondents completing the survey online reporting fewer respiratory conditions. Previous evidence likewise suggests lower reporting of respiratory conditions in self-administered questionnaires [24], although findings across studies have not been consistent [9]. However, the overall pattern of point estimates for the other health conditions remained similar to that observed in the main analysis, with generally lower reported prevalence under web self-completion than interviewer administration, although these differences were not statistically significant. Thus, the finding for respiratory conditions may reflect a broader mode-related pattern in health reporting rather than an effect specific to respiratory conditions.

No significant overall interactions of self-completion contexts with age or sex were observed for GHQ-12 or SF-12, except for age differences in SF-12 PCS. However, as the age-stratified estimates were not statistically significant and direct supporting evidence is limited, this finding should be interpreted with caution. The overall interaction tests did not provide clear evidence that mode effects on chronic conditions varied by age or sex. Although individual contrasts reached statistical significance among adults aged 56 years or older and men, respiratory conditions showed a broadly consistent pattern across age and sex strata. This consistency suggests that the observed differences may reflect a general mode-related reporting pattern rather than clear effect modification by age or sex. Among men, musculoskeletal conditions were reported more frequently in the nurse-administered mode than in social interviewer or web self-completion modes, possibly because the nurse-administered context may facilitate reporting of symptoms that might otherwise be normalized or downplayed [52]. Given the nonsignificant overall interactions and the limited statistical power of the present study, the subgroup pattern should be regarded as exploratory.

This study offers several key advantages over prior research. First, we leveraged an existing randomized allocation of survey modes within a probability-based sample and applied an instrumental-variable approach to address potential selection bias in mode choice, thereby strengthening the generalizability and robustness of our results. Although our focus was on mode effects on measurement, we noted that self-selection can also operate through sample composition as a mode-related process. The instrumental-variable design helped mitigate concerns about such nonrandom mode choice. Second, inclusion of both standardized health scales and doctor-diagnosed chronic conditions allowed us to examine mode-related differences across different types of health indicators and administration conditions. Finally, by comparing the social interviewer-administered mode, web-based self-administration, and a nurse-administered mode, we offer additional insights into how nurse-administered CAPI may be associated with differences in self-reported health.

This study has several limitations. First, although our sample included participants from diverse racial and ethnic backgrounds, the small sample sizes of minority groups necessitated aggregation, limiting our ability to examine survey‐mode effects on self‐reported health outcomes within specific subgroups. Second, reports of doctor‐diagnosed chronic diseases were sparse and therefore combined by disease family, hindering further analysis of condition‐specific reporting patterns. Nevertheless, the effect estimates were generally in the direction of lower odds of reporting conditions with web self-completion than with interviewer-administered modes, but the 95% CIs were wide. Statistical power to detect mode-related differences was limited; post hoc power ranged from 57.2% to 61.1% across the 3 pairwise comparisons. Third, this study only assessed the association between survey mode and self‐reported health and did not directly assess disease-specific stigma. The study therefore could not assess whether the extent or direction of mode differences varied according to the perceived sensitivity or stigma associated with particular conditions. Finally, the asymmetric reallocation process may have resulted in residual confounding of the estimated effect of mode received. If unmeasured respondent characteristics such as internet access, literacy, health, or engagement with the study influenced which initially assigned mode was refused, the asymmetric reallocation structure could have differentially concentrated respondents with those characteristics in particular observed mode groups. Consequently, the estimated effect of mode received may partly reflect these asymmetry-induced compositional differences. However, sensitivity analyses restricted to participants who adhered to their original randomized mode allocation produced broadly similar findings, suggesting that the main results were unlikely to be primarily driven by the asymmetric reallocation of participants across survey modes. Moreover, the observed covariate imbalances between randomized groups indicate that the independence assumption cannot be regarded as fully satisfied on the basis of randomization alone. The instrumental variable approach therefore relied on conditional independence after adjustment for measured covariates. Residual confounding due to unmeasured factors cannot be excluded and remains a limitation.

Overall, this study provides important insights for the implementation of population-based health surveys. First, the absence of differences in GHQ-12 and SF-12 scores across self-completion contexts may support the use of CASI within face-to-face interviews for collecting these measures. Second, no statistically significant mode effects were observed for psychiatric or other doctor-diagnosed conditions. However, given the tendency for web self-completion to yield lower reporting of chronic conditions, mode-related differences, potentially reflecting interviewer probing and clarification, cannot be excluded and warrant further investigation. Finally, there was no clear evidence that mode-related reporting differed by age or sex; the musculoskeletal finding in men remains exploratory given limited power.

Abstract

Background: Privacy concerns represent a primary barrier to the adoption of large language model (LLM) applications, particularly in sensitive domains such as health care. Although a growing body of survey-based research has examined user privacy concerns with LLMs, no standardized instrument exists for measuring this construct.

Objective: This study aimed to develop and validate a concise, standardized questionnaire for assessing user privacy concerns with LLM-based systems, suitable for use by researchers and practitioners such as AI application developers and health care professionals.

Methods: A literature review was conducted to identify privacy-related domains relevant to LLM use. A draft questionnaire was developed and subjected to content validity review by 8 experts. The finalized instrument was administered via Qualtrics to adults aged 18 years or older who were aware of LLM-based applications, recruited through the University of Pittsburgh, LinkedIn, and the Pitt+Me research participant registry between April 2025 and July 2026. Internal consistency reliability and factor structure were assessed, with factor structure examined in a split-sample design, in which exploratory factor analysis (EFA) was conducted on a random one-third of the sample and confirmatory factor analysis (CFA) on the holdout two-thirds.

Results: All questionnaire items achieved acceptable content validity (item-level content validity index >0.80; average scale-level content validity index=0.964). A total of 603 responses were collected. After preprocessing, the final sample comprised 361 participants. Most participants were younger than 35 years of age (198/361, 54.8%), female (230/361, 63.7%), and White (285/361, 78.9%); 88.1% (318/361) held at least a bachelor's degree. The 6-item questionnaire showed high internal consistency (Cronbach α=0.90; McDonald ω=0.90). EFA (n=121) supported a single dominant factor with all standardized loadings ≥0.70. CFA (n=240) showed excellent fit (comparative fit index=0.996; Tucker-Lewis index=0.993; root mean square error of approximation=0.046; standardized root mean square residual=0.057). A 2-factor model separating the transparency- and control-related items fit significantly better than the 1-factor model ($\Delta\chi^2_1$=8.9; P=.003), but the 2 factors were correlated at r=0.83, indicating closely related facets. Because the Fornell-Larcker criterion was met for the transparency and control subscale but not for data use and risk salience, the 6-item total score remains the recommended primary metric.

Conclusions: The LLM privacy concern assessment is a concise, psychometrically sound 6-item instrument that measures privacy concern with LLM-based systems via 2 correlated subdimensions (transparency and control; data use and risk salience) summarized by a single total score. It enables standardized measurement across studies and practical privacy assessment in real-world LLM applications.

Introduction

Background

Large language models (LLMs) have seen rapid and widespread adoption across domains ranging from general-purpose information retrieval to specialized health care consultations. As users increasingly engage with these systems for sensitive tasks, including health queries, financial decisions, and personal problem-solving, privacy concerns have emerged as a primary barrier to adoption and sustained use [1-3]. These concerns are well-founded because user-entered data often include highly sensitive information about health, finances, and personal relationships that could be used in the next round of LLM training. Unlike traditional regulated health platforms, most general-purpose LLMs currently operate outside established comprehensive data protection frameworks, leaving users with limited assurances regarding how their information is handled [4].

Information privacy concern has been investigated since the 1990s through a succession of instruments, each linked to the development of information technology and responding to the data practices of its era [5]. The Concern for Information Privacy (CFIP) scale of Smith et al [6] framed privacy concern as apprehension about organizational data handling, with 4 domains addressing collection, unauthorized secondary use, improper access, and errors. The Internet Users' Information Privacy Concerns (IUIPC) scale of Malhotra et al [7] recasts concern as an appraisal of the fairness of a data exchange, drawing on social contract theory and measures collection, control, and awareness, while the Mobile Users' Information Privacy Concerns (MUIPC) scale of Xu et al [8] draws on communication privacy management theory and measures perceived surveillance, perceived intrusion, and secondary use. Later instruments pursued either integration, nesting several first-order domains under a higher-order general factor, as in Hong and Thong's Internet Privacy Concerns (IPC) scale [9], or reducing the construct to a small number of platform-specific domains, as in the scale of Sheehan and Hoy [10] for online consumers and in the scale of Wang et al [11] for short-form video platforms. Across this lineage, a core recurs, namely, collection, awareness, and use or reuse of data, while the remaining domains and the dimensional structure itself shift with the referent, from organizational record-keeping to the commercial web and then to mobile and social media platforms [6-11], and each shift left the preceding generation of items a poorer fit than it had been. That fragility is not only conceptual but linguistic. Item-interpretation studies show that widely used privacy statements often measure more than 1 construct and are read differently by different populations [12,13], and re-examinations on independent data have repeatedly led to respecification of published factor structures and revealed validity and reliability shortfalls [14,15]. This lineage demonstrates that privacy concern instruments are context-bound. Each of these instruments was created because a shift in technology, referent, theory, or population made prior items ill-fitting. For any new instrument, the dimensional structure, item wording, and cross-context validity must be established rather than assumed.

LLM-based applications meet that same test on more than 1 dimension, which is the basis for developing a new instrument rather than adopting an existing one. First, the referent itself differs, because prior scales address an organization, website, or platform, whereas many users often interact with an LLM as a conversational partner and disclose information in natural language without a clear idea about how their inputs are stored and reused [16]. Second, the data practices also differ. User inputs may be retained for model training, and LLMs can memorize and later reproduce fragments of their training data [17] or infer unstated personal attributes such as employment, location, income, and sex from ordinary text, which is an inferential privacy risk with no close analogue in form-based web interaction [18]. The LLM provider ecosystem is also opaque and multiparty, so retention, sharing, and reuse of data are largely unobservable to the user. Finally, because item meaning does not transfer cleanly across referents [12,13], even a shared construct such as data "collection" is unlikely to be measurement-invariant when the collecting entity is a generative AI model rather than a website.

A first wave of survey studies has begun to measure users' privacy concerns with LLMs and AI chatbots, several of them in health contexts, but each has operationalized privacy through a distinct theoretical lens and for a distinct purpose. Choi et al [1] assessed disclosure willingness and its antecedents across 3 countries using items derived from the antecedents, privacy concerns, and outcomes (APCO) macromodel [5]; Liu et al [2] used privacy concern as a predictor within a behavioral model grounded in uncertainty reduction theory [19]; Liu et al [3] measured privacy awareness and expectation gaps using information flows informed by contextual integrity [20]; and Tran et al [4] used factorial vignettes to assess the contextual conditions under which data sharing is perceived as appropriate. Although each of these instruments provides theoretically rich insights within its specific framework, none was designed to yield a generalizable, stand-alone privacy concern score that could be compared across studies or applied by practitioners to a new LLM system.

What is missing is a validated, purpose-built measure of user privacy concern toward LLMs that is not tied to any single behavioral theory or downstream outcome, and that a researcher or LLM application developer can apply directly to assess privacy concern toward a specific system. This gap motivates the development of a concise, referent-specific instrument that preserves the field's replicated conceptual core, reanchors it to the LLM context, and extends it to concerns unique to conversational AI.

Objectives

The goal of this study is to develop and validate a concise, standardized instrument for assessing user privacy concerns specific to LLM-based systems. The instrument is intended to serve both researchers who need a reusable scale enabling cross-study comparison and practitioners who wish to conduct privacy assessments of specific LLM applications. Development followed a multistage process including item creation informed by the literature, expert content validation, and psychometric evaluation in a general adult sample.

RenderX

Methods

Survey Development

Two authors in the study team (LZ and HW) conducted a literature review to identify privacy domains relevant to LLM use, including technology vendor trust, informed consent, data handling practices, user control, and transparency. Based on this review, a draft questionnaire was developed. A literature search was performed on Google Scholar, PubMed, and Scopus using keywords ["privacy concern" AND (questionnaire OR instrument OR scale) AND (internet OR web OR e-commerce OR "mobile app" OR "short form video" OR "Artificial Intelligence" OR AI)] without date restrictions. LZ and HW worked together and selected articles on questionnaire development and the ones that have been widely adopted in other studies. Some articles were identified from the references of selected articles. We ignored articles that simply applied these questionnaires to measure privacy concern or presented a language translation of them. The domains and questionnaire items from the 6 selected articles [6-11] were extracted and compared against the uniqueness of privacy concerns with LLMs (eg, the opacity of model vendors, new ways of providing personal data, and new ways of reusing user data).

Candidate domains were identified from the comparative synthesis of the 6 foundational instruments and the LLM privacy literature, following recommended practice of grounding a construct's content in theory and prior measurement before item generation [21]. We retained the domains with the strongest cross-instrument replication (data use, awareness, and control) since they were still highly relevant to privacy concerns with LLM applications, and added domains warranted by the distinctive data practices of LLMs (transparency for trust, risk salience, and onward third-party sharing), plus a global-concern domain to support an overall index.

Theoretically, these candidate domains are consistent with the APCO framing of privacy concern as a central antecedent of privacy outcomes [5], with social contract accounts of fairness and control in data exchange [7,22], and with communication privacy management theory's emphasis on control over disclosure boundaries [8]. All of these are strained in the conversational, inference-capable LLM setting. Grounding the domains in this measurement lineage rather than in any single behavioral theory is deliberate because recent LLM questionnaires built on APCO, uncertainty reduction theory, and contextual integrity each measured a different facet of concern and produced noncomparable scores [1-4], so this new questionnaire specifies its content at the construct level to remain usable across those frameworks.

The initial working draft included more than 1 candidate item for 7 domains; through internal discussion, and before the independent content-validity review, the pool was reduced to 1 item per domain. Wording followed the lessons of the interpretation-and-validity literature [12,13]: items are short and adopt a single consistent perspective, that is, the person's own concern or valuation, rather than mixing concern-perception with expectation phrasing [9]. Each item names a referent ("LLMs" or "LLM-based applications") so that responses attach to the intended entity rather than to websites or platforms generally, directly addressing the referent-mismatch problem the validity studies document. Response formats use ordinal Likert-type intensity anchors appropriate to each stem (eg, degree of concern, degree of importance, and frequency).

The instrument is intended as a brief privacy-concern index, scored as a single composite and composed of 1 item per narrowly defined domain, rather than a multi-item-per-factor multidimensional battery. This is a deliberate design choice, not a claim that privacy concern is psychologically unidimensional. Where a construct or domain is concrete and singular, single-item measures can perform comparably to multi-item scales and are defensible on both predictive validity and practical grounds [23-25]. A one-item-per-domain design maximizes content breadth across the privacy space while minimizing respondent burden and the wording-induced interpretation problems that multi-item scales compound [12,13]. The trade-offs, no within-domain internal-consistency estimate and greater sensitivity to item wording, are mitigated by the validation plan below and by the deliberate, theory-anchored specification of each domain. We acknowledge these limitations in the Discussion section, and we regard the instrument as preliminary. To avoid a terminological ambiguity, we note that the measurement model estimated in this study is reflective: each item is treated as an effect indicator of a common latent privacy-concern factor, which justifies the use of factor-analytic and internal-consistency evidence [26].

Responses were measured on a 5-point Likert scale with anchors tailored to each item's stem: importance items were anchored 1=extremely important to 5=not at all important; concern items were anchored 1=extremely concerned to 5=not at all concerned; and the frequency item was anchored 1=always to 5=never. The use of heterogeneous anchors (importance, concern, and frequency) was intentional to match the conceptual content of each item; the subsequent factor analysis tested whether items cohere as a single scale despite the differing anchors. All 3 anchor sets run in the same direction, from the strongest to the weakest degree of concern, so lower raw scores indicate stronger privacy concern, and item scores should be reverse-coded before a composite is formed if higher scores are to denote greater concern. The composite is a unit-weighted sum or mean of the 6 raw item responses, which assumes that the 5 ordinal positions are metrically equivalent across the 3 anchor types. The present data cannot verify that assumption. The items are known only to share a common 5-category format and common direction. We retained unit weighting rather than standardizing items to *z* scores for 2 reasons: unit-weighted composites are generally as predictively useful as differentially weighted ones and more stable across samples [27]; *z* standardization would make the score dependent on the composition of the sample in which it is computed, which is unsuitable for the benchmarking use for which the instrument is intended. Two questions are therefore left open: whether the 3 anchor types function equivalently across respondents, and whether unit-weighted and standardized scoring lead to the same conclusions. Both are discussed in the Limitations and Future Work section.

Validation followed established scale-development guidance [21,28]. Content validity of the questionnaire was evaluated by

XSL•FO

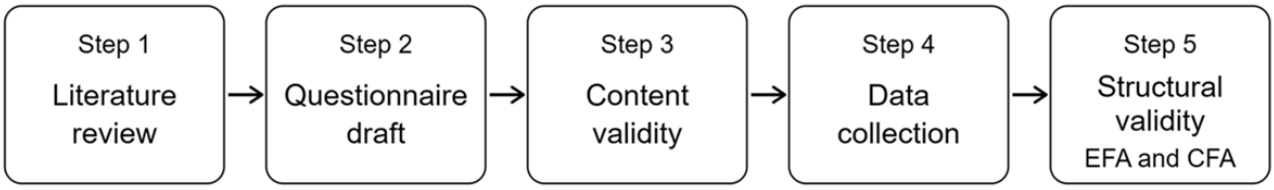
a panel of 8 independent subject-matter experts. To preserve the independence of the appraisal, the panel comprised only experts who were not involved in item construction. They were recruited via research team members' recommendations. Their backgrounds were computer science, information science, and user experience research, and all had extensive experience in questionnaire design and evaluation. Each expert independently rated every item on 2 dimensions, relevance to the target construct (user privacy concern with LLM applications) and clarity of wording, using the 4-point ordinal scale recommended by Lynn [29]: 1=not relevant or clear, 2=somewhat, 3=quite, and 4=highly relevant or clear. Ratings of 3 or 4 were recoded as endorsement and ratings of 1 or 2 as nonendorsement [29,30]. Items for which the majority of reviewers assigned a relevance rating of 1 or 2 were removed. Items receiving low clarity ratings were retained but revised through team consensus during a structured review meeting. For each item, the item-level content validity index (I-CVI) was computed as the proportion of experts who endorsed the item. Because the I-CVI=A/N does not adjust for chance agreement, a modified kappa (κ*) was also calculated by correcting each I-CVI for the probability of chance agreement, $P_C=[N!/(A!(N-A)!)](0.5^N)$, where N is the number of experts, and A is the number endorsing the item; $\kappa^*=(\text{I-CVI}-P_C)/(1-P_C)$ was interpreted as excellent (>0.74), good (0.60-0.74), or fair (0.40-0.59) [31]. At the scale level, both the averaging method (scale-level content validity index [S-CVI]/Ave and the mean of the item I-CVIs) and the universal-agreement (UA) method (S-CVI/UA, the proportion of items endorsed by all experts) were reported [30]. An I-CVI of at least 0.78 for panels of 6 or more experts and an S-CVI/Ave of at least 0.90 were adopted a priori as evidence of satisfactory content validity [29-31]. Structural validity was assessed with exploratory factor analysis (EFA) followed by confirmatory factor analysis (CFA), evaluated against conventional fit criteria [32]. Reliability was reported as internal consistency and composite reliability where applicable. Further details are provided in the Statistical Analysis section.

The panel's ratings are one component of the content validity evidence rather than the whole of it. The theoretical grounding of the candidate domains and the mapping of each item to its domain and to the prior constructs from which that domain derives are reported in Table 1. Because the panel comprised 8 reviewers recruited on the recommendation of research team members rather than by independent nomination, its endorsement does not by itself establish content validity. The size of the panel is also small. Both are noted in the Limitations and Future Work section.

Table . Mapping between proposed questionnaire domains and constructs in prior instruments.

LLM-PCA[a] item	Domain	Antecedent constructs in prior instruments	Primary lineage source
G1. How concerned are you about the ways in which LLMs[b] use your personal data?	Data use (secondary/onward use)	Unauthorized secondary use, information use, use concerns	[6-9,11]
G2. How important is it for you to be informed about how LLMs use your data?	Awareness (notification)	Awareness of collection, awareness	[7,9,10]
G3. How much concern do you have for the privacy of your data when using applications or services that utilize LLMs?	Global privacy concern	Overall or general privacy-concern factor	[7,9]
G4. How important is transparency about data usage to your trust in LLM-based applications?	Transparency (trust-relevant)	Awareness, link to trusting beliefs	[7,9]
G5. How important is it for you to have control over how LLMs use your data?	Control	Control	[7,9]
G6. How often do you think about the potential privacy risks when using LLM-based applications?	Risk salience	Link to risk beliefs	[9]
G7. How important is it for you to know about the specific companies or organizations with whom your data is shared?	Third-party or onward sharing	Unauthorized secondary use, improper access, perceived surveillance, third-party sharing within use concerns	[6,8,9,11]

[a]LLM-PCA: large language model privacy concern assessment.



[b]LLM: large language model.

The revised instrument was then deployed on Qualtrics (Qualtrics International) for an internal pilot test conducted with the full research team. The pilot assessed the question-and-response logic, item flow, and platform implementation. Issues identified during the pilot were resolved prior to participant recruitment. In addition to the privacy-concern items, the survey collected demographic information, including age, race, sex, education level, marital

XSL•FO
RenderX

status, and annual income, to assess potential biases in respondents' answers, plus one screening question to determine whether potential participants had heard of LLMs. If they answered no or did not provide a response to this screening question, they would not be allowed to answer any questions on privacy concerns with LLMs. Responses from individuals unfamiliar with LLMs would not meaningfully reflect privacy concerns about them. The entire procedure is shown in Figure 1.

Figure 1. Flowchart of questionnaire development and validation. CFA: confirmatory factor analysis; EFA: exploratory factor analysis.

Participant Recruitment

Participants were eligible if they were adults (aged ≥18 years), understood English, and had awareness of LLM-based applications. Recruitment was conducted through three channels: (1) bulk email distributed to a random sample of students, faculty, and staff affiliated with the University of Pittsburgh; (2) a posting on LinkedIn; and (3) a posting on Pitt+Me, a research participant registry managed by the University of Pittsburgh. Interested individuals accessed the survey via a link directing them to the Qualtrics platform. When the university's electronic bulk-mail delivery service received a request for an announcement, it randomly selected the targeted audience (faculty, students, and staff in this case) and distributed the announcement. We used the service and made 2 announcements about the study in April and May 2025. In total, the message was delivered to several thousand faculty, students, and staff at Pitt. Study participation was fully voluntary, and we did not pay any compensation to the study participants. The same recruitment message was posted on the website of Pitt+Me in April, and anyone who visited the website in the study period (April 2025 to July 2026) could see the recruitment message and follow the link to answer the questions in the questionnaire.

Ethical Considerations

This study was approved by the University of Pittsburgh Human Research Protection Office (protocol ID: STUDY24110036). Participation was entirely voluntary; participants could withdraw at any time and request removal of their data without penalty.

Data Preprocessing

Prior to analysis, the raw dataset was cleaned using the following sequential criteria. First, records collected during the internal pilot phase were excluded. Second, responses that were entirely blank and responses that contained only demographic answers with no answers to any privacy concern item were removed as nonparticipating records because these entries could not provide any information for the privacy concern questionnaire. Third, participants who indicated that they had never heard of LLMs were excluded, as responses from individuals with no awareness of the technology were considered uninformative for the study's objectives. They were not allowed to answer any further questions in the questionnaire. Fourth, participants who did not answer any privacy concern–related questions were excluded since their data would not be useful for this specific study. These 4 steps removed records that should not be included in the dataset. The fifth step was a decision about how to handle missing data. We chose to only keep records with complete answers to those privacy concern questionnaire items. We adopted complete-case analysis because no imputation approach is free of assumptions, and imputed values could alter the item distributions on which the psychometric analyses depend. Records missing demographic data only were retained since they would not impact the evaluation of the large language model privacy concern assessment (LLM-PCA) questionnaire itself. Finally, administrative columns (eg, response ID, timestamp, and language) were removed from the dataset.

To evaluate whether restricting analyses to complete cases introduced systematic bias, we compared respondents retained for complete-case analysis with those excluded due to partial item nonresponse across all study variables. Continuous variables were compared using independent samples *t* tests, and categorical variables using Pearson chi-square tests of independence. A 2-sided α of .05 was applied. Because these tests were intended to detect potential nonresponse bias rather than to establish statistical equivalence, nonsignificant differences were interpreted as consistent with, but not confirmation of, ignorable missingness.

Statistical Analysis

Descriptive statistics were computed for all demographic variables, with frequencies and percentages reported. Item-level descriptive statistics (mean, SD, count of respondents to each option, and percentage) were computed for each item in the privacy concern questionnaire prior to factor analysis. Psychometric analyses were then conducted on the privacy concern items. Internal consistency reliability was assessed using Cronbach α and McDonald ω, with values ≥0.70 considered acceptable [33,34].

To examine the dimensionality and measurement properties of the scale, we used a split-sample cross-validation design: the complete-case sample was randomly partitioned into 2 parts, with roughly one-third used for EFA and the remaining two-thirds reserved for CFA. Because the total sample was modest for a split-sample design, we treat the EFA as exploratory and hypothesis-generating; confirmatory replication in a larger and independent sample remains necessary, and the reported CFA fit should be interpreted accordingly [32,34].

Because the items were measured on a 5-point Likert scale, we computed a polychoric correlation matrix to characterize

XSL•FO
RenderX

interitem association. Polychoric correlations model an underlying continuous latent response for each ordered-categorical indicator and are the principled measure of association for Likert items. Sampling adequacy was evaluated using the Kaiser-Meyer-Olkin (KMO) measure and Bartlett test of sphericity, both computed from the polychoric matrix. The number of factors to retain was determined by parallel analysis with 500 iterations of resampled data, using the 95th percentile of simulated eigenvalues as the cutoff [35]; Kaiser's eigenvalue-greater-than-one criterion was reported as a secondary index. Factor extraction used maximum likelihood (ML) on the polychoric correlation matrix; when more than one factor was retained, promax (oblique) rotation was applied. ML extraction on a polychoric matrix assumes multivariate normality of the underlying continuous responses, an assumption we adopted as reasonable for ordinal Likert indicators.

A CFA model with all retained items loading on a single latent privacy concern factor was fitted to the CFA subsample using diagonally weighted least squares (DWLS), the appropriate estimator for ordered-categorical Likert indicators. The latent factor variance was fixed to 1.0 to identify the model, allowing all factor loadings to be freely estimated.

Model fit was evaluated at both the global and local levels because satisfactory global fit does not guarantee that a model reproduces every element of the observed covariance structure. Global fit was assessed using the model chi-square statistic with its degrees of freedom and associated *P* value, the comparative fit index (CFI), the Tucker-Lewis index (TLI), the root mean square error of approximation (RMSEA) with its 90% CI, the standardized root mean square residual (SRMR), goodness-of-fit index (GFI), and adjusted goodness-of-fit index (AGFI). The GFI and AGFI are reported for completeness only and are not used to support any conclusion about fit. Conventional cutoffs for acceptable fit were CFI and TLI ≥0.90 (≥0.95 for good fit), RMSEA ≤0.08 (≤0.06 for good fit), and SRMR ≤0.08 (≤0.05 for good fit). These values were treated as descriptive heuristics and not as decision thresholds. They were derived under normal-theory ML with continuous data [32], and simulation work shows that diagonally weighted and unweighted least squares applied to polychoric matrices yield systematically smaller RMSEA and larger CFI and TLI values than ML, so that applying the conventional cutoffs under these estimators tends to understate misfit [36]. Because the model chi-square test has limited power to detect misspecification at moderate sample sizes and the RMSEA is estimated with appreciable sampling variability, we additionally evaluated close fit using the test of close fit (PCLOSE [*P* value for the test of close fit]), which assesses the null hypothesis that the population RMSEA is no greater than .05. Because the model was estimated with DWLS on the polychoric correlation matrix, particular interpretive weight was given to the SRMR, which is the most robust and least biased of the common fit indices under this estimator and ordered-categorical data. The RMSEA was interpreted together with the width of its CI. Local fit was examined through the matrix of residual correlations, computed as the difference between the observed polychoric correlations and the correlations implied by the fitted model. Individual residual correlations were inspected to identify item pairs whose association the model failed to reproduce; absolute residual correlations greater than 0.10 were treated as indicators of localized strain warranting further examination [37]. The magnitude and pattern of the largest residuals were reported to characterize the nature of any local misfit, and their substantive interpretation was considered alongside the global indices in evaluating the adequacy of the model. Global fit was therefore interpreted jointly with this local fit evidence and with the nested model comparison, rather than by asking whether any single index cleared a cutoff.

Composite reliability (ω) was reported as an indicator of internal consistency, and the average variance extracted (AVE) as an indicator of convergent validity. Where a model with more than 1 factor was retained, discriminant validity between factors was assessed using the Fornell-Larcker criterion [38], which requires the AVE for a factor to exceed the squared correlation between factors, and the heterotrait-monotrait ratio of correlations (HTMT)<0.90 because values of HTMT above 0.90 indicate that factors are not empirically distinct. Reliability and AVE were computed for the full item set and for the indicators defining each factor in any multifactor solution. Composite reliability was computed as $\omega=(\Sigma\lambda)^2/[(\Sigma\lambda)^2+\Sigma(1-\lambda^2)]$, and AVE as $AVE=(\Sigma\lambda^2)/k$, where λ is the standardized loading of indicator i, and k is the number of indicators. Conventional thresholds of ω≥0.80 and AVE ≥0.50 were used [34,38].

To assess sensitivity to the random partition, the full procedure, including the item-refinement step, exploratory analysis, and confirmatory analysis, was repeated under 5 random partitions, with all item-reduction decisions made using the exploratory subsample only.

Analyses were conducted in SPSS (version 31; IBM Corp) and Python (version 3.13; Python Software Foundation) using the *pyreadstat* package for SPSS file input, *factor_analyzer* for EFA, and *semopy* for CFA [39]. Path diagrams were first visualized using semopy.semplot and postprocessed for publication.

Sample Size Considerations

Minimum sample size was estimated during participant recruitment from the general rule of thumb of 10 respondents per item for factor analysis. No formal a priori power analysis was conducted, so recruitment remained open for the duration of the fielding period, and the achieved sample was determined by the response to the 3 recruitment channels. The benchmarks set out below are the a priori criteria, against which the planned analyses were judged to be adequately powered. Whether the achieved subsamples met those benchmarks and whether the data satisfied the conditions the benchmarks assume are addressed in the Results and Limitations and Future Work sections.

For the EFA, the required sample size is not fixed by absolute N or by the subject-to-variable ratio alone but depends primarily on the level of communality and the degree to which factors are overdetermined [40]. When communalities are high and a single factor is well defined by multiple indicators, population factors can be recovered accurately even in small samples. de Winter et al [41] similarly demonstrated that well-conditioned data,

XSL•FO
RenderX

characterized by high loadings, few factors, and an adequate number of indicators per factor, yield reliable EFA solutions at sample sizes well below conventional minimums. Neither condition can be verified before the data are collected, so they were treated as criteria to be checked afterward rather than as a basis for setting a target. The a priori benchmark applied was therefore the subject-to-item ratio, for which 10:1 is the common minimum and 20:1 is at the upper end of published recommendations [42]. For a 6-item scale, these ratios correspond to 60 to 120 respondents in the exploratory subsample.

For the CFA, sample size adequacy is commonly evaluated using the ratio of cases to estimated parameters (the N:q rule), for which a ratio of 20:1 is considered ideal and 10:1 an acceptable minimum [37]. A 6-item single-factor specification estimates 12 free parameters (1 loading and 1 residual variance per item), and 1 more for a 2-factor specification, so the rule implies a minimum of 120 to 130 and an ideal of 240 to 260 cases in the confirmatory subsample. Simulation evidence indicates that the requirement for simple confirmatory factor models depends strongly on loading magnitude, with stronger loadings requiring fewer cases [43]; because loading magnitude is itself estimated from the data, that consideration could only be applied after estimation.

In total, if there are at least 180 respondents, both EFA and CFA can be performed. To achieve a more reliable result, the desired sample size is 360.

Results

Candidate Items in the New Questionnaire

The 7 candidate items were written so that each targets a distinct, narrowly defined privacy domain drawn from the synthesis mentioned earlier. The domains retain the field's replicated core (data use, awareness, and control) and extend it to LLM-salient concerns (transparency-for-trust, risk salience, and onward third-party sharing). Table 1 maps each item to its intended domain and to the antecedent constructs in the 6 foundational instruments.

The instrument is deliberately anchored to the most replicated regions of the construct while remaining fit for its new referent. G3 provides a global concern item analogous to overall privacy-concern factors. G2 (awareness) and G1 (data use) instantiate the 2 domains that recur most consistently across the lineage, giving the scale continuity with CFIP, IUIPC, MUIPC, IPC, and the short-form video scale. G5 (control) preserves the control domain, introduced in IUIPC and carried forward in IPC. For LLMs, the domain is especially consequential, because control is exercised through concrete and far-reaching choices: whether user inputs may be used to train future models, and whether conversation history persists across sessions.

The remaining 3 items (G4, G6, and G7) extend these core domains to data practices specific to LLMs. The comparative synthesis of the 6 prior instruments showed that none of them covers these concerns, so each item adds coverage rather than duplicating a domain already represented. G4 reframes awareness as transparency in the service of trust, operationalizing the concern-trust relationship that Hong and Thong [9] established as part of privacy concern's nomological network and that is acute for opaque, multiparty model providers. G6 (risk salience) captures how frequently the risk is cognitively present, a facet motivated by the demonstrated but often underrecognized LLM risks of memorization and inference [17,18] and by evidence that users disclose to conversational agents under flawed mental models [16]. G7 (onward sharing) sharpens the secondary-use and improper-access concerns of CFIP and IPC into the specific, LLM-relevant question of which third parties receive user data, reflecting the provider ecosystem described earlier. Two items (G2 and G4) intentionally draw on the same awareness or transparency region from complementary angles, notification versus transparency-for-trust, broadening coverage of that domain within a unidimensional design. Framing all 7 items as facets of a single privacy-concern construct, rather than as instruments of one behavioral theory, directly answers the fragmentation in recent LLM survey work, that is, APCO-, uncertainty reduction-, and contextual integrity–based measures each captured a different slice of concern and could not be compared [1-4], whereas the LLM-PCA is designed to be theory-agnostic at the point of measurement.

Content Validity

All 7 items demonstrated strong content validity on the relevance dimension (Table S1 in Multimedia Appendix 1). Five items (G2 to G6) were endorsed as relevant by all 8 experts (I-CVI=1.000), and the remaining 2 items (G1 and G7) were each endorsed by 7 of the 8 experts (I-CVI=0.875). Every item thus exceeded the 0.78 retention criterion, as well as the more stringent 0.83 threshold recommended for panels of 6 to 8 experts [29]. Chance-corrected agreement was uniformly excellent (modified $\kappa^* \geq 0.871$), confirming that the observed endorsement was not attributable to chance [31].

At the scale level, the averaging method yielded an S-CVI/Ave of 0.964, exceeding the 0.90 benchmark for satisfactory content validity. The more conservative UA index was S-CVI/UA=0.714, reflecting the 2 items (G1 and G7) on which a single expert each assigned a rating below 3.

Clarity ratings were also favorable, with item-level indices ranging from 0.750 to 1.000 and an S-CVI/Ave of 0.875. One item (G2) fell below the endorsement threshold on clarity alone (I-CVI=0.750, 2 dissenting experts) while retaining unanimous relevance endorsement. It was retained without modification, although its wording may warrant minor refinement in a future revision.

On the basis of these relevance results, none of the 7 candidate items were removed or reworded, and all were administered to study participants on Qualtrics. The relevance criteria were met by every item, which is the basis for that decision. The one shortfall not acted on was the clarity rating for G2 where I-CVI<0.78. Comprehension of wording is better assessed by cognitive interviewing than by expert rating. Its wording is therefore identified as a known weakness of the current version. It needs to be reassessed using cognitive interviewing in future revisions. The entire questionnaire used in this study is available in Multimedia Appendix 2.

Participant Characteristics

A total of 603 survey responses were collected. We first removed 11 responses generated during internal pilot testing, leaving 592 responses. Of these, 108 contained no questionnaire data (no answer to any questions) and were excluded, yielding 484 responses. A further 65 respondents reported no awareness of LLMs (37 answered “No” and 28 left the screening item blank) and were routed out of the survey without completing the remaining items; these were excluded, leaving 419 respondents. In the next step, 21 respondents who did not answer any privacy concern survey questions were excluded from the dataset, leaving 398 eligible respondents. Of the 398 eligible respondents, 361 (90.7%) provided complete data on all analysis variables and 37 (9.3%) had partial item nonresponse. Complete and incomplete respondents did not differ significantly on any measured characteristic (Table S2 in Multimedia Appendix 1). Therefore, 37 respondents who omitted 1 or more privacy concern survey items were excluded to retain complete cases only. The resulting analytic sample comprised 361 respondents. This procedure is shown in Figure 2.

Figure 2. Flowchart of data preprocessing. LLM: large language model.

Of the 361 participants, more than half were younger than 35 years (n=198, 54.8%), most identified as White (n=285, 78.9%), nearly two-thirds were female (n=230, 63.7%), and 88.1% (n=318) held at least a bachelor's degree. Distributions for all demographic variables are presented in Table 2. Overall, the sample was predominantly White, highly educated, and female, which should be considered when interpreting the generalizability of the factor structure and score distributions.

Item Descriptive Statistics

Item-level descriptive statistics for the 7 privacy concern items are presented in Table 3, including mean, SD, frequency of participants choosing each option in each question, and anchor type (concern, importance, or frequency). Items were rated on a Likert scale from 1 (extremely important, extremely concerned, or always) to 5 (not at all important, not at all concerned, or never). Therefore, lower values indicate stronger endorsement. Scoring, including the reverse-coding step, is specified in the Methods section. Item means ranged from 1.94 (G5) to 2.51 (G3) on the 1 - 5 Likert scale, indicating that, on average, participants endorsed moderate-to-high levels of privacy concern (with lower values indicating stronger endorsement). Item-level SDs were between 0.97 and 1.18. Because item dispersion was narrow and similar across items, a unit-weighted composite and one formed from standardized item scores would differ only slightly in this sample. All items used the full 1 - 5 response range. Skewness and kurtosis were calculated as well but not included in the table. Skewness ranged from 0.18 to 0.85 (maximum |skew|=0.85), and kurtosis ranged from −0.94 to 0.04 (maximum |kurtosis|=0.94), all well within conventional bounds (|skew|<2, |kurtosis|<7) for treating items as approximately continuous. Nevertheless, given the 5-point Likert response format, we used polychoric correlations for EFA and DWLS estimation for CFA throughout.

Table . Descriptive statistics and answer distribution for the 7 privacy concern items (N=361)[a].

Item	Mean (SD)	1, n (%)	2, n (%)	3, n (%)	4, n (%)	5, n (%)	Anchor type
G1	2.50 (1.14)	91 (25.2)	86 (23.8)	109 (30.2)	63 (17.5)	12 (3.3)	Concern
G2	2.05 (0.97)	122 (33.8)	131 (36.3)	79 (21.9)	25 (6.9)	4 (1.1)	Importance
G3	2.51 (1.18)	98 (27.1)	76 (21.1)	107 (29.6)	66 (18.3)	14 (3.9)	Concern
G4	2.07 (1.00)	125 (34.5)	122 (33.8)	85 (23.5)	22 (6.1)	7 (1.9)	Importance
G5	1.94 (0.99)	151 (41.8)	113 (31.3)	70 (19.4)	22 (6.1)	5 (1.4)	Importance
G6	2.36 (1.08)	89 (24.7)	120 (33.2)	94 (26)	48 (13.3)	10 (2.8)	Frequency
G7	2.37 (1.01)	74 (20.5)	139 (38.5)	94 (26)	48 (13.3)	6 (1.7)	Importance

[a]Data in columns 1 - 5 indicate the frequency of participants choosing one particular option as the answer to each question.

Instrument Refinement

The questionnaire was initially developed with 7 items, 1 for each privacy-concern domain. Before finalizing the scale, we examined the interitem polychoric correlation matrix and the fit of the 7-item unidimensional model on the confirmatory subsample (n=240). This examination revealed that items G1 ("How concerned are you about the ways in which LLMs use your personal data?") and G3 ("How much concern do you have for the privacy of your data when using applications or services that use LLMs?") were nearly collinear, with a polychoric correlation of 0.91. This indicated that both items assess a respondent's privacy concern with data use, and the strong correlation indicated that they functioned as effectively interchangeable indicators.

To determine which item to remove, we compared 2 reduced 6-item models, one omitting G1 and one omitting G3. Removing G3 produced uniformly good fit (χ^2_9=13.6; *P*=.14; RMSEA=0.046; SRMR=0.057), whereas removing G1 produced only marginally acceptable fit (χ^2_9=17.4; *P*=.04; RMSEA=0.062; SRMR=0.065). In the G1-omitted model, the retained item G3 was the weakest indicator (standardized λ=0.74; communality=0.47), whereas in the G3-omitted model, all retained items loaded more strongly. Because removing G3 yielded superior model fit and stronger indicators, we retained G1 and removed G3. The resulting 6-item scale (G1, G2, G4, G5, G6, and G7) was carried forward for all analyses reported below. Removal of an empirically redundant, conceptually overlapping item is a standard step in scale development; retaining both would have overweighted a single domain and

XSL•FO
RenderX

degraded model fit without adding measurement information. As reported in the Stability Across Alternative Sample Splits section, this removal decision was reproduced in 5 independent exploratory subsamples without consulting the confirmatory subsample.

Reliability

Cronbach α for this 6-item questionnaire was 0.90. Because α increases with both the number of items and the average interitem correlation, this value should be interpreted as reflecting high interitem redundancy in a short scale rather than as independent evidence of measurement quality [33]; McDonald ω, computed from the CFA (ω=0.90), is reported below as a complementary estimate.

EFA

EFA was conducted on the randomly selected EFA subsample (n=121). ML extraction was applied to the polychoric correlation matrix. The polychoric correlations (Table S3 in Multimedia Appendix 1) demonstrated strong but nonredundant interitem association, with off-diagonal correlations ranging from 0.45 (G6 vs G7) to 0.79 (G2 vs G5); removing G3 eliminated the near-collinear pair present in the original 7-item pool. The matrix was well-suited to factor analysis since the overall KMO measure of sampling adequacy was 0.87, in the "good" range, with per-item KMO values from 0.84 (G5) to 0.92 (G7), all above the 0.60 minimum. Bartlett test of sphericity was significant (χ^2_{15}=477.4; P<.001), confirming that the correlation matrix departed substantially from an identity matrix.

Parallel analysis based on 500 simulated datasets supported a 1-factor solution in the exploratory subsample. The first observed eigenvalue (4.17) substantially exceeded the corresponding 95th-percentile random eigenvalue (1.44), whereas the second observed eigenvalue (0.65) fell below its random benchmark (1.25). Kaiser's eigenvalue-greater-than-one criterion likewise retained a single factor. The ratio of the first to the second eigenvalue (6.46) further supported essential unidimensionality. The first eigenvalue accounted for 69.6% of total variance, and after ML extraction, the single-factor solution accounted for 63.6% of common variance. Standardized loadings on the retained factor (Table 4) were uniformly substantial in absolute value, ranging from 0.71 (G7) to 0.88 (G5), and all 6 items exceeded the stricter conventional λ≥0.70 threshold for strong indicator quality. The items with the weakest loadings (G6 and G7) may be candidates for rewording or replacement in future work. Item communalities ranged from 0.50 (G7) to 0.78 (G5). The pattern of eigenvalues, the parallel-analysis decision, and the uniformly high single-factor loadings provided convergent evidence for a dominant general factor in the exploratory subsample and supported fitting the planned single-factor CFA model on the holdout subsample.

Table . Standardized factor loadings from the exploratory factor analysis (EFA; n=121) and from the confirmatory factor analysis (CFA; n=240) for the 6-item large language model privacy concern assessment.

Item	EFA λ[a]	EFA h^2	CFA λ[b]	CFA R^2	Residual[c]
G1	0.77	0.60	0.79[d]	0.62	0.38
G2	0.85	0.72	0.85[d]	0.73	0.27
G4	0.82	0.67	0.83[d]	0.68	0.32
G5	0.88	0.78	0.81[d]	0.65	0.35
G6	0.74	0.55	0.69[d]	0.47	0.53
G7	0.71	0.50	0.69[d]	0.48	0.52

Global Fit

The unidimensional 6-item CFA model was fitted to the holdout subsample (n=240) using DWLS estimation. The model exhibited excellent global fit: χ^2_9=13.6; P=.14; CFI=0.996; TLI=0.993; RMSEA=0.046, 90% CI 0.000-0.093; SRMR=0.057. The nonsignificant model chi-square and CFI/TLI values approaching unity indicated that the unidimensional 6-item model reproduced the observed interitem associations closely. The RMSEA point estimate (0.046) fell within the range conventionally considered to reflect close fit (≤0.06), and the test of close fit was clearly nonsignificant (PCLOSE=.50, testing H : RMSEA≤0.05). SRMR (0.057) fell well within the range for acceptable fit. GFI and AGFI were strong (GFI=0.99; AGFI=0.98). All 6 standardized factor loadings were positive, substantial, and statistically significant (P<.001), with values of 0.79 (G1), 0.85 (G2), 0.83 (G4), 0.81 (G5), 0.69 (G6), and 0.69 (G7). Standardized loadings, R^2 values, and standardized residual variances are presented in Table 4. In total, 4 of the 6 items exceeded the conventional λ≥0.70 threshold for strong indicator quality, and the remaining 2 (G6 and G7, both λ=0.69) fell just below it while remaining well above the minimum acceptable value of 0.50. Item R^2 values ranged from 0.47 (G6) to 0.73 (G2), indicating that the latent privacy concern factor accounted for between 47% and 73% of the variance in each

XSL•FO
RenderX

item. Figure 3 shows the path diagram used in the CFA for the unidimensional model with 6 items.

Figure 3. Confirmatory factor analysis of the 6-item large language model-privacy concern assessment questionnaire. Standardized factor loadings are shown on the paths from the latent factor to each indicator; standardized residual variances are shown next to each error term (e1-e6). The variance of privacy concern was fixed at 1.00 for identification of the standardized solution. All loadings significant at ***P<.001.

Composite reliability was excellent (ω=0.90) above the conventional 0.80 threshold for very good internal consistency, and the AVE was 0.61, exceeding the 0.50 Fornell-Larcker convergent-validity threshold. Taken together, these results support the internal consistency and convergent validity of the refined LLM-PCA at the level of the full 6-item set. The dimensional structure is addressed in the Comparison of 1-Factor and 2-Factor Models section.

Local Fit

Because strong global fit does not guarantee adequate fit at the level of individual item pairs, we examined the residual correlation matrix (Table S4 in Multimedia Appendix 1). Residuals are the differences between observed polychoric correlations and model-implied correlations. Most residuals were small, but 4 of the 15 off-diagonal residual correlations exceeded the 0.10 threshold: G1-G6 (residual=0.21), G2-G5 (residual=0.18), G4-G5 (residual=0.15), and G2-G4 (residual=0.14). The root mean square residual (computed on the polychoric matrix) across all off-diagonal elements was 0.098. In total, 3 of the 4 elevated residuals involved the transparency- and control-oriented items G2 (being informed about data use), G4 (transparency supporting trust), and G5 (control over data use), indicating that these conceptually adjacent items share covariance beyond what the general privacy-concern factor accounts for. The remaining elevated residual, between G1 (data use) and G6 (frequency of thinking about privacy risks), reflects a smaller secondary association. These residuals indicate that although a strictly unidimensional model provides excellent global fit and a robust SRMR (computed on the Pearson covariance), it does not fully reproduce the local covariance among the transparency- and control-related items.

Comparison of 1-Factor and 2-Factor Models

Because the residual analysis indicated localized covariance among the transparency- and control-related items, we compared the unidimensional model (M1) with a 2-factor alternative (M2) on the same CFA subsample (n=240). The 2-factor model assigned the transparency- and control-oriented items to 1 factor (G2, G4, and G5) and the remaining items to a second factor (G1, G6, and G7), with the 2 factors allowed to correlate. Both models were estimated with DWLS on the polychoric correlation matrix. Fit statistics for the 2 models are presented in Table 5.

XSL•FO
RenderX

Table . Comparison of 1-factor and 2-factor confirmatory models (confirmatory factor analysis subsample, n=240).

Model	χ^2 (*df*)	*P* value	CFI[a]	TLI[b]	RMSEA[c] (90% CI)	SRMR[d]	AIC[e]	BIC[f]
One-factor (M1)	13.6 (9)	.14	0.996	0.993	0.046 (0.000-0.093)	0.057	23.21	64.97
Two-factor (M2)	4.7 (8)	.79	1.00	1.00	0.000 (0.000-0.050)	0.032	25.74	70.99

[a]CFI: comparative fit index.

[b]TLI: Tucker-Lewis index.

[c]RMSEA: root mean square error of approximation.

[d]SRMR: standardized root mean square residual.

[e]AIC: Akaike information criterion.

[f]BIC: Bayesian information criterion.

The 2-factor model fits better than the 1-factor model on every index examined: (χ^2_8=4.7; *P*=.79 vs χ^2_9=13.6; *P*=.14; CFI and TLI of 1.00 vs 0.996 and 0.993; RMSEA=0.000, 90% CI 0.000-0.050 vs 0.046, 90% CI 0.000-0.093; SRMR=0.032 vs 0.057). The nested chi-square difference test was significant ($\Delta\chi^2_1$=8.9; *P*=.003), consistent with the localized residual covariance identified earlier. Therefore, the 2-factor specification is the better-fitting model on these data, and the improvement is not marginal. Table 5 also reports the Akaike information criterion and the Bayesian information criterion, both of which favor the 1-factor model. These criteria are likelihood-based, and because the models were estimated by DWLS rather than by ML, the values are derived from the fit function rather than a true likelihood and are not interpretable on their usual scale. They are reported for completeness, and the nested chi-square difference test was used for the model comparison.

We therefore retain the 2-factor solution as the measurement model for the LLM-PCA. The first factor is defined by the transparency- and control-related items (G2, being informed about data use; G4, transparency supporting trust; and G5, control over data use) and is labeled transparency and control. The second is defined by the remaining items (G1, concern about data use; G6, frequency of thinking about privacy risks; and G7, onward third-party sharing) and is labeled data use and risk salience. Standardized loadings in the 2-factor solution ranged from 0.85 to 0.90 on the first factor and from 0.72 to 0.85 on the second.

One property of this solution affects how it should be used. The 2 latent factors correlated at *r*=0.83; therefore, they share approximately 69% of their variance. The evidence on discriminant validity is mixed. The HTMT was 0.85 (<0.90), which indicates that these 2 factors are empirically distinct. The Fornell-Larcker criterion was met for transparency and control, whose AVE (0.77) exceeds the squared factor correlation (0.69), but not for data use and risk salience, whose AVE (0.59) falls below it. In other words, the 2 factors are separable but not fully distinct. The subscale reliability was acceptable (transparency and control: α=0.91; ω=0.91; data use and risk salience: α=0.81; ω=0.81). For these reasons, the 6-item total score remains the recommended primary metric for applied use, and the subscale scores, each a unit-weighted mean of its 3 items, should be reported as secondary, facet-level information.

Stability Across Alternative Sample Splits

To verify that the reported results were not an artifact of the particular random partition, the entire split-sample procedure (item refinement, EFA, and CFA) was repeated under 5 different random partitions, holding the one-third exploratory, two-thirds confirmatory allocation fixed. The findings were stable across all 5 splits. The near-collinearity of the 2 general-concern items exceeded the 0.85 threshold in every exploratory subsample, and the reduced-model comparison, conducted on the exploratory subsample without consulting the confirmatory subsample, indicated removal of G3 in all 5 cases. Parallel analysis retained a single factor in every exploratory subsample (first-to-second eigenvalue ratio=4.3 - 7.6; KMO=0.82-0.87; minimum exploratory loading=0.57-0.71). The confirmatory model showed acceptable-to-excellent global fit on every holdout subsample (χ^2_9=7.7 - 15.8; all *P*≥.07; CFI≥0.993; RMSEA≤0.056; SRMR≤0.064; PCLOSE≥.36), with composite reliability ω=0.90-0.91 and AVE=0.59-0.64. The localized residual strain among the transparency- and control-related items replicated in every split (4-5 residual correlations exceeding 0.10 per split), and G6 and G7 were the weakest indicators in each confirmatory solution (standardized λ=0.67-0.75), consistent with the pattern reported earlier.

Discussion

Principal Findings

This study developed and validated a concise 6-item instrument, the LLM-PCA, for assessing users' privacy concerns regarding LLM-based systems. There are 4 major findings in this study. First, the 7 candidate domains could be reduced to 6 items without loss of content coverage, because 2 general concern items proved to be near-interchangeable indicators. Therefore, one of them was removed from the instrument. Second, the final instrument demonstrated high internal consistency and a clearly dominant general factor in the exploratory subsample. Third, a confirmatory model fitted to an independent holdout subsample reproduced the observed interitem associations closely, and the whole procedure replicated across 5 alternative random partitions of the sample, indicating that the findings are not an artifact of one split. Fourth, the covariance among the transparency- and control-related items is not fully explained by a single general factor. A 2-factor model fit the data better

XSL•FO
RenderX

than a 1-factor model and was retained as the measurement model, separating a transparency and control facet from a data use and risk salience facet. The 2 factors met one of the 2 conventional discriminant validity criteria but not the other, so the instrument is offered as a brief 2-facet measure whose total score remains the recommended primary metric for privacy concern with LLM applications, with facet scores providing secondary detail. To our knowledge, it is among the first peer-reviewed instruments developed specifically for this referent, addressing a gap in the growing body of survey-based research in this area.

Comparison With Prior Work

As described in the Introduction section, prior LLM privacy surveys each used a bespoke instrument built for a different theoretical framework and a different outcome; therefore, the concern levels they report cannot be placed on a common metric with LLM-PCA scores. The comparison drawn here is one of structure and measurement properties rather than of score levels. We do not claim that the instrument derives from, or validates, any single theoretical framework; establishing its theoretical grounding and construct validity will require further work. Table S5 in Multimedia Appendix 1 summarizes the comparison of the LLM-PCA with prior privacy concern instruments and recent LLM privacy studies.

The factor structure observed here should be read against prior work. Earlier general privacy concern scales, such as those developed for organizational, e-commerce, and short-form video platform contexts, have often yielded multifactor solutions capturing dimensions such as collection, unauthorized access, secondary use, and awareness [6,7,10,11]. The present results are consistent with that literature. A 2-factor solution separating transparency and control items from data use and risk salience items fit better than a single-factor solution, and those 2 facets correspond closely to the control and awareness dimensions identified in earlier instruments [7,9]. What the present design cannot do is resolve those facets into well-identified factors, because each domain is represented by a single item and each candidate factor is therefore defined by only 3 indicators. Reporting a single composite score is a decision about parsimony and applied usability at this scale length, not a finding that users hold an undifferentiated view of privacy. Whether privacy concern with LLMs is best represented by 1 general factor or by 2 correlated facets is a question for a longer instrument with multiple indicators per domain. The possibility that an early stage of public understanding contributes to the high correlation between the 2 facets is consistent with findings from Choi et al [1], who found that 66% of their sample had limited knowledge of available privacy protection options in LLMs, and from Liu et al [3], who observed a systematic underestimation of health data risk and a gap between users' stated privacy concerns and their actual expectations. As public understanding of LLM data practices matures, multidimensional solutions may emerge in future validation studies involving more experienced user populations.

Implications

The validated instrument offers practical utility for both researchers and practitioners. For researchers, the availability of a standardized 6-item scale makes it feasible to incorporate privacy concern assessment as a routine component of LLM user studies without imposing significant respondent burden. Its single composite score, with demonstrated reliability, enables meaningful cross-study comparisons, a capability that has been largely absent from the existing literature. For practitioners and AI application developers, the scale provides a concise, validated tool for benchmarking user privacy concern levels before and after system design changes, privacy policy updates, or new feature deployments, supporting data-driven evaluation of user-facing privacy interventions.

The scale's focus on LLM-specific concerns, including data use practices, transparency, user control, and organizational data sharing, makes it particularly relevant for the growing number of commercial and enterprise LLM deployments in health care, education, legal services, and other sensitive domains. In health care contexts, where prior work has shown that privacy concerns can shape users' engagement with AI-assisted consultation [1-3], this instrument could support both predeployment risk assessment and ongoing postdeployment monitoring of user trust. For example, health care organizations deploying LLM-based tools such as clinical decision support systems, patient-facing chatbots, or electronic health record–integrated assistants could administer the scale prior to deployment to establish a baseline of user privacy concern, and again following deployment to detect shifts in trust associated with system changes or privacy policy updates. Because the instrument yields a single interpretable score, it is practical for routine use in clinical and operational settings without requiring psychometric expertise. As a preliminary interpretive aid pending formal norming, and after reverse-coding so that higher scores denote greater concern, mean item scores in the upper part of the scale (roughly ≥4 of 5) may be read as indicating high privacy concern, scores near the midpoint as moderate concern, and scores in the lower part (roughly ≤2) as low concern. These provisional bands are illustrative only and should be calibrated against representative normative samples before being used to guide decisions.

Limitations and Future Work

Several limitations should be considered when interpreting findings reported in this study. First, the sample skewed toward younger, White, highly educated, and predominantly female participants, characteristics that likely reflect the early-adopter demographic of LLM technology. Because privacy attitudes toward AI systems may vary with age, educational background, digital literacy, cultural background, and prior technology exposure, the generalizability of both the scale's factor structure and the observed levels of concern to more diverse populations cannot be assumed. In particular, the overrepresentation of highly educated individuals may mean that the scale's factor structure reflects a relatively privacy-literate population. Replication studies with demographically diverse and community-based samples are needed to evaluate measurement invariance across groups. Because the sex item combined nonbinary respondents with those who preferred not to answer into one category, the response set was less inclusive than current best practice and did not allow sex-diverse participants to be identified separately; future versions should offer distinct

XSL•FO
RenderX

nonbinary and self-describe options in addition to a prefer-not-to-answer choice. Because most respondents identified as White and held at least a bachelor degree, the score distributions reported here should not be treated as normative values for the US adult population, and the provisional interpretive bands suggested in the Implications section should not be applied to more diverse populations until they have been recalibrated. Differential item functioning across education, age, and racial or ethnic groups is untested, so the items may not carry the same meaning among respondents less familiar with LLM data practices, which would affect the factor structure as well as the observed levels of concern.

Second, the questionnaire was validated as a measure of general privacy concerns with LLMs rather than concerns tied to a specific application or use context. While this generality is a strength for cross-study comparability, it means that the instrument's criterion validity, its ability to predict behaviorally relevant outcomes such as disclosure willingness, trust, or system abandonment, remains to be established. Future research should administer the scale alongside behavioral outcome measures and within the context of specific LLM applications, such as AI-assisted clinical decision support or consumer-facing chatbots, to evaluate its predictive utility across different use cases. More specifically, convergent and criterion validity could be established through several complementary approaches. Concurrent validity could be assessed by administering the LLM-PCA alongside established multi-item privacy-concern instruments, such as the CFIP scale, the IUIPC scale, the MUIPC scale, and Hong and Thong's integrated model, within the same sample; moderate-to-strong positive correlations would support convergent validity, whereas weaker associations with conceptually adjacent but distinct constructs, such as general institutional trust, technology acceptance, or privacy self-efficacy, would provide discriminant evidence and help situate the instrument within its nomological network. Criterion validity could then be evaluated against behaviorally relevant outcomes assessed by self-report or, preferably, by observation: the willingness to disclose personal and sensitive (eg, health) information to an LLM, the amount and type of information actually disclosed in logged interactions, the adoption and continued use versus abandonment of an LLM application, and the uptake of privacy-protective options such as opting out of model training, deleting conversation history, or anonymizing inputs. Known-groups comparisons would provide a further line of evidence, with higher concern scores expected among respondents who have previously experienced a privacy breach, who routinely handle sensitive data, or who work in highly regulated professions, such as health care. Because concurrent designs can establish only association, prospective designs in which baseline LLM-PCA scores are used to predict subsequently observed disclosure or adoption behavior would be needed to demonstrate predictive validity, and vignette-based experiments that manipulate contextual factors, for example, the recipient of the data, the purpose of processing, or the presence of consent, would test whether scores respond to theoretically meaningful changes in the information flow.

Third, the study relied on convenience sampling via a single university and its affiliated recruitment platforms. This limits the representativeness of the sample with respect to occupation, geographic region, and general population awareness of LLMs. Future validation studies should target broader, population-based samples.

Fourth, although both subsamples met the a priori benchmarks set out in the Methods section, the split-sample cross-validation design produced an EFA subsample of n=121 and a CFA subsample of n=240. These subsample sizes are modest in absolute terms but adequate for this initial validation: the EFA subsample satisfied the conditions under which small-sample factor recovery is reliable (high communalities and a strongly overdetermined single factor, with KMO=0.87), and the CFA subsample was at or close to the ideal 20:1 ratio of cases to estimated parameters, depending on which specification is counted. The evaluation is post hoc: confirming after the fact that the favorable condition held is weaker evidence than a prospective power analysis would have provided. Nonetheless, the modest absolute sizes may have reduced the precision of factor-loading estimates and the power of fit indices to detect localized misspecification. The 1- versus 2-factor comparison is the analysis most affected: with 3 indicators per factor at this subsample size, it can show that the 2-factor model fits better, but not how the 2 facets behave in relation to external criteria. Replication of the factor structure in independent and larger samples, ideally drawn from distinct subgroups to permit measurement-invariance testing, remains an important next step before the scale is treated as a fully validated instrument.

Fifth, the instrument uses heterogeneous response anchors across items (importance, concern, and frequency) on a common 1 - 5 scale. While this is appropriate for the conceptual content of each item, it assumes that respondents treat position 3 on each anchor type as functionally equivalent. Future work should evaluate whether converting all items to a single anchor type (eg, agreement with statements) yields comparable psychometric properties and potentially simplifies scoring. In addition, composite scores are formed by unit-weighted summation of raw responses without prior standardization, which assumes that the 5 ordinal positions are metrically equivalent across the 3 anchor types. That assumption was not tested here, and the reasons for retaining unit weighting are set out in the Methods section. Future work should compare unit-weighted with standardized scoring in the same sample and report whether substantive conclusions differ.

Sixth, the items were pretested only within the study team and did not undergo cognitive interviewing with lay respondents before fielding. Several items use relatively abstract phrasing and a comparatively high reading level, and the awareness screening item may not have been interpreted uniformly by lay respondents. Because these issues bear directly on content validity, the instrument should be regarded as preliminary, and future work should incorporate cognitive pretesting and readability assessment in community samples. Relatedly, the expert review cannot substitute for the pretesting that was not done. The panel comprised 8 reviewers identified through research team recommendation, which meets the recommended panel size but is small and not independently constituted, and it assessed clarity by inspection rather than by observing how respondents interpreted the items. The obtained clarity index

XSL•FO
RenderX

for G2 fell below the 0.78 item-level criterion because 2 of the 8 reviewers rated below the endorsement threshold despite unanimous endorsement of its relevance. It was retained unchanged, so the wording the expert panel flagged has not been tested on lay respondents. This is a known weakness of the current version.

Seventh, temporal stability of the instrument was not assessed. Because internal consistency cannot establish reliability for single-item domains, test-retest reliability over an appropriate interval is an important form of evidence that remains to be collected in a future study.

Eighth, all data were self-reported, so common method bias cannot be ruled out and associations involving the construct may be inflated relative to multimethod designs [44].

In addition, the items with the weakest loadings (G6 and G7 0.74 and 0.71, respectively) may be candidates for rewording or replacement in future work. Because each domain is represented by a single item, future multi-item per domain development could add parallel indicators for the risk-salience (G6) and onward third-party-sharing (G7) domains, or revise their current wording, to improve their measurement precision. More generally, the one-item-per-domain design carries costs. It yields no within-domain reliability estimate, so no domain score can be corrected for measurement error. It makes each domain maximally sensitive to the wording of a single stem, which is precisely the vulnerability the interpretation literature documents [12,13]. It precludes tests of within-domain measurement invariance across groups. It also limits how well any latent facet can be identified, as the 1- versus 2-factor comparison illustrates. These costs were accepted in exchange for content breadth and brevity, and they are the main reasons the instrument is presented as a brief screening and benchmarking measure rather than as a substitute for a full multidimensional battery.

Conclusions

This study addressed a recognized gap in the LLM privacy research literature by developing and preliminarily validating a concise 6-item instrument for assessing user privacy concerns with LLM-based systems. The scale demonstrated high internal consistency, and a comparison of 1- and 2-factor specifications supported a 2-factor structure comprising a transparency and control facet and a data use and risk salience facet. Because the 2 facets are highly correlated and only partly distinct, the 6-item total score is the recommended primary metric, with facet scores providing secondary detail. Unlike prior instruments in this domain, which were developed within specific theoretical frameworks for narrow research purposes, this LLM-PCA instrument is designed for broad applicability, enabling cross-study comparisons and practical privacy assessments by researchers and AI application developers alike. Future work should prioritize replication in demographically diverse samples, evaluation of criterion validity against behavioral outcomes, and administration within specific LLM application contexts to further establish the instrument's utility and boundary conditions.

Acknowledgments

The authors wish to thank all participants for their time and efforts in answering these survey questions. The authors also thank the editor and the reviewers for their insightful comments, which significantly improved the quality of this manuscript. The authors declare the use of generative AI (GAI) in the research and writing process. The following tasks were delegated to GAI tools under full human supervision: Python code generation for data analysis and data visualization and proofreading and editing on the manuscript drafted by the authors. The GAI tool used was Claude Opus 4.8 (Anthropic). Responsibility for the final manuscript lies entirely with the authors. GAI tools are not listed as authors and do not bear responsibility for the final outcomes.

Abstract

Background: The rapid expansion of mobile technology has accelerated the integration of health applications and conversational AI into clinical and public health practices. To ensure these tools are effective and sustainable, usability evaluations and early user engagement during development are essential. The Health Information Technology Usability Evaluation Scale (Health-ITUES) is a validated and flexible usability assessment instrument that is available in multiple languages and applicable across diverse contexts. However, a Japanese version of this scale has not yet been developed.

Objective: This study aimed to translate and validate a Japanese version of the Health-ITUES, customized for a sexually transmitted infection (STI)–related chatbot, and to support the usability assessment of emerging mobile health tools in Japan.

Methods: We developed a Japanese version of the Health-ITUES using a chatbot under development as a consultation tool for young women regarding STIs. First, the original scale was customized to reflect the chatbot's specific purpose and intended usage context. Following established translation guidelines, we conducted forward translation from English to Japanese, back translation, expert review, and reconciliation. We then evaluated the reliability and validity of the Japanese version in a sample of 301 young women.

Results: The Japanese version of the Health-ITUES demonstrated high internal consistency (Cronbach α=0.85 - 0.98). Confirmatory factor analysis supported acceptable construct validity (root mean square error of approximation is 0.10, comparative fit index>0.90). Additionally, the Health-ITUES scores showed strong correlations with satisfaction and usage intention for the tool (r=0.779 and 0.797, respectively).

Conclusions: The Japanese version of the Health-ITUES provides initial evidence of reliability and validity in an STI-related scenario among young women and may facilitate more rigorous usability evaluations of mHealth and conversational AI tools in Japan.

(JMIR Hum Factors 2026;13:e90483) doi:10.2196/90483

KEYWORDS

mobile health; mHealth; chatbot; usability; translation; validation; sexually transmitted infection; STI; artificial intelligence; conversational AI

Introduction

In recent years, the widespread adoption of smartphones and tablets has led to a significant increase in their daily usage. According to the Ministry of Internal Affairs and Communications' 2024 survey on information and communication usage trends, the individual smartphone ownership rate in Japan has reached 80.5%, with over 90% penetration among individuals aged 13 to 69 years [1]. As information and communication technologies continue to evolve, mobile health (mHealth), which uses smartphones and portable devices for health care, has been rapidly adopted worldwide. mHealth is already applied across various domains, such as health management, patient education, and disease prevention, and is expected to improve health care accessibility and support self-management practices [2-4].

However, several mHealth technologies have become publicly available without sufficient validation of their design,

XSL•FO
RenderX

development, or evaluation processes [5]. Although acknowledging the potential of mobile-based interventions in strengthening health systems, the World Health Organization (WHO) emphasizes the need for careful assessment of their acceptability, effectiveness, feasibility, and equity in its guidelines on digital health interventions [6]. The effectiveness and sustainability of mHealth interventions depend not only on technical performance but also on user-centered evaluations of usability and acceptability [7]. Accordingly, evaluating mHealth technologies requires a more comprehensive approach beyond measuring clinical outcomes alone. It is essential to assess their usability and acceptability from the user's perspective and incorporate user feedback from the early stages of development. In recent years, the emergence of conversational AI systems, such as ChatGPT, has further expanded the scope of mHealth. Although these systems still face challenges related to information reliability and data security, they offer the potential to facilitate interactive bidirectional communication with users, thereby contributing to behavioral change, health education, and self-management support [8,9]. Previous studies have shown that, by demonstrating empathy and a sense of familiarity, chatbots can improve health outcomes in stigmatized areas, such as sexually transmitted infections (STIs) and mental health [10-13]. However, their effectiveness may be limited if they fail to recognize user characteristics, expectations, or levels of understanding [14,15]. Even when large language model–based conversational AIs, such as ChatGPT, provide highly accurate responses, the quality of user interaction can significantly influence the ability to extract relevant information. In some cases, these interactions may even lead to misinterpretations or hinder users' health-related decision-making [16]. Therefore, usability evaluation has become a critical component in the design and assessment of such systems.

Usability is defined as the extent to which users can effectively and efficiently achieve specific goals with satisfaction. Several usability assessment tools have been developed to evaluate these aspects [17]. Early examples include the System Usability Scale (SUS) [18] and the Post-Study System Usabiity Questionnaire (PSSUQ) [19], which were originally designed for general IT systems. However, prior research has indicated that general-purpose usability measures may not adequately capture the specific requirements of health care contexts [20]. Tools such as the Mobile App Rating Scale (MARS/uMARS) [21,22], the mHealth App Usability Questionnaire (MAUQ), and the Health Information Technology Usability Evaluation Scale (Health-ITUES) [23] have been developed for mHealth-specific applications.

Health-ITUES was originally developed using a web-based communication system designed for managing nursing staff schedules [23]. Since then, it has been applied to evaluate the usability of various health technologies, including mobile applications for individuals living with HIV, apps for managing dysmenorrhea, and integrated care systems for older adults [24-27]. The Health-ITUES is one of the few instruments whose psychometric properties have been validated in accordance with the COSMIN (Consensus-Based Standards for the Selection of Health Measurement Instruments) guidelines [17]. Unlike general usability scales (eg, SUS), the Health-ITUES is designed specifically for health information technologies and is grounded in the Health IT Usability Evaluation Model (Health-ITUEM) framework, enabling the evaluation of clinically meaningful usability constructs [23,27]. It maintains conceptual comparability across different contexts while allowing item-level customization to suit specific tasks and objectives within health care systems [28,29].

To date, the Health-ITUES has been translated and validated in several languages, such as Korean [25] and Chinese [26], demonstrating its cross-cultural applicability. However, no validated Japanese version is currently available. We selected Health-ITUES for this study because its health-IT–oriented design, validated psychometric robustness, and flexibility for context-specific item adaptation make it particularly well suited for evaluating an STI-related chatbot scenario targeting young women [25,27]. By developing and validating a Japanese version tailored to STI-related consultations, this study aimed to provide a rigorous and contextually relevant tool for evaluating the usability of emerging mHealth and conversational AI tools in Japan.

Methods

Modification of the Health-ITUES

The Health-ITUES consists of 20 items and can be customized according to the characteristics of the device and the intended use. Originally, it was developed based on the Technology Acceptance Model (TAM) to evaluate the usability of a web-based scheduling system for nursing staff [23]. Subsequently, Schnall et al [27] further validated the scale using a self-management application for individuals living with HIV, focusing on the evaluation of self-management mHealth applications.

In this study, we customized the Health-ITUES for young women experiencing anxiety related to STIs, based on the validated versions used among HIV-positive individuals in the United States and women with menstrual discomfort in South Korea. Prior to initiating the translation and adaptation process, we obtained permission from the original author to develop a Japanese version of the Health-ITUES.

Japanese Version of the Health-ITUES

The translation process adhered to established guidelines for scale translation [30] and followed the sequence as described in the following sections.

Forward Translation and Reconciliation

Two researchers (a physician and a health communication specialist) independently translated the original English version into Japanese. Subsequently, they discussed and reconciled their translations. A health communication research group, comprising physicians and health psychology experts, reviewed the preliminary Japanese version to ensure clarity, cultural appropriateness, and linguistic accuracy.

Back Translation

Two professional medical translators independently translated the Japanese version of the questionnaire back into English.

XSL•FO
RenderX

The translations were then compared to confirm consistency and accuracy.

Back-Translation Review

The authors reviewed the back-translated version by retranslating it into Japanese and comparing it with the initial Japanese draft to identify discrepancies.

Original Author Review

After completing both the forward and backward translations, the original author reviewed the English version of the Japanese Health-ITUES to confirm its content validity.

Cognitive Debriefing

We conducted cognitive debriefing interviews to assess the clarity and contextual appropriateness of the Japanese version. Linguistic validation guidelines recommend a small sample from the target population, with a Japanese guideline suggesting approximately 5 to 8 participants [30-32]. In this study, 6 female students studying at a university without a medical background were interviewed using the Japanese Health-ITUES. They were asked whether any items were difficult to understand or caused hesitation when responding.

Reliability and Validity

We conducted an online survey using a chatbot under development by the authors to evaluate the reliability and validity of the Japanese version of the Health-ITUES. The chatbot was designed to alleviate anxiety related to STIs among young women and to guide them toward appropriate consultation services and testing resources. Internal consistency reliability was assessed using the Cronbach α coefficient. Construct validity was examined through confirmatory factor analysis (CFA), and criterion-related validity was evaluated by examining correlations with user satisfaction and intention to use.

Participants

Participants were women aged 18 to 29 years registered with a Japanese research agency (Asmarq Inc). According to national infectious disease surveillance data [33], reported syphilis cases—one of the major STIs—among women in their 20s have increased substantially since 2020, making this demographic particularly relevant for the chatbot's intended use. Eligibility criteria included the ability to communicate in Japanese, access the survey URL using personal computers or smartphones, and have had at least one prior sexual experience. Individuals who were health care professionals, medical students, or already engaged with STI-related medical services or consultation centers were excluded from the study.

Sample Size

To ensure adequate statistical power in scale validation studies, a commonly used rule of thumb is to recruit approximately 10 participants per item [32,34]. Given that the Health-ITUES consists of 20 items, we estimated the minimum required sample size to be 200 participants. Assuming a 20% dropout rate, the target sample size was set at 250 participants.

Procedure

Participants were recruited through a research agency. The agency randomly selected 57,185 women within the target age range from its registered panel and sent email invitations to participate in the study. Only those who provided informed consent via an embedded survey link were directed to the main questionnaire. The survey was terminated once the number of responses exceeded the target sample size. Data were collected between June 18, 2025, and June 20, 2025. A total of 301 valid responses were obtained.

Participants were informed via a web-based survey interface that the study involved interacting with a chatbot based on a hypothetical scenario (ie, their partner suddenly informed them of symptoms suggestive of an STI). Instructions on how to use the chatbot were also provided. Initially, participants completed prechatbot questions on age, region of residence, occupation, educational background, relationship status, frequency of conversational AI use, and digital health literacy [35]. They then accessed the chatbot interface through a URL embedded in the survey and interacted with it according to the scenario. After the interaction, participants returned to the survey and completed postchatbot questions assessing satisfaction, intention to use, and the Japanese version of the Health-ITUES.

Survey Items

The survey included the following items:

- Participant demographics: the demographics consisted of age, region of residence, educational background, occupation, and relationship status.
- Frequency of conversational AI use: items were rated on a 4-point scale ranging from "never" to "almost daily."
- Digital health literacy: this was measured using 15 items from the Japanese version of the Digital Health Literacy Instrument [35], excluding the subscales for operational and navigational skills.
- Postchatbot satisfaction: items were rated on a 5-point scale ranging from "very satisfied" to "not at all satisfied."
- Intention to use: this item was assessed with the question, "Would you consider using this chatbot if you were experiencing anxiety or concerns about STIs?" and rated on a 5-point scale ranging from "strongly agree" to "strongly disagree."
- Usability: usability was evaluated using the 20-item Japanese version of the Health-ITUES (Table 1).

RenderX

Table . Health-ITUES[a] [27] and Japanese Health-ITUES.

Items in the Health-ITUES [27]	Items in the Japanese version of Health-ITUES
Impact	
1. I think mVIP[b] would be a positive addition for persons living with HIV.	1. I think this chatbot is helpful for young women who have concerns or symptoms related to sexually transmitted infections.
2. I think mVIP would improve the quality of life of persons living with HIV.	2. I think this chatbot will improve the quality of life of young women who have concerns or symptoms related to sexually transmitted infections.
3. mVIP is an important part of meeting my information needs related to symptom self-management.	3. This chatbot plays an important role in helping me get the information I need about concerns and symptoms related to sexually transmitted infections.
Perceived usefulness	
4. Using mVIP makes it easier to self-manage my HIV-related symptoms.	4. Using this chatbot makes it easier for me to get information about sexually transmitted infections and ease my concerns about them.
5. Using mVIP enables me to self-manage my HIV-related symptoms more quickly.	5. Using this chatbot allows me to get information about sexually transmitted infections faster and ease my concerns about them.
6. Using mVIP makes it more likely that I can self-manage my HIV-related symptoms.	6. Using this chatbot increases the likelihood of me getting information about sexually transmitted infections and easing my concerns about them.
7. Using mVIP is useful for self-management of HIV-related symptoms.	7. Using this chatbot is helpful in getting information about sexually transmitted infections and easing my concerns about them.
8. I think mVIP presents a more equitable process for self-management of HIV-related symptoms.	8. I think this chatbot equally helps everyone get information about sexually transmitted infections and ease their concerns about them.
9. I am satisfied with mVIP for self-management of HIV-related symptoms.	9. I am happy to use this chatbot to get information about sexually transmitted infections and ease my concerns about them.
10. I self-manage my HIV-related symptoms in a timely manner because of mVIP.	10. Thanks to this chatbot, I will be able to get information about sexually transmitted infections and ease my concerns about them at the right time.
11. Using mVIP increases my ability to self-manage my HIV-related symptoms.	11. Using this chatbot improves my ability to get information about sexually transmitted infections and ease my concerns about them.
12. I am able to self-manage my HIV-related symptoms whenever I use mVIP.	12. Using this chatbot allows me to get information about sexually transmitted infections and ease my concerns about them at any time.
Perceived ease of use	
13. I am comfortable with my ability to use mVIP.	13. I can feel comfortable using this chatbot.
14. Learning to operate mVIP is easy for me.	14. I can easily learn how to use this chatbot.
15. It is easy for me to become skillful at using mVIP.	15. It is easy for me to master using this chatbot.
16. I find mVIP easy to use.	16. I think this chatbot is easy to use.
17. I can always remember how to log on to and use mVIP.	17. I remember how to access this chatbot and how to use it.
User control	
18. mVIP gives error messages that clearly tell me how to fix problems.	18. This chatbot displays error messages that clearly indicate how to resolve any problems with it.
19. Whenever I make a mistake using mVIP, I can recover easily and quickly.	19. If I make a mistake on how to use this chatbot while using it, I can easily undo it.
20. The information (such as online help, on-screen messages, and other documentation) provided with mVIP is clear.	20. The information provided by this chatbot (online help, messages, etc) is easy to understand.

[a]Health-ITUES: Health Information Technology Usability Evaluation Scale.

[b]mVIP: HIV self-management app.

Statistical Analysis

We calculated the mean scores and SDs for the overall Japanese version of the Health-ITUES and its subscales (impact, perceived usefulness, ease of use, and user control). Ceiling and floor effects (acceptable if <15% at maximum and minimum scores) were examined. We assessed reliability through internal consistency, using the Cronbach α coefficient and composite reliability (CR). Convergent validity was evaluated based on the average variance extracted (AVE). To assess construct validity, a CFA was conducted according to the original 4-factor model. Model fit was evaluated using fit indices, including the

XSL•FO
RenderX

Goodness-of-Fit Index (GFI), Comparative Fit Index (CFI), Tucker-Lewis Index (TLI), root mean square error of approximation (RMSEA), and standardized root mean square residual (SRMR). Criterion-related validity was assessed by examining the correlation coefficients between Health-ITUES scores and conceptually related variables, namely user satisfaction and intention to use the chatbot. All statistical tests were conducted at a 5% significance level using IBM SPSS Statistics version 29.0 and AMOS version 31.0.

Ethical Considerations

This study was approved by the Research Ethics Committee for human participants at Teikyo University (approval numbers: Tei-Rin 24 - 114, dated January 30, 2024, and Tei-Rin 25 - 006, dated May 8, 2025). Participants provided informed consent via an embedded survey link. Participants received a token of appreciation, equivalent to 200 Japanese yen (1 Japanese yen=US $0.006 as of May 8, 2025) in points, for their participation in the study.

Results

Pilot Test

We conducted a pilot test with 6 female university students aged 18 to 22 years, recruited through convenience sampling. All participants were native Japanese speakers and nonmedical majors. They completed the Japanese version of the Health-ITUES and were subsequently interviewed regarding the clarity of language, ease of response, and confidence in their responses. One participant commented, “There were no particular difficulties in responding, but because the chatbot was accessed via a URL rather than through a login, it might be better to revise that wording.” Based on this feedback, we revised item 17 to clarify that the chatbot was accessed via a URL in this study.

Demographic Characteristics

Table 2 presents the demographic characteristics of the 301 participants. Their mean age was 26.3 (SD 2.1) years. Although more than half of the participants were company employees, the sample included a diverse range of occupations, such as students, homemakers, and part-time workers. The most common frequency of conversational AI use was “occasionally” (n=109, 36.2%), followed by “never,” “rarely,” and “almost daily,” each accounting for approximately 20% of responses. When “occasionally” and “almost daily” users are combined, approximately 60% (n=177) of participants reported using conversational AI to some extent, which is consistent with national data indicating that around 50% of young people in Japan use such technologies [36].

Graduate school or higher	9 (3.0)
Other	3 (1.0)
Frequency of conversational AI use, n (%)	
Never	62 (20.6)
Rarely	62 (20.6)
Occasionally	109 (36.2)
Almost daily	68 (22.6)
Relationship status, n (%)	
Has a specific partner	241 (80.1)
Has a nonspecific partner	15 (5.0)
No partner	43 (14.3)
Other	2 (0.7)

The average score on the 15-item Digital Health Literacy Scale (DHLS) was 2.8 (SD 0.4). This result aligns closely with the findings from a study of Japanese university students, which reported an average score of 2.9 (SD 0.4) on the 21-item DHLS [37]. These findings indicate that the study sample is broadly representative of young Japanese individuals in terms of digital health literacy.

Overall Scores

The Health-ITUES consists of 20 items across 4 subscales (impact: 3 items, perceived usefulness: 9 items, ease of use: 5 items, and user control: 3 items), each rated on a 5-point Likert scale (1="strongly disagree" to 5="strongly agree"). Satisfaction was assessed on a 5-point scale (1="not satisfied at all" to 5="very satisfied"), along with intention to use (1="not at all willing to use" to 5="very willing to use"). The overall mean

XSL•FO
RenderX

score for the Japanese version of Health-ITUES was 3.4 (SD 0.9), whereas user satisfaction was 3.1 (SD 1.2) and intention to use was 3.2 (SD 1.2; Table 3). Among the subscales, user control showed slightly lower mean scores, although no substantial differences were observed. No ceiling or floor effects were detected.

Table . Mean scale and internal scale consistency scores (N=301).

Score	Mean (SD)	Cronbach α	CR[a]	AVE[b]
Health-ITUES[c] (overall)	3.427 (0.890)	0.976	—[d]	—
Health-ITUES impact	3.517 (1.012)	0.953	0.948	0.860
Health-ITUES usefulness	3.450 (0.959)	0.976	0.974	0.806
Health-ITUES ease of use	3.443 (0.980)	0.922	0.908	0.667
Health-ITUES control	3.241 (0.960)	0.849	0.830	0.624
User satisfaction	3.080 (1.169)	—	—	—
Intention to use	3.159 (1.209)	—	—	—

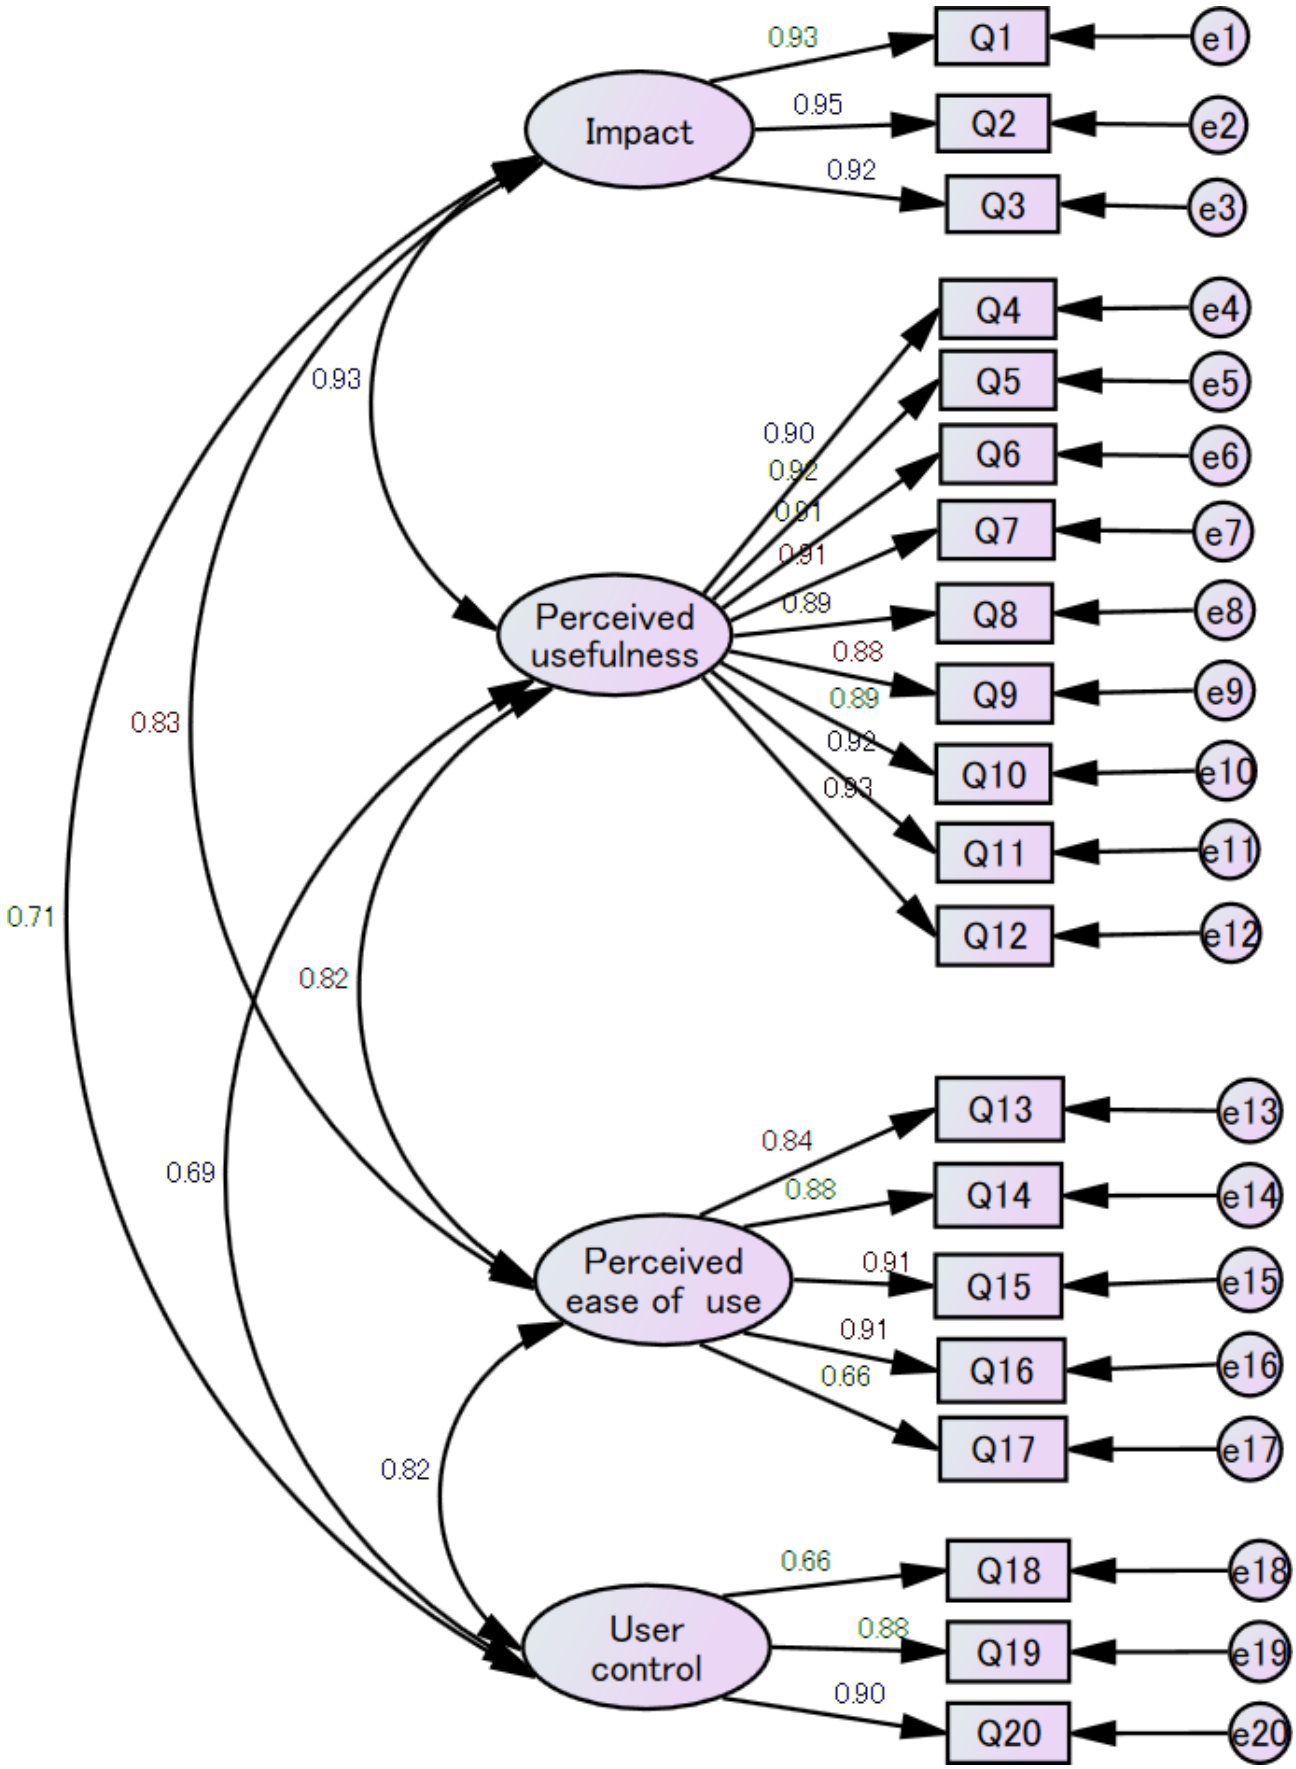
[b]AVE: average variance extracted.

[c]Health-ITUES: Health Information Technology Usability Evaluation Scale.

[d]Not applicable.

Internal Consistency Reliability

The internal consistency and convergent validity were evaluated, with Cronbach α of more than 0.8, CR exceeding 0.70, and AVE exceeding 0.50. As shown in Table 3, Cronbach α coefficients for the subscales ranged from 0.85 to 0.98, indicating high reliability beyond the commonly accepted cutoff of 0.80. The impact and perceived usefulness subscales had particularly high α values (>0.95). The overall Cronbach α for all 20 items was 0.976, which may be attributed to the large number of items in the usefulness subscale and high intersubscale correlations. Descriptive statistics of the 20 items (mean, SD, skewness, kurtosis, and item-total correlations) are provided in Multimedia Appendix 1.



Construct Validity

As the conceptual validity of the original Health-ITUES had already been established, we performed a CFA using maximum likelihood estimation based on the original 4-factor structure. The analysis provided standardized factor loadings to assess the strength of the relationship between items and factors, along with model fit indices.

The path diagram is shown in Figure 1, and Table 4 presents the model fit indices. The CFA results indicated an adequate model fit (CFI=0.94, TLI=0.93, and SRMR=0.032). However, the GFI was relatively low (0.8), and the RMSEA was 0.100, representing the upper limit of the acceptable range [26].

XSL•FO
RenderX

Figure 1. Confirmatory factor analysis path diagram of the Japanese Health-ITUES: Health Information Technology Usability Evaluation Scale.

XSL•FO

Table . Confirmatory factor analysis model fit indices for the Health-ITUES[a].

Fit index	CFI[b]	TLI[c]	RMSEA[d]	SRMR[e]	GFI[f]	Chi-square/*df*
Value	0.935	0.925	0.100	0.0319	0.799	660.92/164
Recommended threshold (desirable)	≥0.90 (≥0.95)	≥0.90 (≥0.95)	≤0.08 (≤0.05)	≤0.08 (≤0.05)	≥0.90	<3.00

[a]Health-ITUES: Health Information Technology Usability Evaluation Scale.

[b]CFI: Comparative Fit Index.

[c]TLI: Tucker-Lewis Index.

[d]RMSEA: root mean square error of approximation.

[e]SRMR: standardized root mean square residual.

[f]GFI: Goodness-of-Fit Index.

Intersubscale correlations ranged from 0.69 to 0.93, indicating strong relationships. In particular, perceived usefulness showed a higher correlation with impact, which is consistent with the findings of previous research [25,26,29].

We examined criterion-related validity by calculating the correlation coefficients between Health-ITUES scores and conceptually related variables, namely user satisfaction and intention to use. The correlations were 0.779 and 0.797, respectively, indicating a strong positive association (P<.001).

Discussion

Principal Findings

The emergence of generative AI has expanded the potential of mHealth. Chatbots are increasingly recognized as promising tools for supporting STI prevention and sexual health education among young people, and their role is expected to grow [11,38-41]. At the same time, usability—including user satisfaction and ease of use—remains critical for promoting continued engagement and facilitating behavior change [39,40].

The instrument selected for this study—the Health-ITUES—was developed as a user-centered evaluation scale based on the Health-ITUEM, which itself was derived from the widely used TAM and specifically adapted for health care technologies [23,28].

This study developed a Japanese version of the Health-ITUES and examined its reliability and validity using a chatbot currently under development as a consultation tool for young women with concerns about STIs. Because the original scale was designed to evaluate an app for adults living with HIV, we adapted the item wording to align with the chatbot's purpose and functions rather than conducting a direct translation.

In this study, we confirmed that the 4-factor structure of the Health-ITUES—impact, usefulness, ease of use, and user control—was largely retained in the context of a Japanese STI-related chatbot.

The translation procedures followed established guidelines, including forward translation by 2 experts in medicine and health communication, review by a multidisciplinary team of physicians and health communication experts, and a back-translation performed by a medical translation specialist. Cognitive debriefing and a final review by one of the authors, who validated the original Health-ITUES, ensured the cultural appropriateness and conceptual consistency of the translated version.

The customized Health-ITUES demonstrated adequate reliability and convergent validity for evaluating the usability of the STI-related scenario chatbot, and the main model-fit indices were satisfactory. In the CFA, although the RMSEA was slightly higher, the overall model fit was still considered acceptable because the other indices indicated a generally adequate level of fit [26]. Strong positive correlations between Health-ITUES scores and both user satisfaction and intention to use further supported criterion validity. These findings indicate that the Health-ITUES supports item-level customization while remaining suitable for multilingual translation and cultural adaptation.

The psychometric evaluation indicated very high internal consistency for the impact and usefulness subscales (Cronbach α>0.95). Although such values reflect strong reliability, they also suggest that some items may capture overlapping aspects of the same construct [42]. This interpretation is supported by the relatively strong interitem correlations observed within these subscales (r>0.85). Although these patterns suggest potential item redundancy and warrant future examination of item reduction or refinement, it is important to note that the Health-ITUES was intentionally designed to allow item-level customization while preserving conceptual comparability across contexts. The higher correlation between impact and perceived usefulness was also observed in previous studies [25,26,29]. Consistent with this, we retained all 20 items in the Japanese version without modifications or deletions.

From a theoretical perspective, this study reinforces the importance of usability as a multidimensional construct in digital health and demonstrates that the 4-factor structure of the Health-ITUES remains stable even when adapted to conversational AI contexts. Methodologically, this study highlights the feasibility of combining item-level customization with rigorous cross-cultural translation procedures while preserving conceptual equivalence. This approach provides a model for adapting usability instruments to rapidly evolving digital health technologies. To date, no other Japanese usability scale has demonstrated conceptual comparability while allowing flexible item-level customization tailored to specific use cases. The Japanese version of the Health-ITUES is expected to serve

XSL•FO
RenderX

as a valuable tool for assessing the usability of mHealth and conversational AI applications as their use expands.

The overall mean Health-ITUES score in this study was 3.4 (SD 0.9), which was lower than that reported in previous studies [24,25]. Several contextual factors may explain this difference. Our evaluation used a chatbot that is still in the development phase, which may have influenced perceptions of quality and usability. In contrast, earlier studies assessed mature, widely used applications developed for long-term engagement by specific patient populations, such as medication adherence support for individuals with HIV [27] or symptom management for dysmenorrhea [25], which may have already achieved high user acceptance. Moreover, this study involved a single-use interaction based on a hypothetical scenario rather than a real-world health context, which may have contributed to the lower scores.

At the same time, these findings highlight a practical advantage of the Health-ITUES: it can be used not only to evaluate relatively mature digital health tools but also to assess prototypes and guide iterative improvement during early-stage development. Future evaluations of the same chatbot using the Health-ITUES under conditions of continued use may help clarify how perceived usability evolves as interactions between users and conversational AI systems accumulate over time. Based on user feedback, we are currently developing an improved version of the chatbot by enhancing its frequently asked question responses and refining error messages. Incorporating the Health-ITUES from the early stages of development may support user-centered improvements and provide an objective basis for monitoring usability changes over time.

From a practical standpoint, the availability of a validated Japanese version of the Health-ITUES enables more systematic and standardized usability evaluations of mHealth and conversational AI tools in Japan.

A key strength of this study was its robust sample size and the diversity of participants in terms of region and occupation. The sample size of 301 participants in our study exceeded the commonly used 10 times per item rule [32,34]. The mean score on the 15-item DHLS (2.8, SD 0.4) aligned with that of previous Japanese studies [37], and the distribution of conversational AI use showed no marked skew, supporting the appropriateness of the sample for usability assessment in this context.

Limitations

This study had some limitations. First, participants were not actual patients or individuals currently experiencing health concerns; instead, we conducted the usability evaluation under a hypothetical scenario. Therefore, the results may not fully reflect real-world usage, and future research should assess its usability in clinical or personal health contexts. Second, the study population was limited to young women. Although we selected this demographic to align with the intended application of the mHealth chatbot, it is important to examine whether the Health-ITUES remains a valid usability assessment tool across other user groups in Japan, such as adult men, older adults, and individuals with chronic conditions, to enhance its generalizability.

Conclusions

This study presented the first Japanese version of the Health-ITUES and provides initial evidence of its reliability and validity in the context of an STI-related chatbot. To our knowledge, no other Japanese usability scale for mHealth combines validated psychometric properties with the flexibility to be customized according to specific use cases. By preserving conceptual equivalence while enabling standardized, user-centered usability evaluation, the Japanese version of the Health-ITUES addresses a critical gap in digital health assessment in Japan. As conversational AI and mHealth applications continue to expand, the Japanese version of the Health-ITUES may serve as a valuable tool for supporting the development, evaluation, and implementation of effective and user-centered digital health interventions.

Acknowledgments

Microsoft Copilot, an AI tool developed by Microsoft, was used to support language editing and translation of the manuscript. The authors reviewed and verified all AI-assisted outputs to ensure accuracy and appropriateness.

Funding

This study was supported by research funding from the Japan Health Academy under the 2024 Public Grant for Health Knowledge and Education and JSPS KAKENHI (grant 25K02857).

Abstract

Background: Effective health monitoring is essential for personalized care and comprehensive health assessment. Personal health indices and profiles offer a concise summary of an individual's overall health, supporting both clinical decision-making and self-management. However, global standardization remains challenging due to diverse practices and data formats across countries.

Objective: This study aimed to present a novel model for computing a personal health index and health profile using the International Classification of Functioning, Disability and Health (ICF) framework. The model was designed to handle incomplete and heterogeneous datasets and aimed to provide standardized, interpretable health metrics.

Methods: We developed a recursive algorithm that calculates the health index based on the hierarchical structure of the ICF, using all available measurements. The model incorporates time decay and linkage reliability to weight input data. Preliminary validation was conducted on data from 505 individuals, using statistical correlation analyses with self-assessed health measures (EuroQol Visual Analogue Scale and pain ratings), and a sensitivity analysis was performed to assess model robustness.

Results: The computed health index showed moderate positive correlations with EuroQol Visual Analogue Scale scores (all $P<.001$) and negative correlations with maximum pain trajectories, supporting its validity. Sensitivity analysis confirmed predictable behavior in response to input changes, and the model demonstrated resilience to missing data.

Conclusions: The proposed model offers a flexible and scientifically grounded approach to computing personal health indices and profiles within the ICF framework. It enables the integration of diverse health data sources and supports the visual representation for clinical and personal use. This model has potential applications in health monitoring, rehabilitation planning, and machine learning–based health informatics.

Introduction

Background

Effectively describing and monitoring a person's health is crucial for tailoring appropriate treatments. Comprehensive information about a person's health enables targeted interventions and provides metrics that emphasize overall health status rather than isolated symptoms.

A personal health index aims to condense a person's overall health into a single numerical value [1]. While the index seeks to summarize health in a singular number, a health profile represents health status through a set of scores [1]. These indices or profiles serve diverse purposes, offering a quick overview of an individual's health status, beneficial for both health care professionals and individuals themselves. This systematic and comprehensible monitoring approach facilitates a broad perspective on health [1].

Given the multifaceted nature of health, summarizing it into a single value or profile requires a framework that can accommodate diverse and interrelated factors. A singular value from a health index can offer a quick overview of a person's

XSL•FO
RenderX

overall health, which is particularly useful in both clinical and self-monitoring contexts [1]. Additionally, exploring various aspects of health offered by a health profile is essential for a more detailed understanding of an individual's health.

Capturing an individual's overall health concisely can be challenging due to the multifaceted factors influencing health and its changes. Prevention, evaluation, treatment planning, and rehabilitation, especially in cases such as low back pain, necessitate consideration of psychosocial and social aspects [2]. It is, therefore, necessary to systematically describe all relevant aspects affecting a person's health in a structured and standardized manner, presenting this information in an easily interpretable format.

Global standardization of health status assessment procedures for health index construction is challenging due to differing standards and practices across countries. Variations in treatment procedures, driven by diverse practices among countries, clinics, and therapists, hinder straightforward concatenation of datasets from separate clinics, especially with the use of different health questionnaires and languages.

Existing health indices often rely on fixed questionnaires or population-level parameters, limiting their adaptability and comparability across contexts. To address these limitations, a universally accepted framework is needed—one that can integrate heterogeneous data and support individualized assessment. In this study, we propose using the International Classification of Functioning, Disability and Health (ICF) [3], developed by the World Health Organization (WHO), as the foundation for constructing a personal health index. The primary goal of the ICF is to establish a standardized language and framework for describing health and health-related states [4]. It serves as a complement to the *International Classification of Diseases* (ICD) diagnosis classification system [4].

The ICF integrates 2 conceptual paradigms of disability—the medical and social paradigms. In the medical paradigm, disability is viewed as a health condition requiring medical care, often stemming from diseases, trauma, or other health conditions. On the other hand, the social paradigm considers disability as a socially created problem necessitating a political response. The ICF, by merging these paradigms, adopts a *biopsychosocial* approach, synthesizing biological, individual, and social aspects of health [4,5].

By leveraging the ICF's comprehensive structure, our model aims to translate this biopsychosocial perspective into a quantifiable health index that can be used in both clinical and research settings. This model has the potential to shift from the current disease-based care model toward a *healthy aging* approach. The WHO's concept of intrinsic capacity reflects a similar emphasis on monitoring functional trajectories across key domains to enable proactive, personalized interventions [6,7]. This approach aims to support a proactive, functioning-based way of tracking individual trajectories [3]. However, despite the clear advantages of the ICF, its practical implementation in clinical practice has proven challenging in various studies [8-11]. We argue that the health index framework introduced in this study also holds promise for simplifying the use of the ICF.

Unlike data-driven models that rely on statistical learning from large datasets, such as machine learning (ML) models that require training and may be prone to overfitting, the proposed health index is computed using a knowledge-driven, deterministic algorithm. This approach is grounded in the hierarchical structure of the ICF and applies predefined rules to aggregate available ICF-coded measurements. It operates independently of any training data or parameter estimation, ensuring consistency, interpretability, and robustness across diverse datasets. As a result, the model can be applied to any ICF-compatible data without modification, making it suitable for scalable and standardized health assessment.

Using the ICF framework involves converting original measurements to new variables in *ICF space* using accepted linking procedures. Throughout the paper, these variables are referred to as ICF codes according to ICF terminology. This approach facilitates the standardization of potentially heterogeneous datasets from different individuals into the same data space.

The health index is then recursively computed from the ICF tree structure using available measurements. Importantly, this computation does not require measurements from every node of the ICF tree, ensuring robustness to missing values. Additionally, if measurements do not cover all relevant health aspects, these gaps can be presented with the health index and health profile, and they can optimally be addressed in future data collection. Once the overall health index value is computed, it becomes possible to explore a health profile—that is, values for each ICF code separately. This approach provides insights into specific sectors of functioning, disabilities, and contextual factors affecting health. By adopting this comprehensive approach, we obtain a nuanced picture of an individual's health, highlighting specific areas that may need improvement. By leveraging the health index, health profile, and the ICF, we can construct a clinical tool that facilitates cross-country data comparison and enables the development of a universal health metric.

In the context of ML, the proposed health index provides a framework for integrating datasets from diverse sources, thereby streamlining data preparation. The importance of maintaining uniform variables across all individuals cannot be overstated, as it is crucial for the development of robust ML models. A lack of standardization can result in smaller subsets, which may compromise the effectiveness of predictive models. Furthermore, the health index can serve as an optimization target in ML, facilitating the use of standardized datasets for predicting individual health outcomes. This could, for example, assist in the selection of personalized rehabilitation pathways. To our knowledge, this study marks the first usage of the ICF framework in forming a personal health index. In the following sections, we present the theoretical foundation, algorithmic implementation, validation results, and implications for clinical practice.

Prior Work

Numerous health indices have been proposed in the literature. This section provides an overview of existing health indices and profiles, with an emphasis on research conducted in the

XSL•FO
RenderX

2000s. A literature search using Google Scholar was conducted in 2023 to identify models that explicitly used the term "health index" within this time frame. The focus was on individual-level health assessment studies, ensuring that the review reflects approaches relevant to personal health rather than population-level metrics.

One of the most straightforward methods for computing a personal health index involves the direct summation of responses to health-related questions. Kubik et al [12] constructed their personal health index by asking 6 questions on a Likert-type scale, ranging from 1 (strongly disagree) to 4 (strongly agree). These questions encompassed an individual's perception of overall health, dietary patterns, and level of physical activity. The resulting health index score ranged from a minimum of 6 to a maximum of 24. Similarly, Frank et al [13] used a comparable summation method by querying participants about their smoking, drinking, exercise routines, and dietary habits to formulate a personal health index. Another simple approach, as demonstrated by Gallup [14], involved a personal health index derived from 5 yes-or-no questions concerning self-perceptions of health. These questions addressed general health problems, feelings of well-restedness, presence of physical discomfort, experiences of worry, and feelings of sadness. The resulting index was computed as the mean of all valid responses multiplied by 100, making the index range from 0 to 100.

Meijer et al [15] introduced a health index with an aim to be internationally comparable. Experts identified 25 variables measuring health and functional ability for inclusion in the index. The included variables consisted of reports of limitations with 10 mobility-related activities, arm and fine motor functions (such as walking, sitting, and reaching), 6 severe limitations with activities of daily living (such as dressing, bathing, and eating), and 7 less disabling problems in instrumental activities of daily living (such as preparing hot meals, making phone calls, and taking medication). Additionally, self-reported health and grip strength were incorporated into the index. The computation of this health index involved fitting the data with a special case of the LISCOMP model, integrating factor analysis and regression models. The health indices were reported to be comparable across different countries but were gender-specific. The primary focus of the study was centered more on examining the population-level health indices across various countries rather than discussing individual-level health indices.

Yi et al [16] developed 4 distinct health indices—namely, cardiovascular, stress, obesity, and management—derived from responses to specific questionnaires and objective measurements. These indices were constructed using weights assigned to each questionnaire item by experts in the field. The cardiovascular and stress indices were computed from a balanced combination of questionnaire responses and objective measurements, whereas the obesity index relied solely on measured data. The management index was formulated from questionnaire responses focusing on lifestyle and dietary habits. To consolidate these individual indices into an integrated health measure, the researchers weighted each element by the inverse of its corresponding standard deviation and summed the values together to create a final integrated health index.

Kohn [17] used multiple correspondence analysis (MCA) to construct a health index. MCA has similarities with principal component analysis (PCA) but is more suitable for discrete variables. The first dimension of MCA was reported to capture 80.4% of the principal inertia, corresponding to the variance in PCA. To facilitate interpretation, the analysis primarily focused on this first dimension, which represented the health index in this context. The range of observed continuous values for the health index was from 1 to 9, with higher values denoting better health. The selected domain of variables encompassed self-assessed health, a 36-point index evaluating mental and emotional health, reported health problems, disability status, a categorical number of accidents, and current smoking status. The suggested index allowed some flexibility for the index user, offering choices such as determining which domains to include when applying MCA for the index creation process.

Poterba et al [18] used PCA in creating the health index. The PCA for this purpose has been used since at least the 1980s [19,20]. In their approach, they used the first principal component as their health index. To aid the presentation, the "raw" health scores were converted into percentile scores for each respondent at different ages. The PCA was computed based on responses to 27 health-related questions, including activities of daily living (eg, difficulties in walking, lifting, or sitting), medical history (eg, experiences with stroke, diabetes, or cancer), self-reported health, BMI, and other relevant information.

Kim et al [21] suggested a toilet-based system for collecting data, such as pulse, blood pressure, oxygen saturation, BMI, electrocardiogram readings, and other vital signals. These data were used to construct 5 separate health indices—namely, heart, blood, fitness, muscle, and mental health index. Each index was derived by summing the respective normalized values together. Total health index represented the combination of all the 5 health indices, although its computation was not described in detail.

Chen et al [22] developed MyPHI, a method for constructing a personal health index. Using soft-label optimization, they created a unique prediction model for each disease category, handling infrequent and sparse data, and prioritizing recent health records. The method outperformed linear support vector machine and logistic regression models in their comparative analysis. Data from geriatric medical examinations, including patient profiling, laboratory tests, physical and external examinations, and mental health questionnaires, were used. Disease categories, derived from a cause of death dataset based on the ICD diagnosis classification, included lung, heart, cerebrovascular diseases, diabetes, stomach, colon, liver, pancreas, septicemia, and hypertension. The method generated a vector of scores reflecting personal health risks across disease categories. According to McDowell's [1] definition, the output could be described as a health profile or a disease index, given its focus on predicting disease-specific risks.

Lai et al [23] introduced a novel personal health index based on the *technique for order preference by similarity to ideal solution*, an established ranking method from 1981, coupled with an independent entropy weighting approach. Additionally, the study used tensor decomposition to address problems

XSL•FO
RenderX

stemming from missing data in health examination records. The authors highlighted the necessity for a more holistic approach to health assessment, acknowledging the multitude of variables collected during health examinations and difficulty in evaluating individual health status through only a small subset of these variables. They, however, selected 9 key health indicators in collaboration with domain experts, forming the basis of their health index. These indicators included systolic and diastolic blood pressure; BMI; total, high-density lipoprotein, and low-density lipoprotein cholesterol levels; fasting blood glucose; triglyceride levels; and thyrotropin. Each indicator held almost equal weight in the final computation of the health index.

The main characteristics of previous health indices and our index are summarized in Table 1. In the table, "*Individual adaptability*" refers to whether the model adapts to individual-specific data rather than relying solely on population-level parameters or fixed weights. A "*Yes*" indicates that the model can compute a personalized health index based on the available data for each individual. In some models (eg, MyPHI), this requires retraining or reconfiguring the model for each disease category or data type.

Table . Summary comparison of previous health indices and our index.

Study	Method	Data type	Individual adaptability	Supports missing data	Independent of training data
Kubik et al [12]	Summation of lifestyle questions	Questionnaire	No	No	Yes
Frank et al [13]	Summation of lifestyle questions	Questionnaire	No	No	Yes
Gallup [14]	Mean of yes or no questions	Questionnaire	No	No	Yes
Meijer et al [15]	LISCOMP model (factor analysis+regression)	Questionnaire+measurements	No	Yes	No

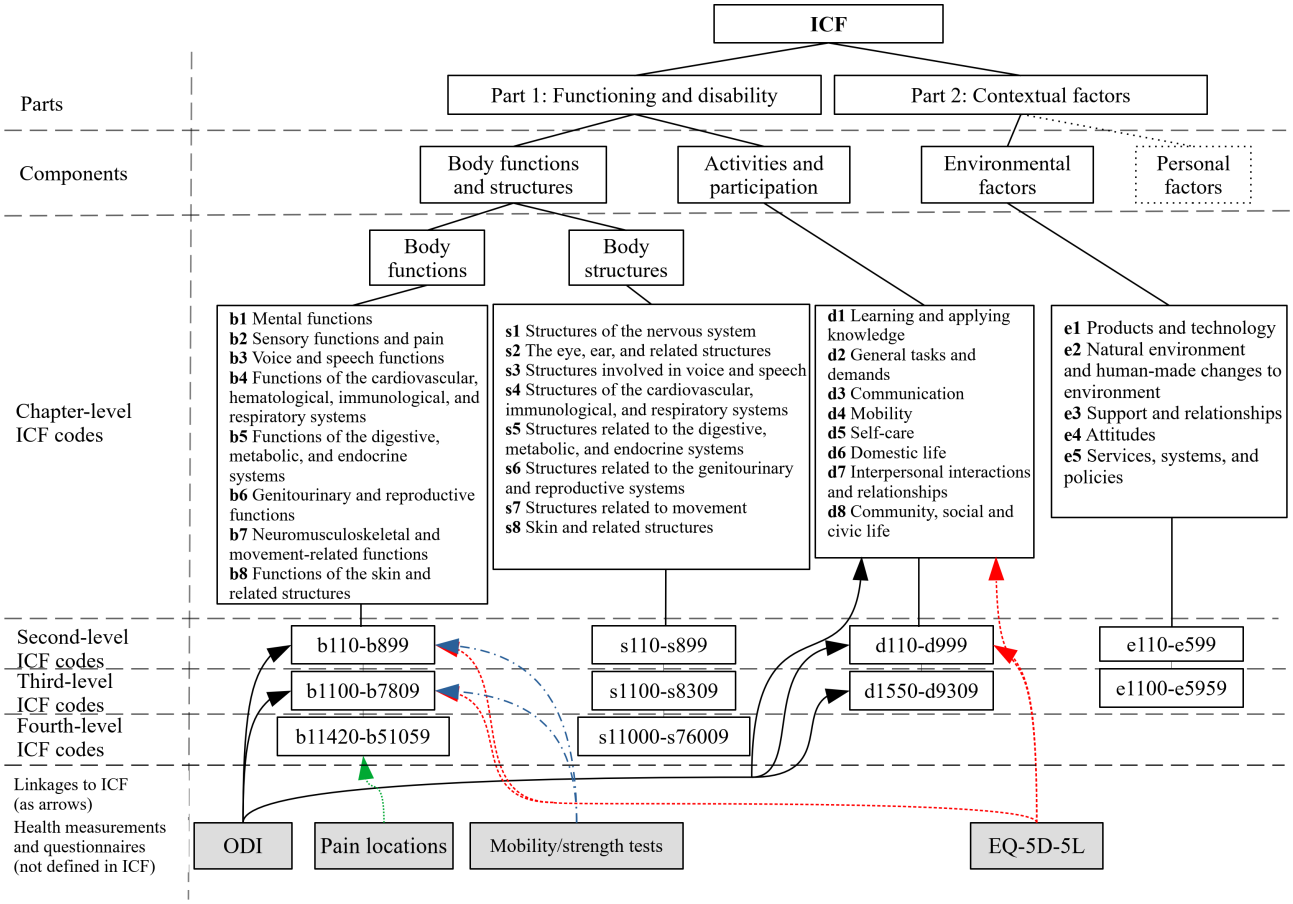
Lai et al [23]	TOPSIS[a]+entropy weighting+tensor decomposition	Health examination records	No	Yes	No
This study	Recursive computation from ICF[b] structure	Any ICF-compatible data	Yes	Yes	Yes

[a]TOPSIS: technique for order preference by similarity to ideal solution.

[b]ICF: International Classification of Functioning, Disability and Health.



Despite the variety of existing health indices, several limitations persist: lack of standardization and limited adaptability to heterogeneous data. Existing indices require retraining and/or manual configuration to accommodate new data types or disease categories. In contrast, the ICF-based personal health index proposed in this study is designed to automatically adapt to the available data for each individual without modifying the model, making it both flexible and standardized, and well-suited for scalable clinical use.

International Classification of Functioning, Disability and Health

Figure 1 provides an overview of the ICF structure. The 4 health measurements or questionnaires used and link to the ICF during the development and preliminary validation are depicted at the bottom of the figure, although they are not part of the ICF itself. Further discussion on these elements is presented in the section "Mapping data to ICF codes."

XSL•FO
RenderX

Figure 1. The hierarchical arrangement of the International Classification of Functioning, Disability and Health (ICF), compiled from data available in [3], along with the health measurements and questionnaires used during validation and their respective connections to the ICF.

The ICF classifies health and health-related problems into 2 main parts: *functioning and disability* and *contextual factors*. These are further divided into 4 main *components: body functions* (*b*) (physiological and psychological functions of body systems), *body structures* (*s*) (anatomical parts of the body), *activities and participation* (*d*) (execution of tasks and involvement in life situations), and *environmental factors* (*e*) (physical, social, and attitudinal environment). Although *personal factors* (background of an individual's life) are part of the structure, they cannot currently be classified using the ICF [4].

The main components of the ICF encompass over 1400 subcategories distributed across 4 hierarchical levels. These categories exhibit a nested structure, where broader categories incorporate more detailed subcategories under the parent category. For instance, the ICF code *The eye, ear and related structures* (*s2*) in the *body structures* component (chapter 2) encompasses separate categories detailing structures such as the eye socket, eyeball, and surrounding areas [4].

The *chapter-level* ICF code is denoted by appending a single-digit number after the component *b*, *s*, *d*, or *e*, such as *b2* referring to the ICF code *sensory functions and pain*. The *second-level* ICF code uses a 3-digit number (eg, *b280* for *sensation of pain*). Moving further, the *third-level* ICF code consists of 4 numbers (eg, *b2801* for *pain in body part*), and the *fourth-level* code expands to 5 numbers (eg, *b28013* for *pain in back*) [4,5].

For classification completeness, an ICF code is accompanied by one or more *qualifiers*. These single-digit numbers signify attributes such as the magnitude of the level of health or the severity of the problem. A dot (.) serves as a separator between the ICF code and the qualifier(s). For instance, a complete ICF code with a qualifier could be *b280.1*, indicating a mild or slight *sensation of pain* [4].

All possible ICF codes support the first qualifier, although its application varies slightly among different main constructs. In *body functions* and *body structures* components, the first qualifier serves as a *generic qualifier*, signifying the extent or magnitude of an impairment. The generic qualifier can have values 0 (*no problem*), 1 (*mild problem*), 2 (*moderate problem*), 3 (*severe problem*), or 4 (*complete problem*). In the *activities and participation* component, the first generic qualifier indicates *performance*, representing a problem in the person's current environment [4,5].

For *environmental factors*, the generic qualifier can be either a *barrier* or a *facilitator*, allowing positive contributors to be recorded. The negative scale is used similarly to the constructs mentioned earlier for barriers, whereas facilitators are indicated using a plus sign (+) as an ICF code or qualifier separator instead of a dot. For instance, ICF code *e145+2* indicates that products for education are a moderate facilitator, distinct from *e145.2*, which signifies that the products of education are a moderate barrier [4,5]. It is worth noting that facilitators are not part of our current health index computation model.

XSL•FO
RenderX

In addition to the first qualifier, additional qualifiers can be defined for *body structures* and *activities and participation*. For example, the nature of impairment can be described using the second qualifier in *body structures* (eg, *s7300.32* indicates a partial absence of the upper extremity) [4,5]. However, as our current computation model uses only the first qualifier, these additional qualifiers are not discussed further in this paper. Throughout the remainder of this paper, the term *qualifier* will exclusively refer to the first qualifier. In our proposed model, we introduce a minor addition to the ICF, which requires 2 attributes for the qualifier, specifically *linkage reliability* and *time elapsed* from the latest valid measurement. These attributes are discussed in the following sections.

Methods

Overview

In this section, we present the materials and methods used for computing the health index. Initially, we introduce the structure of the model used in the computation, outlining its fundamental components. Subsequently, we describe the overarching process involved in deriving the health index from the model. Following this, we delve into a more comprehensive explanation of the model elements, providing further insights into the ICF code–level computations.

Materials

Data Collection and Linkage to ICF

For the initial evaluation of the health index, we used data collected from a singular David Health Solutions clinic, located in Helsinki, Finland, spanning from 2013 to 2019. David Health Solutions is a private health care organization with a global network of clinics, specializing in rehabilitation services. The dataset consisted of 505 individuals (mean age 48, SD 18 y; minimum 12 y, maximum 87 y; women: n=259; and men: n=246) undergoing rehabilitation treatment for diverse problems such as back, neck, hip, knee, shoulder, general health, and other unspecified reasons. Our original dataset included the following questionnaire and measurement datasets:

- Oswestry Disability Index [24]
- A generic health questionnaire EQ-5D-5L (EuroQol 5-dimensional, 5-level) [25]
- Mobility and maximal isometric strength tests using various spine concept rehabilitation machines
- Numeric pain rating scale for pain responses in different body parts [26]

A comprehensive overview of these questionnaires and measurements can be found in Multimedia Appendix 1. It is important to emphasize that we do not claim this to be the definitive optimal dataset; rather, it serves as an illustrative example of potential index usage. An essential preprocessing step in constructing the health index involves converting, or linking, variables from these original datasets to new variables known as ICF codes. The linkage of original variables to ICF codes is described in the following section.

Mapping Data to ICF Codes

The ICF linkage guidelines [27,28] advocate for the training of 2 medical professionals to establish linkages between the original data sources and the qualifiers of the ICF codes. During the linking process, 2 experts will independently create linkage information for each new data source. If their independent linkages match, they are accepted as final. In cases where discrepancies arise, a third expert opinion is sought to determine the definitive linkage.

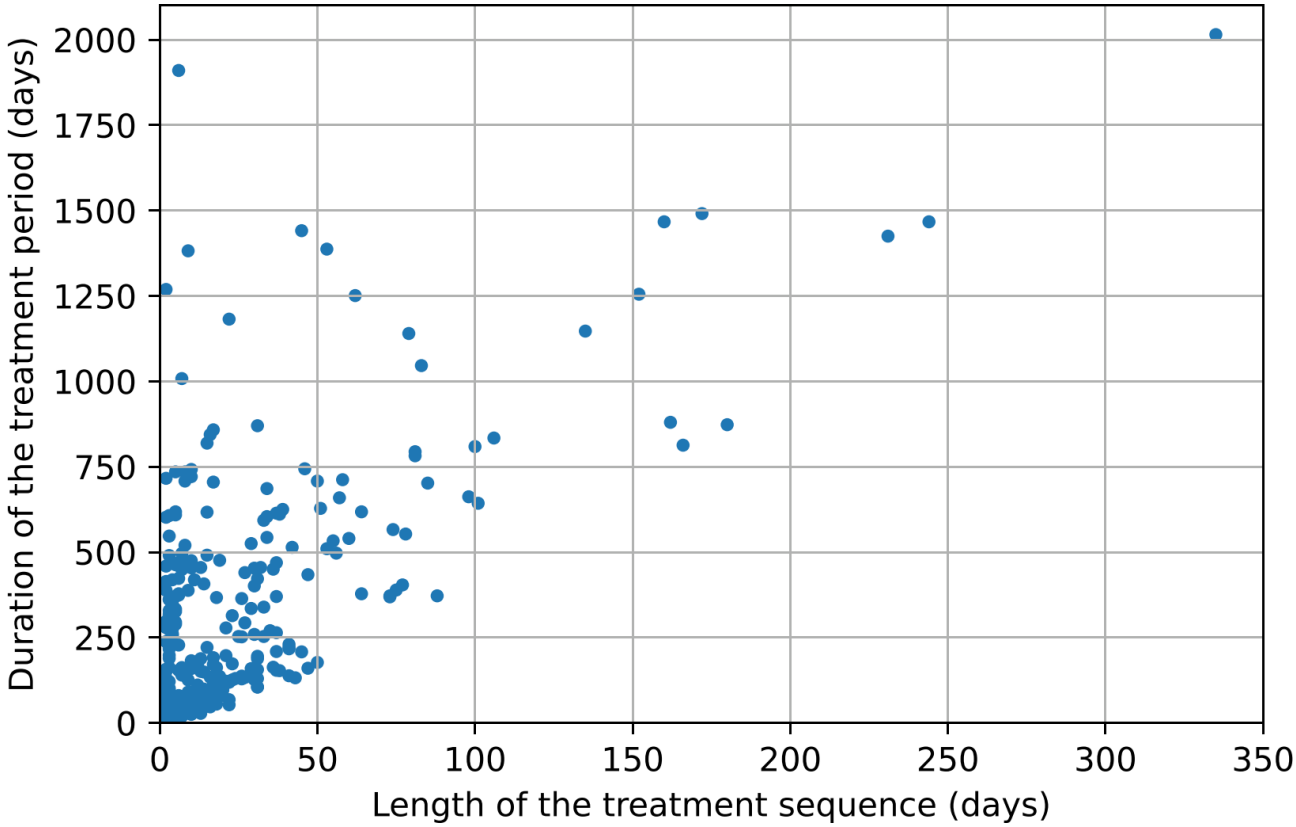
Given the potential coexistence of scientifically validated and self-made (ie, expert derived but not formally validated) ICF linkages in the data, it is crucial to define separate linkage reliability values for different linkage types. Scientifically validated linkages, typically established through consensus procedures outlined in ICF-linking rules, can be assigned higher reliability scores, while nonvalidated linkages are downweighted to reflect their informal nature. Here, $r \in [0,1]$ represents the *linkage reliability* designated for the corresponding source. The index user must specify the r value for every available source before computing the index. For instance, independently validated linkages may be assigned a maximum reliability of 1, whereas self-made linkages could be considered less reliable, resulting in r values typically set to less than 1.

For our dataset, formally validated ICF linkages do not exist, and therefore, we defined ICF linkages ourselves. While this led to lower linkage reliability when compared with formally validated linkages, this is not a limitation in this study because our focus is on the presentation of the new health index concept instead of proposing an optimal dataset for the health index computation. In fact, self-made linkages highlight the fact that the proposed health index concept is generic because it can be applied to heterogeneous datasets without requirements for the initial source and form of the data.

Details of the linkage for each questionnaire and measurement dataset are provided in Multimedia Appendix 1. For the EQ-5D-5L and Oswestry Disability Index questionnaires, data were available for 111 (22%) and 147 (29%) out of 505 individuals, respectively. Pain responses were accessible for 348 (69%) individuals, and mobility or strength test results were available for 420 (83%) individuals. Additionally, EQ-VAS, self-assessed health status on a scale from 0 to 100, was answered by 168 (33%) individuals.

The most frequently available ICF code in the dataset was *b780* (*sensations related to muscles and movement functions*), accessible for 420 (83%) individuals out of 505. The next 3 most common ICF codes available were *b7305* (*power of muscles of the trunk*), *b7355* (*tone of muscles of the trunk*), and *b7401* (*endurance of muscle groups*), all of which were available for 388 (77%) individuals. Codes related to pain localization (b28010, b28013, b28014, and b28015) were each available for 348 (69%) individuals, while b7302 was available for 321 (64%). Moderate availability was observed for b7300, b7350, and b7400, each present for 261 (52%) individuals. Codes b280, d450, and d5 were each available for 182 (36%) individuals. Several additional codes—b1340, d4103, d4104, d430, d470, and d910—were each available for 147 (29%) individuals, while b640 and d7702 were available for 136 (27%). The least

XSL•FO
RenderX



frequently observed codes (b152, b1528, d230, d455, d510, and d540) were each available for 111 (22%) individuals. To be included in the above list, there had to be at least one measurement available for the specified ICF code.

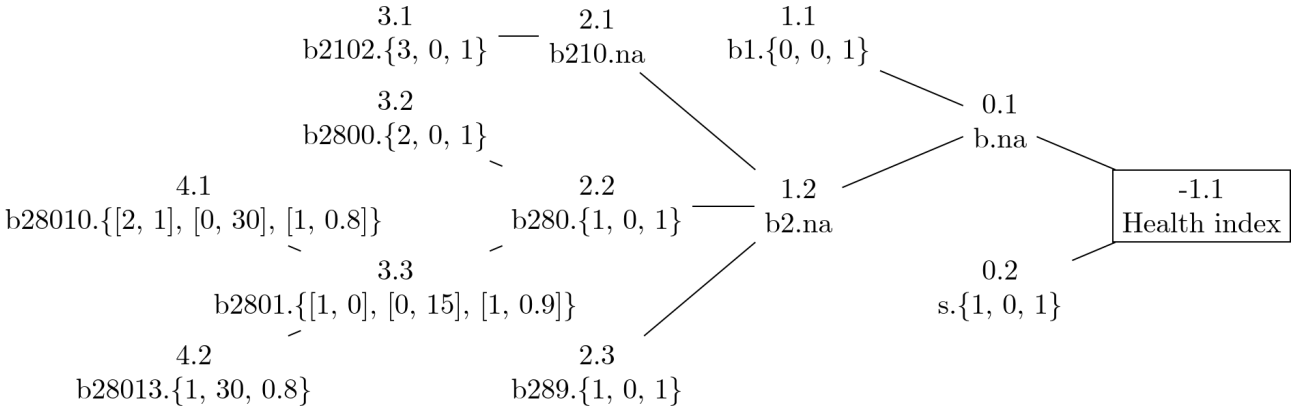
Overview of Collected Data

There are 2 important aspects to explore in the data. First, the *duration* of a treatment period is defined as the number of full calendar days between the initial and final day of the treatment. When treatment occurs only once, the duration is considered 0. Second, we can assess the frequency or the number of treatment days during the treatment period, referred to as the *length* of the treatment sequence. For example, if an individual undergoes treatment for 3 weeks with 4 clinic visits, the duration of the treatment period would be 21 days, and the length of the treatment sequence would be 4.

The median duration of the treatment period in the dataset was 69 days (IQR 0-301). Among individuals with nonzero duration, the median was 221 days (IQR 75-604). The median length of the treatment sequence was 3 days (IQR 1-16). Further exploration of this property is presented in Figure 2. The distribution of the length of the treatment sequence was as follows. A total of 148 (29%) out of 505 individuals had a sequence length of 1 day, indicating that for a substantial proportion of participants, data were available for only a single day. Furthermore, 61 (12%) individuals had 2 days, 44 (9%) had 3 days, and 26 (5%) had 4 days. Longer sequences were observed as follows: 71 (14%) individuals had 5 to 10 days, 48 (10%) had 11 to 20 days, 57 (11%) had 21 to 40 days, 31 (6%) had 41 to 80 days, 12 (2%) had 81 to 160 days, and 7 (1%) had 161 to 335 days.

Figure 2. The duration of the treatment period and the length of the treatment sequence for each individual are presented. Most individuals are clustered in the lower-left corner, indicating relatively short treatments with few individual treatment days.

Ethical Considerations



This study used previously collected and deidentified data from individuals who had provided informed consent for the use of their data in future research. The research did not involve any new interventions, physical or psychological risks, or other elements requiring ethical review as defined by the Finnish National Board on Research Integrity (TENK) guidelines on ethical review in human sciences [29]. Therefore, a separate ethical review was not required. The study was conducted in accordance with the principles of responsible conduct of research and data protection regulations. Personal data were processed in compliance with the EU General Data Protection Regulation, and deidentification was performed using procedures consistent with the Health Insurance Portability and Accountability Act Safe Harbor Method to minimize reidentification risk.

Model Architecture and Components

The proposed model structure aligns with the hierarchical organization of the ICF. Rather than incorporating all potential ICF codes, the model operates on whichever codes are available in a given dataset. In this study, we use the ICF codes listed in Figure 3 solely as an illustrative example of the model's usage; the model itself is designed to be broadly applicable to any ICF-compatible data.

XSL•FO
RenderX

Figure 3. An artificial example of a tree structure containing International Classification of Functioning, Disability and Health (ICF) codes. Each ICF code is represented by 2 rows of information. The first row includes the level number and the ICF code number within that level, separated by a dot. The format used is level.index, where level corresponds to the ICF level (with level 4 being the deepest), and index represents the per-level running index. The ICF codes are listed in alphabetical order at each level, and the running index follows this order. The level labeled as 0 refers to the ICF top components (b, d, e, and s). Level 1 corresponds to the chapter-level ICF codes, level 2 to the second-level ICF codes, and so forth. The second ICF code row indicates the ICF code and 3 attributes associated with it—namely, ICF qualifier x, time elapsed from measurement (TE) (see Multimedia Appendix B in Multimedia Appendix 2 for details on time weighting), and reliability of the linkage r (see section "Mapping Data to ICF Codes" for details on item linkage). The format is ICF_code.{qualifier, TE, reliability}. When a qualifier is not available for the ICF code, na is indicated after the dot. For the sake of simplicity, measurements from the d and e components are not incorporated in the current example, despite being supported.

Within this restricted set of ICF codes, some codes may further be absent—meaning they were not measured for all individuals. Consequently, our model includes both observed codes (those with measurements) and empty codes (those without measurements). Notably, an ICF code within the model can be observed through multiple measurements. This scenario arises when multiple original data variables are linked to the same ICF code. Additionally, a single ICF code may have multiple measurements if linked to data recorded at different time points. Throughout this study, we refer to all linked measurements as *qualifiers*, consistent with ICF terminology.

For illustrative purposes, Figure 3 provides an example of a simplified tree structure containing ICF codes. As previously mentioned, multiple original measurements can be linked to the same ICF code, resulting in the observation of that ICF code through multiple qualifiers.

In Figure 3, we observe 2 ICF codes, each associated with 2 qualifiers, both linked to the same ICF code at the third and fourth levels. The first qualifier in the ICF code *b28010* (4.1) has a value of 2 (the first number inside the square brackets). Additionally, it has attributes—namely, time_elapsed=0 and reliability=1. The second qualifier, originating from a different data source, also corresponds to the same ICF code. It has a value of 1 (the second number inside the square brackets) and attributes—again, time_elapsed=30 and reliability=0.8. Furthermore, empty ICF codes are also included in Figure 3 for illustrative purposes.

It is important to recognize that the example in Figure 3 is simplified and does not incorporate data from the ICF components related to *activities and participation* (*d*) or *environmental factors* (*e*), although these components are indeed supported within the index. Furthermore, it is not common practice to assign measurements directly at the component level. However, in this example, we have made an exception with a qualifier assigned to the *body structures* component.

Health Index Computation

The core concept behind our proposed approach is to systematically propagate information from the deepest nodes to the root of the tree. This process culminates in a single numerical metric known as the health index. Alternatively, if a health profile with multiple scores is desired, these metrics can be directly extracted from any level preceding the root level. We initiate the computation procedure at the leaf nodes of the tree. For instance, consider Figure 3, where we begin with ICF code *b28010* (4.1), then proceed to *b28013* (4.2), and subsequently to the next level represented by ICF code *b2102* (3.1), and so forth. This iterative computation continues until all ICF codes have been accounted for.

To compute the health index, we use a recursive algorithm that traverses the hierarchical ICF structure from the deepest nodes upward. At each level, the algorithm aggregates measurement values (qualifiers) using time decay and linkage reliability weights. This process continues until a single health index value is produced at the root level. The final computed value represents the unscaled health index, which we subsequently scale to a range of 0 to 100 to obtain the final health index. Detailed steps for this computation are outlined in the pseudocode presented in Figure 4, with the relevant equations provided following the algorithm. To streamline the algorithm presentation, some details that solely focus on performance optimization have been omitted. For example, given that the fourth level represents the deepest layer in the ICF framework, there is no practical need to verify child ICF codes at this level.

Figure 4. Health index computation algorithm. ICF: International Classification of Functioning, Disability and Health.

Algorithm 1: Health index computation.

```
Data: ICF code tree with qualifiers
Result: Health index
1  initialize variable level with the deepest ICF code level in the tree
2  while the health index has not been computed do
3      index = 1
4      while there are ICF codes at the level do
5          if there are child ICF codes for the ICF code level.index then
6              compute value of the ICF code x_{level.index} (Eqs. 2, 3, 4)
7              compute time weighting α_{level.index} (Eq. 5)
8              compute linkage reliability r_{level.index} (Eq. 5)
9              foreach child ICF code of level.index do
10                 remove all qualifiers s if they exist
11             index = index + 1
12     level = level - 1
13     if level < −1 then
14         scaled_health_index = HI(x_{−1.1}) (Eq. 1)
15         return scaled_health_index
```

In essence, the algorithm ensures that all available data—whether recent or older or direct or indirect—is systematically weighted and aggregated. By processing the tree level by level, the model maintains consistency and robustness, even when data are missing or unevenly distributed. In the algorithm, the input data consist of an ICF code tree with qualifiers, similar to the one illustrated in Figure 3. The desired output is the health index. The procedure begins by initializing the variable *level* (line number 1) based on the deepest available ICF code level within the data. For instance, in the data represented in Figure 3, there are qualifiers associated with 2 ICF codes at level 4 (4.1 and 4.2). Consequently, the *level* variable would be initialized as 4 in this case. The lowest possible value for *level* is −1, corresponding to the root of the tree. At this root level, the final health index is computed.

The purpose of the outer *while* loop (lines 2 - 15) is to sequentially process the ICF codes within the tree until the root is reached, at which point the health index is computed and returned. Within this loop, the variable *index* is initially set (line 3). The *index* serves as a per-level running counter, resetting to 1 whenever the tree level changes. For instance, in the processing order of ICF codes for the tree depicted in Figure 3, the sequence is 4.1, 4.2, 3.1, 3.2, 3.3, and so forth.

The inner *while* loop (lines 4 - 11) serves the purpose of iteratively performing necessary computations until all the ICF codes at the current *level* have been processed. The first *if* statement (line 5) checks whether child ICF codes are available for the currently examined ICF code, denoted as *level.index*. For instance, in Figure 3, the child ICF codes of *b280* are *b2800* and *b2801*. When child ICF codes are available for a given ICF code, the computation process begins. In lines 6 to 8, we compute the value of the ICF code, denoted as $x_{level.index}$, along with the time weighting $\alpha_{level.index}$ and the linkage reliability $r_{level.index}$. These computations are elaborated in detail in "Computing ICF code values and reliability."

Subsequently, in lines 9 and 10, we remove all qualifiers from the child ICF codes associated with *level.index*. The purpose of this step is to ensure that these values are not reused in subsequent computations. Instead, we rely on the values computed during lines 6 to 8 as we continue the computation process. Additionally, the per-level running index (*index*) is incremented after handling each ICF code (line 11), whereas the level index (*level*) is decremented once all ICF codes at that level have been processed (line 12).

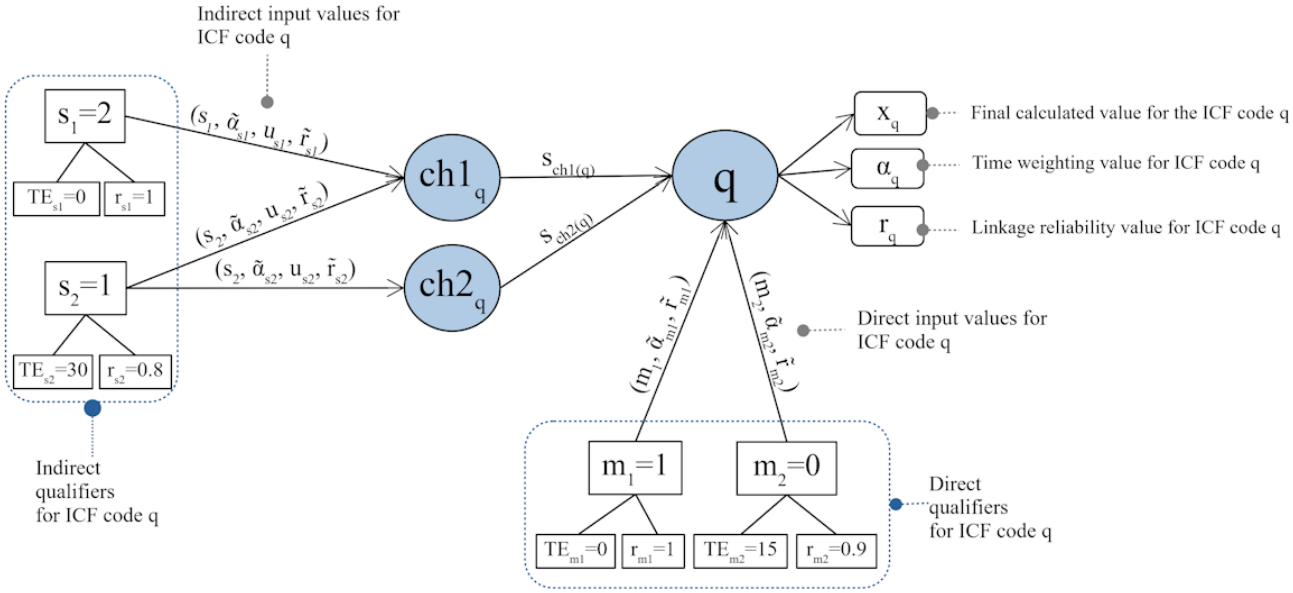
When the level index (*level*) drops below −1, it signifies that we have reached the root of the tree (line 13). At this point, we have computed the raw health index, denoted as $x_{-1.1}$, according to the ICF code numbering scheme depicted in Figure 3. However, this raw value requires transformation to enhance its interpretability. Our desired presentation for the final health index is an integer ranging from 0 (indicating the worst health) to 100 (representing the best health). To achieve this, we invert the source and target values: whereas a raw health index value of 0 corresponds to optimal health, the same value within the target range signifies the poorest health condition.

As higher qualifier values indicate worse health, we invert the raw score to ensure that a higher health index corresponds to better health. This makes the final index more intuitive for clinical interpretation. The transformation is applied as follows, resulting in the final health index denoted as HI (line 14):

$$HI(x_{-1.1}) = \mathrm{nint}\left(100 - 100 \times \frac{x_{-1.1} - \min(x_{-1.1})}{\max(x_{-1.1}) - \min(x_{-1.1})}\right) \quad (1)$$

where nint represents the nearest integer function, x-1.1 is the raw value to be transformed, and min(x-1.1) and max(x-1.1) correspond to the minimum and maximum theoretical or actual

XSL•FO
RenderX



raw values. Given that we know the theoretical minimum (0) and maximum (4) values for the raw health index, our primary approach is to directly scale and invert the raw values to fit our target range. Specifically, we define min(x-1.1)=0 and max(x-1.1)=4. The resulting value after this transformation (line 15) represents the final health index.

Subsequently, once the health index has been computed, the tree is reset to its original state. This entails removing all previously computed values from the ICF codes and restoring all qualifiers to their initial positions. This procedure ensures that any future computations do not inadvertently rely on previously computed values.

Detailed Examination of Components

In Figure 5, we closely examine the components within our tree example. Specifically, we focus on 3 ICF codes: *b28010*, *b28013*, and *b2801*, extracted from Figure 3 for a comprehensive analysis. Each ICF code represents a specific health-related concept.

Figure 5. An International Classification of Functioning, Disability and Health (ICF) code–level example of the health index computation. In this figure, we have a viewpoint of an individual ICF code marked as q. Its child ICF codes are marked here as $ch1_q$ and $ch2_q$.

Let us denote the ICF code whose output value we compute as *q*. In Figure 5, this corresponds to node 3.3 (*b2801*) from Figure 3. Additionally, *q* has 2 child ICF codes: ch1q (equivalent to ICF code 4.1, *b28010*) and ch2q (equivalent to ICF code 4.2, *b28013*). These 3 codes are highlighted in blue color in Figure 5. Measurements mapped to these ICF codes are also shown in Figure 5 and are denoted as m1,m2,s1,s2∈ . Owing to the ICF mapping performed as a preliminary step, values of these measurements are strictly between the range 0≤m1,m2,s1,s2≤4, encompassing the range of qualifiers in the ICF. Separate notation is used for direct (m_i) and indirect (s_j) measurements from the point of view of the code of interest (*q*) to highlight the different roles of the measurements in the health index computation. The origin of the measurements is not important in the context of this example. We also illustrate that a single measurement (see S_2 in Figure 5) can contribute to multiple ICF codes. The qualifiers play a crucial role in linking to specific ICF codes, as indicated by arrows. In this illustrative example, they are as follows:

1. A *moderate problem* (qualifier s1=2) is recorded for ICF code *pain in head and neck* (*b28010*/ch1q). The measurement is made on the latest available day in the treatment period, as indicated by TEs1=0, and its linkage reliability is defined as the strongest possible (rs1=1).
2. A *slight problem* (qualifier s2=1) is recorded for ICF codes *pain in head and neck* (*b28010*/ch2q) and *pain in back* (*b28013*/ch2q). The measurement was made 30 days ago from the perspective of the latest available measurement, as indicated by TEs2=30, and its linkage reliability is defined as (rs2=0.8).
3. A *slight problem* (qualifier m1=1) is recorded for ICF code *pain in body part* (*b2801*/*q*). The measurement is made on the latest available day in the treatment period, as indicated by TEm1=0, and its linkage reliability is defined as the strongest possible (rm1=1).
4. A *no problem* (qualifier m2=0) is recorded for ICF code *pain in body part* (*b2801*/*q*). The measurement was made 15 days ago from the perspective of the latest available measurement, as indicated by TEm2=15, and its linkage reliability is defined as (rm2=0.9).

The different components are marked in Figure 5:

- *Direct qualifiers (D) for ICF code q*: m1 and m2 are the *direct qualifiers* for ICF code *q*. In other words, they are directly linked to *q*. TEm1 is the age of a qualifier measured in full days, and rm1 denotes the reliability of the linkage.
- *Direct input values for ICF code q*: These values (mi, α~mi, r~mi) are associated with ICF code *q*. While the qualifier mi can be directly attached to the ICF code, other values must be computed based on the available data.
- *Indirect qualifiers (I) for ICF code q*: This component represents the 2 available qualifiers, s1 and s2, for the 2 child ICF codes ch1q and ch2q. Qualifiers s1 and s2 serve as the *indirect* qualifiers for ICF code *q*. They are linked to *q* through its child ICF codes. The time elapsed value

XSL•FO
RenderX

for s1 is denoted by TEs1, and its source linkage reliability is given by rs1.

- *Indirect input values for ICF code q*: These values (sj, α~sj, usj, r~sj) are associated with the child ICF codes. They are used to compute the values sch1(q) and sch2(q) for the child ICF codes.

There are 3 outputs in the diagram:

- *Final computed value for the ICF code q*: Denoted as xq, this represents the ultimate value associated with ICF code *q*. It comprises both *direct* and *indirect* qualifiers. Specifically, xq is the weighted average of all available qualifiers: s1, s2, m1, and m2. In this case, it would be computed as follows: xq=(β~m1Dm1+β~m2Dm2+sch1(q)+sch2(q))/(β~m1Dm1+β~m2Dm2+β~s1I+β~s2I+β~s2I) where β terms refer to weighting coefficients. Details regarding the equation are explained in the following section.
- *Time weighting value for q*: Denoted as αq, this value represents the weighted mean of all available time weighting α values, as defined in Equation 5.
- *Linkage reliability value for q*: Represented by rq, this value is the weighted mean of all available *r* values, also defined in Equation 5.

Computing ICF Code Values and Reliability

In the previous section, we explained the computation of ICF code values using a practical example for clarity. Now, in this section, we delve into a broader discussion on the computation of ICF code values and their associated reliability measures.

Determining ICF Code Values

The value of the ICF code *q* is defined as follows:

(2)xq=(∑i∈Dβ~miDmi+∑k∈chqβ~xkIxk)/(∑i∈Dβ~miDmi+∑k∈chqβ~xkI+∑j∈kβ~sjIsj)

This definition consists of 4 separate elements:

1. Function f is a weighting function that can be selected to either give emphasis to higher qualifiers (exponential weighting) in data or to highlight lower qualifiers (logarithmic weighting). It is also possible to use no weighting at all (linear weighting). The different weighting functions are presented in more detail in Multimedia Appendix 2.
2. The first sum term ∑i∈Dβ~miDmi represents the weighted sum of qualifiers mi directly linked to the ICF code *q*. Here, *D* denotes a set of *direct qualifiers*—that is, those qualifiers that are directly linked to *q*. Additionally, we introduce a total weighting term βD for direct qualifiers:

   (3)βmiD=α~mir~mi

   In this expression, α and *r* play essential roles. The first element, α, serves as a time weighting value that accounts for the age of the corresponding qualifier. Generally, as a qualifier ages, its influence diminishes in the computation. Further details on time weighting are discussed in Multimedia Appendix 2. The second element, *r*, corresponds to the linkage reliability defined in "Mapping data to ICF codes." Notably, in Equation 2 and Equation 3, the terms β, α, and *r* carry the tilde notation (β~,α~,r~). This notation signifies that normalized values are used instead of raw values. A standard normalization procedure ensures comparability across different values. Refer to the Multimedia Appendix 2 on normalization for the 2 relevant equations.
3. The second sum term ∑k∈chq∑j∈kβ~sjIsj represents the weighted sum of qualifiers sj that are indirectly linked to the ICF code *q* via its child ICF codes. Here, chq refers to a child ICF code of *q* that possesses either a qualifier or a computed value. Consequently, each child ICF code of *q* contributes to the overall computation. The inner sum iterates through all the qualifiers associated with the child ICF code.

   Here, *I* denotes a set of *indirect qualifiers*. We introduce a total weighting term for indirect qualifiers, denoted as βI. This term is a slightly modified version of the weighting term shown in Equation 3, defined as follows:

   (4)βsjI=α~sjr~sjusj

   where usj quantifies the *uniqueness of source* for the qualifier sj. Specifically, it is computed based on the number of linkages between sj and child ICF codes of *q*. It is defined as usj=1/zj,zj∈N+, where zj represents the total linkages involving sj and child ICF codes of *q*. The purpose of introducing *u* is to adjust the qualifier weighting when the same source contributes to values for 2 or more ICF codes under the same parent ICF code. The terms α and *r* have the same purpose as in Equation 3.
4. The third sum term ∑k∈chqβ~xkIxk mirrors the second sum term discussed earlier. However, there is a crucial distinction: it operates on the computed values (*x*) rather than the qualifiers (*s*). Notably, the second sum term becomes unnecessary here, as each child ICF code corresponds to a single computed value. Furthermore, the concept of uniqueness of source does not apply in this context. Consequently, we define β~xkI similarly to Equation 3, as β~xkI=α~xkr~xk.

Assessing ICF Code Reliability

There are 2 values, αq (equivalent to αlevel.index in Figure 4 algorithm, line 7)—the weighted mean of time weighting α—and rq (equivalent to rlevel.index on line 8)—the weighted mean of linkage reliability *r*—that are computed for xq. They are defined almost identically to xqin Equation 2:

(5)αq=∑i∈Dβ~miDαmi+∑k∈chq∑j∈kβ~sjIαsj+∑k∈chqβ~xkIαxk

For computing rq, we replace the α term in the equation with *r*. Here, the β~ terms determine the weightings for each α or *r* component. These values, αq and rq, are attributes to the xq value and are intrinsically associated with it.

Results

Overview

In this section, we present the results of applying the proposed health index model to the David Health Solutions dataset. While some methodological details are included to support interpretation, the focus is on the outcomes of the validation analyses. The computed health indices for all individuals in the dataset underwent preliminary validation by comparing the results with self-reported EuroQol Visual Analogue Scale (EQ-VAS) responses and maximum pain ratings.

XSL•FO
RenderX

Two validation groups were established. The first group had a treatment period duration of at least 90 days, whereas the second group adhered to a 30-day limit. In the first group, the length of the treatment sequence (as described in "Overview of Collected Data") was a minimum of 10 days. For the 30-day group, the treatment sequence length was at least 5 days. Individuals could be assigned to both groups, provided that the day and qualifier preconditions were met.

To explore the effect of different time weightings, we computed Pearson correlation coefficients for various time decay constants (γ). Multimedia Multimedia Appendix 2 provides a detailed definition of γ. The chosen values for γ were as follows:

- $\cdot\gamma 1=(1/20)1/30\approx 0.905$ represented a very heavy time decay, where a 30-day-old qualifier contributed only 5% of its original time weight.
- $\cdot\gamma 2=(1/3)1/30\approx 0.964$ represented our estimated preliminary potential time decay value in a real-life scenario. Practically, this value implies that a measurement made 30 days ago was given one-third of its original time weight.
- $\cdot\gamma 3=1$ signified no time decay at all.

The algorithm was implemented using the Python programming language [30]. Statistical analyses were conducted using SciPy [31], and figures were generated with Matplotlib [32].

Comparing Self-Assessed Health Status Responses With Health Index

First, the health index was computed without emphasizing either lower or higher qualifiers. In Table 2, the EQ-VAS response was compared with the health index, and Pearson correlations are presented for both groups. We also explored the influence of changing the time decay constant (γ). The results predominantly reveal moderate positive correlations between the EQ-VAS response and the computed health index. The 90-day group consisted of 84 individuals, with a total of 125 EQ-VAS responses recorded. While most individuals had only one recorded EQ-VAS response, some provided 2, 3, or even 4 responses—all of which were used in the computations. The 30-day group included 115 individuals, with a total of 159 EQ-VAS responses.

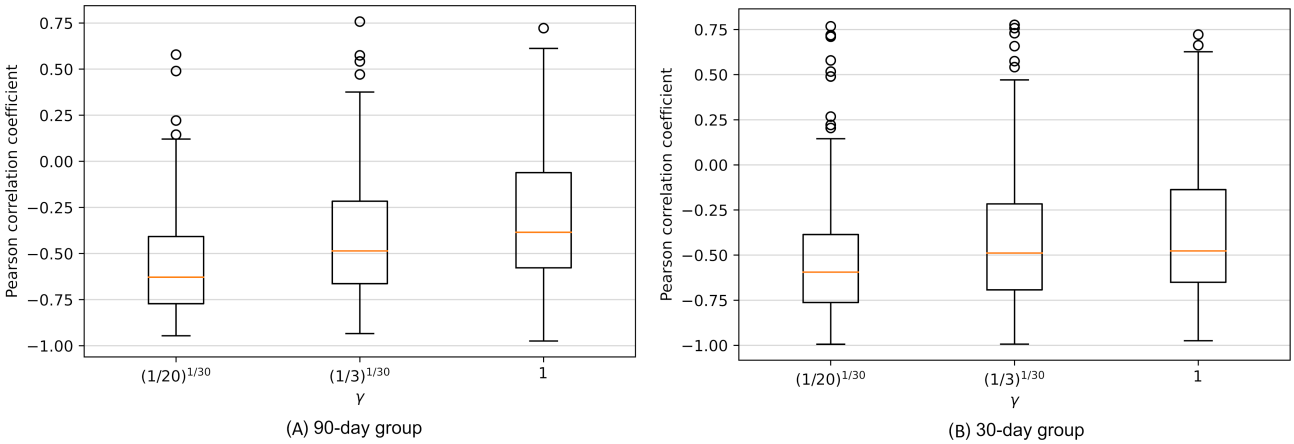
Table . Pearson correlations for the EQ-VAS[a] response versus health index[b].

γ	30-d group	90-d group
(120)1/30	0.690	0.642
(13)1/30	0.700	0.659
1	0.654	0.599

[a]EQ-VAS: EuroQol Visual Analogue Scale.

[b]All reported correlations are statistically significant (P<.001).

Comparing Maximum Pain Responses With Health Index



In the context of maximum pain versus the health index, we individually computed the Pearson correlation for each person between the maximum pain trajectory and the health index trajectory. We define maximum pain as the single highest value among the 4 self-assessed pain responses. Subsequently, a maximum pain trajectory was formed for each individual. As this information was also used in computing the health index, there was inevitably at least some correlation between the 2 values. However, this comparison provides a useful second perspective for model validation.

To prevent data from incorrectly showing significance, we applied the Bonferroni correction in the maximum pain versus health index trajectory correlation computations. Specifically, the α level was divided by n.

Figure 6 presents the distribution of correlation values for the 2 groups. Notably, a slight upward trend in median correlation is visible in both groups: as γ increases, the median correlation approaches zero. In all cases, the correlation was negative, varying approximately from low to moderate. There were small differences in the n values for the different groups. In some configurations, the health index value remained constant for certain individuals, making correlation computations impossible. These persons were omitted from the computations.

XSL•FO
RenderX

Figure 6. Boxplots illustrating Pearson correlations between the health index and maximum pain trajectories. (A) 90-d group, where the correlation medians for the 3 time decay groups (n=133) are −0.628, −0.486, and −0.385. (B) 30-d group, with correlation medians for the 3 time decay groups at −0.594, −0.489 (n=184), and −0.477 (n=182).

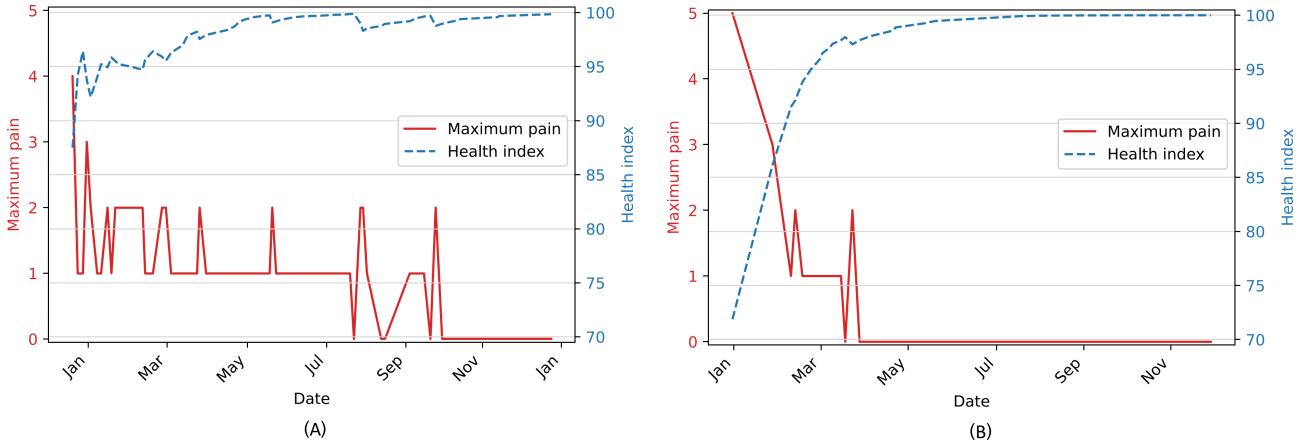
Examining the portions of significant correlations, we observed that for the 90-day group, Bonferroni-corrected significant (P<.05) portions were 55% for γ1, 41% for γ2, and 31% for γ3. In the 30-day group, the similar portions were 41% for γ1, 29% for γ2, and 23% for γ3. These findings suggest that as the length of the treatment sequence and duration of the treatment period increase, more significant correlations emerge.

In Table 3, we further examine the effect of time series length by binning the maximum pain versus health index trajectories of individuals into 3 bins based on the length of the treatment sequence. The table presents both the 90-day group and the 30-day group, separated by a comma. These results also indicate that as more data points are included in the trajectory, the significant portion increases. Additionally, in Figure 7, 2 example individuals and their maximum pain versus health index trajectories are presented.

Table . Correlation statistics between maximum pain and health index, using a 3-bin approach based on treatment sequence length[a].

Bin[b]	Day ranges	Bonferroni significant (P<.05) portions[c]	Median correlations	Subset n[d]
1	[10, 26], [5, 15]	18.8%, 7.9%	−0.385 (IQR −0.702 to −0.082),−0.569 (IQR −0.815 to −0.261)	48, 63
2	[27, 42], [16, 32]	37.5%, 18.3%	−0.508 (IQR −0.695 to −0.327),−0.376 (IQR −0.577 to −0.074)	40, 60
3	[43, 325], [33, 325]	68.9%, 65.6%	−0.509 (IQR −0.636 to −0.312),−0.511 (IQR −0.670 to −0.299)	45, 61

[a]The time decay value was defined as γ_2.



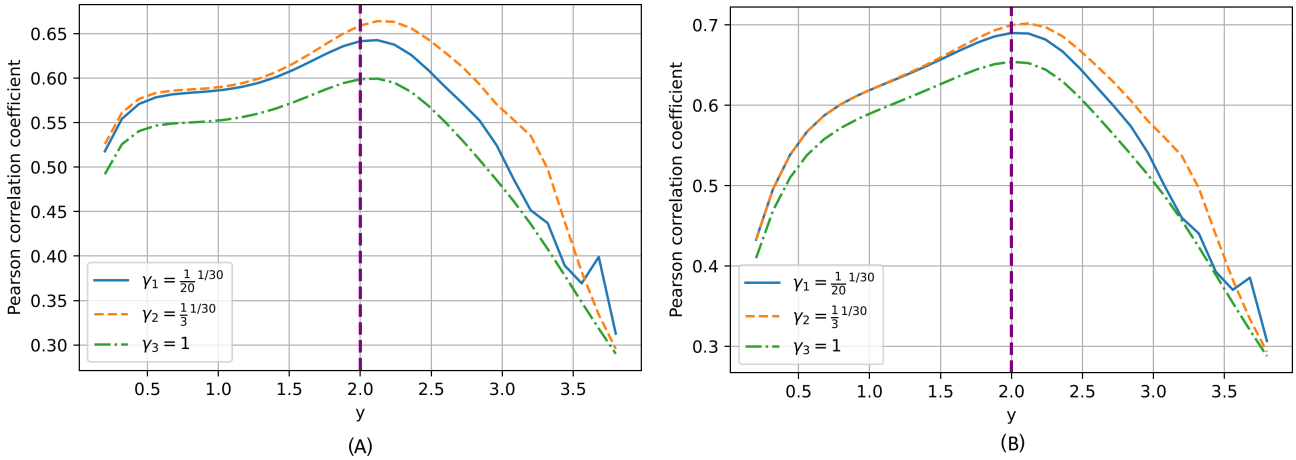
[b]The 3 bins are approximately equal in size (tertiles). For each bin, we specify the range of treatment sequence lengths included. For instance, bin 1 encompasses individuals with treatment sequences lasting from 10 to 26 days (in the 90-d group) or from 5 to 15 d (in the 30-d group).

[c]Proportion of correlations that remain significant after Bonferroni correction at a 0.05 significance level.

[d]Number of individuals included.

XSL•FO
RenderX

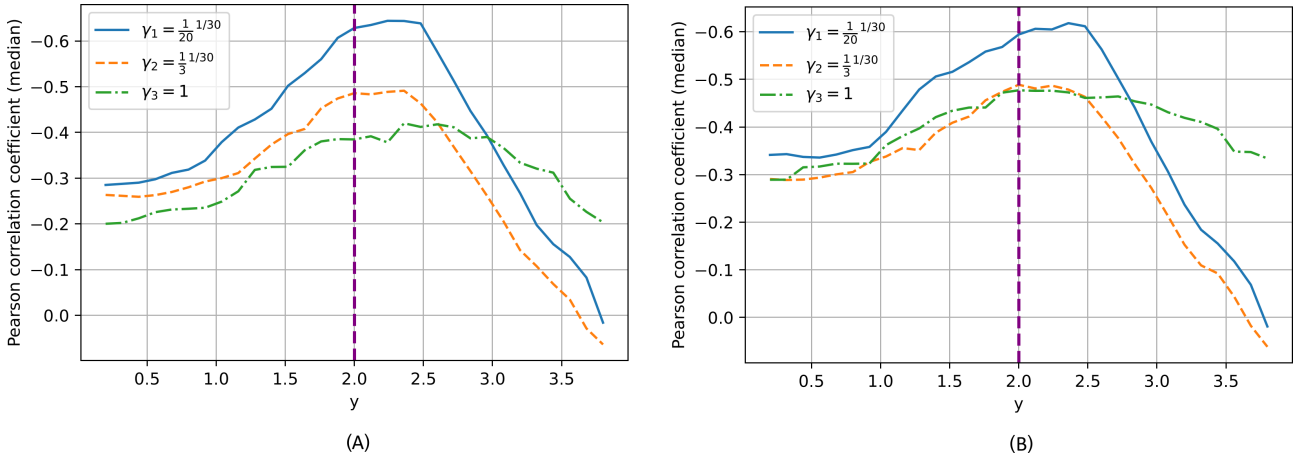
Figure 7. The maximum pain versus health index trajectories for 2 example individuals. The first case (A) demonstrates a moderate negative correlation with a treatment sequence length of 40 d. The second case (B) represents an extreme scenario with a very high negative correlation with a treatment sequence length of 28 d. Both cases share the same time decay value, γ_2. Notably, the Bonferroni-corrected correlations were statistically significant (P<.001).



Impact of Nonlinear Weighting

In this section, we explore the impact of qualifier weighting on correlations. The model allows for the calibration of qualifier weighting by adjusting the parameter y. The weighting can operate under three distinct functions: (1) when $y \in (0,2)$, the weighting is exponential, which implies that higher qualifier values carry more weight; (2) when $y \in (2,4)$, the weighting is logarithmic, indicating that lower qualifier values are given more weight; and (3) when y=2, the weighting is linear, meaning that all qualifier values are treated equally, without any specific weighting. For details on value weighting, please refer to Multimedia Appendix 2.

In this study, we examined a total of 31 values for the y parameter. These values were selected to be evenly spaced on both sides of the linear case (y=2), ranging from y=0.2 to y=3.8 with intervals of 0.2. The results of the Pearson correlation between the health index and EQ-VAS response are depicted in Figure 8. For the 90-day group, the highest correlations for all 3 γ values were observed at y=2.12, with correlation values of 0.643, 0.664, and 0.599, respectively. In contrast, for the 30-day group, the highest correlations were observed at the linear weighting point (y=2). The correlations at this point are identical to those presented in Table 2.



In the context of maximum pain versus the health index, the median correlations for both groups are depicted in Figure 9. For the 90-day group, the 3 γ values exhibited the highest negative correlations of −0.644 (at y=2.24), −0.491, and −0.420 (both at y=2.36), respectively. Conversely, the 30-day group demonstrated correlations of −0.618 (at y=2.36), −0.489, and −0.477 (both at y=2).

Figure 8. Pearson correlations between the health index and EQ-VAS response for 3 time decay constants. (A) 90-d group (n=125) and (B) the 30-d group (n=159).

Figure 9. Median Pearson correlations between the health index and maximum pain for 3 time decay constants. (A) shows the 90-d group (γ_1, γ_2: n=133, γ_3: n=132, 133) and (B) the 30-d group (γ_1, γ_2: n=184, γ_3: n=181, 182, 183).

Fundamental Sensitivity Analysis

The objective of conducting a sensitivity analysis is to understand how variations in input parameters influence the outcome of a model, in this case, the health index [33]. Our aim is to verify that the model behaves predictably and logically when modifications are made to the input variables. For instance, an increase in a single qualifier, while other qualifiers remain constant, should result in a decrease in the health index.

The ICF structure consists of over 1600 distinct ICF codes, each potentially having qualifiers. We use a simple data sample, as shown previously in Figure 3, to investigate the model's response to a straightforward scenario: an increase or decrease in qualifier. In this scenario, we do not consider the reliability value (r) and assume it to be 1 for all qualifiers.

We target nodes that possess one or more qualifiers for value changes, with a particular emphasis on the qualifier and its impact on the final health index. For each targeted node, we explore all possible qualifiers ranging from 0 to 4, while maintaining constant values in other nodes, as illustrated in Figure 3. This setup produces 45 distinct health index outcomes, including the default.

The outcomes of the fundamental sensitivity analysis are detailed in Table 4. Throughout this analysis, the health index exhibited anticipated behavior. It is evident that ICF codes closer to the root (ie, the health index) of the tree exert a greater influence on the health index. Conversely, alterations in the most remote parts of the tree exert minimal influence on the overall health index. An additional characteristic worth noting is the time weighting. For example, alterations in the most recent qualifier, denoted as $b28010_1$, exert a greater influence on the outcome compared to modifications in the qualifier from 30 days ago, represented as $b28010_2$.

On the basis of the empirical patterns in this dataset, we propose 2 preliminary default parameters for future use: a moderate time decay value (γ=(13)1/30) and a linear weighting function (y=2). These settings offered stable behavior and consistent correlations across both EQ-VAS and pain trajectories. They should be revisited when applying the model to other populations or more extensive ICF datasets.

Table . Outcomes of the health index from the sensitivity analysis. ICF codes b2801 (3.3) and b28010 (4.1) have 2 recorded qualifiers, each marked with a subscript of 1 or 2 to indicate their temporal sequence, with 3.3_1 denoting the most recent qualifier. All other qualifiers were consistently fixed to the values shown in Figure 3. The time weighting, γ, was fixed at (1/3)1/30

Qualifier[a]	S 0.2	b1 1.1	b280 2.2	b289 2.3	b2102 3.1	b2800 3.2	$b2801_1$ 3.3_1	$b2801_2$ 3.3_2	$b28010_1$ 4.1_1	$b28010_2$ 4.1_2	b28013 4.2
0	85.04	73.71[b]	74.59	75.34	82.74	75.46	74.09	73.71[b]	74.48	73.84	74.09
1	73.71[b]	67.94	73.71[b]	73.71[b]	79.73	74.59	73.71[b]	73.49	74.09	73.71[b]	73.71[b]

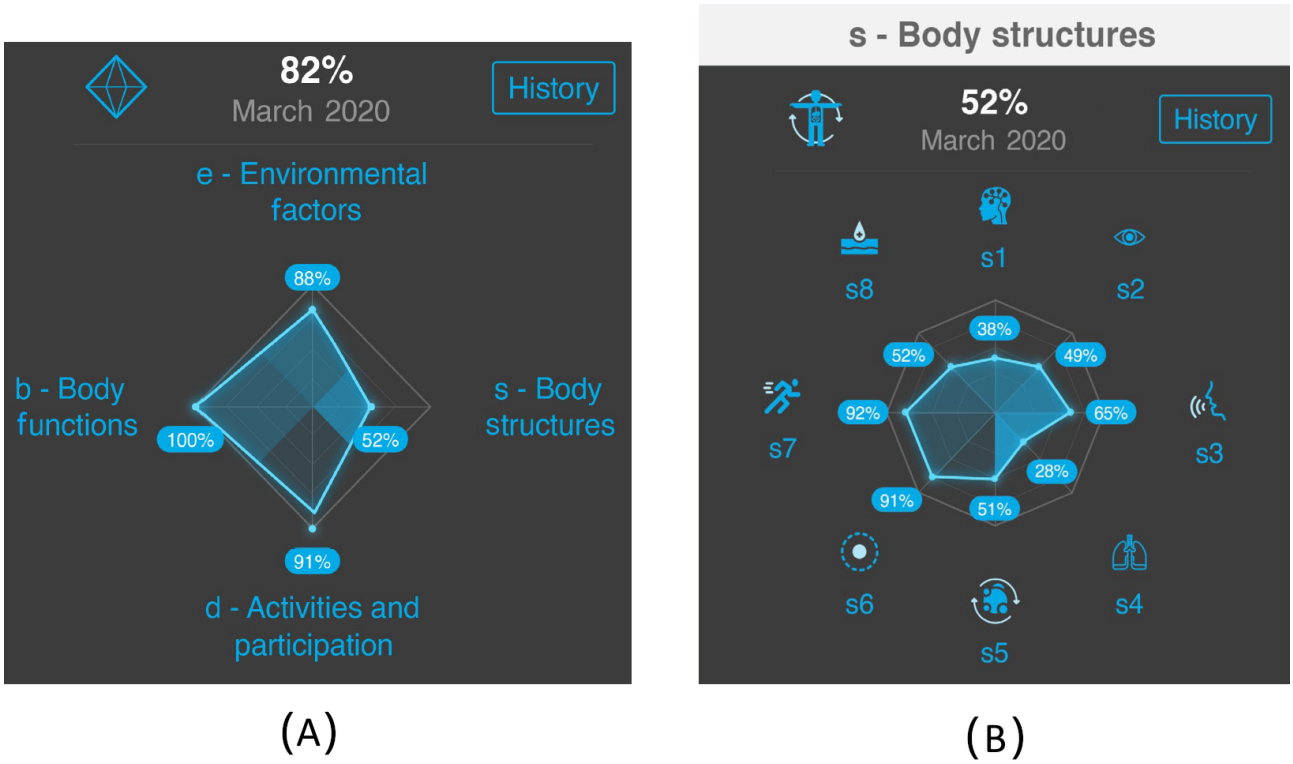
Discussion

Principal Results and Comparison With Prior Work



In clinical practice, the health index could serve as a decision support tool for rehabilitation planning, chronic disease management, and progress tracking. For example, a physiotherapist could use the health index to track a patient's recovery from back pain, identifying which functional domains are improving and which require further intervention. By providing a standardized and interpretable metric, it enables clinicians to quickly assess patient status, identify areas needing intervention, and monitor changes over time. The health profile further supports personalized care by highlighting specific domains of functioning and disability.

This study demonstrated that the proposed ICF-based health index correlates meaningfully with self-reported health measures. Moderate positive correlations with EQ-VAS and negative correlations with maximum pain trajectories support the index's validity. Sensitivity analyses confirmed that the model responds predictably to changes in input qualifiers, with recent measurements exerting greater influence. The model also proved robust to missing data, successfully computing health indices across varying levels of data completeness. Furthermore, the impact of time decay and qualifier weighting parameters was systematically explored, revealing optimal configurations that enhance correlation strength.

From the existing research discussed in "Prior Work," it is evident that the assessment of overall health status and the computation of health indices have followed varied approaches, using a diverse set of variables. Our approach to computing the health index and health profile is quite different from the methodologies discussed there. Below, we highlight significant divergences and commonalities between past methodologies and our approach.

First, our proposed model exhibits a generic nature: it does not assume a predetermined set of variables for utilization. Instead, the model is based on the established ICF framework, enabling its adaptability to any dataset encoded in the ICF-compatible format. However, to ensure the derived health index comprehensively reflects overall health status, the set of ICF codes—forming the foundation of computation—should evidently encompass all aspects relevant to determining the health of the individual. This selection of ICF codes may vary individually; for instance, collecting specific information on low back pain might not contribute substantially if the individual does not experience this condition. Nevertheless, our proposed model maintains the capability to compute the health index across a spectrum, ranging from scenarios with very sparse data (where only one ICF code is available, for instance) to the theoretical extreme where all ICF codes are accessible. Deriving the health index from diverse datasets offers a unique advantage. However, this can potentially become a drawback if the characteristics of the data are not incorporated into the interpretation of the results. Visual inspection of the health index and health profile, along with information on how much data has been collected (called *coverage*), as exemplified in Figure 10, can aid in this process.

Figure 10. Preliminary graphical presentation of an individual's health index and health profile. A high-level view is shown in panel A, while panel B explores the health profile further in one of the components. In panel A, the overall health index, exemplified here as 82%, is displayed at the top. Additionally, the 4 main components of the International Classification of Functioning, Disability and Health are presented. These components constitute a basic-level health profile. Panel B provides a more detailed view into the body structures component, showcasing the chapter-level values and their respective coverages.

XSL•FO
RenderX

Furthermore, it is essential to highlight here that we do not prescribe any specific ICF sets for application; our preliminary validation using collected data represents just one potential usage. Notably, extensive research exists that defines ICF core sets outlining fundamental ICF codes crucial for various aspects related to functioning, disability, and health. For example, Cieza et al [34] defined a minimal generic set of domains for describing functioning and health for adults. Additionally, more specific core sets have been introduced, eg, for chronic conditions [35], including low back pain, diabetes mellitus, obesity, depression, and others.

Second, our proposed model operates independently from existing data—meaning that it does not rely on training data, coefficients, or predefined major model parameters. Instead, its core parameters stem directly from the hierarchical structure of the ICF, acting as weightings for different levels within this structure. Thus, one can compute the health index for an individual if there is some ICF-coded data available for that person. Moreover, the health index computed for an individual remains entirely distinct and unaffected by the health indices of others. In this aspect, our approach shares similarities with simpler summation-based methods (see, eg, [12-14]).

It is important to note the absence of a definitive *ground truth* for overall health status—there exists no singular, reliable response variable that could serve as a benchmark for validating any health index. In one study using ML [22], cause of death for specific diseases was used as the ground truth. Notably, our approach refrains from using ML elements, in part due to the absence of a definitive response variable for overall health. Furthermore, our aim does not involve predicting risks for specific diseases; instead, the model focuses on providing a concise estimation of health status. We argue that our model enables, through the use of ICF, a more holistic view on health, since by the WHO definition health is “not merely the absence of disease and infirmity,” but “is a state of complete physical, mental and social well-being” [36]. Moreover, aspects such as daily life activities, mental health, and social interactions best encapsulate most people’s intuitive notion of health [34,36], all of which the ICF is adept at capturing.

Finally, our proposed model is designed to handle the longitudinal aspect of infrequent health records and missing data fluently. These are important characteristics of health data [37]. However, only 2 studies (see [22,23]) considered these problems in their approaches. Nonetheless, we argue that our proposed methodology stands out for its simplicity and use of the inherent hierarchy within the ICF framework. Our model operates without expecting identical variables for different individuals. As the only prerequisite is to have the data in the ICF-compatible format, in fact, the whole concept of missing data is eliminated from the model’s perspective. Each individual’s data are processed independently, rendering the model robust against common health data problems. Consequently, the model generates output for any dataset meeting minimal requirements. Our objective is to give precedence to recent qualifiers in the computation of the health index, while still considering past qualifiers to a certain extent. This approach not only ensures a comprehensive view of the individual’s health status but also allows both experts and individuals to track the progression of various health-related trajectories over time.

Overall, existing research aligns with several aspects of our study objectives, notably in acknowledging disparities in data across various countries [15] and addressing challenges related to sparse, infrequent data with missing values [22]. However, existing health indices and profiles in previous studies primarily rely on predefined attributes for computing the final health index.

Limitations

The ICF framework empowers its users to delineate the health and functioning of an individual in a highly detailed manner, beyond the first generic qualifier. In the *body structures* construct, the second qualifier can be used to indicate the nature of the change in the respective body structure, whereas the third qualifier specifies the location, for instance, left or right [4,38]. Moreover, in the *activities and participation* construct, the second generic qualifier (capacity) is used to denote limitations without assistance [4]. The proposed model, however, uses only the first generic qualifier, thereby not leveraging any additional information potentially provided by these other qualifiers.

In the context of the ICF’s *environmental factors* construct, the first qualifier can be used to signify either the positive effects (facilitators) or the negative effects (barriers) of the environment [4]. The current model is only equipped to handle barriers; hence, the potential positive impact of possible facilitators on the health index is not incorporated into the proposed model.

Qualifiers 8 (*not specified*) and 9 (*not applicable*) are not accommodated by the proposed model. At present, the values are treated as ordinal, and these nominal values cannot be used. This limitation might lead to a loss of some information, as these qualifiers are used in the ICF system to record information that cannot be captured using the [0,4] value range. Qualifier 8 should be applied when there is a problem, but the severity of that problem is unknown. Additionally, qualifier 9 is typically used in a situation when the use of the category is not appropriate for the individual [38]. These qualifiers have also been used in practical applications [39].

Taken together, these constraints mean that the current implementation captures only a portion of the information the ICF framework can offer. Expanding the model to incorporate additional qualifiers and environmental facilitators would allow it to reflect a broader range of clinically relevant information while keeping the computational framework unchanged.

A potential limitation concerning the practical usability of the model is that sparse data might provide a misleading impression about a person’s overall health. However, a basic data coverage metric can be used to assess the comprehensiveness of the data used and thereby also the reliability of the index outcome. Enhancing the coverage metric is also a key area for future improvements. The total coverage value could potentially be defined as a fraction representing the number of chapter-level codes that have associated measurements. To achieve a complete coverage of 100%, there would need to be a minimum of one measurement under each chapter-level code within the *body structures* component’s *s1* to *s8*, as well as all other chapter-level

XSL•FO
RenderX

codes across the remaining 3 main components. In addition, as the ICF does not currently contain the classification of the personal factors, such as an individual's age, they cannot be used in the current computation process. Moreover, the inclusion of personal factors has been identified as relevant and useful for the application of the ICF in different settings [40].

The dataset used for the preliminary validation of the health index is admittedly suboptimal, lacking the ability to encapsulate certain elements that define functioning. This study does not explicitly endorse the use of this particular set of ICF-coded data. Instead, we advocate for the use of datasets that offer a more comprehensive representation of all facets encompassed in the ICF for future applications. The existing ICF core sets can serve as a potential foundation for identifying the essential data required to collect for each specific condition. One possible solution would be to collect data that adheres to at least the minimal generic set proposed by Cieza et al [34], ensuring a baseline level of coverage across applications. An additional limitation in the preliminary validation dataset is that several variables were linked to ICF codes using expert-derived rather than formally validated linkages. Although these are downweighted using the linkage reliability parameter, formally validated linkages would further strengthen the results. The methodological framework itself is unaffected, but future applications may benefit from datasets where validated linkages are available. Incorporating formally validated or multirater ICF-linking procedures would improve reliability and external validity.

Another minor concern regarding the validation process is the current lack of differentiation between individuals under the age of 18 years and adults. The few individuals under 18 are incorporated into the larger group without any distinct consideration.

Conclusions

We assert that the ICF framework is a solid foundation for developing a health index. As a globally recognized and standardized classification system, it provides a common language and conceptual basis for describing comprehensively factors influencing an individual's health and functioning. Since its inception, the ICF has found extensive application in a variety of fields. These include, but are not limited to, clinical practice, policy formulation, social policy, and educational sectors [41]. Furthermore, it has become an indispensable tool in population health research projects worldwide [42].

An added advantage of the ICF is its compatibility with various questionnaires used to assess treatment response. These questionnaires have been linked to ICF codes, enabling the conversion of questionnaire responses into ICF code qualifiers. Many of these linkages have been scientifically validated, and comprehensive guides are available to establish new linkages for emerging datasets [28,38].

The proposed methodology consolidates information from various heterogeneous international sources, including interviews or anamnesis, validated questionnaires, physical tests, cognitive tests, etc, into a single, easily accessible location. This compatibility and consolidation process is crucial for advancing AI solutions. The training of ML algorithms requires identical variables from all individuals analyzed. Without dataset homogenization, only subsets of individuals and/or variables can be analyzed concurrently, reducing the predictive power of the trained models.

A single numerical value can be a useful tool for visualizing the individual's condition before and after treatment and for tracking rehabilitation progress. However, to provide a more comprehensive view of an individual's situation, we also aim to delve into the main categories at a more detailed level, rather than inferring a person's functional capacity solely based on a single numerical value. Consequently, our proposed method is adaptable for computing a health profile. Within the ICF context, a basic health profile would likely include separate scores for each of the 4 ICF components: *body functions*, *body structures*, *activities and participation*, and *environmental factors*. These components can be further expanded for a more detailed examination of the elements within each category, providing comprehensive information about the individual.

Our goal is to make the health index and health profile highly illustrative, catering to both professionals and individuals undergoing treatment. If extensive data are recorded for an individual in the ICF, it can be challenging to assess and quickly understand the individual's situation. The health index and health profile of an individual can also be presented visually, as shown in Figure 10, providing a concise overview of the individual's condition.

Such visualizations can be integrated into electronic health records (EHRs) or patient portals, allowing both clinicians and patients to engage with the data. For clinicians, this supports efficient triage and treatment planning; for patients, it enhances understanding and motivation by making health status tangible and actionable. As the index is based on ICF codes, it can be integrated into existing EHR systems and used across institutions and countries, supporting interoperability and standardized health assessment.

The health profile allows for a deeper evaluation of specific domains of functioning, which can be particularly motivating by highlighting areas of improvement and those requiring attention. Previously, extracting and presenting such information was labor-intensive and often difficult for patients to interpret. The proposed model simplifies this process and improves accessibility. Additionally, a data coverage metric can help assess the completeness of the health profile, guiding clinicians in identifying gaps in assessment. In Figure 10, coverage is visually represented using transparency: low transparency indicates high data availability, while high transparency signals limited coverage. This visual cue supports informed decision-making and encourages targeted data collection to improve the reliability of the health index.

In current clinical practice, not all potential ICF subcategories are used. However, we continue to strive for a holistic understanding of an individual's functional capacity. This is achieved through a combination of questionnaires, interviews, and tests, allowing us to gather extensive information, even if some ICF subcategories remain unfilled. For instance, when data from specific areas such as strength tests are entered into

XSL•FO
RenderX

the system, it automatically assigns the appropriate ICF codes based on the results. Our proposed health index framework serves as a tool to standardize this process, thereby improving the efficiency and consistency of data collection and analysis in clinical settings.

Future Work

Our ongoing efforts to enhance the index involve addressing the existing limitations outlined earlier. Specifically, we aim to improve the support for qualifiers beyond the initial qualifier and implement mechanisms to alert index users about insufficient data. Additionally, a step forward would be conducting a clinical validation of the index. Whereas the statistical analysis presented in this study provides an initial glimpse into the index's functionality, a comprehensive clinical assessment will be needed to validate its practical utility.

A concrete example of the index usage is in the field of rehabilitation, where an iterative cycle based on the ICF, known as the Rehab-Cycle, has been developed for streamlined rehabilitation management [43]. This cycle describes different phases of rehabilitation: assessment, assignment, intervention, and evaluation. The use of the health index facilitates the generation of a compact numerical measure for both the preintervention assessment and postintervention evaluation in clinical practice. Furthermore, this index can assist in enhancing resource allocation and selecting appropriate interventions during the assignment and intervention phases. As a result, it allows for a more thorough evaluation of rehabilitation effectiveness and enables comparisons across various countries and rehabilitation methodologies.

Beyond rehabilitation, the health index has potential applications in broader clinical contexts. In primary care, it could support routine health assessments by providing a standardized snapshot of patient functioning. In geriatrics, it may help monitor age-related decline and guide interventions for healthy aging. Although intrinsic capacity (IC) was not directly assessed in this study, our approach aligns closely with the IC framework, and future work may explore how the proposed health index could support IC-oriented monitoring and proactive care models as outlined in recent WHO digital health initiatives. In mental health, the index could be used to track functional outcomes and support personalized treatment planning. Integration into EHRs or patient-facing platforms could enable real-time monitoring, enhance clinician-patient communication, and support shared decision-making.

With the prospective incorporation of ML techniques, the health index or health profile scores could serve as optimization targets within predictive models. This strategy allows for a comprehensive improvement of an individual's health, rather than concentrating on a single health parameter. For instance, it could assist in determining the optimal rehabilitation pathway or treatment strategy for an individual. Additionally, the standardized nature of the index supports cross-institutional and international data harmonization, which is essential for scalable AI applications in health informatics.

Abstract

Background: The usability of electronic health records influences patient safety, clinical efficiency, and the sustainable digital transformation of health care. While tools such as the System Usability Scale exist, few are based on structured software quality models or align with local regulatory frameworks, particularly in low- and middle-income countries.

Objective: This study aims to develop and psychometrically validate an instrument to assess electronic health record usability, based on the ISO 25010 (International Organization for Standardization) quality model, and in accordance with the Peruvian Technical Health Standard (Norma Técnica de Salud [NTS]).

Methods: A 3-stage methodological study was conducted following COSMIN (Consensus-based Standards for the Selection of Health Measurement Instruments) guidelines. First, a 23-item instrument was developed, grouped into 7 usability dimensions based on ISO 25010. Second, content validity was assessed using a modified Delphi method with 10 experts, using Aiken's V coefficient. Third, structural validity and reliability were evaluated in 115 participants (physicians, nurses, and administrative staff) using confirmatory factor analysis and Cronbach α. Additionally, the module's functional compliance with the NTS was verified.

Results: The instrument demonstrated excellent psychometric properties among 115 participants (53 physicians, 48 nurses, and 14 administrative staff); high content validity (Aiken's V=0.95; 95% CI 0.84 - 0.98), excellent internal consistency (α=.968), and optimal factor fit (Comparative Fit Index=1.000; Tucker-Lewis Index=1.001). Overall usability was perceived as very high by 94 of 115 users (81.7%), and high by 21 of 115 users (18.3%), with no perceptions at lower levels. The module met 28 of 35 requirements (80%) of the Peruvian Technical Health Standard. Administrative staff reported higher satisfaction (13/14, 93% rated it as very high) compared with clinical professionals (81/101, 80% rated it as very high), particularly in the dimensions of error protection and operability.

Conclusions: This study provides the first fully psychometrically validated instrument in Spanish based on ISO 25010, System Usability Scale, and other theoretical foundations for evaluating the usability of information systems. The results highlight the importance of considering both international standards and local regulatory requirements (NTS) in the design of digital health systems. The instrument is applicable in Spanish-speaking contexts and can serve as a reference for future usability evaluations in the region as well as in low- and middle-income countries.

Introduction

Digitization and Usability in Electronic Health Record Systems

Electronic health record (EHR) systems have become essential tools for improving the quality of medical care, reducing errors, and optimizing clinical processes [1]. However, their effectiveness depends critically on their usability, particularly in high-workload health care settings such as Peru, where health care professionals face time and resource constraints [2]. From the patient's perspective, studies have also been conducted on EHRs, highlighting the physician's central role within the workflow. Evidence shows that physicians who use EHRs to exchange information with their patients, develop care plans, and provide other services tend to report higher satisfaction with computerized systems [3]. On the other hand, there are also studies revealing that the adoption of health information systems has led to medical errors attributed to technological failures, although there are certain perceptual discrepancies between clinical and information technology (IT) professionals regarding their causes. While IT experts attribute errors to technical failures such as poor interfaces and lack of training, physicians point to contextual and human factors such as workload, familiarity with new systems, and inadequate processes [4]; it is important to note that physicians work under very tight schedules and require IT tools that truly provide support; therefore, there are various challenges to be addressed in different parts of the world depending on culture, technological capacity, socioeconomic status, government policies, and other factors; thus, it remains a subject of study for various researchers [5-9].

Context of the Peruvian Health Care System

Similarly, Peru faces challenges; given that the existence of fragmented medical records or the inability to locate a medical record—even within the same Healthcare Service Provider Institution (Instituciones Prestadoras de Servicios de Salud [IPRESS])—creates problems of information fragmentation and wasted man-hours in human resources due to the need to repeatedly fill out a new medical record, which hinders the provision of comprehensive, quality health care due to the lack of important information from previous medical records; this same issue is mentioned in the Peruvian government's Technical Implementation Document for the National Registry of Electronic Medical Records (Registro Nacional de Historias Clínicas Electrónicas [RENHICE]) in section 6.3, which states the following: "In our country, almost all medical records are handwritten. If a patient visits an IPRESS for the first time, a new medical record is opened, which involves recording data (administrative and clinical) on forms that are part of the medical record. On the other hand, when the patient returns for a subsequent visit, the staff cannot locate their manual medical record (Historia Clínica Manual [HCM]); therefore, they must re-enter the data. Likewise, the procedure is repeated when a patient changes their address, changes IPRESS facilities, or is located anywhere else in the country. Currently, a patient has as many medical records as the number of IPRESS facilities they have visited, and they may have more than one record at the same IPRESS facility. In response to this problem, the government has established the Technical Health Standard (Norma Técnica de Salud [NTS]) for Medical Record Management; however, this cannot be resolved without an adequate computer system to assist in managing medical records within a specific IPRESS—a system that can be adapted to the institution's specific needs while adhering to the Peruvian government's NTS, given that it applies to all IPRESSes, whether public, private, or mixed.

Regulatory Framework: NTS and the Need for Regulatory Alignment

Therefore, there is a need for a Clinical Record Management Information System that incorporates the criteria or considerations of the National Technical Standard (NTS) for Clinical Record Management; this system must meet usability criteria so that users are satisfied when using this tool. According to [10], the ease of use of a system can reduce errors, thereby contributing to efficiency and allowing physicians to spend more time with patients; hence the importance of evaluating usability, since studies cited in the research indicate that physicians experience usability issues, particularly when working with EHRs, which result in lengthy training periods and lost productivity. It is worth noting that usability could mean the difference between life and death; furthermore, it is argued that usability issues arise in medical devices, procedures, and even diagnostic tools; therefore, there is a need to conduct a study on the evaluation of the impact of NTS on the implementation of the Clinical Records Module in relation to its usability.

Usability Gaps and Human Factors in EHRs

According to studies, what is now known as electronic medical records (EMR) has been in use since the 1980s, primarily in developed countries. Subsequent studies were conducted on their use, as it was perceived that physicians were resistant to change; consequently, it was observed that physicians adopt the use of these systems once they perceive their utility for their patients; thus, it was concluded that the key lies in ensuring that the software tools are easy to use and highly beneficial for the medical team [11]. The evaluation of EMR management tools is almost continuous, as it positively or negatively affects the care provided to patients by physicians. Therefore, they report having surveyed users—primarily physicians and nurses who interact directly with the tool in question—and found that while the tool facilitates greater data capture, it also impacts medical staff time, as they spend more time at the computer, which in some ways reduces the time available for patient care; consequently, they concluded that the tool has minimal impact on patient care. On the other hand, they showed minimal satisfaction with the tool; however, there was resistance to returning to handwritten records [12]. Another study also notes a minimal impact from the implementation of EMR systems, and the implementation of EMR management software in health care facilities is increasingly widespread [13].

Cultural diversity, economic conditions, and other factors influence the adoption of technological alternatives; therefore, it is recommended to have a plan that coordinates the entire EMR implementation process, considering the current

XSL•FO
RenderX

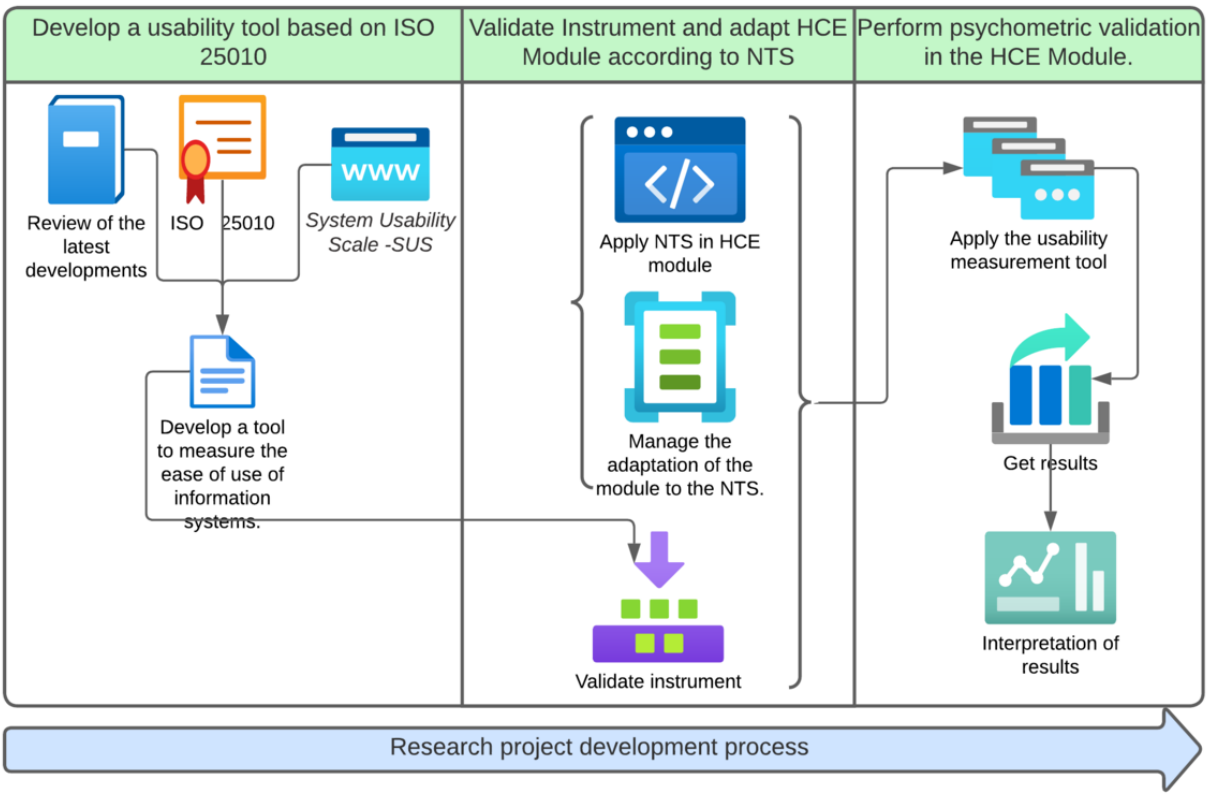
organizational context, given that some countries face challenges, particularly those that are underdeveloped or developing [14]. This implies restructuring the curricula for training health care professionals, as well as providing EMR training to all staff at the institution [15]. On the other hand, studies are also being conducted on the impact of the EHR on patients by allowing them access to their records, thereby enhancing safety in medication management and providing greater control over medication [16].

The need for EHR management platforms in the health care systems of various countries is critical, as, despite the challenges, they are cost-effective to maintain because they enable faster searches, reducing the time and cost of locating patient records; consequently, they are being widely adopted worldwide [17]. These platforms can be classified into several types, such as government, commercial, organizational, or multi-organizational; however, it is important to highlight certain key characteristics they must meet, such as data interoperability, displaying the appropriate level of detail in information, and compliance with health care privacy regulations; the aforementioned aspects still pose a challenge in terms of compliance [18].

The transition to the EHR has been a fundamental advancement in the medical field, as it allows for the consolidation of clinical information, improves evidence-based decision-making, enhances access to information, and facilitates multidisciplinary collaboration. However, the implementation of EHRs has revealed significant challenges regarding efficiency, reliability, and the potential increase in medical-legal risk; that is, it is not a perfect solution; as medical malpractice lawsuits involving EHRs highlight documentation errors caused by various factors such as information fragmentation, access failures during system outages, issues with electronic data transfer, ineffective alerts, and a lack of integration among hospital systems (interoperability); which can compromise patient care and expose providers to legal liability. Therefore, the correct completion of documentation in the EHR is of utmost importance; errors in data entry generally occur due to the use of prefilled templates or the copying of unverified data; this necessitates continuous improvement of EHR systems to optimize their functionality, as well as the establishment of protocols to ensure that records are complete, accurate, and faithfully reflect the clinical assessment. In this way, it ensures that EHR platforms are not merely tools for storing information, but rather a comprehensive system supporting medical care that considers medical-legal aspects and patient safety [19]; hence the importance of EHR systems adhering to health sector regulations. It is also worth noting that there is a study evaluating the suitability of EHR data using a framework called ISPOR (International Society for Pharmacoeconomics and Outcomes Research) to ensure the relevance and validity of the information generated by EHRs; this framework includes 2 components: data delineation and data suitability for the purpose; each component involves a series of checklists [20].

Apart from the challenges mentioned above, interoperability is a critical factor for the success of health information systems, as it enables the secure and efficient exchange of patient data among different health care providers; however, there are many challenges with the integration and the automatic and secure exchange of information among the various EHR health care systems [21]. Consequently, organizations often face challenges in achieving successful technology implementation; therefore, it is of vital importance to conduct a comprehensive analysis of the opinions of internal and external users regarding EHR software decisions; this can help improve and optimize EHR information systems and reduce technology acceptance gaps [22].

The objective of this research was to design and psychometrically validate a usability evaluation instrument based on the ISO/IEC 25010 (International Organization for Standardization/International Electrotechnical Commission) standard for EHR systems in the Peruvian context. Specifically, the study sought to: (1) integrate the usability dimensions of ISO 25010 with the System Usability Scale (SUS) and other relevant theoretical foundations, constructing a comprehensive instrument in Spanish; (2) validate the instrument through expert judgment using Aiken's V coefficient and confirm its psychometric properties through confirmatory factor analysis (CFA) and reliability analysis; and (3) evaluate the usability of an EHR module implemented in accordance with the Peruvian NTS, identifying the degree of regulatory compliance and differences in the perception of usability among different types of health care professionals (physicians, nurses, and administrative staff). This study aims to fill the gap identified in the literature regarding the lack of standardized instruments in Spanish, with psychometric validations that integrate international quality standards with local health sector regulations, providing a validated tool that can be replicated in similar contexts in Latin America, such as in low- and middle-income countries.



Methods

Study Design

This study followed a 3-stage sequential instrument development and validation methodology, aligned with the COSMIN (Consensus-based Standards for the Selection of Health Measurement Instruments) guidelines for psychometric studies in health. The first stage (theoretical development) integrated the usability attributes of ISO 25010, SUS, and other theoretical foundations on usability. The second stage (content validation) used the modified Delphi method with 10 experts, in addition to aligning the functionality of the electronic health record (Historia Clínica Electrónica [HCE]) module with the functional requirements of the Peruvian Technical Health Standard (NTS), while the third stage (structural validation and reliability) included the application of the instrument to 115 end users; this process is shown in Figure 1.

XSL•FO
RenderX

Figure 1. Research development methodology. HCE: Electronic Health Record (Historia Clínica Electrónica); ISO: International Organization for Standardization; NTS: Norma Técnica de Salud (Technical Health Standard); SUS: System Usability Scale.

Participation and Context

For content validation, a total of 10 experts were deliberately recruited, distributed as follows: 5 specialists in areas related to software development, 3 researchers with experience in systems evaluation, and 2 professionals from the health care sector. This selection aimed to incorporate the usability quality attribute, in accordance with the guidelines established in the ISO/IEC 25010 standard and the SUS questionnaire. This methodological approach has been previously used in similar studies [23,24].

For structural validation and reliability (psychometric), the study obtained an institutional authorization letter and involved 115 workers from a hospital network in the Puno region, distributed across the following professional categories: physicians (53/115, 46%), nurses (48/115, 42%), and administrative staff (14/115, 12%), all with at least 6 months of experience using the EHR module. The sample size was determined in accordance with the recommendation of 5 participants per item of the instrument (23 items → n=115), meeting the methodological criteria required for the application of CFA.

Likewise, it should be noted that ISO/IEC 25010:2011, which replaces the previous ISO/IEC 9126-1:2001, defines 2 models: a quality-in-use model and a product quality model, each with its corresponding characteristics. Regarding the in-use quality model, the aim is to quantify the “usability” of the application strictly related to the end user of the product [25].

Development of the Instrument

The initial questionnaire consisted of 23 items organized into 7 dimensions, which were based on the quality model of the ISO/IEC 25010 standard: (1) functional adequacy, (2) learnability, (3) operability, (4) protection against user errors, (5) esthetic presentation, (6) accessibility [26], and (7) user satisfaction. Theoretical support regarding instruments and techniques for measuring “usability” was sought, and the decision was made to develop a Spanish-language instrument based on ISO/IEC 25010:2011 and supported by the SUS and other instruments addressing the subject in question. Subsequently, the modified Delphi technique [27,28] was followed, since the traditional technique was not strictly adhered to; however, given the nature of an instrument already theoretically grounded, supported by a review of the state of the art, at least 2 rounds were necessary to obtain adequate feedback from 10 expert judges who were selected as described in the previous subsection.

Content Validity

The experts evaluated each item based on 3 criteria (relevance, appropriateness, and clarity) using a 5-point Likert scale (where 1 represents the minimum value and 5 represents the maximum value). The results were analyzed using Aiken’s V coefficient, with values ≥0.80 considered acceptable. All items exceeded this threshold (average V=0.95), although some items regarding accessibility required reformulation after the first round of evaluation. The Delphi process was concluded after 2 rounds

XSL•FO
RenderX

upon reaching stability in the responses (change <5% between rounds).

Likewise, during this stage, improvements were made to the EMRs module, prioritizing compliance with the Peruvian State Technical Health Standard; a compliance schedule was developed for task management; and finally, a checklist was created comparing the requirements outlined in the NTS with the functionalities included in the EHR module to assess the level or degree of implementation of the requirements within the module; Subsequently, functional tests were conducted prior to the system going live and its subsequent use by system users, such as doctors, nurses, and professionals from other areas.

Structural Validity and Reliability

Data Collection

The usability instrument was administered virtually via Google Forms, in accordance with the recommendations of the CHERRIES checklist for electronic survey reporting [29]. Participation was voluntary, and informed consent was obtained digitally prior to the survey. The survey was disseminated internally to health care professionals within the hospital network and administrative staff through corporate communication channels. No monetary incentives were provided. The survey consisted of 23 mandatory questions, and incomplete surveys were excluded. To prevent multiple submissions, controlled distribution through institutional corporate channels served as a restriction mechanism. Email addresses were not collected, nor were IP addresses logged, to maintain participant anonymity. A total of 115 complete responses were included in the final analysis. The response rate could not be calculated due to the institutional distribution methods. Data were exported directly from Google Forms to a secure database and analyzed using Jamovi software.

Statistical Analysis

The instrument was administered via an electronic form (Google Forms) during October-November 2024. The data were analyzed using Jamovi 2.3.28 [30]. Finally, construct validity and reliability were assessed using Cronbach α and CFA [31,32]; the latter was conducted following the standard recommendation of using between 5 and 10 participants per item or at least 100 participants [33]. In this study, we opted for 5 participants per item for CFA, given that the study population met this requirement at the facility where the case study was conducted.

Ethical Considerations

This study was not subject to full review by the ethics committee, as it meets the requirements for exemption under applicable Peruvian national regulations. Specifically, according to Ministerial Resolution No. 233-2020-MINSA, which approves the “Ethical Considerations for Health Research Involving Human Subjects” issued by the Peruvian Ministry of Health (Ministerio de Salud [MINSA]), survey-based studies that are anonymous and noninterventional are classified as low-risk or risk-free and, therefore, do not require full approval by the ethics committee. Furthermore, the study complied with Peru’s Law No. 29733 (Personal Data Protection Law) and its Regulatory Decree D.S. No. 003-2013-JUS, which guarantees the confidentiality and anonymity of participants’ data. Likewise, prior to data collection, written institutional authorization was obtained from the American Clinic of Juliaca (January 18, 2024). Informed consent was also included directly in the web-based survey instrument. Participants were informed that their responses would be collected anonymously and used exclusively for research purposes, and that their continued participation constituted implied consent. We confirm that this study falls under category (2): it was not submitted for ethical review, as it met the exemption criteria due to its anonymous, noninterventional, and survey-based nature, in accordance with the aforementioned national policy. Participants did not receive any financial or other compensation for their participation in this study.

Results

Instrument Developed

Following a review of the state of the art and validation by expert judges in 2 rounds, the Spanish-language instrument based on ISO 25010 was validated, as shown in Multimedia Appendix 1 [34-41].

Content Validity Results

This instrument was the result of an evaluation by 10 expert judges who assigned a rating on a scale of 1 to 5, where 1 represents the minimum value, and 5 represents the maximum value; these results were processed using Aiken’s V statistic to assess the content validity of the aforementioned instrument with a 95% confidence level, corresponding to 1.96.

In accordance with the previous paragraph, favorable results were obtained, with the average Aiken’s V coefficient yielding a value of 0.95, indicating that the instrument has very good content validity; these results can be verified item by item in Multimedia Appendix 2, where the mean score is 4.8 and the SD is 0.37; the lower confidence interval limit is 0.84 and the upper confidence interval limit is 0.98; these results are consequently positive for the proposed instrument, which is intended to evaluate the usability of a computer tool.

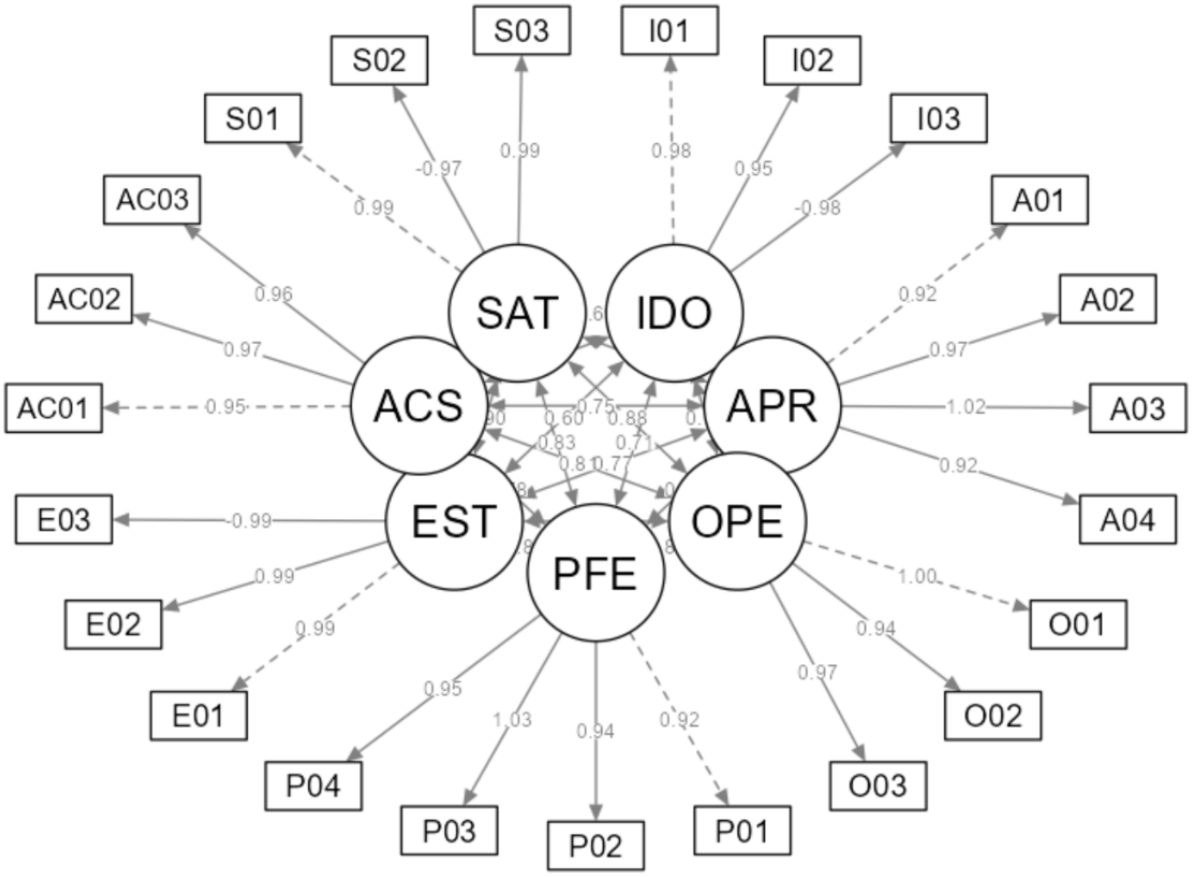
Similarly, the Aiken V results were grouped by dimension, and these also showed favorable results, with the lowest score in the accessibility dimension (an average of 0.93) and the highest score in the operability dimension (an average of 0.97), as shown in Table 1.

XSL•FO
RenderX

Table . Aiken V results by dimension.

Dimension	Recognition of suitability	Learnability	Operability	User error protection	User interface aesthetics	Accessibility	Satisfaction	General
Relevance	0.958	0.931	0.983	0.96	0.93	0.93	0.95	0.949
Relevance	0.967	0.938	0.958	0.94	0.95	0.94	0.94	0.948
Clarity	0.950	0.969	0.975	0.97	0.95	0.93	0.95	0.957
TOTAL	0.958	0.946	0.972	0.956	0.944	0.933	0.947	0.951

Additionally, the medical records module has been adapted to meet the requirements of the Peruvian State Technical Health Standard (NTS); first, a list of requirements based on the NTS was compiled; subsequently, the corresponding adjustments were made to the EHR module; this was managed through a task schedule; and finally, a checklist was created comparing the requirements implemented according to the NTS with the functionalities of the module in question; resulting in an 80% implementation of the requirements, with 20% remaining pending based on the total number of requirements; these were classified according to the following options: YES (Implemented), NO (Not Implemented), and Partial (Partially Implemented), with scores of 1, 0, and 0.5, respectively. The aforementioned results can be found in Multimedia Appendix 3.



Psychometric Evaluation Results

The results of the pilot usability evaluation study with the developed instrument allowed for CFA, a statistical technique used to verify that the data from a model fit a predefined theoretical structure. Jamovi was used as the statistical analysis tool, yielding favorable results for the instrument in question: the CFI (Comparative Fit Index) has a value of 1, which measures model fit, and the scaled value is 0.994, indicating a perfect fit and a very good fit, respectively; likewise, the Tucker-Lewis Index has a value of 1.001 and the scaling of 0.993, which shows an excellent fit in both cases; similarly, this is the case for the Bentler-Bonett Norm-Normed Fit Index, where the model is 1.001 and the scaled value is 0.993, both indicating an excellent fit and a very robust model; on the other hand, the Relative Noncentrality Index measures relative noncentrality fit; the result for the model is 1.001 and the scaled value is 0.994, both of which also suggest an excellent fit; As for the NFI (Bentler-Bonett Normed Fit Index), which compares the model to the null model, the values are favorable, with the model at 0.997 and the scaled value at 0.980, indicating a base model with an excellent fit; Regarding the Bollen's Relative Fit Index, the model corresponds to 0.997 and the scaled value to 0.976, similarly indicating a good fit; these results can also be observed in Multimedia Appendix 4.

The results of the proposed usability measurement instrument model align with the predefined theoretical construct, as can also be seen in Figure 2.

XSL•FO
RenderX

Figure 2. Usability evaluation model. ACS: Accesibilidad (Accessibility); APR: Aprendizabilidad (Learnability); EST: Estética (Esthetics); IDO: Idoneidad (Appropriateness); OPE: Operatividad (Operability); PFE: Protección Frente a Errores (Error Protection); SAT: Satisfacción (Satisfaction).

Additionally, the instrument's reliability was calculated using Cronbach α based on the results, yielding a value of .968, as shown in the results processed by Jamovi (Multimedia Appendix 5). This demonstrates high internal consistency and a high correlation among the items in the measurement of the construct.

Finally, the results of applying the instrument developed in accordance with ISO 25010 were obtained; for this purpose, the same principles proposed by John Brook in the development of the scales were considered to subsequently generate the results by dimension and in general. Although there are several techniques for processing SUS results [42], it was deemed appropriate to work with the rating scale technique, given that most existing instruments in other areas use the rating scale technique; therefore, the score ranges shown in Table 2 were considered to obtain the results.

Table . Scales for evaluating usability and its dimensions.

Dimension	Very low	Low	Moderate	High	Very high
Recognition of suitability (3-15)	3 - 5	6 - 8	9 - 11	12 - 13	14 - 15
Learnability (4-20)	4 - 7	8 - 11	12 - 14	15 - 17	18 - 20
Operability (3-15)	3 - 5	6 - 8	9 - 11	12 - 13	14 - 15

Based on the above rating scale table, the following descriptive statistics were obtained regarding the results for each dimension of the Usability Factor assessment tool for computer products, as shown in Multimedia Appendix 6.

Regarding the overall usability factor score based on the developed instrument, the following descriptive statistics were obtained: mean 4.82, median 5, mode 5.00, sum 554, SD 0.388, IQR 0.00, minimum 4, and maximum 5. These results indicate a high overall usability factor score.

Referring to the frequency table of the overall result, it can be seen that 81.7% of users perceive usability to be very high, and 18.3% of users perceive it to be high, thus demonstrating that the EHRs Module used by the institution in the case study meets the usability criteria for a software product, as shown in Table 3.

However, descriptive differences were found in usability scores among professional groups, with administrative staff obtaining slightly higher scores than clinical staff, as shown in Multimedia Appendix 7. No inferential statistical comparisons were performed.

Table . Frequency of the usability factor.

Usability	Counts	Percentage of total (%)	Cumulative percentage (%)
High	21	18.3	18.3
Very high	94	81.7	100.0

Discussion

Main Findings

This study successfully developed and validated a usability evaluation instrument based on ISO 25010 with excellent psychometric properties (Aiken's V=0.95, Cronbach α=0.968, CFI=1.000). Application of the instrument revealed that 94 of 115 users (81.7%) perceived the usability of the EHR module as very high, while the module met 28 of 35 requirements established by the Peruvian NTS (80%). Descriptive differences in usability perception were identified between clinical and administrative professionals. Highlighting three main findings: (1) Good results in psychometric properties, (2) positive perception of usability with slight differences between professional areas, and finally, partial compliance with the Peruvian NTS.

Beyond local application, this work supports the global conversation on the digital transformation of health care. The World Health Organization's Digital Health Strategy highlights the need for contextualized evaluation frameworks to ensure that digital health systems are safe, effective, and people-centered. In this vein, usability is not merely a software feature but a factor that influences clinical performance, patient safety, and professional well-being. Poor usability of RHRs has been linked globally to increased cognitive load, documentation burden, and burnout among clinical staff. By combining the usability criteria of the ISO 25010 standard with local regulatory compliance requirements, this work proposes a framework to evaluate not only the system's functionality but also the alignment between technological design and actual clinical workflows. However, most validated usability tools have been developed in high-income contexts and may not fully represent the sociotechnical realities of low- and middle-income countries, where infrastructure limitations, fragmented medical records, and evolving regulatory frameworks pose unique challenges. This instrument addresses this gap by operationalizing usability within a dual framework: international quality standards and national health regulations. This approach transforms usability scores into policy-driven digital health governance, making usability evaluation a tool for strengthening the health system, rather than merely a postimplementation metric.

Comparison With Other Research

Following a systematic review, similar studies have been identified in European countries; these place significant emphasis on measuring the acceptance of hospital HIS (Hospital Information Systems) [43] through models such as the technology acceptance model and unified theory of acceptance and use of technology, where nurses are the users with the highest ratings and training is identified as one of the determining factors. On the other hand [44], a study reveals that both the technology acceptance model and unified theory of acceptance and use of technology remain valid models for predicting the acceptance of HIS by health care professionals in hospital settings. Likewise [45-47], provided qualitative and mixed methods evidence regarding the perceptions of internal users regarding HIS in European hospitals. Meanwhile, in the Latin American context, there is a scarcity of studies related to the usability or acceptance of hospital HIS; likewise [48,49], confirm that, in general, there is significantly less scientific output in digital health due to structural reasons, given that scientific output is concentrated more in high-income countries [50,51]; therefore, after an exhaustive search, only 2 studies [52,53] were identified that were closest to implementation in the Latin American context; one was implemented in Mexico and the other in Brazil; neither evaluated acceptance factors. However, a meta-analysis study [54] conducted across multiple international contexts on professional burnout related to the use of EHRs indicates that insufficient acceptance of the system has negative consequences for the well-being of health care personnel. Hence the importance of evaluating internal users' acceptance of hospital information systems, as was done in this study; where the perceived level of the MHC's (Módulo de Historias Clínicas [Medical Records Module]) usability is very high at 81.7% and high at 18.3%; whereas in other studies [55] relatively related to usability evaluation, results were higher than those obtained in this study, with a score of 83.1; however, a direct comparison is not possible since the calculation method in this study is based on percentages, whereas the cited study on OpenEDC evaluation uses numerical scores; the cited study

XSL•FO
RenderX

involved 16 users, while our case study had a population of 115 users.

On the other hand, there is also another study [56] related to metadata management that evaluates the usability of a metadata repository called CoMetaR; 12 individuals participated in the study, in which 3 modules were evaluated, obtaining scores of 81, 81, and 72, respectively. For this, they used the SUS, which is one of the most widely used instruments for usability evaluation.

Regarding the subject of the study [57], the authors report that they conducted a systematic review in which they observed, across several primary studies, the existence of technical and social challenges in achieving quality in health information systems; according to the studies examined, various tools were used to assess software quality, including SUS, After-Scenario Questionnaire, and Nielsen's heuristics, among others; however, only 3 out of 17 studies included the processes of ISO/IEC 25010 and ISO 9126; thus, they noted that there is no precise description of how to translate these standards into practice; that is, there is a lack of success stories, case studies, and other materials describing lessons learned regarding the application of quality standards. In line with the statements of the cited authors, this study addressed the development of a usability evaluation scale based on ISO 25010 to serve as a reference for future work related to the quality of software products.

In another systematic review [58] regarding the evaluation of usability in telemedicine tools, the authors found that many studies did not use standardized instruments, which hindered an adequate description of the usability of telemedicine tools; although it is reported that most of the studies included in the systematic review demonstrate good usability, this is not specified in percentage or numerical terms, which would allow for comparisons or the identification of improvements; on the other hand, they also note that most studies use patients as the study population for usability and very rarely internal users; even here, the situation differs in the European context or in high-income countries compared with Latin American countries such as Peru. In line with these findings and in contrast to them, this study evaluated the usability of the MHC among internal users using a validated instrument based on ISO 25010, presenting statistical data on content validity, reliability, and CFA (structural validity) to serve as a foundation for future research.

Likewise, another systematic review study [59] on usability evaluation in mobile apps for physical rehabilitation reports that there are a variety of approaches and instruments for such evaluation; that many of them lack a theoretical foundation and psychometric properties regarding usability evaluation instruments; given that they found a large number of custom-developed instruments, such as hybrid instruments or those adapted from existing ones, the latter being limited by sample size, which impairs their validity; this highlights the need for alternative approaches to increase flexibility while ensuring the psychometric properties of the instruments; on the other hand, regarding the theoretical foundation of usability, they found gaps in the connection with theoretical usability models such as the ISO standards or similar ones; in contrast to the gaps perceived and reported in systematic review research studies. This research study has sought to address the reported gaps by developing an evaluation instrument based on ISO 25010, while also incorporating its corresponding psychometric properties, although it has limitations regarding cross-cultural validity that could be addressed in future studies.

It has been observed that most systematic review studies have limitations that prevent an adequate analysis; since existing research in the literature lacks standards or guidelines to facilitate an adequate analysis of the usability of IT products, as reported by [60] in their study evaluating the usability of portable devices and complementary health applications; there, they found a variety of instruments used to assess usability, yet one that outnumbered other instruments was the SUS; despite this, only 16 of the 68 studies included in the study used any statistical analysis, and only one-third of the studies explicitly reported the measurement of usability or perceived usability; however, they had difficulty distinguishing the evaluation of the wearable device from that of the accompanying mobile app; thus highlighting the lack of standardized frameworks that allow for the proper evaluation of the usability of wearable devices and complementary apps; demonstrating the need for further research to bridge the existing gap between usability and user experience.

Limitations

Although this study provides a robust instrument, some limitations suggest avenues for future research: the sample was limited to an urban hospital network, so validation in rural areas with less technological infrastructure is recommended. Likewise, it would be valuable to: (1) evaluate the impact of improving specific dimensions (eg, accessibility) on real clinical indicators (eg, reduction in medical errors), and (2) develop implementation guidelines that link usability results to user-centered design protocols. These lines of work could bridge the gap between evaluation and best practices in EHR systems, transforming usability from an abstract concept into a measurable driver of health care quality and patient safety in the region. Despite the limitations, the instrument provides comprehensive psychometric validation based on ISO 25010, paving the way for future research on cross-cultural validation and application in diverse contexts.

Conclusions

This study developed and validated an instrument for evaluating the usability of information systems, which is aligned with the dimensions of ISO 25010. The results demonstrated excellent psychometric properties, with a near-perfect factor fit (CFI=1.000, Tucker-Lewis Index=1.001) and exceptional reliability (Cronbach α=0.968). The application of the instrument in a real-world setting revealed that 81.7% of users perceived usability as "very high," validating not only the tool itself but also the importance of considering local regulatory frameworks in the design of digital health systems, such as Peru's NTS. These findings represent a significant advance over generic instruments such as the SUS, by offering systematic alignment with ISO 25010, and, on the other hand, the alignment of information systems with local legislation (NTS).

XSL•FO
RenderX

The research identified certain differences in the perception of usability according to professional roles: while administrative staff reported higher satisfaction (93% “very high”), doctors and nurses gave more critical ratings (80%), particularly in dimensions such as “error protection” and “operability.” These findings align with the alignment or adaptation of information systems to the NTS, but provide specific solutions for the Peruvian context. The main practical implications include: (1) the need to redesign workflows for critical clinical tasks, (2) prioritizing ongoing training focused on usability, and (3) establishing periodic evaluations using this instrument as part of the continuous improvement processes for EHR systems. Additionally, the study revealed that 20% of the NTS requirements (primarily interoperability) were not implemented, highlighting urgent areas for technological development.

Acknowledgments

The authors would like to thank the hospital network in the Puno region for facilitating access to health care personnel (doctors, nurses, and administrative staff) and for their valuable participation in the validation of the instrument. We would also like to thank the 10 expert judges who participated in the content validation process using the modified Delphi technique for their time and specialized contributions, which helped improve the quality of the assessment instrument.

Funding

This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors. Article processing charges will be covered by Universidad Peruana Unión, Juliaca, Peru.

Authors' Contributions

All authors contributed equally to this study. DM-P and AP-H participated in the conceptualization of the study, development of the assessment instrument, data collection and analysis, as well as manuscript drafting and psychometric validation of the instrument. MEH-F contributed to the methodological validation, review of the study design, and critical review of the intellectual content. EG-Q and JO-L participated in the statistical analysis and interpretation of the results. All authors reviewed and approved the last version of the manuscript for publication.

Abstract

Background: Major depressive disorder (MDD) is a prevalent and impairing mental health condition characterized by persistent low mood and diminished energy. Self-report instruments, such as the Patient Health Questionnaire-8 (PHQ-8), are frequently used in clinical and research settings for depression assessment.

Objective: We developed, redesigned, and tested 2 alternative versions of the PHQ-8 that incorporate visual elements and reframed statements aimed at improving acceptability and comprehension.

Methods: In a mixed methods study, 20 participants with high subclinical to moderately severe depressive symptoms provided feedback after completing 3 versions: the standard PHQ-8 form, our version augmented with visual aids, and our version that combined visual aids with rephrased item statements for greater clarity and engagement.

Results: Eighty percent (16/20) of participants preferred one of the augmented PHQ-8 versions over the standard questionnaire (P=.006).

Conclusions: Participants reported that the augmented versions improved their understanding of survey items, reduced response burden, and increased engagement, suggesting that visual and linguistic design modifications may enhance the patient experience in depression screening.

Patient Health Questionnaire-8; PHQ-8; survey design; depression; human-computer interaction; user experience

Introduction

Background

Clinicians and researchers distribute health questionnaires every day across a variety of media, such as phones, tablets, computers, or paper forms in clinical waiting rooms. Although these instruments are ubiquitous, patients often report challenges related to engagement and ease of use, motivating design research aimed at improving respondent experience and potentially supporting more consistent reporting behaviors [1].

Psychiatrists and psychologists often heavily rely on the Patient Health Questionnaire (PHQ)-8 (or PHQ-9, which includes an additional item assessing suicidal ideation) to assess major depressive disorder (MDD) severity [2-8]. In this paper, we aimed to explore the redesign of the PHQ-8 by enhancing question framing and language and adding metaphor-based visualizations. Specifically, we created 2 new questionnaires to address limitations of the standard PHQ-8 version, one augmented with visual aids and another that combined visual aids with rephrased item statements to provide greater clarity and engagement. We tested these 2 new versions with participants with depressive symptoms to evaluate the effectiveness of the new designs in terms of patient experience.

We aimed to examine the following research questions:

- How do our redesigned questionnaires, augmented with visuals and other elements, effectively address the limitations of the current PHQ-8?
- Do the augmented PHQ-8 questionnaires show acceptability when tested?

XSL•FO
RenderX

- What contributes to patient preferences for the standard or the augmented PHQ-8 questionnaires?

While design adaptations cannot eliminate all limitations common to mental health screening tools, they may improve user experience, comprehension, and perceived engagement.

Related Work

Overview

Our research is situated at the intersection of the clinical and human-computer interaction literatures. Specifically, the following subsections review how conventional questionnaires often fail to adequately engage patients and accurately capture subjective mental health experiences, the influence of mood symptoms and perceptions of stigma on self-reporting practices, and design strategies for enhancing patient engagement and understanding.

Challenges in Self-Report Questionnaires and Known PHQ-8 Biases

We first broadly examine issues with participant burden and engagement in filling out patient questionnaires before examining research on the PHQ-8 specifically. Self-report questionnaires collect important subjective data and are the gold standard for understanding a patient's condition, particularly for mental health conditions. However, questionnaires can be difficult and burdensome to fill out, especially when a person is busy [9,10]. Research shows that patients generally have low questionnaire response rates, provide careless responses, and struggle with health questionnaire literacy [11-17]. These challenges reflect the general properties of self-report instruments rather than limitations unique to the PHQ-8.

Prior work across diverse clinical populations, including hospice and youth mental health settings, has shown that patients often perceive standardized questionnaires as impersonal or insufficiently reflective of their lived experiences, which can reduce engagement [18,19]. Although these findings are not specific to depression screening, they illustrate broader challenges in designing self-report tools that feel meaningful, comprehensible, and engaging to respondents. These findings highlight a widespread need among patients in mental health, hospice, and general care for improved questionnaire design that minimizes boredom and fosters a greater sense of being understood.

Prior research has demonstrated that the PHQ-8 is subject to several areas of bias that differ from broad research on survey engagement. The main areas highlighted in prior research are recall bias, social desirability bias, and context-dependent comprehension issues. First, in exploring recall bias, recent research has demonstrated that PHQ-8 results have "modest peak-end recall bias" when tested in that the most intense and proximate emotion disproportionately affects the recall and reporting of symptoms [20]. These findings were further examined in another study that demonstrated fluctuations in patients' ability to recall symptoms, although the recall bias was not statistically significant [21]. PHQ-8 responses may also be influenced by social desirability bias.

Although social desirability bias and recall bias both impact the PHQ-8, comprehension issues are another element that is critical to examine. For example, a recent study found that when tested in another context, there were incorrect interpretations of half of PHQ-8 items and, specifically, issues in interpreting the time scale aspect of the rating [22,23]. Such misunderstandings may partially contribute to discrepancies occasionally observed between clinician-rated and self-rated depression severity [24]. Overall, many of these challenges (eg, recall bias, response burden, and social desirability) are common across screening instruments and modes of administration; thus, design improvements may help mitigate but not fully eliminate them.

Mood Questionnaires Need to Take Into Account Common Symptoms

Anhedonia is a common symptom in MDD, where patients experience a loss of interest, motivation, engagement, and inability to experience pleasure. Patients often describe anhedonia as involving not only reduced interest but also a broader flattening of emotion and diminished capacity for joy [25,26]. Therefore, when questionnaires are boring and unengaging, they can be particularly challenging for such patients to complete, compromising response rates and accuracy.

Another major component of depressive symptoms relates to perceived stigma. Stigma is known to interfere, at minimum, with how individuals choose to self-identify in having a mental illness, such as perceived need and help-seeking behavior [27,28]. Research has begun to address minimizing stigma-based bias in questionnaire design, particularly with respect to reducing social desirability bias [29]. Overall, considering 2 commonly occurring depression symptoms are anhedonia and stigma, it is important to work to understand ways to further increase participant engagement and reduce social desirability bias in the PHQ-8 survey for patients with MDD. These factors underscore the importance of designing depression assessments that minimize perceived judgment and support honest self-disclosure.

The PHQ-8 Might Have a Familiarity Bias

The PHQ-8 is the most popular questionnaire for assessing depression [30-34]. Recent studies have begun to untangle the relationship between reaction time and PHQ-8 results in individuals with depression, those with depression not seeking treatment, and those with depression seeking treatment. There was a notable difference in reaction time, as well as other observed psychometric properties, in patients with MDD completing questions 3, 7, 8, and 9 of the PHQ-8 more quickly between those who sought treatment and those who did not. These differences indicate the potential for familiarity bias to affect specific questions of the PHQ-8, yet no large empirical study has tested this claim further [35].

Designing for Patient Engagement and Understanding

We hypothesize that reasons for the PHQ-8 questionnaire failing to accurately capture MDD symptoms may be due to the instrument's structure and presentation of questions, particularly in terms of how both its visuals and texts could better promote engagement and motivation.

XSL•FO
RenderX

Visual-based design methods, such as interactive formats and adaptive questions, have begun to be implemented in surveys to enhance patient engagement. Broadly, there has been a rise in using design methods to encourage patient acceptance and understanding across a number of digital platforms, such as conversational agents, collaborative care, vital monitoring, and online cognitive behavioral therapy training [36-42]. For example, a chronic pain survey was developed in which patients select facial expressions to self-report pain levels. The study found high validity in this measure and that patients reported lower response burden and increased response motivation [36].

Other visual designs have explored the use of photos to measure affect, particularly the Photographic Affect Meter interface that asked respondents to select from a variety of pictures to choose the image that best represented their current mood. Evaluation of the Photographic Affect Meter instrument has shown strong validity and ease of use [43]. A similar photo-based questionnaire has been created to measure current pain levels [36]. Collectively, these studies demonstrate that visual and interactive elements can improve usability, reduce response burden, and increase engagement across various health contexts [36,43,44].

Visual designs based on the connection of emojis and mood have also been implemented. Studies on emoji-based tools, such as the EmojiGrid and the Emoji Current Mood and Experience Scale, highlight the potential of visual surveys to be both engaging and valid across a variety of settings [45,46]. However, emojis may be less effective in capturing nuanced emotional states, particularly among individuals experiencing high emotional intensity [47].

Many other studies have found that visual interface elements increase perceived usability and enjoyment and help patients feel more relaxed and happier [48,49]. Furthermore, research finds that increased visual appeal can lead to increased trustworthiness [50]. Considering that patients with mental health concerns often face a sense of stigma when completing assessments [18], visual elements may be an important way to build engagement and trust and elicit more honest responses. Our research, therefore, aims to overcome PHQ-8 challenges related to boredom, stigma, and inaccurate responses by exploring the design of a questionnaire that incorporates visual elements to enhance respondent user experience and engagement.

In addition to visual design, the phrasing and structure of questionnaire items also influence respondent engagement and comprehension. Text-based design is equally important, as the language and framing of items can substantially influence survey experience and response quality. In particular, it is helpful to frame survey items as a question rather than as a statement, as the PHQ-8 currently does [51]. Such framings can also impact how comfortable respondents feel in sharing negative responses [52,53]. Open-ended questions are another effective technique to encourage patient comfort and honesty, as such formats allow for more authentic feedback [54]. A hybrid approach of including a Likert scale with an open-ended question can enhance patient comfort and engagement even without the need for artificial intelligence or large language models to appropriately scale the response [54]. Overall, prior work indicates that incorporating language that is compassionate and open-ended can help encourage respondent engagement and honesty [55-57]. We therefore experimented with modifying the PHQ assessment to evaluate whether such question framings could enhance engagement.

Despite extensive research on self-report burden, visual communication, and item design across health questionnaires, relatively little work has examined how these principles can be applied to improve the PHQ-8 itself. Existing studies reveal important limitations such as recall biases, social desirability influences, and comprehension challenges, but these issues are typically reported at the level of general self-report methodology rather than addressed through targeted redesign of PHQ-8 items or layout. Furthermore, while visual and interactive elements have shown promise in enhancing engagement in other symptom-tracking tools, their effects on depression screening instruments remain largely unexplored, and prior work has rarely assessed whether such design changes preserve psychometric properties. Taken together, this literature highlights a clear gap: the need for systematically designed and evaluated adaptations of the PHQ-8 that incorporate visual elements and improved item phrasing to support patient engagement and understanding without compromising validity. Our study addresses this gap by developing and testing 2 redesigned PHQ-8 formats that integrate these design principles.

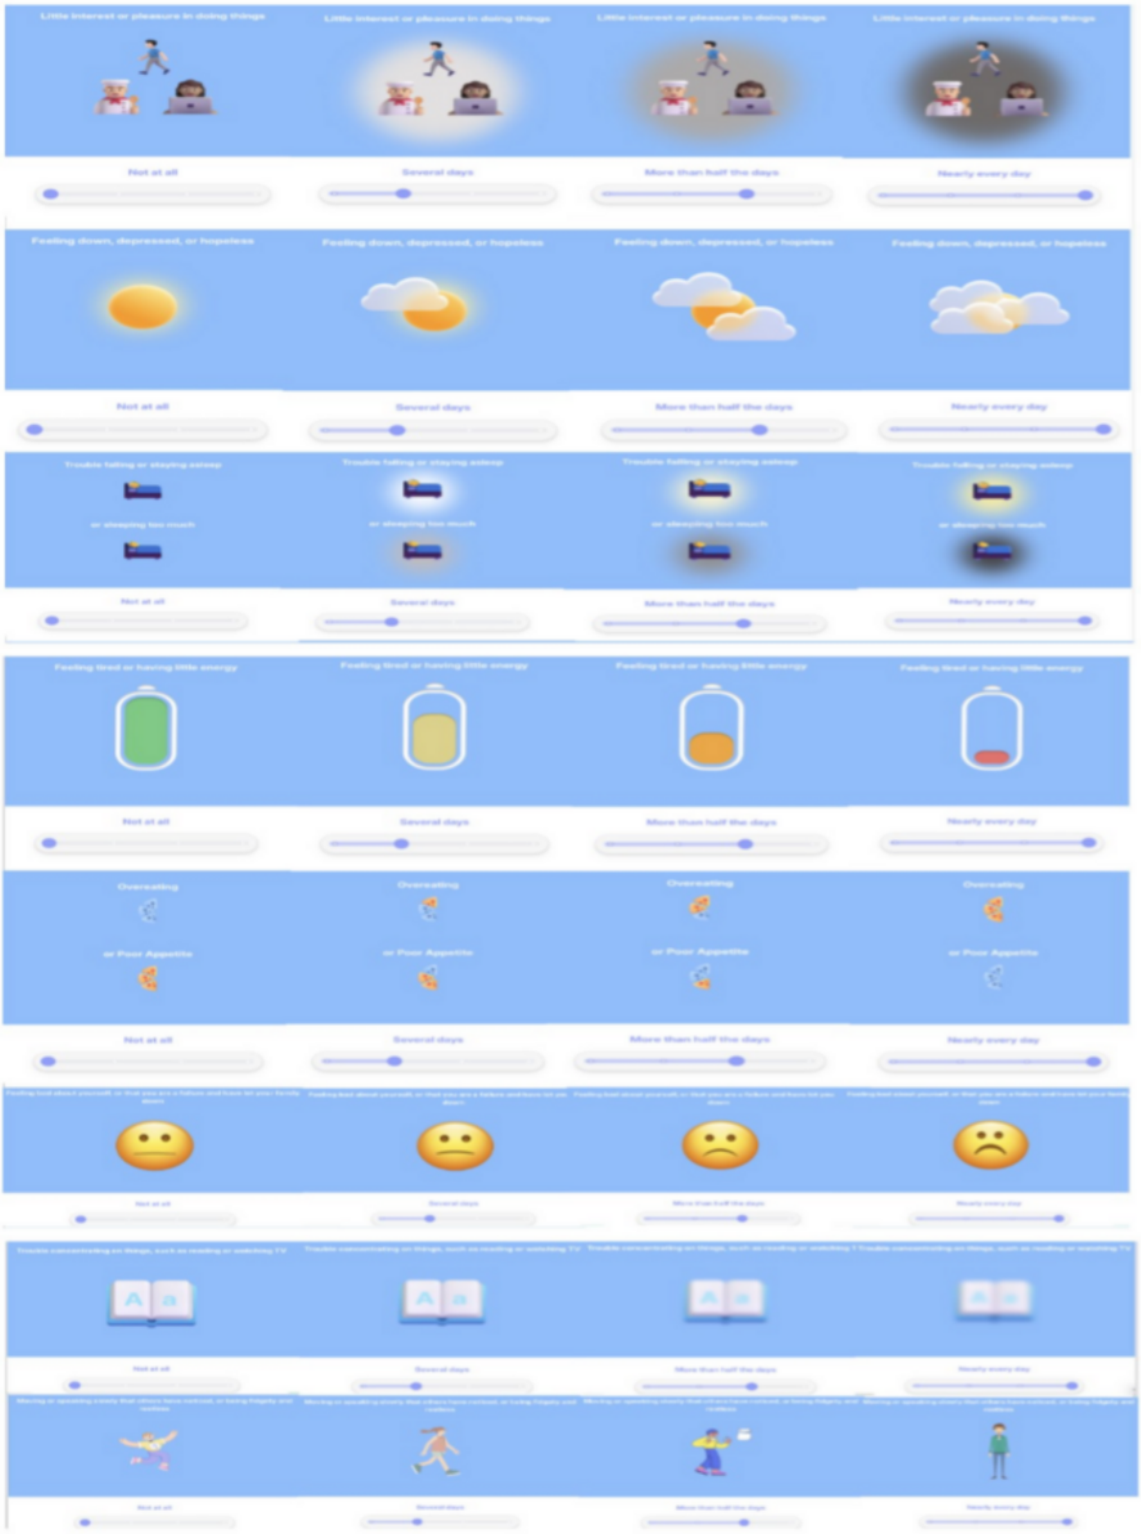
Methods

Participants

Participants were recruited from a larger Dartmouth study that examined digital treatments for anxiety and depression. Participants were recruited from across the United States via Google and Meta Ads. Individuals had previously completed the PHQ-8 and General Anxiety Disorder-7 screening questionnaires and were eligible for recontact if they were aged between 40 and 65 years, lived in the United States, and demonstrated high subclinical to moderately severe depressive symptoms (PHQ-8≥8). From this pool, we recruited 20 participants (women: n=16, 80%; and men: n=4, 20%). Their mean PHQ-8 score at screening was 14.84 (SD 5.18), which is approximately 5 points above the clinical threshold of 10. Three participants scored below the clinical threshold of 10.

Data Collection

Each participant completed a semistructured interview via Zoom lasting 30 to 60 minutes. Interview topics included condition acceptance, social support, mindset, stigma, and technology preferences. Specifically, the questions most salient to this study were as follows: At what age did your depression begin? How many years have you been living with depression? Are you currently seeking treatment? Is there any treatment or medication you've done to help your condition in the past?



Following the interview, participants were given 2 PHQ-8, as shown in Figure 1 (we did not include the 9th question regarding suicidality, as we had already screened for this, as described earlier). The "Visual PHQ-8" (Figure 1) used the same statements of the standard PHQ-8 accompanied by

XSL•FO
RenderX

visualizations. The “Reframed PHQ-8” (Figure 2) modified the assessment statements to open-ended questions, while using the same visualizations from our Visual PHQ-8. We rephrased all the PHQ-8 items to be open-ended and more conversational. All the questions besides item 1 reflect concrete feelings or behaviors, whereas item 1 reflects a motivational state (“little interest or pleasure in doing things”). Using a “how” structure helps preserve that motivational-state meaning, while a “do you...” phrasing would incorrectly frame the item as a feeling or behavior rather than a motivational state. After completing each questionnaire, we asked participants about their experience in filling out the questionnaire and whether there was anything they would change about it. Finally, we asked participants if they had a preference among the various PHQ versions (standard, visual, and reframed) and to elaborate on such reactions. To enable us to examine links between survey preference and psychological status, participants were then given the following questionnaires: Interpersonal Social Support to capture dimensions of social support (eg, tangible, appraisal, and belonging) [58,59]; Trait Hope Scale [60,61], which is known to predict positive outcomes and resiliency; Kind of Person Scale [62,63] and Dweck Growth Mindset Scale [64] to assess growth mindset and reactions to adversity; and the Stigma Scale for Chronic Illnesses to assess psychological distress and patient performance [65].

Figure 1. Our visual Patient Health Questionnaire-8 design that augments the standard questionnaire with visual aids.

XSL•FO
RenderX

Figure 2. Our reframed Patient Health Questionnaire-8 design that both augments the standard questionnaire with visual aids and also rephrases survey items.

Data Analysis

Interviews were transcribed and coded using an inductive qualitative approach. Two researchers independently reviewed all transcripts, developed an initial codebook, and resolved discrepancies through consensus. Themes were organized around depression history, current treatment status (ie, whether an individual was actively seeking therapy or medication), and questionnaire preferences.

We conducted 1-tailed exact binomial tests to evaluate whether the proportion of participants preferring augmented PHQ versions significantly exceeded chance (50%). In addition, we analyzed participants' responses to each of the PHQ-8 questionnaires. Specifically, we computed means and SDs for each questionnaire group and conducted intraclass correlation coefficients (ICCs) between the questionnaires. Finally, we analyzed responses to the Interpersonal Social Support [58,59], Trait Hope Scale [60,61], Kind of Person Scale [62,63], Dweck Growth Mindset Scale [64], and the Stigma Scale for Chronic Illnesses [65] to identify associations between those responses and participants' preferences among the different PHQ-8 versions.

Ethical Considerations

The study conducted at Dartmouth was approved by the Committee for Protection of Human Subjects under study 32782. All activities in this study were conducted under the approved protocol and complied with institutional and federal guidelines for research on human participants. All participants gave informed consent and were compensated ($20 per hour) at the completion of the study. We attest to maintaining privacy and confidentiality of all research subjects' data.

Results

Overview

Our data showed that 80% (16/20) of participants preferred one of the redesigned PHQ-8 formats over the standard version. This preference for an augmented version of the PHQ-8 was statistically significant under a 1-tailed exact binomial test (proportion: 0.80, 95% CI 0.56-0.94; P=.006), indicating an above-chance likelihood that a participant prefers a redesigned PHQ-8 (Figure 1) compared to a traditional PHQ-8 (Figure 3, Tables 1 and 2). Only 20% (proportion: 0.20, 95% CI 0.06-0.44) of participants preferred the standard PHQ-8, indicating a minority preference for the nonaugmented version.

Participants who preferred the redesigned questionnaire with visualizations (PHQ-8 mean 12.50, SD 5.34) had higher PHQ-8 scores than participants who preferred the traditional statements (PHQ-8 mean 9.75, SD 2.99). Additionally, the trend followed that those who preferred visualizations over statements had higher stigma scores (mean 23.19, SD 9.63) and lower hope

XSL•FO
RenderX

scores (mean 40.94, SD 8.64) than those who preferred statements (stigma: mean 21.25, SD 10.11; and hope: mean 51, SD 6.58).

Figure 3. The Patient Health Questionnaire-8 in standard form.

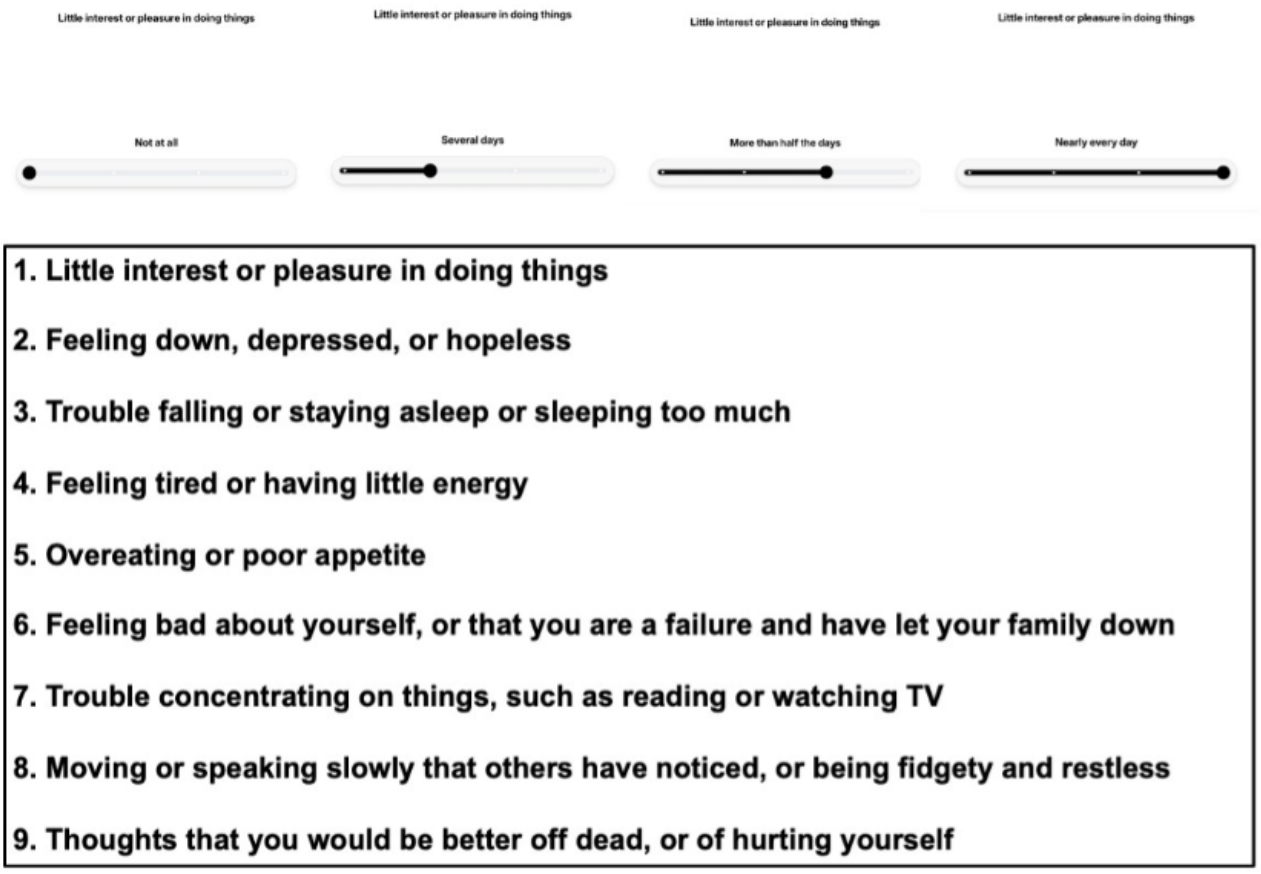

Table . Patient Health Questionnaire (PHQ) responses, summarized according to survey type preference.

Participants' favorite questionnaire	Count (N=20), n (%)	PHQ-8: statements (mean 11.95), mean (SD)	PHQ-8: statements and visualizations (mean 11.00), mean (SD)	PHQ-8: statements and questions (mean 10.60), mean (SD)	Trait hope scale (mean 42.95), mean (SD)	Stigma scale (mean 22.80), mean (SD)	Growth mindset (mean 10.11), mean (SD)	Kind of person (mean 28.50), mean
Prefer statements	4 (20)	9.75 (2.99)	6.75 (4.86)	6.75 (2.06)	51.00 (6.58)	21.25 (10.11)	10.50 (6.24)	28.00 (4.08)
Prefer questions and visualizations	7 (35)	11.29 (5.53)	10.71 (5.02)	10.43 (4.58)	38.14 (12.13)	25.29 (9.93)	11.14 (5.01)	27.43 (7.21)
Prefer statements and visualizations	9 (45)	13.44 (5.32)	13.11 (5.75)	12.44 (6.48)	43.11 (4.17)	21.56 (9.66)	9.00 (3.38)	29.56 (3.78)
Prefer either questions or statements and visualizations	16 (80)	12.50 (5.34)	12.06 (5.41)	11.56 (5.64)	40.94 (8.64)	23.19 (9.63)	10.00 (4.21)	28.63 (5.44)

XSL•FO
RenderX

Table . Response per question for the 3 Patient Health Questionnaire-8 (PHQ-8) versions.

Questionnaire type	Anhedonia, mean (SD)	Hopelessness, mean (SD)	Sleep, mean (SD)	Fatigue, mean (SD)	Appetite, mean (SD)	Self-esteem, mean (SD)	Concentration, mean (SD)	Movement, mean (SD)
PHQ-8: statements	1.75 (1.00)	1.85 (1.03)	2.00 (0.97)	2.10 (0.91)	1.15 (1.12)	1.25 (0.85)	1.35 (1.05)	0.55 (0.84)
PHQ-8: statements+visualizations score	1.45 (1.09)	1.55 (1.05)	2.05 (0.94)	1.95 (1.05)	1.00 (1.12)	1.10 (0.64)	1.35 (1.14)	0.50 (0.83)
PHQ-8: questions+visualizations score	1.30 (0.97)	1.40 (1.05)	2.00 (1.17)	1.55 (1.32)	1.00 (1.08)	1.42 (0.96)	1.40 (1.14)	0.55 (1.00)

We next discussed the differences between the augmented versions (ie, questions and visualizations vs statements and visualizations) descriptively, as the primary statistical analysis evaluated whether participants preferred an augmented PHQ-8 compared to the standard version. We only use descriptives in discussing the differences between the augmented versions, as both augmented conditions incorporated visualizations and the study design did not include a condition with just rephrased questions, limiting the ability to generalize and analyze the effect of question phrasing independently. We now specifically examine the adapted versions, where 45% (9/20) of participants (proportion: 0.45, 95% CI 0.23-0.68) preferred the visual-only PHQ-8, and 35% (7/20) of participants (proportion: 0.35, 95% CI 0.15-0.59) preferred the version that combined visuals with reframed questions. The 95% CI for each of the augmented versions demonstrates a similar spread of preference for the questions and visualizations and statements and visualizations, which could be further studied in future experiments.

Participants Who Preferred Visualizations

Participants who preferred the addition of visualizations (Figure 1) strongly emphasized that they felt more engaged and experienced more pleasure while taking the questionnaire. For example:

> *It was more engaging and fun...I really liked that. I liked having the visual.* [Participant 18]
>
> *I did find it more fun.* [Participant 19]
>
> *I liked the little emojis. That was sort of fun.* [Participant 17]

Importantly, we identified that the visualizations not only were more engaging but also prompted more reflective responding. For example, participants noted that:

> *It would make me stop and think. About things that I generally don't.* [Participant 1]
>
> *I think some of the visuals were helpful in thinking through the question.* [Participant 11]

Both these participants noted that having the visual helped them pause and think more deeply about the question.

Participants Who Preferred Visualizations and Questions

Participants who had a preference for the questionnaire that included both visualizations and reframed questions (Figure 2) explained that this design helped them feel both cared about and understood. Furthermore, participants discussed that the wording felt less negative:

> *I liked the way that they were worded. Like they just seem softer than the normal [instrument phrasings].* [Participant 6]

Similarly, other participants expressed that the reframed questions felt less negative and confrontational, and more compassionate and genuine in checking in on a person's status. For example:

> *The questions were phrased differently, and I liked that. It didn't feel negative. It was more like, "oh, we would like to know this," rather than "we know you're like this, just admit it."* [Participant 9]

This theme related to a sense of being cared about and understood was further elaborated by 2 other participants:

> *Yeah, I like these questions better...They speak to you a little bit more.* [Participant 12]
>
> *It felt more understanding, and it felt like whoever was at the other end of the survey really wanted to know to help, rather than really wanting to know because it will be useful to them.* [Participant 14]

The second common theme was that participants felt that the reframed questions enabled them to be more thoughtful in responses. For example:

> *They made me think more... It's getting at the same information, but I like the way it was worded. It is a more thoughtful way, I think.* [Participant 6]

Another participant echoed this statement, noting that:

> *It made me think because it doesn't phrase it the same way that the doctors do. I had to think about what are you asking.* [Participant 9]

The ability of the redesigned questions to be more thought-provoking may partly stem from providing a break from the repetitive nature of the traditional PHQ-8 statements:

> *I'm so used to those questions I just kind of speed through them.* [Participant 6]
>
> *...they get so repetitive. I've done where you track it; it just gets really like, "okay, I was depressed yesterday, I'm depressed today...* [Participant 9]

In this way, participants emphasized that the redesigned questions helped overcome the repetitive nature of the PHQ-8

XSL•FO
RenderX

and, in turn, helped them to be more thoughtful in their responses.

Participants also explained the redesigned questions and visuals also supported better item comprehension:

> *The questions were a lot better than the statements...Sometimes with the statements, it's difficult to put together what it actually means.* [Participant 16]

> *The cloud and gray sky [visualization and question], I was like, "oh, I can imagine that.*" [Participant 19]

Overall, while these participants explained that they felt that responses to the traditional PHQ-8 were "difficult to put together," they expressed that new visualizations helped them "imagine" the statements better.

Participants Who Preferred Statements

Despite most participants preferring redesigned versions of the PHQ-8, 20% (4/20) of participants had a preference for keeping the PHQ-8 the same with no addition of a visualization or reframed question. We observed 2 main themes for these individuals. First, they found the addition of the visualizations to be hard to relate to. For example:

> *The visualizations are distracting because it's somebody else's picture.* [Participant 3]

This participant and another also noted their distaste for the aesthetics of the visualizations, referring to them as childish:

> *they seemed kind of child-like.* [Participant 3]

> *I think the text is enough. [Better than the] stupid smiley face chart they have at the hospitals and doctors' offices.* [Participant 3]

Another theme that we observed was that the visualizations were seen as unnecessarily lengthening the self-report process or generally not necessary given how familiar participants were with the standard PHQ-8:

> *Honestly, I don't really pay attention to the visuals, so I don't think they're necessary.* [Participant 3]

They later explained that just having the statement was sufficient and efficient:

> *it just makes it shorter, sweeter, faster, less to look at, and less to concentrate on.* [Participant 2]

Participant 20 felt similarly as she had regularly taken the PHQ-8 after attending therapy and psychiatry sessions for over 20 years and therefore preferred the traditional format she was so accustomed to.

Potential Visualization Improvements

We also asked participants to provide feedback on visualizations and share any ideas for potential improvements. Some feedback about the self-report interface would be easily addressable; for example, tweaking the digital survey to automatically shift to the next question could help respondents more smoothly transition from question to question:

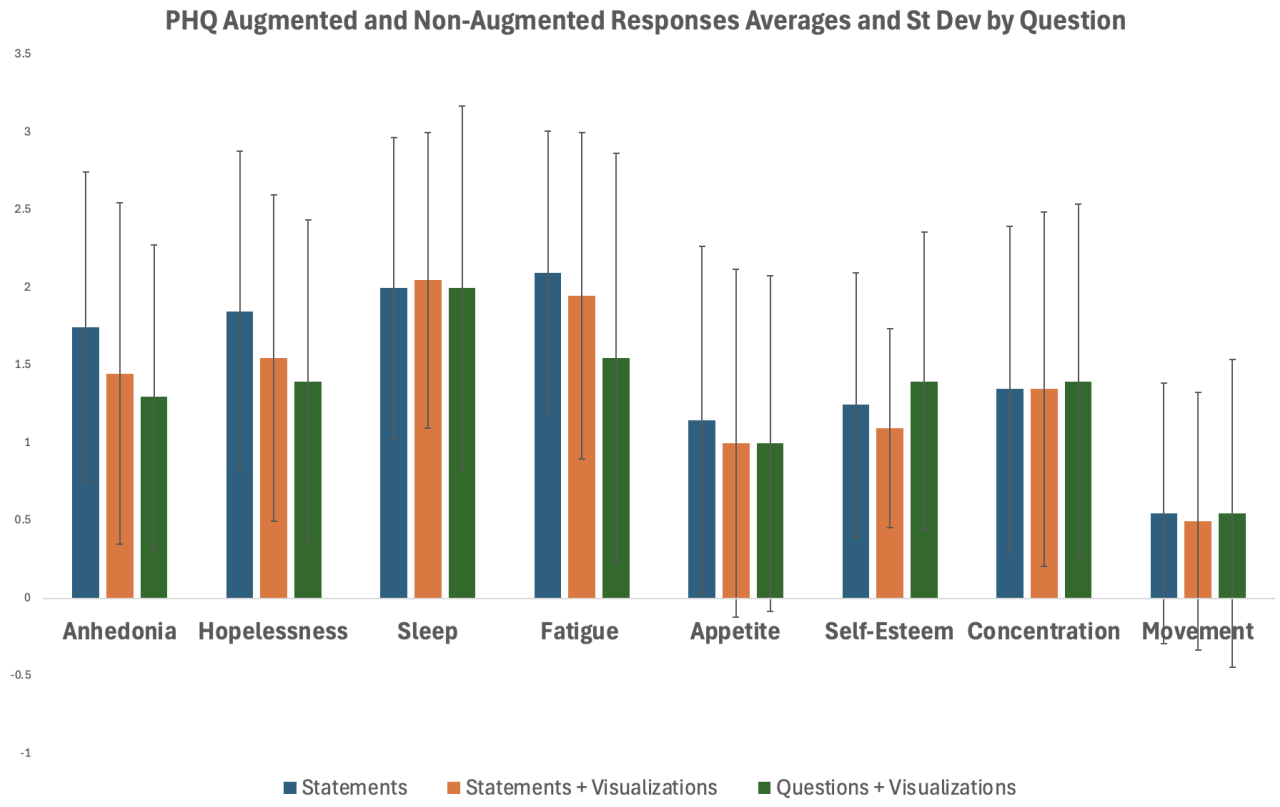
> *Not the visuals, but I wish I didn't have to press next next next so many times.* [Participant 13]

Other feedback applied to specific PHQ-8 questions. For example, in question 7 ("Trouble concentrating on things, such as reading the newspaper or watching television"), our design increasingly blurred out the visual as the scale increased, and one participant (participant 5) expressed that this design was difficult to see given vision issues. Another participant emphasized that they desired a consistent runner emoji for question 8 (participant 17), and another participant requested questions 3 and 5 to be separated out (participant 12).

Survey Preference and Patient Histories

We observed a tendency for participants who had been more recently diagnosed to have a higher preference for a redesigned PHQ-8 questionnaire. More specifically, participants who had been diagnosed earlier preferred statements (average time since diagnosis 23, SD 17 y), whereas participants who had been diagnosed later preferred visualizations (average time since diagnosis 18, SD 11 y), and the most recently diagnosed participants preferred visualizations and questions (average time since diagnosis 16, SD 7 y). While this effect is not statistically significant when tested with a one-way ANOVA, it suggests that there is a potential trend where individuals with depression may become accustomed to a specific format over time, whereas those more recently diagnosed individuals may face challenges engaging with these conventional self-report instruments. Of participants who preferred the statements format (n=4), 50% (n=2) were not seeking therapy, 25% (n=1) were in therapy and taking antidepressants, and 25% (n=1) were taking antidepressants but not in therapy. On the other hand, of participants who preferred the statements and visualizations format (n=9), 22% (n=2) were not seeking therapy, 33% (n=3) were in therapy and taking antidepressants, 22% (n=2) were in therapy but not taking antidepressants, and 11% (n=1) were taking antidepressants but not in therapy. All participants who preferred the question and visualization (n=7) format of the survey were actively in therapy, and 86% (n=6) were also taking antidepressants.

Scoring of PHQ-8 Surveys Compared



The PHQ-8 surveys included 8 questions, all on the same scaling of 0 to 3 with a maximum score of 24. In our sample, the average score of the PHQ-8 in standard form (Figure 3) was 11.95 (SD 5.03), 11 (SD 5.62) for our visual PHQ-8 design that augments the standard questionnaire with visual aids (Figure 1), and 10.6 (SD 5.45) for our reframed PHQ-8 (Figure 2). The total score for each PHQ-8 questionnaire showed ICCs that were highly consistent across the 3 surveys (average raters ICC=0.96, 95% CI 0.93-0.98; $P<.001$).

Individual Questions of PHQ-8 Surveys Compared

Overall, the movement, sleep, concentration, and appetite responses between the 3 versions stayed fairly consistent with the maximum change in averages at 0.15. However, questions related to more visible and stigmatized symptoms seemed to show more variability between the 3 versions, where anhedonia, hopelessness, fatigue, and self-esteem had still low but higher variability maximum change in averages at 0.55 between versions (Figure 4).

XSL•FO
RenderX

Figure 4. Each of the 3 versions of the Patient Health Questionnaire (PHQ)-8's individual question responses compared to each other.

The ICC showed high statistical significance across all 8 questions. For anhedonia and fatigue, the ICC estimates ranged from 0.64 to 0.70 (P<.001), whereas for hopelessness, sleep, appetite, concentration, and movement, the ICC estimates ranged from 0.88 to 0.96 (P<.001). Furthermore, all 8 questions show moderate to high correspondence with the traditional PHQ-8 and statistical significance. This correspondence helps to indicate that the augmented versions are able to effectively measure the psychometric properties assessed in the traditional version of the PHQ-8.

Discussion

Principal Findings

This study demonstrates that thoughtfully redesigning PHQ-8 items through the addition of visual elements and conversational reframing may improve people's subjective experience of completing depression screeners. Across our sample, most participants reported that the redesigned versions felt more engaging, supportive, or easier to interpret compared to the standard PHQ-8. While these adaptations do not change what is being measured, they appear to influence how users approach the task, with some describing the redesigned items as prompting more reflection or making the questions feel more personally meaningful. These findings align with broader work showing that visual and linguistic framing can shape how people make sense of self-report assessments. Specifically, we explored augmented versions of the PHQ-8 instruments, incorporating visualizations and reframed statements aimed at improving respondent engagement and comprehension. Specifically, we examined participant feedback after completing 3 versions of the PHQ-8: the standard form, a version augmented with visual aids, and a version that combined visual aids with item questions rephrased for greater clarity and compassion. We next reflect on the acceptability and overall experience of each of these versions.

Overwhelming Majority Enjoyed Augmented PHQ-8 Versions

We observed that 80% (16/20) of participants had a significantly greater preference for either augmented version of the PHQ-8 compared to the standard version of the instrument. For the 45% (9/20) of participants who most preferred the version augmented only with visuals, we observed themes related to how these additions promoted higher engagement and thoughtfulness in responses. Although augmented designs for health questionnaires have yet to be tested in the context of depression, previous work that tested the addition of visuals in patient populations such as chronic pain and affect found similar results, suggesting that visualizations may be broadly beneficial. Indeed, the addition of visuals is known to induce greater trustworthiness [50], reduce response burden, and increase response motivation [43,66]. Such findings were mirrored in this study, where patients reported feeling more engaged and thoughtful when using the augmented PHQ-8 with visualizations. Additionally, incorporating visuals into the questionnaires may elicit greater self-reflection, which could influence how participants articulate their internal states in their responses.

For the 35% (7/20) of patients who most preferred the addition of visuals and new question framings, we established a few main themes based on their feedback, which emphasized that these designs helped respondents feel more thoughtful, cared for, and understood. Such findings resonate with prior work

XSL•FO
RenderX

where patients were more comfortable, engaged, and authentic in responding to questions rather than statements [51,54-57].

Overall, our findings highlight that survey items augmented with visuals and revised phrasings help patients be more thoughtful while responding, feel more cared for and understood, and generally experience less response burden. An interesting future study, now that this redesign has been piloted, would be to integrate the feedback from our study and test the 3 versions with new patients who are not already so used to the standard format (ie, no change management needed).

The Minority of Patients Who Enjoyed the Standard Version

Examining the 20% (4/20) of patients who preferred the standard version of the PHQ-8, these participants highlighted that they found the visualizations and question changes to be distracting and that these augmentations lengthened the time it took for them to finish the questionnaire. Their feedback indicated that such reactions may stem from participants feeling a lack of connection to the visual and linguistic changes (eg, not resonating with the metaphor of energy as a battery visualization). Another potential factor we saw was a repetition and familiarity bias, where participants prefer surveys that they are more familiar with [67-69], given many of these participants had been diagnosed earlier and had been using the standard PHQ-8 for a longer number of years. Finally, these participants pointed out how the augmented questionnaire was longer and/or involved more content to consume. While our goal with the augmented questionnaires was to increase engagement and response motivation with these additional visual and textual elements [51,54-57], this feedback is a good reminder that such designs could be perceived as more burdensome or time-consuming for some individuals.

Patient Preferences in Relation to Demographic Characteristics and Survey Features

We first examined the impressions of those participants who preferred the PHQ-8 augmented with visual aids. These individuals displayed common characteristics in that they were diagnosed with MDD slightly later, on average, than those who preferred the standard statement-based survey. Additionally, more of these participants were actively seeking therapy. As mentioned, we suspect this may be due to less of a repetition bias or familiarity bias that may affect respondents who have a longer history of using the PHQ-8 as part of treatment [67-69]. Furthermore, therapy is known to not only help patients cope with their condition but also to develop greater condition acceptance and both somatic and emotional awareness [70-72]. Participants who are actively seeking therapy may therefore prefer an augmented survey that greater reflects their subjective awareness about condition on both cognitive, emotional, and physical levels.

Further exploring links between patient profiles and survey preferences, we observed a clear trend where participants with a lower depression score, higher trait hope scale, and lower stigma preferred the traditional PHQ-8 statements over the augmented versions. Said another way, as a participant's levels of depression and stigma increase and hope decreases, there appears to be a stronger preference for augmented PHQ-8 designs (Table 1). We believe this suggests the standard PHQ-8 may be better suited for someone with a more mild condition and that as condition severity worsens, the addition of visualizations and linguistic changes allows for the questionnaire to remain approachable while avoiding perceptions of stigma or judgment [28]. For example, this sense of judgment or marginalization can be seen in an aforementioned quote: "we know you're like this, just admit it." Given that prior research has demonstrated the impact that stigma and anhedonia have on survey responses [27-29] and that the current state of the PHQ-8 can fall short in accurately assessing MDD [3,7], it seems that a respondent's levels of perceived stigma are a key characteristic to understand when determining whether an augmented questionnaire may be more appropriate to deliver.

Survey Responses

The primary goal of this study was to determine if a PHQ augmented with visual and linguistic elements was acceptable and engaging for individuals with depression. Encouragingly, we found that 80% of participants did enjoy and prefer an augmented questionnaire. We also found that scores were reliable and accurate based on ICCs across all 3 questionnaires (2 augmented questionnaires and the 1 standard PHQ-8 questionnaire). Examining specific questionnaire items, we found that the movement, sleep, concentration, and appetite responses among the 3 versions had the highest agreement, whereas the more visible and stigmatized symptoms of anhedonia, hopelessness, fatigue, and self-esteem had moderate agreement compared to the same items with the traditional PHQ-8. Specifically, participants reported lower scores for these stigmatized symptoms on the PHQ-8 version augmented with visuals. We had hypothesized that our visuals would reduce shame and stigma, leading to higher scores. However, we found that the stigmatized symptom item scores reduced. We hypothesize that the addition of the visuals may have unintentionally softened or reframed the symptoms, which may have led to participants reporting symptoms with less severity. Another potential explanation for the score decrease is that individuals with higher stigma may underreport their symptoms with the addition of the visualizations. Therefore, future work is needed to examine this pattern and unpack how visualizations influence shame, stigma, and self-reporting.

Limitations and Improvements for Future Research

This study was able to demonstrate broad acceptability and engagement with the redesigned questionnaires; however, it had several limitations that need to be addressed in future studies. First, the sample size was limited to only 20 participants, which limits the generalizability of the study. The study was able to demonstrate that participants engaged with the new material. In future studies, we could further examine test-retest reliability and conduct a large-scale validation study. Additionally, participants completed the questionnaires after an interview about their depression symptoms and symptom management. Although participants' opinions on the visualizations should likely not have been influenced by this interview, future studies without an interview prior could better control for any possible effect. The study is limited by

XSL•FO
RenderX

demonstrating that participants preferred the visual format; however, this study did not test whether this preference accurately corresponds to improved internal validity or accuracy of PHQ-8 ratings. The variation of scores across the formats, although small, indicates that visual elements may influence responses, and therefore, future work would need to ensure psychometric validity of the new measures.

Our sample primarily relied on middle-aged adults (aged 40 - 65 y), which could have impacted the relationship with how participants interpreted and connected with the visual aids. Further testing across other age groups could determine if the effects from our study are reproducible age-independent. Additionally, in future studies, increasing the sample size could discern the impact of age and help-seeking behaviors on participants' views on each of the questionnaires and ensure test-retest reliability. One immediate next step is to explore a variety of additional questionnaire refinements based on participant feedback, including, as discussed previously, smoother transitions between questions, keeping visual designs sensitive to differences in people's visual abilities, using consistent emojis across item scales, and separating out questions that currently mix multiple assessments into one. In these future studies, we also intend to add a fourth survey option, which is to use the same open-ended questions tested in our study but without the addition of the visualizations. The questionnaire will retain its same length yet provide more empathetic and thought-provoking questions. It is necessary to examine more repeated and longitudinal testing of the redesigned instruments to assess their reliability and their user experience over time and in real-world self-report scenarios. Additionally, although the questionnaires had response options that were frequency-based, it is possible that some participants interpreted the visual aids as symptom intensity rather than frequency. It is possible that this juxtaposition could have influenced the interpretation of specific survey items. We intend to further explore how participants interpreted the addition of visuals and if they shifted from frequency to intensity of symptoms in future studies.

Conclusions

In exploring 2 new PHQ-8 designs that augmented the standard version with visuals as well as reframed item language, we found that participants overwhelmingly supported these augmented PHQ-8 versions. Participants expressed that they felt more engaged, understood, and thoughtful in making self-reports, suggesting that the augmented versions may better capture subjective experience and ultimately provide a more accurate diagnostic assessment. Furthermore, our findings highlight how integrating visual and linguistic modifications into depression screening tools can enhance patient experience without compromising the instrument's fundamental validity. Overall, this study provides design strategies and preliminary evidence in how to update widely used self-report instruments to be more patient centered.

Abstract

Background: Concurrent mixed mode designs for data collection may introduce mode-specific biases. This study investigated mode effects between computer-assisted website interviewing (CAWI) and computer-assisted telephone interviewing (CATI) in the concurrent mixed mode study CoVerlauf.

Objective: This secondary analysis of previously published results explored associations between the choice of interview mode and socioeconomic characteristics, the number of reported post-COVID-19 symptoms, and response patterns in symptoms collected via multiple-choice (MC) and free-text items.

Methods: Associations were calculated using multiple logistic regression analyses, mixed effects logistic regression analyses, and gamma generalized linear models. Selection and measurement effects in symptom counts were analyzed with the back-door method.

Results: Among 1779 participants, 77.8% (1384/1779) chose CAWI, and 22.2% (395/1779) chose CATI. Odds of selecting CATI were lower with a higher education (odds ratio [OR] 0.46, 95% CI 0.34 to 0.63), for those represented by another person (OR 0.28, 95% CI 0.13 to 0.56), and with each additional symptom experienced at the time of the interview collected from MC (OR 0.86, 95% CI 0.77 to 0.96). Compared with those aged 50 years to 59 years, the odds increased with age (60 - 69 years: OR 2.26, 95% CI 1.53 to 3.36; 70 - 79 years: OR 4.98, 95% CI 3.12 to 7.97; ≥80 years: OR 17.29, 95% CI 9.34 to 33.11) and each additional symptom experienced at infection collected via MC (OR 1.09, 95% CI 1.04 to 1.15) and free-text items (OR 1.94, 95% CI 1.61 to 2.37). Odds of responding to free-text items were higher with CATI (OR 5.22, 95% CI 4.25 to 6.42), for women (OR 1.57, 95% CI 1.30 to 1.89), for those with ≥3 pre-existing conditions (OR 1.44, 95% CI 1.07 to 1.96), with missing information on educational attainment (OR 1.95, 95% CI 1.11 to 3.42), and for each additional MC symptom (OR 1.15, 95% CI 1.12 to 1.19). Odds of collecting additional symptoms from free-text items were lower with CATI (OR 0.58, 95% CI 0.41 to 0.82) but increased with each additional MC symptom (OR 1.08, 95% CI 1.02 to 1.14), ≥2 pre-existing conditions (2: OR 1.8, 95% CI 1.02 to 3.00; ≥3: OR 2.0 95% CI 1.18 to 3.43), and ages 40 years to 49 years (OR 2.0, 95% CI 1.13 to 3.55). Selection effects were found for the number of symptoms at infection collected via MC (difference –0.63, 95% CI –0.95 to –0.31) as were measurement effects for symptoms collected via MC at infection (difference 0.97, 95% CI 0.47 to 1.5), via free text at infection (difference 0.40, 95% CI 0.29 to 0.52), and via free text at the time of the interview (difference 0.15, 95% CI 0.05 to 0.25).

Conclusions: Our results suggest that interviews via CATI resulted in higher numbers of reported symptoms collected via MC and free text and that both selection and measurement effects contributed to this increase. However, no evidence was found that the interview mode affected the overall findings of the CoVerlauf study.

Introduction

Background

Researchers often offer study participants the choice among different interview modes (eg, online, telephone, in person, or paper and pencil) with the purpose of broadening participation [1]. Computer-assisted website interviewing (CAWI) and computer-assisted telephone interviewing (CATI) are two modes commonly used as data collection methods in population-based studies. CAWI is a self-administered, web-based reporting method in which respondents are provided with a link to an online questionnaire that they generally complete on their own and on an internet-enabled device of their preference [2]. CATI, by contrast, is an interviewer-administered method, where trained interviewers serve as intermediaries to ask each question aloud and record responses using a combination of telephone communication and computer-guided technology [3]. Although CAWI mainly uses visual communication channels handled by the participants themselves, CATI uses aural communication and relies on the presence of the interviewers to capture responses.

The use of different interview modes can influence how study data are collected. On the one hand, preferences for interview modes can be significantly associated with selection effects: Participants picking the same mode may also share similar socioeconomic and demographic characteristics, including their use of digital technology [4]. For example, younger age groups from higher socioeconomic backgrounds and urban areas might be more inclined to use digital communication methods, while older age groups or those who habitually stay at home (eg, due to unemployment) might prefer analog ones [1] for exchanging information [5-8]. On the other hand, the use of different interview modes may also lead to measurement effects: systematic variations in how participants respond to identical questions caused by mode-specific intrinsic features (see [9,10]). For instance, interview modes involving a direct interaction with interviewers are subject to different kinds and degrees of information bias than self-administered modes (eg, diagnostic bias or social desirability bias). Collectively, population-based studies may face a situation where participants with similar characteristics choose the same interview mode, which, in turn, subjects them to data collection procedures that induce systematically different response patterns.

Existing research on the effects of mode-specific differences between CAWI and CATI (eg, visual vs aural communication channels and absence vs presence of interviewer, respectively) on response frequency and content has yielded mixed results. From one side, research suggests that CAWI respondents may be more likely to complete online questionnaires with minimal time and cognitive effort, providing shorter, if not incomplete, answers than with other modes [11]. From another side, there is evidence that CAWI may lead to more sincere and extensive answers because it allows participants to respond more calmly, at one's own pace, and with a higher sense of privacy [7]. Correspondingly, the odds of social desirability bias (ie, inclination to adjust answers to conform with anticipated expectations and norms) may vary between interview modes when interrogated about sensitive health topics. For instance, research reports lower odds of social desirability when using CAWI for answers concerning HIV testing [12], whereas higher odds are reported when using CATI for answers about symptoms of infectious diseases, mental health, or substance abuse due to the presence of an interviewer [13-15].

At the same time, research on interviewer effects has indicated that the nature of the spoken interaction in CATI results in a higher number of responses than in self-administered modes, such as CAWI [16]. Furthermore, related research shows mixed results on the effect of the different modes depending on whether the questions are with or without predefined response categories (ie, multiple-choice vs free-text items). Although one meta-analysis found that item response behavior was similar between question formats across all methods [17], a more recent study suggested that CATI respondents systematically selected more options within multiple-choice items, resulting in higher item response proportions to certain questions than with CAWI [18]. Similarly, another study concluded that CAWI questionnaires resulted in fewer free-text items overall compared with CATI [11].

Aside from frequency of response, another line of research has also pointed to between-mode differences in the content of answers. For example, the content of free-text items regarding satisfaction with particular topics in CAWI may be more likely to contain negative feedback than that in CATI [19]. Past studies have also demonstrated that free-text items are particularly prone to interviewer and recall effects in spoken interactions, potentially resulting in differential reporting between CATI and CAWI [16,20,21]. The literature also suggests that, although CAWI might induce primacy effects (eg, inclination to select the first options read from a list of options) [22,23], it is unclear whether CATI is more susceptible to either primacy or recency effects (eg, inclination to select the last options presented from the same list read aloud) [13].

These findings are reiterated in medical and epidemiological literature specifically studying the effect of interviewer- and self-administered mode choices and question format on response patterns. For example, Milton and colleagues [24] found that, related to sensitive mental health and well-being topics, the reporting of symptoms by young Australians (aged 16 years to 25 years) is dependent on whether the interview is self-administered. Overall, they observed a higher disclosure of such high-sensitive items in online-based surveys. Similarly, Zager Kocjan and colleagues [25] highlighted that merging data collected from items asking on psychological functioning from different modes into a single dataset may result in structural noninvariance with significant mean differences between these two types of modes. Namely, the authors observed a greater tendency for respondents to report fewer depressive symptoms when interviewers were directly involved in data collection, potentially resulting in the underestimation of the actual prevalence or severity of symptoms compared with responses collected anonymously through an online portal. The auditory versus visual nature of the interview is also found to have systematic differential response order effects on how respondents report sensitive symptoms [26]. For example, Cernat and colleagues [26] found that items collected from the Center

XSL•FO
RenderX

for Epidemiologic Studies Depression scale are sensitive to primacy and recency effects depending on the interview mode. Although CAWI respondents tended to select items from the beginning of the lists, CATI respondents were more likely to choose those at the end of the list.

Research Objective

This study investigated the potential effects of using different interviewing modes (CATI vs CAWI) on participant response patterns to questions about symptoms experienced in the CoVerlauf study. Conducted in Germany in 2021, the CoVerlauf study provided evidence on the odds of experiencing a post-COVID-19 condition after contracting a verified SARS-CoV-2 infection [27]. The study concluded that more than 12% of participants (203/1612, 12.6%) who reported at least one symptom at the time of their infection experienced symptoms of a post-COVID-19 condition 3 months after the infection (ie, ongoing symptoms of fatigue, breathing difficulties, and cognitive complaints following their initial infection). Since all enrolled participants could select either CAWI or CATI to complete the study questionnaire, mode effects might have impacted data collection and findings. In particular, the choice of the interviewing mode may have not only been associated with the participants' characteristics and health status but also influenced how participants interacted with the multiple-choice and free-text items beyond their shared characteristics.

This study serves two main research objectives: (1) to determine whether there is an established link between the participants' choice of the interview mode (CAWI vs CATI); their health, socioeconomic, and demographic characteristics; and the number of reported post-COVID-19 symptoms; and (2) to identify whether the free-text items regarding if participants experienced "any other symptom" aside from those listed in the multiple-choice items systematically differed between the two mode groups.

Methods

Ethical Considerations

All procedures in the CoVerlauf study were performed in accordance with the ethical standards of the institutional or national research committee and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards. The CoVerlauf study was approved by the Ethics committee of Bremen University (reference number 2020 - 05-EILV). Written consent was obtained from all participants in the study or the legal guardians of those aged younger than 18 years. Participation was voluntary and without any monetary or nonmonetary compensation. The article does not include personal information, identifying details, or identifiable features of research participants.

Study Design

This study used existing data from 1779 individuals with a verified SARS-CoV-2 infection aged between 1 year and 98 years from the City Municipality of Bremen, Germany, who participated in the CoVerlauf study [27]. A detailed description of the study design and the recruitment protocol as well as the questionnaire in German and in English can be found in [27]. Briefly summarized, CoVerlauf explored how even mild cases of COVID-19 could also be associated with a post-COVID-19 condition, defined as reporting at the time of the participants' interview 3 months after the infection at least two of the following symptoms: fatigue, a cognitive disorder, or breathing difficulties. The study used a questionnaire survey to collect self-reported participant data on the symptoms they experienced at 2 different time points. Family members or caretakers could also answer the questionnaire in the place of persons unable to answer the questionnaire by themselves (eg, minors, older adults, or incapacitated persons). Persons were invited via land mail by the Public Health Department of the City Municipality of Bremen (Germany) if they had either tested positive for SARS-CoV-2 or been diagnosed with COVID-19 by a physician between March 1, 2020, and January 31, 2021. One reminder letter was sent out 12 weeks to 16 weeks after the initial invitation letter. Enrolled participants were first contacted by field staff to determine their preferred interviewing mode for completing the questionnaires (CATI or CAWI; concurrent mixed mode design [28]). CATI interviews were conducted by study nurses who all had multiple years of experience in recruitment and data collection for epidemiologic population-based studies and were trained in conducting standardized interviews. To record participants' answers, interviewers used a special version of the online questionnaire that, in addition to the questions, included instructions and transitional statements to be read out during the interviews [2]. CAWI questionnaires were self-administered by the participants.

A first set of questions asked participants to recall the symptoms they experienced at the time of their infection and the first weeks afterward (hereafter, referred to as "time of infection"). A second set of questions asked participants about their long-term symptoms at the time of the interview, which was conducted at least 90 days after their diagnosis (hereafter, "time of interview"). Two question formats were used to collect the information on symptoms experienced at both time points. First, participants were provided with a multiple-choice list of 13 common COVID-19 infection symptoms (common at the time of questionnaire inception): fatigue, respiratory problems, diarrhea, fever, joint pain, scratchy throat, cough, headache, sniffles, chills, nausea, loss of taste, and loss of smell. Second, a free-text item offered the opportunity to provide additional symptoms.

Free-text items were subjected to a word frequency analysis that resulted in the classification of 15 additional symptoms: "hair loss," "tightness of chest," "circulatory problems," "cognitive symptoms," "dermatological skin symptoms," "eye symptoms," "gastrointestinal symptoms," "heart problems," "loss of appetite," "mental difficulties," "nose & ear symptoms," "sensory skin symptoms," "sleep difficulties," and "flushing & sweats." The free-text items were then subject to an independent screening, coding, and consensus procedure by 2 reviewers. The study also gathered data on the participants' weight and height, pre-existing conditions, and socioeconomic status. Additionally, the duration required to complete the questionnaire was automatically logged by the CAWI and CATI software and measured in minutes for each respondent. In 4 instances, the

XSL•FO
RenderX

interview duration was longer than 1000 minutes, indicating that the interview was interrupted for more than 16 hours (CATI: 3; CAWI: 1). These outliers were excluded for the creation of figures (maximum duration after removal: 110 min) and replaced with imputed values using linear regression imputation with the MICE (multivariate imputation by chained equations) algorithm [29] for the regression analysis. A sensitivity analysis, which involved repeating the regression as a complete-case analysis excluding the 4 outliers, revealed no differences (Multimedia Appendix 1).

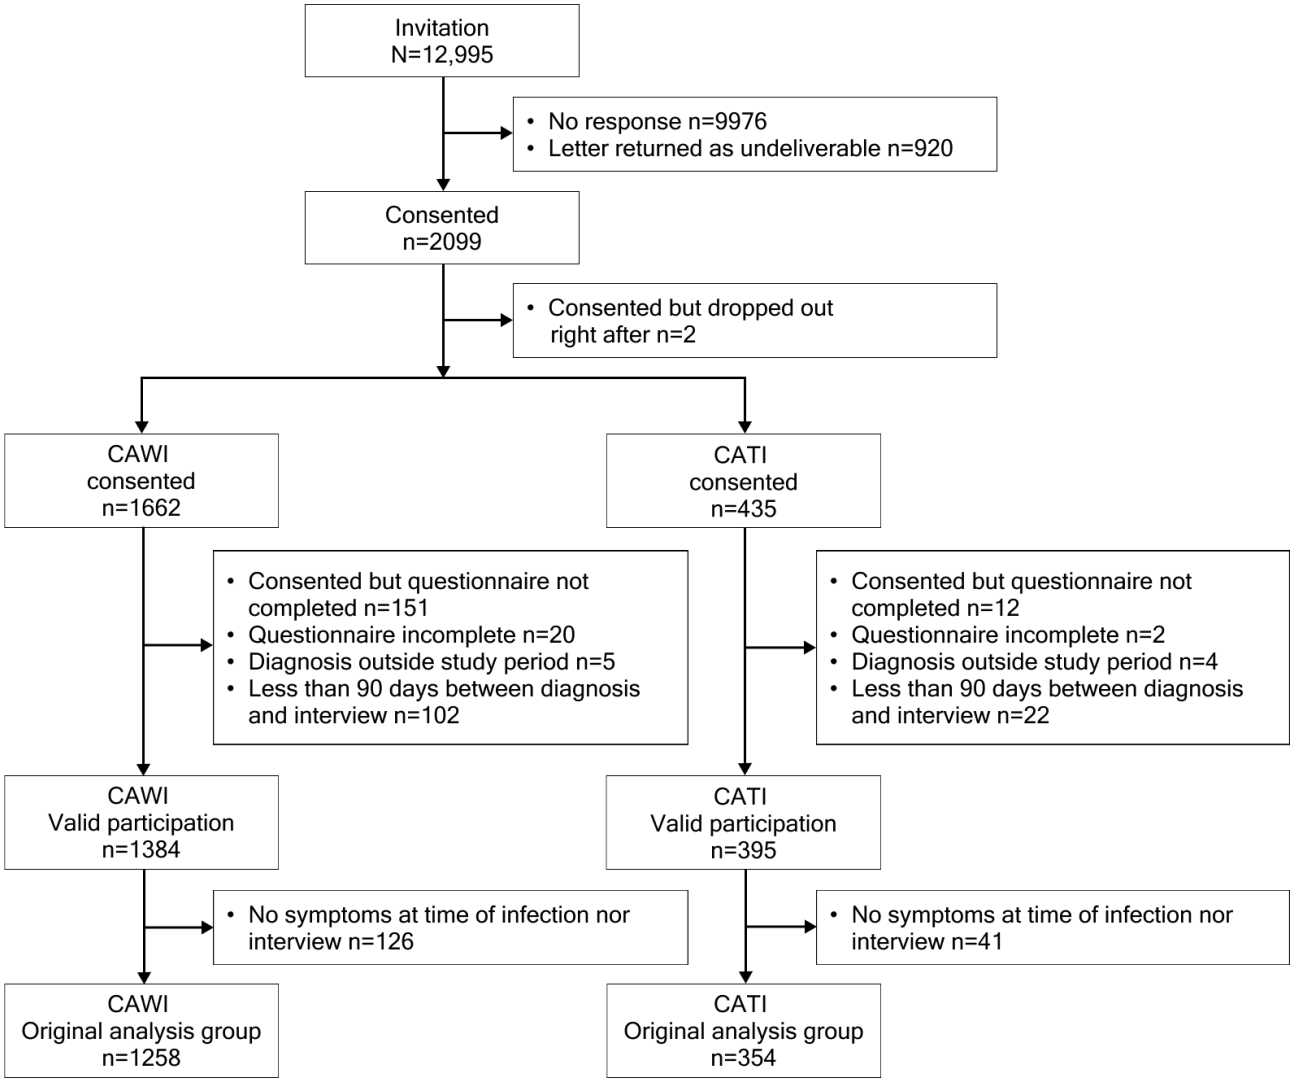
Statistical Methods

This study first examined the interviewing mode preference (CATI vs CAWI) of participants to the CoVerlauf study. A multiple logistic regression analysis was conducted to assess the relationship between the choice of mode and the number of symptoms collected from answers to the multiple-choice and the free-text items at the time of infection and interview separately. The corresponding regression model (equation 1 in Multimedia Appendix 2) included sociodemographic and health indicators as explanatory variables, namely sex (female vs male), age categorized into 8 age groups (0 - 17, 18 - 29, 30 - 39, 40 - 49, 50 - 59, 60 - 69, 70 - 79, ≥80 years), educational attainment based on the International Standard Classification of Education (ISCED) scale (low: 1, 2; medium: 3, 4; high: 5, 6), weight status categorized according to BMI and calculated from self-reported body weight and height (normal: BMI <25 kg/m²; overweight: BMI 25 - 30 kg/m²; obese: BMI ≥30 kg/m²), and the number of pre-existing conditions (0, 1, 2, vs ≥3). The model also included a dichotomous variable "self-reported" ("self" vs "proxy") to differentiate whether the participant self-reported their answers or had another person answer on their behalf. As in the original publication [27], missing values in the variables for weight status and educational attainment were coded as a separate category "Missing."

Furthermore, the study investigated the role of the mode in response patterns to the 2 free-text items on additional symptoms through 2 separate mixed effects multiple logistic regression analyses (equations 2 and 3 in Multimedia Appendix 2). For theses analyses, data were restructured into the long format, where participants were represented with 2 rows: one for their responses at the time of infection and another for those at the time of interview. As such, the 2 models were conducted on a dataset with twice the number of observations than the number of participants considered in each of the analyses. The first model examined the association between the mode (CATI or CAWI) and answering free-text items ("response" vs "no response"). The second model focused on the subset of individuals who answered these questions, assessing how the interview mode influenced the probability of identifying and collecting at least one or more additional symptoms (+1 symptom) compared with none (0 symptoms). Both analyses included the aforementioned sociodemographic and health variables. To account for potential dependencies within individuals, both models incorporated random effects for responses from the same individuals (ie, ID) and time point of the reported symptoms (ie, time of infection and time of interview).

A gamma generalized linear regression model with log link function was used to analyze the outcome variable of overall interview duration (in minutes) and estimate time differences between the 2 mode groups (equation 4 in Multimedia Appendix 2). The choice of the model was based on the overall right-skewed distribution and because the outcome variable is continuous.

The back-door method was used to disentangle selection and measurement effects in the observed mode effects on symptom counts [30,31]. Derived from causal inference theory, this method consists of comparing answers to one of the interview modes (principal mode) to counterfactual answers generated from other modes (alternative modes) that assume the respondents had used the principal mode. To create counterfactual answers, propensity score weights are calculated from a set of variables that are assumed to be insensitive to the choice of the interview mode (eg, age). Outcome differences between the unweighted and weighted answers in the alternative mode are assumed to capture selection effects, whereas differences between the weighted alternative mode and the principal mode quantify measurement effects. For the current analysis, CAWI was selected as the principal mode, and a set of counterfactual answers $CATI_W$ was created using propensity score weights, which were calculated using the interview mode as the outcome variable and sex, age category, educational attainment (low and medium vs high), and number of pre-existing conditions (0, 1, and 2 vs ≥3) as independent variables. Mean differences and 95% CIs were calculated for each of the 4 symptom counts (ie, from the multiple-choice and free-text items at time of infection and interview). In addition, we calculated standardized mean differences (SMDs) with 95% CIs to make the effects comparable across outcome variables.



All statistical analyses were executed using R version 4.3.3. The logistic regression model was executed using the stats package [32], while the mixed effect logistic regression models used the lme4 package in R [33]. Propensity score weights were calculated using the package WeightIt [34], and SMDs were calculated using the package smd [35]. Results for all regression models with interview mode as outcome are reported as odds ratios (OR) with 95% CIs, and results from the model with duration as outcome are reported as mean ratios (MRs) with 95% CIs. Subgroup differences were assessed with Pearson χ^2 tests with Yates continuity correction.

Results

Among all enrolled participants (n=1779), 77.8% (1384/1779) used CAWI, and 22.2% (395/1779) used CATI to complete the CoVerlauf questionnaire (Figure 1).

XSL•FO
RenderX

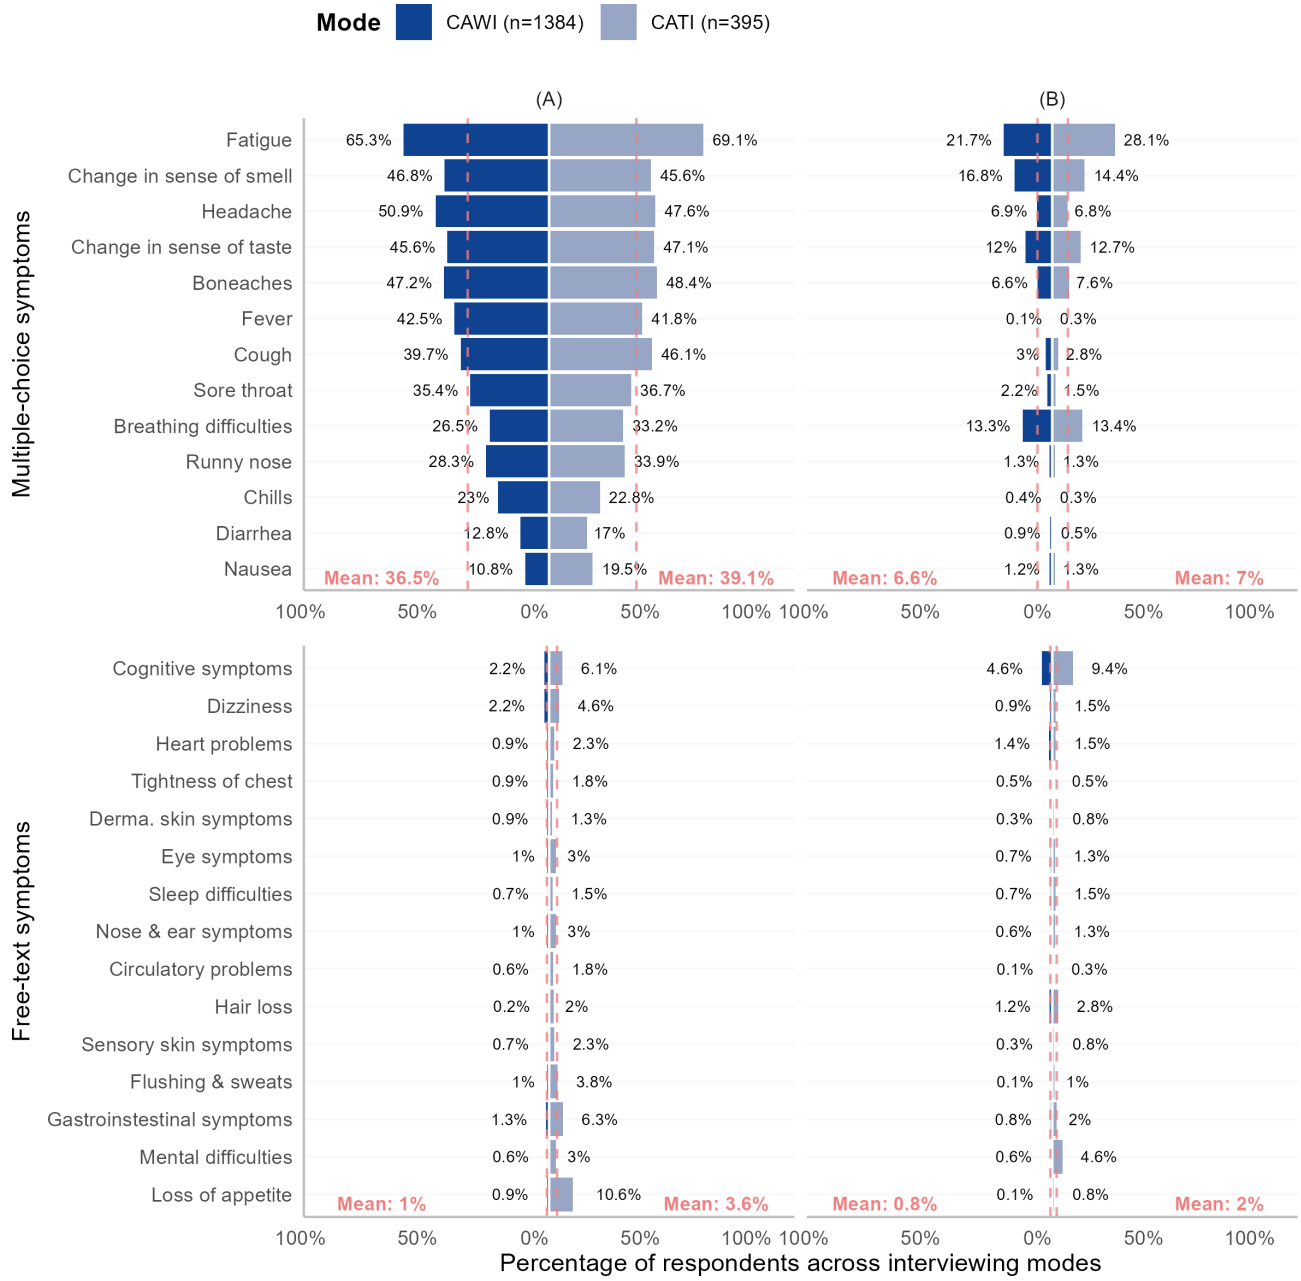


Figure 1. Flowchart of study participants across interview modes of computer-assisted website interviewing (CAWI) and computer-assisted telephone interviewing (CATI).

Compared with CAWI participants, the percentages of participants reporting symptoms was consistently higher with CATI at both time points and across the 13 multiple-choice and 15 free-text items (Figure 2).

XSL•FO
RenderX

Figure 2. Comparison of percentage of participants reporting post-COVID-19 symptoms at the (A) time of infection and (B) time of interview in multiple-choice and free-text items across interviewing modes. CATI: computer-assisted telephone interviewing; CAWI: computer-assisted website interviewing.

The multiple logistic regression analysis assessing associations between sample characteristics and the choice of CATI against CAWI revealed significant differences across most age groups, educational ISCED attainment categories, and the number of symptoms submitted at both the time of infection and interview for both question formats (Table 1). The odds of choosing CATI were lower for participants with a high education (OR 0.46, 95% CI 0.34 - 0.63) relative to those with an upper-secondary education level. In comparison with participants 50 years to 59 years old, participants became more likely to choose CATI with increasing age (60 - 69 years: OR 2.26, 95% CI 1.53 - 3.36; 70 - 79 years: OR 4.98, 95% CI 3.12 - 7.97; ≥80 years: OR 17.29, 95% CI 9.34 - 33.11). Those in age groups younger than 50 years to 59 years old were increasingly less likely to choose CATI, although ORs significantly differing from 1 were only observed in the age group 18 years to 29 years (OR 0.56, 95% CI 0.33 - 0.93). Participants who had their questionnaires completed by another person (ie, proxy respondents) were overall less likely to use CATI (OR 0.28, 95% CI 0.13 - 0.56) than those who responded for themselves. Note that participants in the lowest age group were 1.6 times more likely to use CATI (OR 1.63, CI 0.80 - 3.32), which might be partly explained by the high proportion of their questionnaires completed by a proxy respondent (Multimedia Appendix 3).

The odds of selecting CATI increased by 9% and almost doubled for each additional symptom collected from the multiple-choice (OR 1.09, 95% CI 1.04 - 1.15) and free-text (OR 1.94, 95% CI 1.61 - 2.37) items inquiring about symptoms experienced at the time of infection. The odds of selecting CATI were 14% lower for each additional symptom collected from the multiple-choice items inquiring about symptoms experienced at the time of interview (OR 0.86, 95% CI 0.77 - 0.96). Although the 95% CI included 1, these odds increased for symptoms collected from the free-text items (OR 1.21, 95% CI 0.94 - 1.54).

The odds of responding to the free-text items across time points (infection and interview) were calculated using mixed effects multiple logistic regression analysis (left columns in Table 2). Note that the unit of observations in this analysis is each of the 2 free-text items (n=3558) answered by each participant, rather than the participants themselves (n=1779). Results indicated that participants using CATI were nearly 5 times more likely to respond to the free-text items than those using CAWI (OR 5.22, 95% CI 4.25 - 6.42). Female participants were 57% more likely to provide additional information (OR 1.57, 95% CI 1.30 - 1.89). Participants who reported 3 or more pre-existing conditions were 44% more likely to answer the free-text item (OR 1.44, 95% CI 1.07 - 1.96) than those reporting no pre-existing conditions. For each additional symptom collected from the multiple-choice items, the odds of responding to the free-text items increased by 15% (OR 1.15, 95% CI 1.12 - 1.19). Participants in age groups younger than 39 years (0 - 17 years: OR 0.46, 95% CI 0.25 - 0.82; 18 - 29 years: OR 0.63, 95% CI 0.45 - 0.87; 30 - 39 years: OR 0.59, 95% CI 0.42 - 0.81) and those in the age group of 70 - 79 years (OR 0.63, 95% CI 0.43 - 0.91) were less likely to respond to the free-text items than those aged 50 years to 59 years. Participants with missing ISCED information were nearly twice as likely to respond to these items (OR 1.95, 95% CI 1.11 - 3.42).

[e]ISCED: International Standard Classification of Education.

The answers to free-text items were further investigated by assessing the effect of the mode on whether additional symptoms were identified or extracted at either the time of infection or interview. This was done by conducting a mixed effects logistic regression analysis on the subset of answers from participants who did engage with the free-text items (n=729; right columns in Table 2). The outcomes of the regression analysis showed that the odds of collecting additional symptoms from the free-text items was 42% lower for answers from CATI questionnaires (OR 0.58, 95% CI 0.41 - 0.82). These odds rose by 8% for each additional symptom reported in the multiple-choice items (OR 1.08, 95% CI 1.02 - 1.14). The odds increased 2-fold for participants who reported 2 or more pre-existing conditions than those reporting none (2: OR 1.8, 95% CI 1.02 - 3.00; ≥3: OR 2.0, 95% CI 1.18 - 3.43). Participants aged 40 years to 49 years were twice as likely to provide answers that resulted in the collection of additional symptoms (OR 2.0, 95% CI 1.13 - 3.55).

Some participants' sociodemographic characteristics, the number of symptoms they reported (Figure 3), and the time they took to complete their interviews were associated with their interview mode preference (Table 3). A gamma generalized linear model with log link function revealed that choosing CATI over CAWI was associated with an 8% increase in interview duration (MR 1.08, 95% CI 1.01 - 1.16). Across all types of symptom counts, the duration increased between 2% and 18% per additional symptom reported (infection multiple choice: MR 1.02, 95% CI 1.01 - 1.03; infection free-text: MR 1.18, 95% CI 1.13 - 1.23; interview multiple choice: MR 1.03, 95% CI 1.01 - 1.06; interview free-text: MR 1.09, 95% CI 1.03 - 1.15). Reporting a higher number of pre-existing conditions was also associated with longer interview durations (2: MR 1.13, 95% CI 1.03 - 1.24; ≥3: MR 1.10, 95% CI 1.00 - 1.22). Furthermore, all age groups younger than 50 years had shorter interview durations (0 - 17 years: MR 0.84, 95% CI 0.71 - 0.99; 18 - 29 years: MR 0.80, 95% CI 0.72 - 0.88; 30 - 39 years: MR 0.80, 95% CI 0.73 - 0.88; 40 - 49 years: MR 0.84, 95% CI 0.77 - 0.92), while participants in the age group of 70 years to 79 years participated in longer interviews (MR 1.26, 95% CI 1.12 - 1.42).

[d]MC: multiple choice item.

[e]Not applicable.

[f]ISCED: International Standard Classification of Education.

Applying the back-door method [30,31] to disentangle selection and measurement effects revealed a selection effect: The mean number of symptoms collected via the multiple-choice questions on symptoms experienced at the time of infection increased by approximately 0.6 (difference −0.63, 95% CI −0.95 to −0.31) after weighting the CATI sample to align with the CAWI sample (Table 4). When expressed in terms of SMD, this increase corresponded to a small effect size (SMD −0.19, 95% CI−0.33 to −0.05) according to common benchmarks (eg, Cohen *d*: 0.2=small, 0.5=medium, 0.8=large). Noticeable measurement effects were also identified: Symptoms reported via CATI were associated with higher counts collected through multiple-choice items at the time of infection (difference 0.97, 95% CI 0.47 to 1.5), free-text items at the time of infection (difference 0.40, 95% CI 0.29 to 0.52), and free-text items at the time of the interview (difference 0.15, 95% CI 0.05 to 0.25). Quantified as SMD, this amounted to a large effect size for symptom counts collected via free-text items at the time of infection (SMD 0.55, 95% CI 0.43 to 0.66) and medium effects sizes for symptom counts collected via multiple choice at the time of infection (SMD 0.31, 95% CI 0.19 to 0.42) and free text at the time of the interview (SMD 0.25, 95% CI 0.14 to 0.36).

Table . Selection and measurement effects, quantified as raw differences (D) and standardized mean differences (SMD), in the number of reported symptoms (N_{Sx}) collected with either multiple-choice (MC) or free-text items at the times of infection and interview.

N_{Sx}	CATI[a] (n=395), mean (SD)	$CATI_W$[b] (n=395), mean (SD)	CAWI[c] (n=1384), mean (SD)	Selection (CATI-$CATI_W$)		Measurement ($CATI_W$-CAWI)	
				D (95% CI)	SMD (95% CI)	D (95% CI)	SMD (95% CI)
Infection MC	5.09 (3.40)	5.72 (3.49)	4.75 (2.93)	−0.63 (−0.95 to −0.31)	−0.19 (−0.33 to −0.05)	0.97 (0.47 to 1.5)	0.31 (0.19 to 0.42)
Infection free-text	0.53 (0.90)	0.55 (0.86)	0.15 (0.54)	−0.02 (−0.10 to 0.06)	−0.02 (−0.16 to 0.12)	0.40 (0.29 to 0.52)	0.55 (0.43 to 0.66)

Interview free-text	0.30 (0.75)	0.28 (0.76)	0.13 (0.44)	0.02 (−0.04 to 0.08)	0.03 (−0.11 to 0.17)	0.15 (0.05 to 0.25)	0.25 (0.14 to 0.36)

[a]CATI: computer-assisted telephone interviewing.

[b]$CATI_w$: set of counterfactual answers created using propensity score weights.

[c]CAWI: computer-assisted website interviewing.

To investigate whether the overall observed differences in response frequency associated with the interview mode may have influenced the results of the main analysis reported in the original study [27], we repeated its analysis with the additional variables “interview mode” (CATI vs CATI) and “self-reported” (self vs proxy). The comparison between the results of the original and the modified models (Multimedia Appendix 4) revealed minimal differences. Since this analysis excluded all individuals who did not report any symptoms (n=167), we additionally checked for any systematic differences between the latter and participants who reported at least one symptom (n=1612). No evidence for statistically significant differences was found between the distribution of the two subgroups of participants (χ^2_1=0.45, *P*=.504; Multimedia Appendix 5).

Discussion

Principal Findings

This study examined the effect of using CAWI and CATI on the response patterns of participants in the CoVerlauf study. In particular, the study compared sample characteristics of participants selecting each mode, as well as their responses to multiple-choice and free-text items about their infection and postinfection symptoms.

In total, the number of questionnaires completed by CATI was roughly 3.5 times lower than that completed by CAWI [3]. Although CAWI participants were over 2 times more likely to belong to the highest ISCED levels and tended to be younger (except for minors), the majority of CATI participants were from lower ISCED levels and aged 60 years and older. Participants reporting a higher number of symptoms in the multiple-choice items and who submitted additional post-COVID-19 symptoms as free-text items were also more likely to have chosen CATI to complete the questionnaire. Similar to earlier studies [5-8,36], the self-selection of CoVerlauf participants to either mode was associated with their personal circumstances (eg, age and educational background). In this sense, the possibility of using different modes might have been both a matter of accessibility and inclusion (eg, for individuals with lower digital dexterity) and an opportunity to cater to the needs of individuals with severe postinfection symptoms or unresolved questions about their COVID-19 experience.

The clustering around the mode may also be reflective of a preference to speak directly with the researchers and specialists,

XSL•FO
RenderX

as the spoken interaction would potentially enable participants to spontaneously inquire about unresolved questions. Notably, respondents experiencing a higher number of symptoms were more likely to have chosen CATI. Correspondingly, this reasoning further explains why proxy respondents for participants in the lowest age group (eg, concerned parents) could have chosen CATI rather than to self-administer the questionnaire online. However, it must be noted that participants were not given any indication prior to their decision with whom they would be speaking; in this case, the interviews were conducted by study nurses.

Furthermore, the study identified that the use of the two modes may have influenced data collected and resulted in measurement effects, indicating that response behaviors differed across the modes. The odds of answering the free-text items were 5 times higher for CATI respondents, whereas the odds of actually collecting additional symptoms from these questions were only half for respondents of CATI than of CAWI. These findings were also directly reflected in the overall response duration (measured in minutes) of the questionnaires between the two mode groups, where CATI respondents took longer on average to complete both item formats.

A further analysis using the back-door method [30,31] to untwine selection and measurement effects revealed evidence for selection effects only for multiple-choice items inquiring on the number of symptoms at the time of the infection. At the same time, evidence for measurement effects was observed for symptoms collected from multiple-choice items for both time points, as well as for symptoms from free-text items at the time of infection. These patterns suggest that, although participants with more symptoms were more likely to choose CATI over CAWI (ie, selection effect), CATI was also more effective at eliciting a higher number of symptom reports.

These results possibly hint at a “chattiness factor” in spoken interactions, as the use of CATI led to collecting more free-text items although not forcibly leading to identifying any additional symptoms. Survey research argues that direct interaction between interviewer and respondents, such as in the case of CATI, can cause deviations from the standardized interview procedures, even when strict standardized guidelines are used (eg, verbatim reading of questionnaire items, nondirective probing, and the use of neutral feedback) [37,38]. As a result, lengthier and unscripted content may not be fully avoided despite standardization efforts. Moreover, as suggested for health survey research, in atypical situations, such as those experienced by the CoVerlauf respondents, response accuracy, particularly for free-text items, may be associated with the respondent’s ability to seek or receive further clarification rather than on the strict adherence to a standardized protocol [39]. In this sense, the higher number of free-text responses from CATI questionnaires may stem from the immediate and personal interaction rather than from the questions alone. Allegedly, it could also be argued that CAWI is not as effective as CATI at capturing additional information through the free-text items. As highlighted by the analysis on response duration, the difference in time between the two modes for multiple-choice items was proportionally smaller than that of the free-text items, which might be indicative of the lower effectiveness of the online format at engaging respondents to elaborate on further symptoms (eg, due to the effort needed to structure answers in written form rather than express them spontaneously).

Additionally, the study revealed that CoVerlauf participants reporting more symptoms in the multiple-choice items, with ≥2 pre-existing conditions, and aged 40 years to 49 years were the most likely to submit free-text items with identifiable symptoms. Together, the higher numbers of symptoms and pre-existing conditions might be indicative of an increased self-awareness and previous experience describing health conditions to researchers and other health care professionals. Although this was the case for all participants, independently of their interview mode, submitting free-text items may have been particularly pronounced in the CATI interviews by diagnostic biases, occurring when interviewers inadvertently make assumptions about participants’ health status based on answers provided to initial questions in an interview. As the odds of identifying additional symptoms in the free-text items rose with the number of previously stated symptoms in the multiple-choice list, it cannot be ruled out that interviewers varied their intensity or form of asking or probing for follow-up information to the free-text questions. Typically, this effect can be countered by appropriate interviewer training, as was done in the CoVerlauf study. Definitely ruling out a diagnostic bias post hoc, however, would require audio recordings of the telephone interviews, which were not created due to privacy concerns.

Overall, this study found that measurement effects may arise when using a concurrent mixed mode approach. By including the interview mode as a covariate in the original analysis reported in [27], which investigated post-COVID-19 conditions, this study found that the mode effects observed here would not have changed the original conclusions. A generally discussed solution to isolate or mitigate these effects would be to randomly assign eligible participants to available modes and, as such, control for selection biases. However, a randomized single-mode approach would have the drawback of increasing the odds of study withdrawal for participants who find the assigned interview mode inaccessible or unsuitable for sharing their personal information. Such approach of mode randomization would therefore defeat the purpose of inclusion and broadening participation or response.

In this sense, enabling a speech-based response within the CAWI questionnaires, namely for free-text items, could facilitate isolating the mode effects without defeating the purpose of representativeness. Providing such an option could allow researchers to simultaneously isolate the effect of the interviewer’s presence on eliciting open-ended answers and the effort required for participants to type elaborate responses with, for example, support of speech-to-text technology.

Strengths and Limitations

This analysis made use of a large socioeconomically diverse sample and a combination of different analytical methodologies to explore the problem of mode effects from multiple perspectives.

However, only self-reported data on symptoms and pre-existing conditions were available. Therefore, it was not possible to

XSL•FO
RenderX

validate whether the observed differences between CATI and CAWI corresponded to differences in health status (ie, a selection effect). None of the analyses included the severity of symptoms, which may have also influenced the choice of interview mode, because neither question format assessed the severity of the symptoms [27]. The analyses could not control for possible differences in interviewer involvement during the telephone interviews because the interviews were not recorded. Since the interview mode was not randomly assigned, the model adjusting for mode choice might still provide biased estimates (eg, if the mode selection is a result of the outcome or confounds with other unmeasured covariates). Finally, the validity of the back-door method used here critically depends on the assumption that the selected back-door variables fully capture the selection effect on the variables of interest, an assumption that eludes empirical testing. As already highlighted by other studies, current methodologies do not allow for easily detangling self-selection mode effects from measurement mode effects and its factors [40,41].

Conclusions

Although the choice of interview mode was associated with the frequency of reported symptoms and the number of free-text answers, no evidence was found that the interview mode systematically affected the results or conclusion reported in the CoVerlauf study [27]. Moreover, the use of concurrent elective modes for data collection was effective at covering and engaging participants from different age, education, and health groups in the CoVerlauf study. Concurrent mixed mode approaches to data collection can be an effective solution to address the diversity of participants' communication needs and preferences without biasing the final results of a population-based study.

Funding

This study was partially supported by Leibniz ScienceCampus Bremen Digital Public Health, which is jointly funded by the Leibniz Association (W4/2018), the federal state of Bremen, and the Leibniz Institute for Prevention Research and Epidemiology–BIPS. The funding source had no role in the design, data collection, data analysis, or decision to submit the manuscript for publication.

Data Availability

Data analyzed for the current study are not publicly available due to privacy concerns but will be made available upon reasonable request to the corresponding author (rach@leibniz-bips.de).

Abstract

Background: Chatbots are increasingly deployed across various domains; however, systematic evaluation of their usability remains limited, particularly in non-Western contexts. The 11-item Chatbot Usability Scale (BUS-11), a multidimensional instrument grounded in human-computer interaction theory, has demonstrated strong psychometric properties in prior studies; however, a validated Chinese version does not exist, despite China being one of the largest chatbot markets.

Objective: This study aimed to translate, culturally adapt, and validate the BUS-11 for Chinese users.

Methods: Following established cross-cultural adaptation procedures, the scale was forward- and back-translated, reviewed by an expert committee, and pilot-tested for clarity and feasibility. A main validation study was then conducted with 214 participants, who completed 438 evaluations of the chatbots across 10 widely used systems.

Results: Psychometric analyses demonstrated excellent scale-level content validity index (ie, 0.92), strong internal consistency (Cronbach α=0.92), and a clear 3-factor structure (Accessibility, Interaction Process Quality, and Information Quality), explaining 56.1% of the variance. Meanwhile, privacy or security and response time were retained as single-item indicators. The Chinese BUS-11 was concise, user-friendly, and psychometrically robust.

Conclusions: This work fills a critical gap by providing the first validated instrument for assessing chatbot usability in Chinese contexts, enabling reliable cross-cultural comparisons and supporting both research and practical design evaluation in human-computer interaction.

KEYWORDS

chatbot; usability; satisfaction; user experience; cross-cultural adaptation

Introduction

Chatbots (conversational agents) are artificial intelligence systems designed to interact with users through natural language dialog [1]. They have become increasingly ubiquitous across the globe in domains ranging from online retail and customer service to public administration and health care [2-4]. China represents a particularly active context for chatbot adoption, with large-scale use in commercial platforms, government service portals, and hospital-based patient guidance systems [5-7]. As chatbots become embedded in everyday services, their usability becomes increasingly consequential because it shapes user satisfaction, acceptance, and sustained engagement [8].

In human-computer interaction (HCI), usability refers to how easy, efficient, and satisfying a system is for users to achieve their goals [9]. For chatbots, usability extends beyond general ease of use to include interaction qualities that are specific to conversation—such as turn-taking, dialog coherence, response appropriateness, and perceived trustworthiness [10,11]. However, commonly used usability instruments (eg, the System Usability Scale) were developed for graphical user interfaces and provide limited coverage of conversational properties central to chatbot interaction [12]. To better reflect the chatbot context, the Chatbot Usability Questionnaire (CUQ) adapts traditional usability constructs to conversational agents, emphasizing ease of use, navigability, clarity of onboarding, and basic error handling [13]. Yet, the CUQ remains anchored in general usability notions and may insufficiently capture AI-specific determinants of sustained chatbot use, including information adequacy, contextual understanding, responsiveness, and privacy- and trust-related concerns.

To address these gaps, Borsci et al [10,14] proposed the 11-item Chatbot Usability Scale (BUS-11), a theory-driven, chatbot-native instrument developed from HCI principles and validated through multistage psychometric testing across different chatbot systems and contexts. The BUS-11 operationalizes chatbot usability as a multidimensional construct encompassing Accessibility, Interaction Process Quality, Information Quality, Privacy and Security, and Response Time, thereby facilitating comprehensive evaluation and cross-system

XSL•FO
RenderX

comparability. Despite its growing international adoption, a validated Chinese version of the BUS-11 is currently lacking, which limits the rigorous measurement of usability in one of the world's largest chatbot markets.

Cross-cultural adaptation of usability instruments requires ensuring semantic, conceptual, and cultural equivalence to preserve measurement validity across contexts [15]. Building on established adaptation guidelines and prior localization efforts in Chinese HCI research [16], this study aims to translate and culturally adapt the BUS-11 into Chinese and to evaluate its psychometric properties. Specifically, we (1) conducted a rigorous translation and cultural adaptation of the BUS-11, (2) examined reliability, validity, and factor structure using data from 214 participants and 438 chatbot evaluations, and (3) provided initial evidence on Chinese users' perceptions of chatbot usability to facilitate future cross-cultural comparisons in chatbot user experience (UX) research [17].

Methods

Scale Translation and Cultural Adaptation

Overview

Following authorization from the original scale's corresponding author, the translation of the BUS-11 into Chinese was conducted using the Brislin translation model as improved by Jones et al [18]. Consistent with established guidance for cross-cultural instrument adaptation (eg, forward-back translation with expert reconciliation), we documented all translation decisions to ensure semantic and conceptual equivalence. The specific steps are as follows: (1) forward translation: the researcher and a bilingual professional proficient in both Chinese and English independently translated the original BUS-11 into Chinese. Discrepancies and alternative phrasings were recorded in a reconciliation log and resolved through consensus, resulting in an initial Chinese draft; (2) back translation: another bilingual translator, whose native language was Chinese, translated the initial Chinese draft back into English, producing a back-translated English version; (3) consistency check: a monolingual English-speaking expert familiar with the BUS-11 reviewed and compared the original scale with the back-translated version. Any residual inconsistencies (eg, colloquialisms or culture-specific expressions) were discussed in joint meetings with all translators until consensus was achieved, ensuring conceptual and semantic consistency; (4) final translation: a final Chinese translation was prepared collaboratively by all translators, incorporating adjustments from the consistency review, thus establishing semantic equivalence with the original BUS-11. Minor wording refinements were made for clarity and idiomatic naturalness (no item content was substantively altered). At the end of the cultural adaptation process, the final Chinese version of the BUS-11 and the original English items are presented side by side in Table 1 to facilitate direct comparison of item wording and to enhance the transparency of the adaptation procedure.

Table . Original English and Chinese versions of the 11-item Chatbot Usability Scale (BUS-11).

Dimension in English (Chinese)	Item in English (Chinese)
Access the chatbot's functions (一, 访问聊天机器人的功能)	• The chatbot function was easily detectable (容易找到此聊天机器人的各种功能 [例：修改聊天机器人使用的语言或修改头像]) • It was easy to find the chatbot (找到此聊天机器人的入口是一件简单的事)
Quality of chatbot functions (二, 聊天机器人功能的质量)	• Communicating with the chatbot was clear (与此聊天机器人的沟通过程是顺畅的) • The chatbot was able to keep track of context (此聊天机器人能够保持上下文的连贯性) • The chatbot's responses were easy to understand (此聊天机器人的回复易于理解)
Provide quality of conversation and information (三, 提供对话和信息的质量)	• I find that the chatbot understands what I want and helps me achieve my goal (我感觉此聊天机器人理解我的目的，并协助我达成目的) • I believe the chatbot informs me of any possible privacy issues (此聊天机器人提供的信息量是合适的，不多不少) • The chatbot only gives me the information I need (此聊天机器人只提供了我需要的信息) • I feel like the chatbot's responses were accurate (我觉得此聊天机器人的回复内容正确无误)
Privacy and security (四, 隐私和安全)	• I believe the chatbot informs me of any possible privacy issues (我相信此聊天机器人会告知我任何潜在的隐私问题)
Response time (五, 回复时间)	• My waiting time for a response from the chatbot was short (我等待聊天机器人回复的时间是短的)

XSL•FO
RenderX

Cultural Adaptation

In June 2024, we convened an expert committee (n=6) to evaluate the cultural appropriateness of the Chinese translation. The expert committee comprised 6 specialists drawn from the broader panel reported in Table 2, all of whom had doctoral-level training or senior professional experience in HCI, usability or UX evaluation, health informatics, or scale development. Eligibility criteria included: (1) formal training in a relevant discipline, (2) demonstrated experience in chatbot-related research or usability evaluation, and (3) prior involvement in scale development, instrument adaptation, or related methodological work. Each expert independently compared the Chinese items with the original BUS-11 and assessed semantic and conceptual equivalence, idiomatic appropriateness, and readability. Disagreements were resolved through iterative discussion until consensus was reached. Revisions focused on wording-level refinements to improve clarity and align the tone with standard Chinese conversational norms, without altering the intended coverage of the construct.

Table . Background information of the experts.

Expert	Sex	Age (years)	Education	Experience (years)	Domains	Title
1	Male	37	Doctorate	5	Human-Computer Interaction	Researcher

[a]UX: user experience.

Pilot Study

Overview

To ensure participants evaluated chatbots after a realistic, standardized interaction, we designed representative use-case tasks for 10 commonly used chatbot systems in China (refer to Table 3 for details). For example, participants were instructed to interact with Taobao's intelligent customer service, simulating a typical query related to membership benefits: "Your friend recommends you purchase Taobao's 88vip. Please use Taobao's chatbot 'Smart Customer Service Xiao Mi' to help you understand the specific benefits of 88vip. Log in as instructed and converse with this chatbot." Refer to Multimedia Appendix 1 for details. Immediately after completing the assigned task, participants filled out the Chinese BUS-11 about that chatbot. The same task-rating flow was later applied in the main study.

XSL•FO
RenderX

Table . Overview of the chatbots evaluated in the study. General-purpose large language model (LLM)-based chatbots (eg, Doubao, Wenxin Yiyan, and Kimi) were evaluated using a single domain-specific task to ensure consistency with the task-based evaluation applied to all systems.

Chatbot (developers)	Domain	Platform	Primary function	Example task
AliMe (Taobao; Alibaba)	E-commerce	App or web	Customer service	Understanding Taobao 88VIP benefits
Zhihu Zhida (Zhihu Inc)	Knowledge Q and A[a]	App or web	Knowledge explanation	Pomodoro study method
Tencent Cloud Presales Bot (Tencent Holdings Ltd)	Enterprise services	Web	Product consultation	AI[b] functions in Tencent Meeting
Gaokao Xiaozhi (Zhangshang Gaokao)	Education	App or web	Academic counseling	University and major recommendation
Bank of China Online Bot (Bank of China)	Finance	Web	Banking consultation	Credit card selection
Ctrip Xiaoyou (Ctrip)	Travel	App or web	Booking assistance	Hotel room information
Huawei Xiaoyi (Huawei)	Consumer electronics	App	Technical support	Battery performance troubleshooting
Doubao (ByteDance)	Interview preparation	Web	Conversational assistance	Interview question coaching
Wenxin Yiyan (Baidu)	Education or assessment	Web	Question analysis	Exam question analysis
Kimi (Moonshot AI)	Health information	Web	Medical Q and A[a]	Hepatitis B test interpretation

[a]Q and A: question and answer.

[b]AI: artificial intelligence.

Sample and Data Collection

In July 2024, a pilot study involving 15 participants was conducted at a Beijing-based company, using convenience sampling. Participants completed the Chinese BUS-11 after performing designated tasks with selected chatbots. Completion times were recorded, and qualitative feedback regarding item clarity, ambiguity, and comprehension difficulties was collected through structured interviews. The pilot's primary aims were to assess task feasibility, confirm average completion time, and identify any items requiring wording refinements. Pilot data were used only for refinement and were not included in the main validation dataset.

Outcomes Informing Quality Control

Based on the observed average completion time (~5 minutes 20 seconds), we set a priori a data-quality rule for the main study to exclude online questionnaires completed in less than 5 minutes, in addition to removing any incomplete submissions.

Content Validity Validation

Between June and July 2024, 8 domain experts (HCI, informatics, chatbot engineering, and scale development; refer to Table 2) independently rated the relevance of each Chinese BUS-11 item to its intended dimension using a 4-point scale. Content validity was quantified to explicitly confirm item relevance and construct representativeness in the Chinese linguistic and cultural context following translation and cultural adaptation, even though no substantive changes were made to the original item content [19]. The item-level content validity index (I-CVI) was computed as the proportion of experts assigning ratings of 3 or 4, and the average scale-level content validity index (S-CVI) was calculated as the average of the I-CVIs. Criteria of I-CVI≥0.78 and S-CVI≥0.90 were used to indicate acceptable-to-excellent content validity. I-CVIs ranged from 0.875 to 1, with 4 items (items 3, 4, 6, and 11) achieving unanimous relevance (I-CVI=1). The average S-CVI was 0.920, indicating excellent content validity of the Chinese BUS-11. All content validity analyses were completed before the main psychometric validation study.

Main Validation Study: Participants, Measures, Procedure, and Analysis

Participant Recruitment

Participants were recruited via social media platforms (eg, Red Note [Xiaohongshu Information Technology] and WeChat [Tencent Holdings Ltd]) according to predefined inclusion criteria: native Chinese speakers or individuals proficient in Chinese and aged 18 years or older. Recruitment followed an online convenience sampling approach; participation was voluntary. Each participant was randomly assigned to interact with 3 distinct chatbots (selected from the 10 systems), performing 1 predefined task per chatbot and completed the BUS-11 immediately after each interaction. Thus, each participant contributed 3 independent chatbot evaluations, yielding a repeated-measures data structure (evaluations nested within participants). For psychometric analyses (eg, reliability and exploratory factor analysis [EFA]), evaluations were analyzed at the evaluation level (N=438); design implications of repeated measures are discussed in the "Limitations" section.

Sample Size Estimation

Based on factor analysis requirements (5 - 10 times the number of items, accounting for a 20% invalid rate), a minimum sample size of 69 participants was established. We targeted ≥70 participants and exceeded this target, ultimately recruiting 214

XSL•FO
RenderX

participants who provided 438 evaluations, thereby improving the robustness of reliability and factor-analytic estimates.

Participant Characteristics

We analyzed 438 valid chatbot evaluations submitted by 214 participants (69 males and 145 females), with each participant randomly assigned to evaluate 3 of 10 popular Chinese chatbot systems using the Chinese BUS-11. The sample skewed young, with 67.3% (144/214) aged 18 - 24 years and 22.4% (48/214) aged 25 - 30 years, and was highly educated, with 93% (199/214) holding a bachelor's degree or above, and represented multiple industries, most prominently health care (52.8%, 113/214) and education or training (11.7%, 25/214). Most respondents had prior exposure to chatbots (79%, 169/214) and at least moderate familiarity (43%, 92/214) reported being familiar or very familiar, while 27.5% (59/214) reported being unfamiliar or very unfamiliar. These characteristics suggest a relatively tech-savvy cohort, which should be considered when interpreting generalizability. Detailed distributions are provided in Table 4.

Often (5-6)	25 (11.7)
Every day (7)	21 (9.8)

XSL•FO
RenderX

Measures

Two primary instruments were used:

1. General demographic questionnaire: collected participant demographics and chatbot usage patterns.
2. Chinese BUS-11: a culturally adapted 11-item scale assessing chatbot usability across 5 dimensions. Because 2 BUS-11 dimensions ("Privacy and Security" and "Response Time") are single-item constructs in the original instrument, they were retained in the survey but treated as single-item indicators in factor-analytic planning (refer to "Data Analysis" section).

Data Collection

Data were collected electronically via Tencent Questionnaire. Participants completed tasks on their own devices and then accessed the BUS-11 through a survey link. Strict criteria ensured data quality, and questionnaires that were not fully completed were directly discarded. Based on pilot timing, online questionnaires completed in less than 5 minutes were excluded to reduce insufficient-effort responses. In the pilot experiment, the research team measured the time taken to complete the questionnaire, with an average duration of 5 minutes and 20 seconds. The finalized main study dataset comprised 438 valid chatbot evaluations.

Data Analysis

Data were exported to Microsoft Excel, verified, and analyzed using IBM SPSS Statistics (version 26.0). Reliability was evaluated using Cronbach α coefficients for the overall scale and for each of its multi-item dimensions. Structural validity was assessed via EFA after sampling-adequacy checks (Kaiser-Meyer-Olkin [KMO] index and Bartlett test of sphericity). We used a principal components extraction with the Kaiser criterion (eigenvalues >1.0) and scree plot inspection to determine the number of factors and applied varimax rotation to aid interpretability. Standard criteria guided item retention: primary factor loadings of ≥0.40, absence of substantial cross-loadings (≥0.30), and conceptual interpretability of the resulting factor solution. Salient loadings were defined as those with values of ≥0.40. In line with the instrument's structure, the EFA focused on the 9 items related to multi-item dimensions; the 2 single-item dimensions ("Privacy and Security" and "Response Time") were not included in the EFA but were retained as single-item indicators in descriptive analyses. $P<.05$ was considered statistically significant for inferential tests (eg, Bartlett test of sphericity). We note that principal component analysis (PCA) is commonly used in early-stage exploratory work for data reduction and structure discovery, and future work may complement this with common-factor methods (eg, principal axis factoring) and confirmatory factor analysis (CFA) once larger samples are available.

Ethical Considerations

This study was approved by the Ethics Committee of the School of Nursing, Peking Union Medical College (approval no PUMCSON-2023-10). All participants provided electronic informed consent before participation. Participation was voluntary, and participants could withdraw at any time without penalty. No personally identifying information was collected in the analytic dataset. Data were stored securely and analyzed in deidentified form.

Results

Scale Reliability and Validity

Structural Validity

Before factor extraction, data suitability was confirmed (KMO=0.743; Bartlett $\chi^2_{36}=628.185$; $P<.001$) because 2 BUS-11 dimensions are single-item constructs ("Privacy and Security" and "Response Time") and they were not included in the EFA. The analysis, therefore, used the remaining 9 items (refer to Figure 1 for the scree plot).

In this study, PCA and varimax orthogonal rotation were used to extract common factors. Nine items (items 10 and 11 were excluded from the EFA due to having only 1 item each) were analyzed and combined with the scree plot (Figure 1), and 3 common factors with eigenvalues greater than 1.0 were ultimately extracted, accounting for a cumulative variance contribution rate of 56.107%. The results of the EFA for this experiment are shown in Table 5.

XSL•FO
RenderX

[a]Not available.

XSL•FO
RenderX

EFA with varimax rotation revealed a clear 3-factor structure for the Chinese version of BUS-11 (Table 5). The 3 factors explained 15.2%, 19.6%, and 21.3% of the total variance, respectively, accounting for a cumulative 56.1% of the variance. Factor 1 (Accessibility) consisted of 2 items reflecting the ease of locating and using chatbot functions, with strong loadings (0.840 and 0.760). Factor 2 (Interaction Process Quality) consisted of 3 items that described conversational smoothness, coherence, and comprehensibility, with loadings ranging from 0.716 to 0.759. Factor 3 (Information Quality) consisted of 4 items related to understanding user intent, the appropriateness of information, the absence of irrelevant content, and the reliability of responses, with loadings ranging from 0.627 to 0.739.

Only factors extracted by the eigenvalue >1 criterion are shown. Item domain labels reflect the original BUS-11 conceptual domains and are provided for reference.

Internal Consistency (Reliability)

The overall internal consistency of the Chinese BUS-11 was excellent (Cronbach α=0.92). By factor, reliability was acceptable to excellent, as indicated by Accessibility (Cronbach α=0.79), Interaction Process Quality (Cronbach α=0.91), and Information Quality (Cronbach α=0.93). Reliability was not computed for the single-item dimensions ("Privacy and Security" and "Response Time"). Item-level diagnostics (Table 6) showed corrected item-total correlations ranging from 0.453 to 0.819, indicating that all items were positively associated with the overall scale score. Cronbach α (if an item was deleted) ranged from 0.91 to 0.93, suggesting that removing any single item would not meaningfully improve internal consistency.

Table . Mean, SD, corrected item-total correlation, and Cronbach α (if an item is deleted) for the 11-item Chatbot Usability Scale (BUS-11).

Item	Values, mean (SD)	Corrected item-total correlation	Cronbach α (if an item is deleted)
1	3.79 (1.187)	0.539	0.93
2	3.57 (1.059)	0.616	0.92
3	3.77 (0.952)	0.819	0.91
4	3.77 (0.923)	0.785	0.91
5	3.79 (0.946)	0.816	0.91
6	3.66 (0.982)	0.817	0.91
7	3.57 (0.979)	0.785	0.91
8	3.53 (0.96)	0.771	0.91
9	3.55 (0.992)	0.798	0.91
10	2.80 (0.998)	0.453	0.93
11	4.08 (0.866)	0.469	0.93

User Feedback on Item Clarity and Acceptability

Overall, participants reported that the Chinese BUS-11 was easy to understand and straightforward to complete. Most respondents indicated that the items were clear and adequately reflected their experiences with chatbot interactions. The average completion time was approximately 5 minutes, suggesting that the scale imposed a minimal response burden and was suitable for use in both research and applied settings without causing respondent fatigue.

While feedback was generally positive, one recurrent issue was identified. Participants provided optional open-ended comments on item clarity and completion experience. Comments were reviewed and summarized into recurring issues. Three themes emerged: (1) ambiguity in interpreting the privacy/security item, with some participants indicating uncertainty about what constitutes "risk disclosure" in chatbot interactions; (2) context-dependence of judgments, where respondents noted that perceived usability varied by task type and chatbot domain; and (3) overall clarity and low burden, with many respondents reporting that the items were easy to understand and could be completed quickly. These feedback themes informed our interpretation of the psychometric findings and priorities for future refinement.

Sensitivity Analysis Across Sociodemographic Variables

To examine the robustness of the Chinese BUS-11 across user subgroups, we conducted sensitivity analyses by gender, age, and prior experience with chatbots (refer to Table 7). No significant differences in overall BUS-11 scores were observed between male and female participants (*P*=.12), nor across major age groups (*P*=.84), suggesting stable performance across these demographic characteristics. In contrast, participants with prior chatbot experience reported slightly higher BUS-11 scores than those without such experience (*P*=.03). This pattern indicates that the scale is sensitive to meaningful differences in user familiarity with chatbot interaction, while remaining robust across core sociodemographic variables.

25 - 30	3.49 (0.95)		
31 - 40	3.30 (0.67)		
41 - 50	3.93 (0.67)		
Prior chatbot experience		*t* test	.03
Yes	3.64 (0.71)		
No	3.46 (0.78)		

Discussion

Rigorous Localization and Cultural Adaptation

This study localized the BUS-11 for the Chinese context, providing a standardized instrument for evaluating chatbot usability in China. Given BUS-11's theory-driven and multidimensional design, its adaptation is particularly relevant for contemporary conversational systems. Following established cross-cultural adaptation practices, we applied a forward-backward translation workflow (inspired by the Brislin model) combined with iterative expert committee review to ensure semantic and conceptual equivalence [20]. The expert panel (HCI/human factors–oriented) focused on pragmatic clarity, idiomatic appropriateness, and cultural relevance, resulting in a Chinese BUS-11 that remained closely aligned with the original without substantive item revisions.

Notably, the absence of major item-level changes should not be interpreted as evidence that culture is irrelevant to chatbot usability. Instead, cultural effects may operate more subtly, shaping how users interpret and prioritize usability facets (eg, privacy expectations, responsiveness norms, and conversational politeness) rather than necessitating overt rewording. Such differences may be reflected in response patterns and the observed factorial organization, underscoring the importance of future work using multigroup approaches (eg, measurement invariance testing) and direct cross-cultural comparisons to examine whether BUS-11 functions equivalently across cultural groups and whether certain dimensions show differential salience in Chinese users. In addition, consistent documentation of translation decisions improves transparency and supports reproducibility for subsequent adaptation work and comparative HCI research [20]. Given the rapid expansion of chatbot deployment across service domains [21], a psychometrically grounded Chinese BUS-11 can facilitate rigorous UX benchmarking in China and enable more meaningful integration of Chinese user evidence into the broader HCI literature [22].

Participant Sample and Representativeness

Our sample selection aimed for diversity in gender, age, education, and industry background, resulting in a broad cross-section of Chinese chatbot users. In practice, however, the achieved sample was skewed toward younger, highly educated adults. Most participants were aged 18 - 30 years, and more than 90% held at least a bachelor's degree. While this profile likely reflects the early adopters of new technologies [23] and those most engaged with contemporary chatbot applications, it also introduces some limitations on generalizability. Younger and tech-savvy users may have different usability perceptions than older or less technologically experienced individuals. Prior research in human factors has noted that older adults can face unique usability challenges and may interact with technology in distinct ways [24]. Our current sample underrepresents such groups, as well as users from rural areas or lower educational backgrounds, which means the usability impressions captured by the scale might not fully reflect the broader population of potential chatbot users. On the positive side, the concentration of experienced users in our sample could heighten sensitivity to subtle differences in chatbot interaction quality—these users are likely familiar with a variety of interfaces and may provide discerning feedback. The inclusion of participants from a range of industries (eg, education, health care, internet or information technology, and so on) is another strength, as it suggests the scale items were interpreted meaningfully across different usage contexts. Indeed, the BUS-11 was designed to be domain-agnostic, and our results tentatively support its applicability in multiple sectors. However, some fields (eg, finance and construction) were represented by relatively few respondents, so conclusions about those domains should be drawn cautiously. Likewise, because recruitment relied on convenience sampling (primarily in a few urban regions), there may be regional or cultural subgroup differences within China that our study did not capture. In summary, our sample provides a solid initial test of the scale among active chatbot users, but it is not fully representative of all user segments. Future research should broaden the sampling frame to include older adults, less frequent technology users, and a wider geographic distribution to ensure the Chinese BUS-11 is robustly validated for the general population. Broadening the participant base in this way would enhance the scale's universality and address the western, educated, industrialized, rich, and democratic bias analog in the Chinese context, thus

XSL•FO
RenderX

strengthening confidence that the tool works well for all target users, not just the young and educated subset.

Reliability, Validity, and Key Psychometric Findings

Overview

We conducted a comprehensive psychometric evaluation of the Chinese BUS-11, including assessments of content validity, construct (factorial) validity, internal consistency reliability, and user feedback on item clarity and practical usability. Overall, the findings provide strong evidence that the localized scale retains the scientific integrity of the original instrument. Here, we discuss each set of findings in turn, relating them to established benchmarks and prior research, and interpret their implications for the scale's use in HCI and human factors studies.

Content Validity

By consulting a panel of 8 experts to review the relevance of each item, we established that the content validity of the Chinese BUS-11 is high. The I-CVI for every item was very strong, with 4 items (Items 3, 4, 6, and 11) achieving an I-CVI of 1 (ie, unanimously deemed highly relevant by all experts). The remaining items also scored well above conventional acceptability thresholds [25]. Given that an I-CVI≥0.78 is often considered the minimum when 6 or more experts are involved, our results indicate that each item is considered clearly representative of the intended construct by domain specialists. The S-CVI was 0.920 (both by the averaging method and the universal agreement method), exceeding the common cutoff of 0.90 for excellent content coverage of a construct. These indices confirm that the BUS-11 (Chinese version) has comprehensive content coverage and the items collectively cover the important facets of chatbot usability without obvious omissions. This outcome was facilitated by the diverse expertise of our review panel, which included professionals in HCI, usability engineering, and systems engineering. Their varied perspectives helped ensure that the items were not only translated correctly but also conceptually appropriate for Chinese users. In practical terms, the high content validity suggests that Chinese BUS-11 can confidently be used to gauge chatbot usability aspects as intended—such as efficiency, clarity of answers, and user comfort—without missing key elements. The rigorous content validation process, in line with recommended scale development procedures, provides a solid foundation for the subsequent construct validation. It also offers reassurance to practitioners that the instrument has face validity in the local context (the items make sense to experts and presumably to end-users as well). We believe this strong content validity will help drive adoption of the scale in both research and industry evaluations, as stakeholders can trust that the instrument measures what it is supposed to measure (ie, salient user experience factors for chatbots).

Structural Validity (EFA)

To examine the underlying factor structure of the Chinese BUS-11, we carried out an EFA on the survey responses. Preliminary checks confirmed that our data were suitable for factor analysis: the KMO measure of sampling adequacy was 0.743, which is above the usual threshold of 0.60 and can be considered "middling" to "good" [26], and the Bartlett test of sphericity was highly significant, indicating sufficient interitem correlations for extracting latent factors. Using principal component extraction with varimax rotation, we identified a 3-factor solution that best fit the data. These 3 extracted common factors had eigenvalues greater than 1 and together accounted for about 56.1% of the total variance in users' responses. A cumulative variance above approximately 50% is acceptable in behavioral research, given the complexity of HCI measures, so 56% indicates that the scale captures a substantial portion of the usability perception variance in our sample. Each factor showed a clear thematic grouping of items, reflecting distinct dimensions of the chatbot user experience. Notably, 2 specific usability aspects (ie, "Privacy and Security" and "Response Time") were each originally measured by a single item in the BUS-11. As single-item facets, they could not load onto multi-item factors in the EFA and were thus analyzed separately (we examined their scores independently rather than including them in the factor structure). The remaining nine items clustered into three coherent factors: (1) Accessibility (eg, ease of accessing and using the chatbot, such as simple interface and low effort to start the interaction), (2) Interaction Quality (covering the smoothness, coherence, and understandability of the conversational exchange), and (3) Information Quality (assessing the relevance, clarity, and correctness of the chatbot's responses, without unnecessary redundancy). This structure is broadly consistent with the original conceptual framework of the BUS scale, which encompassed multiple dimensions of chatbot usability [10], but our findings suggest a somewhat more consolidated factor model in the Chinese context.

In the original development of the BUS, a 5-factor model (BUS-15) was proposed, which included separate dimensions for privacy and response speed alongside factors analogous to those we found [10]. Our EFA results imply that Chinese users may not distinguish as many separate categories, instead perceiving a more integrated set of usability factors. Attributes related to the conversational process and functional outcome appear to intertwine; users who find the interaction process smooth also tend to perceive the information provided as high quality, suggesting an underlying general perception of "interaction effectiveness." Interestingly, a recent re-examination of BUS-11 in a large multichatbot dataset also identified a simpler factor structure than initially theorized [27]. Our findings align with that perspective, reinforcing the idea that a parsimonious model (fewer and broader factors) can sufficiently capture chatbot usability evaluations. It is worth noting that we chose to retain the "Privacy and Security" and "Response Time" items as standalone indicators in the instrument, due to their importance in usability (users do care about privacy and speed) and their presence in the original scale. However, from a psychometric standpoint, single-item factors are suboptimal because they do not allow for internal consistency reliability estimation and cannot capture the breadth of a construct. Best practices in scale development typically recommend having at least 2 - 3 items per factor to achieve adequate reliability and construct representation [28]. Therefore, one implication is that future refinement of the Chinese BUS might involve expanding these facets—adding a couple of items to better gauge the privacy/security aspect of chatbot use (eg, covering data

XSL•FO
RenderX

protection, user consent, and so on) and the responsiveness aspect (eg, not just speed but also perceived responsiveness or promptness). For now, including those single items ensures that our localized scale does not lose any content relative to BUS-11, and they provide useful standalone measures (eg, designers might specifically want to see ratings of privacy transparency). In summary, the EFA supports the structural validity of the Chinese BUS-11 by confirming that its items coherently measure multiple distinct dimensions of usability. The identified 3-factor structure captures the major themes of chatbot usability experience in our sample. This structure provides an empirical basis for scoring or interpreting the scale (eg, computing subscale scores for Accessibility, Interaction Quality, and Information Quality) and sets the stage for future confirmatory testing to verify whether this structure generalizes to other samples or holds under more stringent statistical criteria.

User Feedback on Item Clarity

The observed variability in interpreting the privacy/security item suggests that privacy-related usability judgments may be more sensitive to users' privacy literacy and to how risk information is surfaced in routine interactions, consistent with prior privacy research indicating limited user engagement with privacy policies and disclosures [29,30]. From a measurement perspective, this supports retaining privacy/security as a relevant usability facet while motivating future refinement (eg, adding additional items or more concrete wording) and the use of cognitive interviewing to improve interpretability across user subgroups [31]. In addition, the brief completion time (≈3 - 4 minutes) suggests that the Chinese BUS-11 imposes low respondent burden, comparable to widely used usability instruments and suitable for rapid assessment in applied settings [32,33].

Limitations

While this study yielded encouraging results for the Chinese adaptation of BUS-11, several limitations must be acknowledged to contextualize the findings and guide future work. First, the sample, as discussed, was not fully representative of all user demographics. The geographic distribution of participants was relatively narrow (with many users from a few major cities), and certain age groups (especially adults aged older than 50 years) and occupations were underrepresented. The current sample underrepresents such groups, as well as users from rural areas or lower educational backgrounds, which means the usability impressions captured by the scale might not fully reflect the broader population of potential chatbot users. Indeed, the BUS-11 was designed to be domain-agnostic, and the results tentatively support its applicability in multiple sectors. However, some fields (eg, finance and construction) were represented by relatively few respondents, so conclusions about those domains should be drawn cautiously. Likewise, because recruitment relied on convenience and snowball sampling (primarily in a few urban regions), there may be regional or cultural subgroup differences within China that this study did not capture. This means the current validation is most directly applicable to younger, educated Chinese users in urban settings. Caution should be used in generalizing the psychometric results to, say, older adults or rural users, who might interact with chatbots differently or have different usability concerns. Expanding the sample in future studies will be important to verify that the scale maintains its reliability and validity across a broader swath of the Chinese population. Additionally, larger and more heterogeneous samples would allow for analyses of measurement invariance—checking whether the scale functions equivalently across subgroups such as older vs younger users, or high-frequency vs low-frequency chatbot users [34]. In addition to representativeness concerns, the overall sample size should be considered a methodological limitation. Although the study included 438 chatbot evaluations, these ratings were provided by 214 participants, which may be modest for robust factor-analytic procedures. According to the International Test Commission Guidelines for Translating and Adapting Tests [35], stable and generalizable factor solutions are typically supported by larger participant samples. The relatively limited number of participants in this study may therefore constrain the stability and generalizability of the extracted factor structure and other psychometric estimates. Future studies with larger and more diverse samples are needed to further confirm the robustness of the Chinese BUS-11's factor structure and measurement properties.

Second, certain BUS-11 dimensions in the current form rely on a single item (notably the "Privacy and Security" and "Response Time" facets). Single-item measures, while convenient, provide limited psychometric information. They can neither capture the full breadth of a construct nor estimate internal consistency for that construct. The strong performance of the overall scale notwithstanding, the precision and reliability of those facets could be improved. Future research should consider enriching these dimensions by developing and testing additional items. For example, the privacy facet might be expanded with items addressing whether the chatbot clearly asks permission for data usage or whether it provides settings for privacy control. The response time facet might include an item on whether the chatbot's speed meets user expectations or if delays ever cause frustration. Of course, any new items would themselves need to undergo translation and validation. The trade-off is that adding items could slightly increase completion time, but as long as the total remains reasonable (eg, <2 minutes increase), it would likely be worth it for a more robust scale. In short, the current findings highlight the need to bolster those single-item constructs for a more rigorous measurement model [28].

Third, this study primarily evaluated the scale in general usage scenarios (common chatbot systems for generic tasks) and did not deeply examine how the scale performs in specific industry contexts or use-case scenarios. It remains an open question whether users in specialized domains—such as health care, education, finance, or customer service—interpret and prioritize the BUS-11 items similarly. Different contexts may put extra emphasis on certain usability aspects; for instance, in health care chatbot applications, issues such as empathy, trust, and accuracy of information might be even more critical [36], whereas in e-commerce chatbots, speed and transactional clarity could dominate user satisfaction. The inability to test such variations is a limitation. It is possible that the BUS-11 might require minor tweaks or weighting adjustments to be optimally effective in certain domains, or it may prove to be robust as

XSL•FO
RenderX

is—we simply do not have the data yet to say. Future validations should include a variety of chatbot types and domains to ensure the scale's content validity and structure hold in those settings, or to highlight any domain-specific gaps that could be addressed by additional context-specific items.

Additionally, this study did not use external, established usability instruments to assess convergent validity. Although the BUS-11 is conceptually grounded in usability theory, the absence of a comparator scale—such as the System Usability Scale or other widely used usability measures—limits the ability to empirically examine whether the Chinese BUS-11 correlates appropriately with validated measures of related constructs. As a result, the current validity evidence is primarily restricted to internal structure and reliability and does not allow for a direct assessment of alignment with existing usability benchmarks. Future studies should consider incorporating one or more established usability scales to evaluate convergent (and potentially discriminant) validity, thereby strengthening the overall validity framework and situating the Chinese BUS-11 more clearly within the broader landscape of usability measurement tools. Moreover, test-retest reliability was not assessed due to the cross-sectional design. Therefore, the temporal stability of the Chinese BUS-11 could not be directly evaluated. Future studies should administer the scale to the same users across time points to examine score stability when the usability of a chatbot system remains unchanged.

Finally, the psychometric analysis relied on EFA due to the novelty of applying the BUS-11 in Chinese. We have not yet conducted a CFA on a separate sample, which would be the next step to confirm whether the 3-factor model (plus the 2 single-item factors) holds under stricter modeling conditions. A CFA would allow us to test the hypothesized factor structure (possibly including correlated factors or a higher-order factor of overall usability) and to adjust for measurement errors [37]. It would also enable a formal comparison of alternative models—for example, whether a structure with 5 distinct factors (if privacy and speed were expanded) fits significantly better than a 3-factor structure, or whether a single-factor model (treating usability as unidimensional) is decisively inferior to a multifactor model. Additionally, with a large enough sample, multigroup CFA could be used to test measurement invariance across key groups (eg, male vs female, younger vs older, and different regions), ensuring the scale operates equivalently [34]. Because the current sample size was modest for CFA and was collected as a single group, we reserve these confirmatory analyses for future work. In summary, the use of EFA was appropriate for initial validation; however, further confirmation via CFA is needed to solidify the factor structure and verify that the Chinese BUS-11 meets the standards of psychometric validity expected for a widely applicable research instrument.

The exploratory factor analytic results should be interpreted considering the factor extraction approach used in this study. We note that PCA is commonly applied in early-stage exploratory research for data reduction and initial structure discovery; however, PCA does not explicitly model latent constructs. As such, while appropriate for an initial examination of the scale structure, this approach provides only preliminary evidence regarding the underlying factor model. Future research with larger samples may complement these findings by applying common-factor methods (eg, principal axis factoring) and conducting CFA to more rigorously test the latent structure of the Chinese BUS-11.

Conclusion

This study delivers a validated Chinese adaptation of BUS-11 with excellent internal consistency, strong expert-rated content validity, and a clear 3-factor structure for multi-item facets (Accessibility, Interaction Process Quality, and Information Quality), while preserving the privacy and speed facets conceptually. The instrument fills a measurement gap for chatbot UX evaluation in China and provides researchers and practitioners with a concise, psychometrically sound tool suitable for laboratory and field contexts alike. Future work should establish temporal stability, convergent validity, and confirmatory structure and expand coverage to underrepresented user groups and domain-specific scenarios to further strengthen its utility and generalizability.

Abstract

Background: Digital health technologies offer new opportunities for cognitive screening and monitoring among older adults. In Thailand, where dementia prevalence is rising, accessible web-based cognitive tools remain limited despite their potential to facilitate early detection and community-based assessment. Understanding usability and validity is critical to ensure successful implementation in real-world contexts.

Objective: This study aimed to develop and validate a web-based application, *Healthy Brain Test*, for cognitive and functional assessments in dementia screening among older Thai adults. Specific objectives were to (1) design user-centered cognitive modules covering key cognitive domains and (2) evaluate correlations between the web-based assessments and conventional clinical tools to determine diagnostic cutoffs for cognitive impairment.

Methods: We designed *Healthy Brain Test* as a self-administered web application suitable for older users and their caregivers. The platform includes digital versions of the Thai Mental State Examination (e-TMSE), a clock drawing test, and a category verbal fluency test, along with electronic versions of the short form of the Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE-16) and cognitive instrumental activities of daily living (IADLs). Participants completed both web-based and paper-based assessments. Correlations between modalities were analyzed, and receiver operating characteristic (ROC) curves were generated to determine sensitivity and specificity. Data were analyzed using SPSS for Windows, version 30.0 (IBM Corp) and MedCalc Statistical Software (MedCalc Software Ltd).

Results: A total of 198 older adults participated (women: 137/198, 69.2%; median age 69.4 years), with 57.1% (113/198) having more than 6 years of education. Of the 198 participants, 44 were diagnosed with major neurocognitive disorder, 58 were diagnosed with mild neurocognitive disorder, and 96 were cognitively normal. The e-TMSE showed strong agreement with the traditional TMSE (r=0.837; P<.001). Category verbal fluency, IQCODE-16, and IADL modules also demonstrated significant correlations (P<.001). The e-TMSE achieved an area under the ROC curve of 0.84 (bootstrapped 95% CI 0.78 - 0.89); a cutoff ≤23 provided 88.6% sensitivity and 70.1% specificity for identifying major neurocognitive disorder. Participants reported high ease of use and engagement during pilot testing.

Conclusions: *Healthy Brain Test* demonstrated strong validity and usability as a web-based cognitive and functional assessment platform for dementia screening. Its integration of established cognitive measures into a digital interface enables remote, accessible, and user-friendly evaluation for older adults and caregivers. Future research should assess long-term feasibility, user adherence, and integration with clinical workflows to support large-scale screening initiatives.

KEYWORDS

Alzheimer disease; cognitive screening; dementia; functional assessment; neurocognitive disorders; neuropsychology; web application

Introduction

Cognitive performance often declines with normal healthy aging [1], with measurable deficits in episodic memory, working memory, verbal fluency, and executive control processes such as visual attention and set-shifting [2]. These age-related changes do not inevitably progress to dementia. However, dementia remains a significant public health challenge in Thailand, and prevalence rises sharply with age. A national survey reported that 3.3% of Thai adults aged 60 years and older have some form of dementia, increasing from 1% at ages 60 years to 64 years to 31.3% among those aged 90 years and older [3].

Digital technologies have advanced cognitive screening, offering potential benefits for clinical treatment, therapeutic interventions, and behavioral research. Web-based applications now extend beyond screening to support self-management, caregiver education, cognitive rehabilitation, and remote clinical monitoring. Recent studies indicate that such applications can contribute across the dementia care continuum [4-8].

In Thailand, web-based dementia care applications are still early in development. *Dementia U-Care*, designed to help community health workers screen and monitor cognitive data, has demonstrated feasibility and positive user experiences [9]. Vorasut and Tantatsanawong [10] introduced smartphone-based screening tools using the Thai version of the Mini-Mental State Examination (MMSE; *MMSE-Thai 2002*) with text-to-speech and audio recording. More recently, Yangyuensathaporn et al [11] validated the Application-Based Cognitive Screening Test for older Thai adults, reporting 92.9% sensitivity and 70% specificity.

Standard neuropsychological instruments, including the MMSE and Montreal Cognitive Assessment (MoCA), have long served as benchmarks for detecting early cognitive impairment. The MMSE has a sensitivity of 87% to 97% and specificity of 70% to 82% depending on the population and selected cutoff points [12]. The MoCA, designed to be more sensitive to mild cognitive impairment, typically achieves about 90% sensitivity and approximately 87% specificity [13].

Given population aging and the demand for accessible screening, there is a need to develop localized, culturally appropriate digital tools. Therefore, we designed *Healthy Brain Test*, a test battery usable via a web-based application on tablet computers and mobile phones. Our objectives were to develop a web-based cognitive and functional assessment platform aimed at dementia screening in older Thai adults and to design diverse cognitive modules targeting different cognitive domains. We also sought to evaluate correlations between the web-based assessments and traditional tools.

Methods

Study Population

Participants older than 40 years were prospectively and purposefully recruited from the Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand. Recruitment aimed to evaluate cognitive and functional performance for dementia screening using a dedicated web-based application. All participants had either relatives or long-term caregivers who could provide relevant information on cognitive status and daily functioning at present and over the past 10 years.

Inclusion and Exclusion Criteria

The inclusion criteria were provision of informed consent after full explanation of study objectives and procedures; adequate literacy, vision, and hearing; and ability to read and comprehend Thai. The exclusion criteria were acute confusion, impaired decision-making capacity due to cognitive or medical conditions, and severe physical or psychiatric illness.

Diagnostic Classification

The diagnoses of major and mild neurocognitive disorders were established according to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, Text Revision* (*DSM-V-TR*) criteria [14]. Cognitively healthy control participants were recruited from relatives or spouses of patients and community volunteers. These individuals had no reported cognitive decline, demonstrated normal performance on cognitive assessments, and maintained independence in daily functioning.

Ethical Considerations

All participants provided written informed consent before enrollment. The study protocol was approved by the Human Research Protection Unit, Faculty of Medicine Siriraj Hospital, Mahidol University (COA No. Si 982/2021), and conducted in accordance with the Declaration of Helsinki. All participant data were kept confidential and anonymized in accordance with the approved ethical protocol. Participants in Phase I received 100 (US $3.20) for their participation, while participants in Phase II did not receive any financial compensation.

Study Design

This study used a user-centered design approach to develop and validate a web-based cognitive and functional screening application for the early detection of dementia. Development proceeded through 3 consecutive phases involving collaboration among computer scientists, health informaticians, psychologists, and neurologists. All phases were guided by clinical relevance, usability, and data security considerations.

Phase I: Prototype Development and Usability Testing

In Phase I, we developed a prototype of the *Healthy Brain Test* web-based application and iteratively refined it to optimize

XSL•FO
RenderX

usability. The application was designed for Android-based systems to ensure widespread accessibility and compatibility with mobile devices commonly used in community and clinical settings. Usability testing sessions with volunteer participants generated feedback that informed successive iterations of the user interface. The interface comprised 2 sections. The home page introduced the application, provided general usage instructions, and presented an electronic informed consent form. Users were required to review and agree to the consent before accessing the assessment modules. The assessment section included 5 digital cognitive and functional tasks adapted from established neuropsychological assessments. Each task was preceded by a brief, standardized instructional message, and the design enhanced interactivity while reducing reliance on motor skills. Initial trials were conducted with volunteer participants to ensure content comprehension, ease of use, and engagement.

Phase II: The Pilot Study

A pilot study at Siriraj Hospital, Thailand, evaluated the validity of the *Healthy Brain Test* web-based cognitive screening application against traditional paper-and-pencil assessments. A total of 77 participants were enrolled (50 women and 27 men). Participants were categorized into 3 groups: 21 with major neurocognitive disorder (mild to moderate dementia), 23 with mild cognitive impairment, and 33 cognitively normal control participants. Each participant completed both conventional and digital cognitive assessments. The traditional paper-and-pencil assessments included the standard Thai Mental State Examination (TMSE) and the clock drawing test (CDT), administered under the supervision of trained clinicians. After the paper-and-pencil tests, participants were guided through the web-based *Healthy Brain Test* application. The full assessment session lasted approximately 1 hour to 2 hours depending on participant performance.

Phase III: Practical Use and Data Collection

In the final phase, we implemented the *Healthy Brain Test* web-based application in real-world settings across 5 health centers in Thailand. The sites were Siriraj Hospital, Vajira Hospital, Phatthalung Hospital, Phitsanulok Health Center 2, and Nakhon Phanom Hospital. This phase aimed to assess practical use in community-based and clinical environments and to facilitate the early detection of cognitive impairment and dementia. The application was accessible via health care professionals or self-assessment under observation, and participants could complete the digital screening autonomously or with minimal assistance. This approach supported broader reach and feasibility across diverse settings, including rural areas. We enrolled 198 participants (137 women and 61 men). Based on clinical evaluation, participants were categorized as follows: 44 with major neurocognitive disorder, 58 with mild cognitive impairment, and 96 with normal cognition. Digital screening assessed cognitive and functional performance using 5 standardized tasks embedded in the application. We also collected demographic and educational data and stored them on secure cloud servers, ensuring confidentiality and compliance with data protection standards.

The Healthy Brain Test Web-Based Application

Healthy Brain Test is a web-based digital cognitive and functional screening tool that integrates 5 core neuropsychological tasks digitally adapted from validated conventional tests widely used to assess cognitive function. The battery included the following 5 tasks: a slightly modified electronic TMSE (e-TMSE); the CDT implemented as the Clox test; and a category verbal fluency test (VFT). The remaining tasks were the short form of the Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE-16) and cognitive instrumental activities of daily living (cognitive IADLs). Illustrative screenshots of the assessment modules are shown in Figure 1.

XSL•FO
RenderX

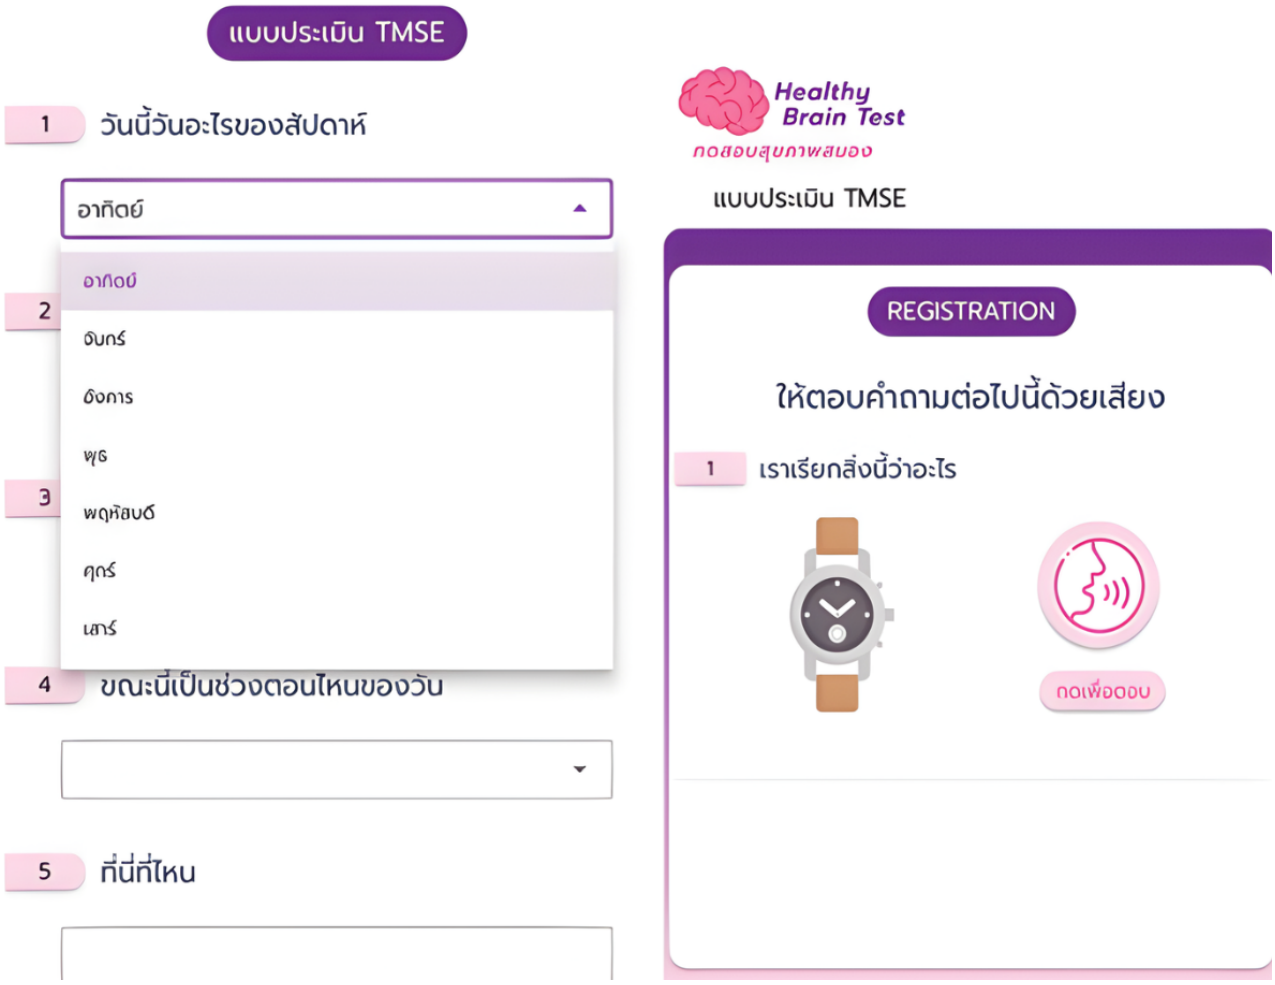
Figure 1. Healthy brain test module overview illustrating the list of 5 modules: electronic Thai Mental State Examination (e-TMSE), the Clox test (digitized clock drawing), category verbal fluency test (animal naming), short form of the Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE-16), and cognitive instrumental activities of daily living (cognitive IADLs).

Electronic Thai Mental State Examination

The e-TMSE, a digital adaptation of the standard paper-and-pencil TMSE [15], was designed to assess cognitive function through an interactive web-based interface. The traditional TMSE consists of 11 items covering 6 cognitive domains: orientation, registration, attention and calculation, recall, language, and visuospatial abilities. Each component was implemented in the digital platform, and the original maximum total score of 30 points was preserved. Participants used touch to choose from on-screen options or to handwrite responses for language items. Samples of the e-TMSE test screens are shown in Figures 2 and 3.

XSL•FO
RenderX

Figure 2. Electronic Thai Mental State Examination (e-TMSE) sample screens showing orientation and registration, which use touch-based entry.



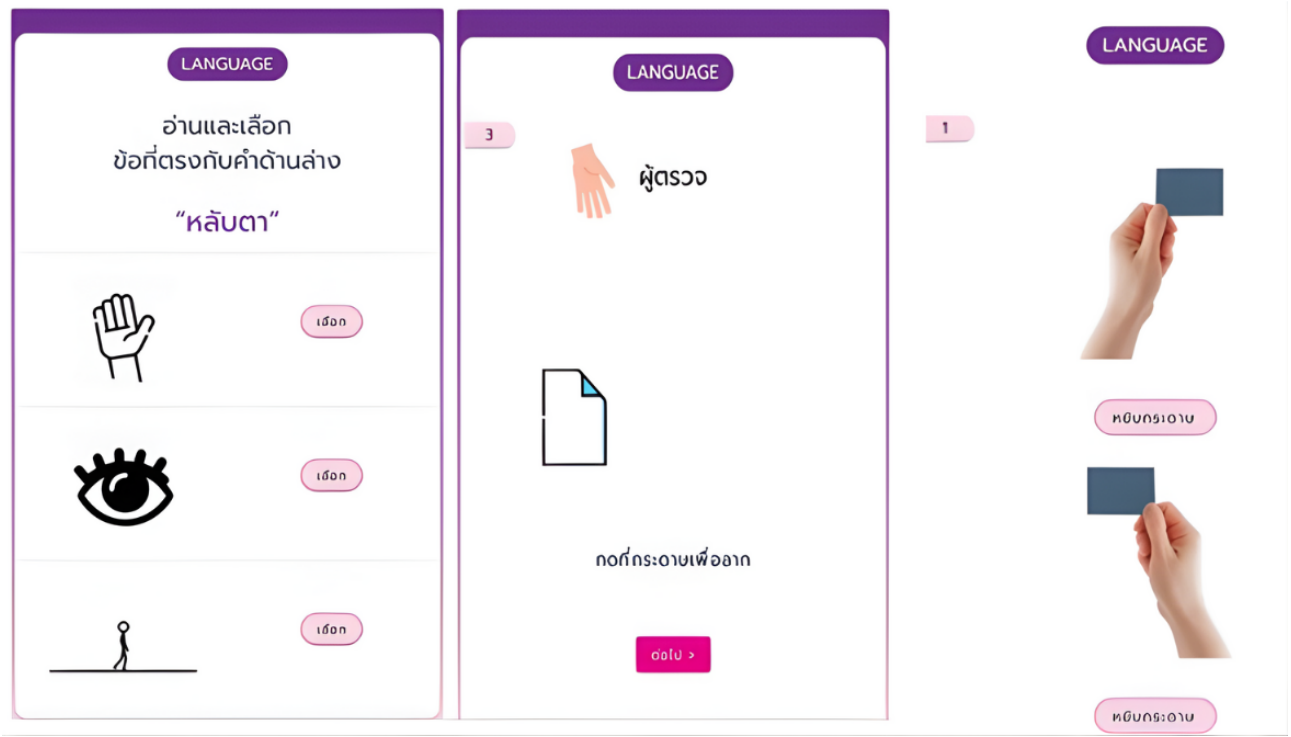


Figure 3. Electronic Thai Mental State Examination (e-TMSE) sample screens showing the language items, which allow on-screen handwriting and choice selection.

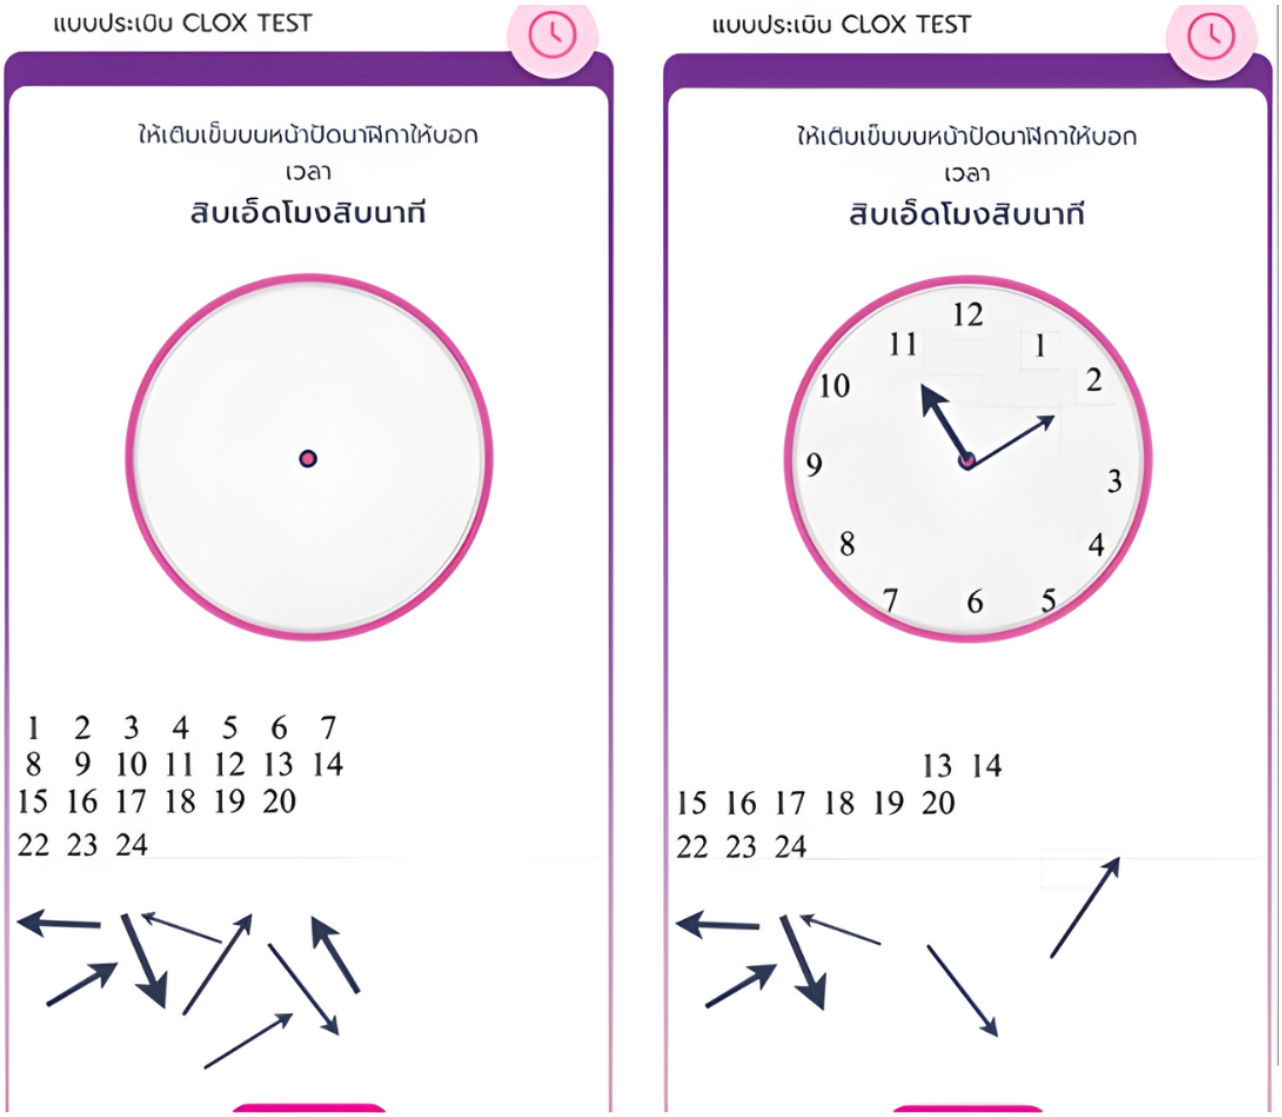
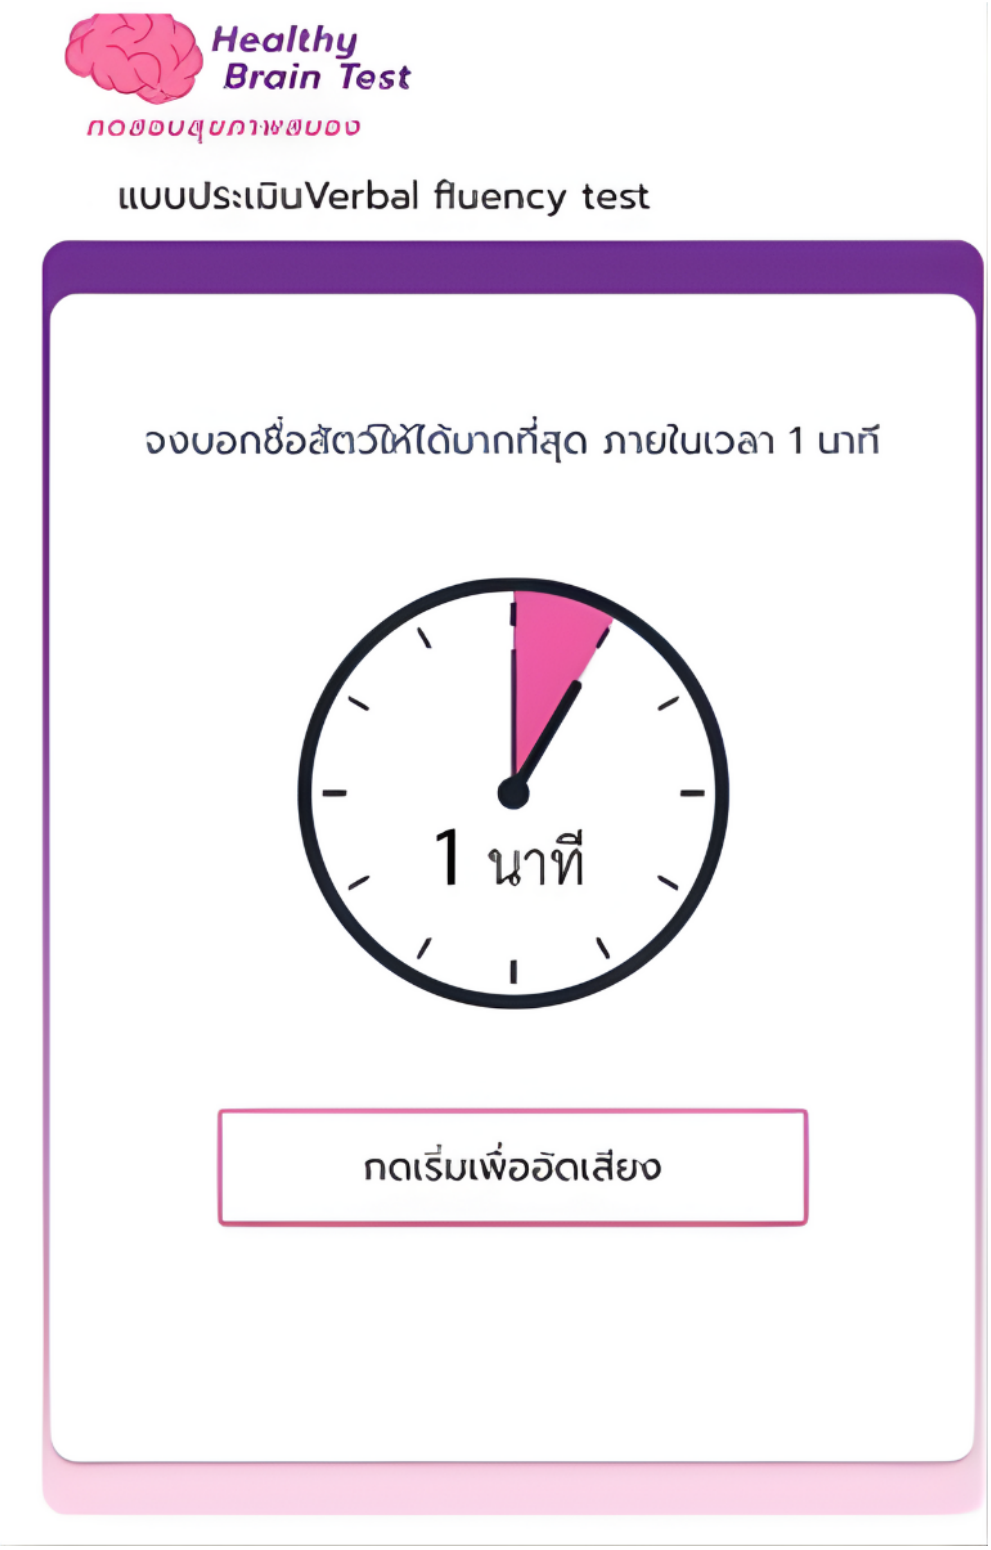


XSL•FO
RenderX

Clock Drawing Test

The CDT is widely used to assess visuospatial ability and executive function and has attracted interest for early cognitive impairment screening [16]. In this study, a digitized CDT variant, the Clox test, was implemented within the *Healthy Brain Test* application. Participants drew a clock showing a specified time on a touch-based interface. The test used a 10-point scale, where 0 indicated severe impairment and 10 represented normal performance. Illustrative screenshots are shown in Figure 4.

Figure 4. Digitized clock drawing (the clox test) sample screens showing how participants draw a clock showing a specified time on a touch-based canvas.



Category VFT

The category (semantic) VFT is a well-established neuropsychological measure that assesses executive function and semantic memory and shows high sensitivity for detecting cognitive impairment, including mild cognitive impairment and dementia [17,18]. In this task, participants generate as many words as possible from a specified category within a limited time, typically 1 minute. In this study, we used the animal naming category and instructed participants to name as many animals as possible within 1 minute. Illustrative screenshots are shown in Figure 5.

XSL•FO
RenderX

Figure 5. Category verbal fluency test (animal naming) sample screens, in which participants name as many animals as possible in 1 minute. The interface provides standardized instructions and timed entry.

Short Form of the Informant Questionnaire on Cognitive Decline in the Elderly

The short form of the IQCODE consists of 16 items that assess informants' perceptions of a participant's cognitive decline by comparing current performance with performance 10 years earlier. In this study, informants were relatives, long-term paid caregivers, or neighbors who had been providing some care. They rated change on a 5-point scale from 1 (much improved) to 5 (much worse), and the score was the mean of the 16 items [19].

Cognitive IADLs

The cognitive IADL module in *Healthy Brain Test* is derived from the validated Thai Activities of Daily Living (ADL) scale [20]. The instrument includes 6 basic ADL items and 7 cognitive

XSL•FO
RenderX

IADL items, and it evaluates the capacity to perform essential daily tasks that require physical function and cognitive integration. The Thai ADL measure has shown strong psychometric properties, including high test-retest reliability and robust construct validity. It also shows strong correlations with the TMSE, Clinical Dementia Rating, Barthel Index, and Functional Activities Questionnaire.

Measurements

Baseline Assessment

Trained physicians and neurologists conducted structured interviews to obtain baseline clinical and demographic data, including age, sex, educational attainment, and cognitive status.

Statistical Analysis

We calculated the required sample size using an estimated dementia prevalence of 20% in older Thai adults based on national guidelines [21]. With 95% confidence and a 5% margin of error, we applied the standard prevalence formula:

$$n=Z2\times P\times(1-P)d2$$

where n is the required sample size, Z is the 95% confidence Z-score (1.96), P is the expected prevalence (0.20), and d is the margin of error (0.05). This yielded a minimum sample size of 246 (5% margin of error) participants.

Although our planned sample size was 246 participants, the final sample comprised 198 participants. Precision is therefore slightly lower than planned; 95% CIs are reported for key estimates. For example, a 20% prevalence has a 95% margin of error of about 5.6% at n=198 versus 5.0% at n=246. However, if the web application for cognitive screening is good enough, the results should still be satisfactory. Moreover, in Thailand, medical services at general hospitals in the peripheral areas of the country are overloaded, causing investigators to be unable to complete sufficient case collection for this study. Data analysis was performed using SPSS version 30 (IBM Corp) and MedCalc Statistical Software (MedCalc Software Ltd). Descriptive statistics summarized baseline demographic and clinical characteristics. To assess validity, we computed Spearman correlation coefficients between digital test scores and conventional paper-and-pencil scores (TMSE and the CDT) because the data were not normally distributed. We considered $P<.05$ statistically significant. We also conducted receiver operating characteristic (ROC) curve analyses to evaluate the application's ability to distinguish cognitively impaired individuals from cognitively normal control participants. We calculated the area under the curve (AUC) for each digital test domain to quantify overall diagnostic performance.

Results

Phase II: Participant Demographics and Initial Validation

This phase evaluated concordance and diagnostic accuracy between traditional paper-and-pencil assessments and web-based application tests. A total of 77 participants were categorized into 3 groups: those with dementia (n=21), those with mild cognitive impairment (n=23), and cognitively normal control participants (n=33). The dementia group had a significantly higher mean age than the other groups (P=.003). All cognitive and functional measures differed significantly between groups (all P<.001). The dementia group had the lowest performance on paper-and-pencil TMSE, e-TMSE, clock drawing, and verbal fluency, and they had the highest ADL, cognitive IADL, and IQCODE-16 scores, indicating greater functional impairment and cognitive decline. Demographic characteristics for all 77 participants are shown in Table 1.

Digital and Standard Cognitive Screening Tests

The paper-and-pencil TMSE and e-TMSE had a strong, statistically significant correlation (Spearman ρ=0.837, *P*<.001), indicating that the digital version reflects the traditional assessment. The mean paper-and-pencil TMSE score was 26.04 (SD 3.87; median 27), while the mean e-TMSE score was 24.91 (SD 4.18; median 25). Subdomain analysis showed comparable performance across most cognitive components. The score distribution indicated a population predominantly comprising cognitively intact individuals and those with mild cognitive impairment. Details are provided in Table 2.

[a]Correlation of the total scores between versions: Spearman ρ=0.837 (*P*<.001).

Phase III: Full Study Implementation

A total of 198 participants were classified into 3 diagnostic groups: dementia (n=44), mild cognitive impairment (n=58), and cognitively normal (n=96). This total was lower than the planned 246 from the prevalence-based calculation. The median age differed significantly across the groups (*P*<.001). Participants with dementia were older (median 73, IQR 69.25 - 79 years) and had the highest proportion with only a primary education (30/44, 68.2%). Cognitive and functional measures differed significantly across all assessments (*P*<.001). Median e-TMSE scores were lowest in the dementia group (18.5, IQR 12.0 - 22.0) and highest in the cognitively normal group (26.0, IQR 23.0 - 28.0). The scores for the Clox test and the category VFT showed a similar pattern. Table 3 presents the baseline participant characteristics for the full implementation sample.

Digital Cognitive Test: e-TMSE and Cognitive Assessment

Figure 6 illustrates the correlation matrix showing associations between the e-TMSE and related cognitive and functional assessments. Positive correlations were observed between the e-TMSE and the paper-and-pencil CDT (r=0.501) and the category VFT (r=0.565), indicating convergence with other cognitive measures. In contrast, negative correlations were found between the e-TMSE and informant-reported or functional measures, including the IQCODE-16 (r=−0.637) and the ADL score (r=−0.706). These patterns reflect inverse relationships between cognitive performance and functional independence.

XSL•FO
RenderX

Analysis of Cognitive and Functional Assessments for Dementia Screening

We conducted ROC analyses to evaluate the web-based application's diagnostic accuracy for distinguishing individuals with normal cognition from those with major neurocognitive disorder. Figure 7 shows the ROC curves, and Table 4 summarizes the performance metrics. The AUC values were as follows: e-TMSE, 0.842; Clox test, 0.774; category VFT, 0.785; IQCODE-16, 0.884; ADL, 0.901; and cognitive IADLs, 0.906. Among these, cognitive IADLs and ADL had the highest discriminatory power. The e-TMSE yielded an optimal cutoff score of ≤23, with a sensitivity of 88.64% and a specificity of 70.13%. The details are provided in Table 4.

Of the 198 participants, 24 (12.1%) were 80 years old or older (9 dementia, 3 mild cognitive impairment, 12 controls); 16 (66.7%) of these 24 individuals had only a primary education. Approximately 5% to 10% of the total cohort (primarily older adults and those with lower education) required assistance but completed the assessment satisfactorily with medical supervision. Errors were most common in drawing tasks for which finger or stylus use was advised. Dropout rates were consistent across sites (5% - 10%). Satisfaction scores (Table S1 in Multimedia Appendix 1) and domain variations that were likely attributable to sociodemographic factors (Tables S2-S3 in Multimedia Appendix 1) are provided in Multimedia Appendix 1.

Figure 7. Receiver operating characteristic (ROC) curves for digital measures distinguishing major neurocognitive disorder: (A) electronic Thai Mental State Examination (e-TMSE), Clox test, and category verbal fluency test and (B) activites of daily living (ADLs), cognitive instrumental activities of daily living (IADLs), and 16-item Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE-16). The area under the curve (AUC) values, 95% CIs, and operating thresholds appear in Table 4.

[f]IQCODE-16: 16-item Informant Questionnaire on Cognitive Decline in the Elderly.

[g]ADLs: activities of daily living.

[h]IADLs: instrumental activities of daily living.

Discussion

Principal Findings

Web-based cognitive screening applications are a promising approach for early detection of cognitive impairment, particularly in resource-limited settings such as Thailand. We evaluated the feasibility and diagnostic accuracy of digitizing established neuropsychological assessments—the TMSE, clock drawing, verbal fluency, IQCODE-16, and ADL functional evaluations—into a web-based format. Our findings suggest that these web-based tools can reliably identify cognitive impairment and provide screening performance comparable to traditional paper-and-pencil methods.

The TMSE, culturally adapted from the MMSE, is widely used in Thailand as a standard cognitive screening tool for dementia. It evaluates orientation, attention, memory, language, and visuospatial abilities, and prior validation studies reported 85% to 90% sensitivity and 80% to 90% specificity for detecting dementia in Thai populations [15].

This study developed and evaluated a web-based TMSE adaptation (e-TMSE) that preserved the original assessment structure and scoring criteria. Using a diagnostic cutoff of ≤23, the e-TMSE achieved an AUC of 0.84 (95% CI 0.78 - 0.89), indicating a high level of discriminative ability for identifying dementia. Sensitivity and specificity were 88.64% and 70.13%, respectively, and were comparable to those of the traditional TMSE. In addition, e-TMSE scores correlated significantly with paper-and-pencil TMSE scores (r=0.837, P<.001), supporting the concurrent validity of the digital format. Subdomain analyses showed comparable diagnostic performance across most cognitive components, although slight discrepancies were noted in registration and language. These discrepancies may reflect user interaction with the digital interface, particularly among participants with limited touchscreen experience.

The CDT is a brief, effective screening tool for visuoconstructional skills and executive function, which are commonly impaired in dementia. Prior studies reported 76% to 85% sensitivity and 81% to 86% specificity for detecting dementia [22]. In our web-based adaptation, the Clox test achieved an AUC of 0.77 (95% CI 0.71 - 0.83), with a cutoff of ≤7; sensitivity was 68.17%, and specificity was 75.32%. Although these values are somewhat lower than some traditional CDT benchmarks, they indicate moderate diagnostic accuracy and support digital screening utility. Performance differences may reflect technological literacy, touchscreen familiarity, and fine motor skills, which can influence task execution and response accuracy in older adults.

The VFT assesses executive function and lexical retrieval. Our implementation used the category (semantic) variant and resulted in an AUC of 0.79 (95% CI 0.72 - 0.84) with a cutoff of ≤11. Sensitivity was 70.73%, and specificity was 74.03%, indicating moderate diagnostic accuracy. Semantic fluency, particularly animal naming, is especially useful for early detection of cognitive impairment. Monsch et al [23] reported 100% sensitivity and 92.5% specificity for semantic fluency in distinguishing patients with Alzheimer disease from control participants who had normal cognition. Similarly, a meta-analysis by Henry et al [24] found that semantic fluency declines early in Alzheimer disease and vascular cognitive impairment, reinforcing its role as an early diagnostic marker. Furthermore, studies with individuals with mild cognitive impairment have shown that semantic fluency can be a sensitive

XSL•FO
RenderX

and efficient screening tool for early stages of dementia [18,25]. In addition to its diagnostic value, the VFT is simple to administer, cost-effective, and readily adaptable to digital formats. These features make it suitable for large-scale screening and for use in primary care or community-based settings.

The IQCODE provides complementary dementia screening by capturing caregiver-reported longitudinal cognitive change and by circumventing patient insight deficits, which are common in dementia. Previous research reported 80% to 90% sensitivity and specificity for distinguishing dementia from normal aging [26,27]. In our study, the short-form IQCODE (IQCODE-16) showed a significant negative correlation with e-TMSE scores (r=−0.637, P<.001), consistent with earlier IQCODE and TMSE findings (r=−0.679, P<.001) [19]. This consistency supports the concurrent validity of the IQCODE-16 as a reliable screening instrument. IQCODE-16 achieved an AUC of 0.88 (95% CI 0.83 - 0.93), with a cutoff of >3.562. Sensitivity was 88.64%, and specificity was 75.32%, with a marginally higher AUC than e-TMSE (AUC=0.84). These findings highlight clinical relevance, particularly in community-based or resource-limited settings where cultural, educational, or language barriers may affect performance-based testing.

Functional assessments, especially ADL, provide essential context regarding the real-world impact of cognitive decline on daily functioning. Although not diagnostic in isolation, declines in ADL—particularly cognitive IADLs—are predictive of dementia progression. Our cognitive IADL component achieved an AUC of 0.91 (95% CI 0.86 - 0.94), with a cutoff of >1; sensitivity was 84.09%, and specificity was 75.32%. The ADL measure achieved an AUC of 0.90 (95% CI 0.85 - 0.94), with a cutoff of >3; sensitivity was 72.73%, and specificity was 92.86%.

Adapting neuropsychological and functional assessments to web-based platforms, such as *Healthy Brain Test*, represents meaningful progress in dementia screening. These platforms can expand access in resource-limited regions and facilitate earlier detection of cognitive decline. In Thailand, geographic and socioeconomic disparities limit access to specialized care, and a culturally adapted, validated digital tool may help bridge screening gaps in community-based settings. In our findings, dropouts were most common among the oldest-old and those with lower education levels, primarily due to unfamiliarity with digital technology. Issues also arose from misaligned user expectations; for instance, participants often wished to erase specific lines during drawing tasks, whereas the application only permitted clearing the entire page to redraw. Additional factors contributing to dropout included poor user interface design (eg, small font sizes, login difficulties) and physical health limitations (eg, visual impairment, hand tremors). Our study recruited individuals with diverse baseline characteristics regarding age, education, and diagnostic status (dementia, mild cognitive impairment, and normal controls). It is well-established that economic conditions differ regionally in Thailand; generally, the central, southern, and northern regions are wealthier and report better health outcomes than the northeast. These socioeconomic and cultural variations may explain some of the observed differences in cognitive performance, both within the normal group and across the entire cohort at each study site.

The global adoption of mobile and web-based cognitive screening tools has expanded, offering promising alternatives to traditional paper-and-pencil assessments across clinical and community settings. The commercially available *BrainTest* reported 71% sensitivity and 90% specificity compared with comprehensive neuropsychological assessments [28]. Similarly, *M-CogScore*, which includes memory, attention, and executive tasks, achieved an AUC of 0.85 (95% CI 0.80 - 0.91) and outperformed the MMSE-2 (AUC=0.78, 95% CI 0.72 - 0.84) for distinguishing individuals with normal cognition from those with impairment [29]. In parallel, mobile cognitive screening tools designed for smartphones and tablets provide additional advantages over traditional modalities [30].

Nevertheless, important limitations persist. Previous studies [30,31] noted that most self-administered electronic tools lack rigorous psychometric validation. Practical barriers include touchscreen usability challenges among older adults with limited digital experience, as well as broader issues of digital literacy. In addition, digital tools may be less able to detect subtle behavioral, emotional, or motivational cues that inform clinical assessment. These limitations are especially pronounced in resource-limited settings, where disparities in technology access and health services can further hinder effectiveness.

In Thailand, electronic cognitive assessments have been used for over a decade. A 2018 validation study of the computerized TMSE [32] demonstrated a strong correlation with the standard pen-and-paper TMSE. The percentage of agreement between the two methods was 92.5%, with a Kappa coefficient of 0.85 (P<.001). The duration of the standard pen-and-paper TMSE was slightly shorter than that of the computerized TMSE (7.31 min vs 7.97 min; 95% CI −1.159 to −0.175; P=.09). More recently, a study on the Thai electronic MoCA [33] reported a high correlation for total scores, with a concordance correlation coefficient of 0.919 and a mean difference of −0.204 (95% CI −6.311 to 5.904). All cognitive subdomain scores showed moderate to high concordance correlation coefficient values exceeding 0.4. Furthermore, functional assessment is crucial for determining the stage of cognitive performance. Therefore, it is essential to evaluate both cognitive function and ADLs concurrently. ADLs can be self-reported or observed by family members who can provide feedback to clinicians. In the context of Thai culture, where extended families are common, family members play a vital role in observing daily functioning and providing this necessary feedback.

Thailand's cultural, linguistic, and socioeconomic factors require careful consideration when implementing web-based cognitive screening tools. Our study showed that *Healthy Brain Test*, a web-based cognitive assessment application, is clinically useful for the early detection of dementia. The tool demonstrated good psychometric performance and was validated across diverse Thai populations in multiple regions, strengthening the applicability of the findings.

Several limitations warrant consideration. The sample comprised mostly individuals with normal cognition, mild cognitive impairment, and mild dementia, with limited evaluation of

XSL•FO
RenderX

performance in moderate to severe dementia. Most notably, the final sample size was lower than the planned target of 246, which may have reduced the precision of estimates. However, a 20% prevalence of dementia with a 95% CI and with a margin of error of 5.6% led to the sample size of 198 participants in our study. Assessments were conducted under professional supervision to ensure understanding in the local Thai pronunciation, which may not reflect real-world, unsupervised use. However, caregivers can possibly play this role by helping individual older adults at home. Further limitations of our study primarily concern digital literacy and accessibility. First, a lack of digital experience was evident; the majority of older Thai participants were unfamiliar with drawing on touchscreens (eg, tablets or smartphones). However, they were able to perform tasks correctly after receiving instruction. In the context of unsupervised community testing, co-resident children or visiting family members can play a crucial role in encouraging older adults to adopt new technologies. For example, the Thai medical system successfully implemented telemedicine during the COVID-19 era, and hospitals continue to use it for patients in remote areas. A key factor in this success is the assistance provided by younger family members during assessments. Second, regarding physical and sensory impairments, Thailand's universal health coverage scheme allows individuals with vision or hearing problems to receive fully reimbursed treatments, such as cataract extraction with lens implantation and hearing aids. Third, regarding the need for technological support, older adults with cognitive impairment may require caregivers to set up or assist with web-based assessments. Despite this support, 5% to 10% of our cohort were unable to complete the assessment. Fourth, socioeconomic factors such as cost, income level, and access to reliable internet and devices may pose barriers. To address this, the Thai government has set a goal to establish free internet access zones in every village, and digital devices imported from China are becoming increasingly affordable. Last, technological anxiety remains a common issue among older adults.

Although our study included a relatively small sample size, it was conducted across 4 distinct provinces: Bangkok (Siriraj and Vajira Hospitals), Phitsanulok (Northern Thailand), Nakhon Phanom (Northeastern Thailand, bordering the Mekong River and Laos), and Phatthalung (Southern Thailand). We recently signed a Memorandum of Understanding with the Department of Medical Services, Ministry of Public Health, to deploy this web-based cognitive screening test nationwide over the next 3 years. Based on the insights gained from this widespread implementation, we anticipate developing a second iteration or an abbreviated version of the assessment.

Future research should evaluate *Healthy Brain Test* in unsupervised community-based settings, explore integration with digital health infrastructure, and enable longitudinal tracking of cognitive change. Implementation should be supported by health care professionals to ensure appropriate interpretation of results and timely referral for further evaluation or intervention.

Conclusion

This study demonstrates that the *Healthy Brain Test* web-based application is valid, efficient, and accessible for early detection of cognitive impairment. The battery comprises the following assessments: e-TMSE, CDT, category VFT, IQCODE-16, and ADL. The digital test scores correlated strongly with traditional paper-and-pencil assessments, supporting the reliability and clinical applicability of our web-based cognitive screening application. This simple, rapid tool is well-suited for identifying cognitive impairment in primary care and community-based settings. Further studies should validate performance in unsupervised and diverse populations and support integration into routine cognitive health screening protocols.

Abstract

Background: The escalating prevalence of screen-related eye fatigue has become a health burden in the digital era worldwide, yet routine monitoring relies largely on subjective reports. This underscores the urgent need for clinically applicable, objective diagnostic solutions. Ocular metrics provide an objective method to assess computer vision syndrome, or asthenopia.

Objective: This study aimed to develop and evaluate an integrated at-home system for predicting short-term deteriorated asthenopia using objective ocular metrics. This system classifies the short-term risk level for practical monitoring and automatically generates a session report that summarizes metrics to complement symptom-based evaluation.

Methods: We developed EyeFatigue Tracker, an integrated at-home system delivered via a desktop app, comprising a head-mounted device to record binocular infrared eye videos, a deep learning (DL) model to extract ocular metrics, and a machine learning (ML) classifier to estimate asthenopia risk. The DL model, trained on an in-house dataset, segments the palpebral fissure, pupil, and iris from recorded videos to derive ocular metrics. To build the prediction model, participants were recruited to complete a 1-hour computer gameplay session. Changes in the Computer Vision Syndrome Questionnaire (CVS-Q) scores served as the primary outcome measure to classify participants into deteriorated and nondeteriorated asthenopia groups. Metrics showing significant between-group differences were used as inputs for four ML models, including support vector machine (SVM), decision tree, extreme gradient boosting (XGBoost), and random forest, to identify deteriorated asthenopia. Model performance was evaluated with fivefold cross-validation.

Results: This study enrolled 38 participants aged 19-31 (mean 24.8, SD 3.11) years. Following visual tasks, participants' CVS-Q scores were higher compared to baseline values (mean 9.21, SD 4.57, vs mean 6.76, SD 3.76; $P<.001$). Alongside the critical flicker fusion frequency (CFF), nine key features were selected as predictive indicators, with the top five reflecting fissure length variability (variance, coefficient of variation, and SD), average blink duration, and pupil size variability (coefficient of variation). Most ML models exhibited high discriminative ability, with the random forest achieving the best overall performance (mean accuracy 0.720, SD 0.035; mean area under the receiver operating characteristic curve 0.850, 95% CI 0.830-0.860).

Conclusions: The findings highlight the potential of objective indicators in identifying individuals at risk for asthenopia following computer gameplay. The ML models using ocular biomarkers identified in this study achieved plausible discriminative ability

Introduction

Background

With advancements in technology and the widespread use of digital devices, complaints about asthenopia, or computer vision syndrome, have rapidly increased [1]. The worldwide prevalence of asthenopia has reached 60 million, with an additional 1 million new cases reported annually [2]. Asthenopia encompasses a range of subjective symptoms, including eye fatigue, eye swelling, dryness, blurred vision, and orbital pain [3,4], often along with musculoskeletal discomfort, such as neck pain [5]; neuropsychological symptoms, such as headaches and dizziness [6]; and general malaise [7]. Although typically transient, the symptoms can be recurrent and persistent [8]. These symptoms affect not only visual comfort but also overall health and work productivity [2]. The increasing prevalence of visual fatigue has thus become a significant burden on both individuals and society, emphasizing the urgent need for effective diagnostic and management strategies.

Existing Assessment Methods and Research Gap

Despite its growing impact, there is no unified standard for diagnosing asthenopia. Existing assessment approaches can broadly be categorized into subjective symptom questionnaires and objective physiological or ocular video–based methods. Most studies rely on subjective questionnaires, with the Computer Vision Syndrome Questionnaire (CVS-Q) being a widely used tool for assessing the frequency and severity of asthenopia symptoms [3]. Such questionnaires are free to use in large populations, but participants still need to complete multiple items and calculate total scores. In routine or remote use, they may also have questions about specific items that cannot be answered promptly by eye care professionals, which makes these tools less practical for frequent at-home monitoring. In addition, objective physiological measures, such as the critical flicker fusion frequency (CFF), have been explored [9,10]. Although the CFF offers a quantifiable approach, its reliability in assessing asthenopia and its potential as a surrogate measure remain controversial [11]. Other objective metrics, such as blinking patterns, eye movement metrics, accommodative function, and pupil dynamics, offer additional quantitative insights into asthenopia [12-15]. These physiological metrics can provide reproducible endpoints but usually require dedicated clinical equipment and in-clinic testing, which reduces their feasibility for routine, at-home monitoring. For example, accommodative function reflects the eye's ability to focus but requires specialized equipment and clinical expertise, limiting its practicality. Similarly, eye-tracking devices, such as the Tobii system, can capture eye movement data, including fixation and saccade metrics [16]. However, these devices are often costly and require sophisticated analysis to interpret the data accurately [17]. More recently, some groups have combined blink, pupil, and eye movement features into portable platforms, such as smartphone-based eye movement–recording apps and virtual reality (VR) headsets with integrated eye tracking, to assess visual behavior and visual fatigue in everyday digital tasks [18,19]. Beyond these approaches, video-based deep learning (DL) methods have been used to recognize ocular anatomy in other domains, such as cataract surgery and biometrics [20-22]. Previous studies have used explicit image feature extraction steps to improve pupil and iris recognition performance in cataract surgery videos or eye gaze–tracking tasks [23-25]. Clinical studies have also applied objective pupillometry to quantify how cataract surgery affects pupil size and constriction dynamics [26]. Overall, these systems show that it is possible to automatically extract eye structure information from videos in controlled, task-specific settings, but they were not developed to monitor visual fatigue or short-term changes in symptoms during everyday screen use. In the context of visual fatigue, DL methods have been used to extract blinking patterns (eg, frequency and duration) and pupil dynamics (eg, accommodation speed) from video data to assess visual fatigue [14,27]. Although these approaches show promise, no system has yet succeeded in integrating these multiple objective metrics into a portable, convenient, and cost-effective solution for the comprehensive evaluation of asthenopia.

Objectives and Contributions of This Study

To address these challenges, we proposed a novel portable, at-home system that uses DL algorithms to simultaneously measure blinking patterns, eye movement metrics, and pupil parameters. By integrating these metrics, the device may provide a more comprehensive and objective assessment of asthenopia. Specifically, this study (1) developed an integrated at-home system that records binocular infrared (IR) eye videos and derives anatomy-aware ocular metrics, (2) identified ocular biomarkers associated with short-term deteriorated asthenopia using a standardized computer gameplay protocol, and (3) evaluated multiple machine learning (ML) models to classify at-risk individuals based on these biomarkers. This approach aims to offer a practical and accessible tool for identifying individuals prone to visual fatigue in real-world settings.

Methods

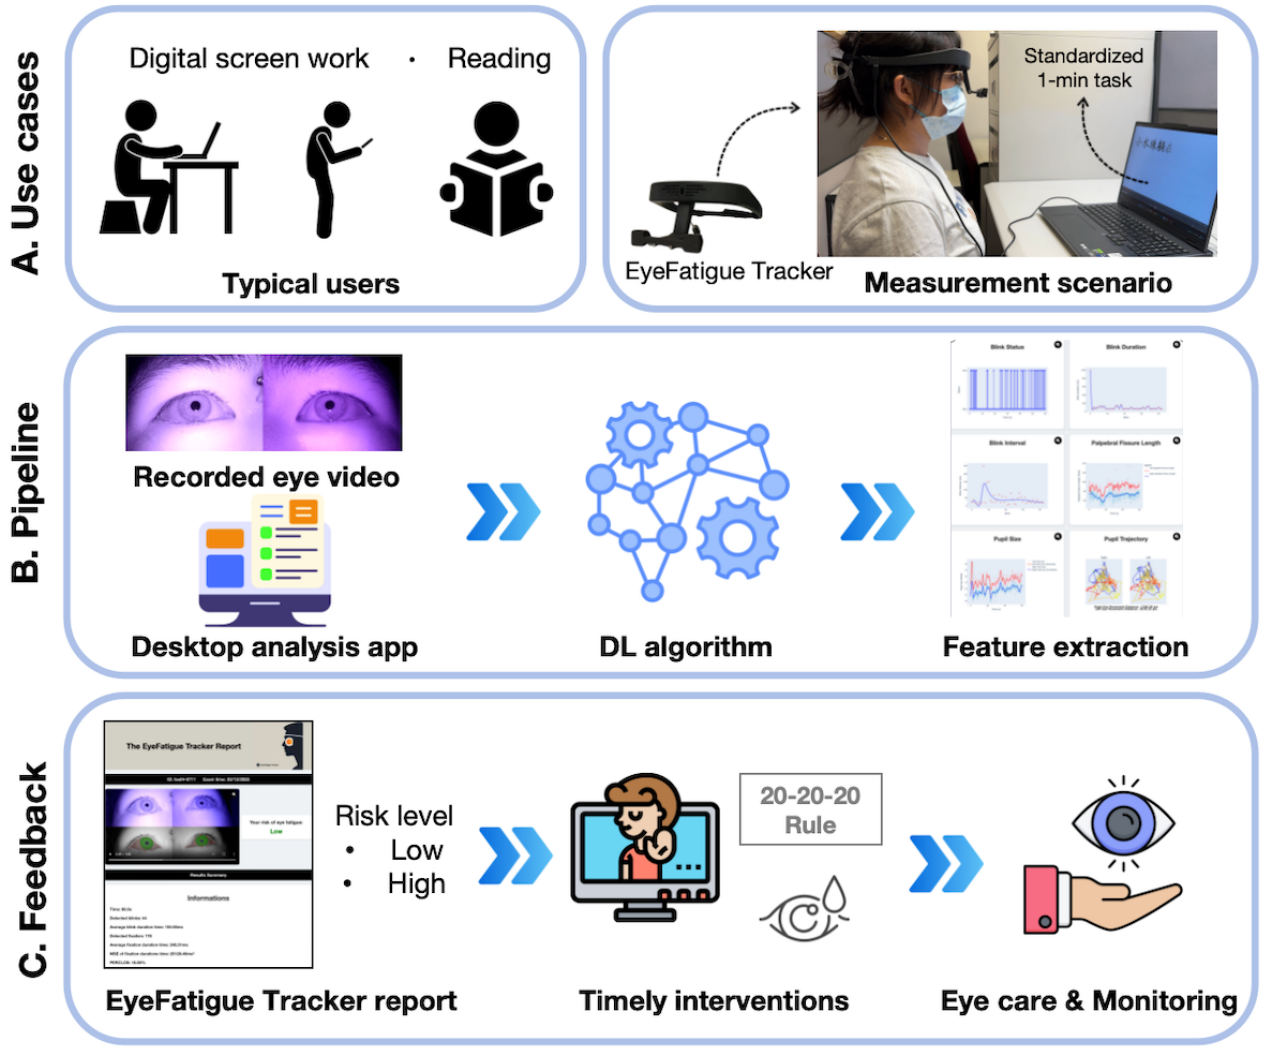
Ethical Considerations

Ethical approval was obtained before the study began from the Institutional Review Board (IRB) of the Hong Kong Polytechnic University (reference #HSEARS20240425002). The study adhered to the tenets of the Declaration of Helsinki. Written informed consent was obtained from all participants prior to study participation, and participants were informed that they

XSL•FO
RenderX

could withdraw from the study at any time without a penalty. All study data were deidentified before analysis and were stored securely to protect participant privacy and confidentiality. Participants received HK $350 (~US $45) as compensation for their participation. Potentially identifiable participant images were included only where scientifically necessary, and separate written consent for publication was obtained from the individuals concerned.

Data Collection



This prospective observational study was conducted between July and August 2024. Participants aged 16-35 years were included. Exclusion criteria encompassed individuals with the presence of diseases that may cause eye pain or headaches, such as glaucoma, keratitis, strabismus, conjunctivitis, iridocyclitis, ocular trauma, or other self-reported conditions; color vision deficiency; illiteracy; or cognitive dysfunction.

Sociodemographic information and general health history were collected from the participants. Following this, each participant engaged in four consecutive 15-minute computer games on a laptop (2560×1600 resolution, 240 Hz refresh rate) for a total of 60 minutes of continuous screen use. The games consisted of simple but engaging tasks (maze navigation [28], block stacking [29], obstacle avoidance [30], and sports-themed minigames [31]) to maintain attention, while providing sustained visual load (see Figure S1 in Multimedia Appendix 1). The total duration and task design were chosen to create short-term, measurable changes in visual fatigue, while preserving compliance, in line with prior work showing that approximately 1 hour of continuous digital device use can significantly aggravate visual fatigue [32]. Each participant first completed a 1-minute text-reading task (Multimedia Appendix 2), then performed the four game sessions, and immediately completed the same 1-minute text-reading task. During each text-reading task, the participant wore the EyeFatigue Tracker device, which recorded their ocular videos. The task consisted of three consecutive 20-second segments with progressively reduced contrast, smaller font size, and more complex text, increasing in difficulty from easy to moderate to difficult in a fixed order, so that we could examine how ocular metrics changed as visual and cognitive load increased within a brief standardized trial. This stepwise change in contrast, font size, and text complexity is consistent with prior work showing that smaller text, lower contrast, and more demanding reading conditions can increase visual fatigue and mental workload in digital reading tasks [33,34]. For analysis, these three segments approximately corresponded to the frame ranges 200-600 (easy), 600-1200 (moderate), and 1200-1800 (difficult) after discarding the first 200 frames.

Data collected included habitual visual acuity (HVA), tear film break-up time (TBUT), CVS-Q scores [3], Stanford Sleepiness Scale (SSS) scores [35], Karolinska Sleepiness Scale (KSS) scores [36], Fatigue Assessment Scale (FAS) scores [37], CFF values, and ocular metrics (blinking patterns, eye movement metrics, and pupil parameters). The CVS-Q served as the primary subjective measure of asthenopia and was used to define deteriorated and nondeteriorated asthenopia groups. The SSS and the KSS captured current and recent sleepiness, and the FAS assessed overall fatigue, allowing us to examine whether changes in ocular metrics are specifically related to visual fatigue rather than general tiredness. The CFF was included as a classical psychophysical index of visual fatigue to compare with the proposed ocular video–based metrics. The HVA was measured by the Early Treatment Diabetic Retinopathy Study (ETDRS) chart at 4 m. The TBUT was recorded as the time interval between the last blink and the first tear film dry spot following fluorescein instillation, using a slit lamp. The severity of asthenopia, current sleepiness, recent (last 10 minutes) sleepiness, and overall fatigue were assessed using the CVS-Q, SSS, KSS, and FAS questionnaires, respectively, with higher scores indicating greater severity. CFF values were measured using Handy Flicker HF-III (Neitz Instrument), and the average value of ascending and descending thresholds were recorded. A decrease in CFF values reflects increased visual fatigue. Ocular objective metrics were extracted from the 1-minute video recorded by the EyeFatigue Tracker device. The overall experimental setting and visual task timeline are illustrated in Figure 1A (measurement scenario).

RenderX

Figure 1. Overall flowchart of the EyeFatigue Tracker system and study workflow. (A) Typical users and standardized measurement scenario during a 1-minute reading task with the head-mounted EyeFatigue Tracker. (B) Analysis pipeline: Infrared eye videos are processed by a mask R-CNN–based segmentation model to obtain masks of the palpebral fissure, iris, and pupil. From these masks, objective ocular metrics are extracted, including blink parameters, pupil dynamics, and eye movement metrics. Statistically significant metrics are then used as inputs to ML classifiers (SVM, decision tree, random forest, and XGBoost) to estimate the short-term risk for deteriorated asthenopia (low vs high). (C) Feedback module: The desktop app displays the predicted risk level, provides a brief session report summarizing key ocular metrics, and can be used for home-based eye care, longitudinal self-monitoring, and telemedicine follow-up. DL: deep learning; ML: machine learning; mask R-CNN: mask region-based convolutional neural network; SVM: support vector machine; XGBoost: extreme gradient boosting.

Proposed EyeFatigue Tracker System

System Overview

Figure 1 presents the EyeFatigue Tracker workflow used to estimate the risk of asthenopia deterioration. The EyeFatigue Tracker system classifies each 1-minute recording into a risk level (low/high) for asthenopia deterioration during at-home use. The device consists of a lightweight head-mounted binocular IR camera module, paired with a desktop analysis app, mounted on an adjustable plastic frame, which can be worn over habitual spectacles at a normal working distance from a computer screen. It connects to a standard laptop via a single USB cable and does not require a chinrest or dedicated laboratory setup, making it feasible for use in home and office environments. The hardware was assembled from off-the-shelf components to keep material costs low. Two IR cameras were used to capture videos of both eyes at a frame rate of 30 frames per second (fps). We used 940 nm near-infrared (NIR) illumination, together with an 850 nm long-pass IR filter (cut-on at 850 nm) mounted in front of the camera lens to suppress visible light from the display/ambient illumination and reduce glare-related artifacts. This rate was chosen as a practical trade-off between temporal resolution and computational cost: Blinks are brief (about 100-150 ms), so markedly lower frame rates (eg, 10-15 fps) may miss the full closing and reopening phases and distort blink duration, blink interval, and percentage of eyelid closure (PERCLOS), whereas much higher frame rates would substantially increase data size and processing time without a clear benefit for our target task. Participants wore EyeFatigue Tracker while performing a 1-minute text-reading task, during which a video containing 1800 frames (1 minute) was recorded for feature extraction. IR ocular videos were recorded at 3840×1080 pixels and 30 fps, and frames were downsampled to 480×135 pixels for training and 640×180 pixels for inference in the DL models.

RenderX

Deep Learning–Based Eye Anatomy Recognition

We used two nonoverlapping datasets. Dataset A is an in-house eye video dataset from 100 subjects with different eye states (open, half-open, closed, left-right scanning), and we selected 1000 labeled eye images and used them exclusively to train and validate the segmentation model. Dataset B is an independent cohort recruited in this study (see the *Data Collection* section) and was used for feature extraction and predictive modeling.

Instance segmentation of ocular anatomy was implemented in Detectron2 [38] with a mask region-based convolutional neural network (mask R-CNN; residual network [ResNet]-50 backbone + feature pyramid network [FPN]), which we selected after a preliminary comparison with a U-Net–based model showed that the mask R-CNN produced more stable and accurate masks for small ocular structures (pupil boundary and palpebral fissure), while remaining feasible to train and run on a standard laptop. Prior to segmentation, IR frames underwent lightweight preprocessing to suppress overexposure and normalize intensity. Annotations were stored in Common Objects in Context (COCO)–style format and registered as Detectron2-compatible datasets. Segmentation outputs were grouped into three anatomical structures: palpebral fissure, pupil, and iris. All recordings were visually inspected, and videos with severe artifacts or segmentation failures were excluded to ensure that subsequent analyses primarily reflected true ocular behavior. The model was initialized with weights pretrained on the COCO instance segmentation task and then fine-tuned on Dataset A only (3000 iterations, batch size=2, learning rate=2.5×10^{4}). Due to graphics processing unit (GPU) memory constraints and the small-scale nature of the dataset, we used a batch size of two images per iteration, which is standard for a mask R-CNN in Detectron2 and provided stable convergence for this task. Training/validation/test splits were made at the participant level to avoid subject-level leakage. This model enables precise differentiation of various eye regions. We reported the Dice similarity coefficient (Dice) and intersection over union (IoU) in two forms: macro (unweighted mean across classes) and micro (global aggregate). Per structure metrics were macroaveraged across left and right eyes, whereas the microaveraged performance was obtained by aggregating all structures and images before computing the Dice, IoU, and COCO-style average precision (AP)/average recall (AR) using the Detectron2 COCOEvaluator. One-to-one instance matching was performed using the Hungarian assignment at IoU≥0.5. We also reported COCO metrics via Detectron2's evaluator, including the AP and AR at AP averaged from IoU 0.50 to 0.95 (AP@0.50-0.95), AP at IoU 0.50 (AP@0.50), and AR averaged from IoU 0.50 to 0.95 (AR@0.50-0.95). For clinical interpretability, metrics were also summarized after aggregating to eye (palpebral fissure), iris, and pupil.

Assessment Metric Computation and Risk Prediction

Based on the segmentation results, we extracted blink times, blink duration, blink interval, PERCLOS, fissure length, fixation number, fixation duration, eye movement distance, and pupil constriction speed. The average blink duration represented the mean length of each blink, while the blink interval referred to the duration between two consecutive blinks. Blink times were measured as the total number of blinks per minute. PERCLOS was defined as the proportion of time during which the eyes remained at least 80% closed. The fixation number represented the number of fixations per minute, while the average fixation duration represented the average length of each fixation. The eye movement distance was computed from the pupil centroid trajectory extracted from the pupil segmentation masks. For each frame, the pupil center was estimated, and the total movement was calculated as the cumulative Euclidean distance between consecutive centroids. Frames in which the pupil was not visible (eg, during eye closure) were automatically excluded from the calculation. The pupil constriction speed indicated the rate of pupil size change during constriction and dilation. To minimize the influence of the initial eye-opening movements in the video, the variations of ocular metrics were analyzed between frames 200 and 1800. For variability features, we calculated the SD, variance, and coefficient of variation of pupil size and fissure length within each frame range (200-600, 600-1200, 1200-1800) and across all frames (200-1800) separately for the pre- and posttask recordings. The difference in each variability metric was defined as posttask minus pretask and compared between groups. The corresponding change features were then calculated as the difference between post- and pretask summary statistics. Point-wise subtraction of raw signals was not performed.

Objective metrics were compared between the deteriorated and nondeteriorated asthenopia groups, defined using changes in CVS-Q scores. Participants were classified as having deteriorated asthenopia if their posttask CVS-Q score increased by ≥3 points compared to baseline; all others were assigned to the nondeteriorated asthenopia group. Statistically significant features were selected as inputs for the four ML models for predicting short-term deteriorated asthenopia. Statistical feature filtering (P<.05) was used to define candidate ocular biomarkers and was not re-estimated within each cross-validation fold; this design choice may introduce selection bias and was therefore noted as a limitation. This feature-filtering step was performed on the full dataset and served to define a fixed set of input features for subsequent ML analyses, rather than as a data-driven feature selection step within the model training pipeline. These ML models include both classical classifiers (SVM and decision tree) and modern tree-based ensemble methods (random forest and XGBoost), which have shown strong and robust performance in time-series prediction tasks in previous studies [39-41]. To improve robustness and mitigate variability due to dataset partitioning, an 80/20 training-test split was first applied, with the test set fully held out from all training procedures. Model training and evaluation were then conducted on the training set using stratified fivefold cross-validation, and performance was assessed using the area under the receiver operating characteristic curve (AUROC). ML models were trained on statistically significant features (P<.05) after z-score normalization, with synthetic minority oversampling technique (SMOTE) oversampling applied exclusively within the training data of each cross-validation fold. Before oversampling, the dataset contained 42 fatigued and 34 nonfatigued samples; after SMOTE, the training data in each fold were balanced to 42 samples per class, while validation and test sets retained the original class distribution. Hyperparameters for the SVM,

XSL•FO
RenderX

decision tree, random forest, and XGBoost were optimized using stratified fivefold grid search cross-validation on the training data. Hyperparameter tuning and cross-validation–based performance estimation were performed on the training set, while an independent test set was used only for final evaluation. Details of the model-specific evaluation parameters are provided in Table S1 in Multimedia Appendix 1. The final SVM used a radial basis function (RBF) kernel with principal component analysis (PCA) retaining 95% variance. Tree-based models (decision tree, random forest, XGBoost) were trained using their best-performing parameter combinations identified through the grid search. Performance metrics were derived from stratified fivefold cross-validation on the training set, while the independent test set was used only for an additional one-time validation of the selected models. After obtaining the AUROC for each fold, we computed the mean AUROC across all five folds to provide a more stable and generalized estimate of the model's discriminatory ability. Feature importance was assessed using the model with the best performance, where the relative contribution of each feature to predicting deteriorated asthenopia was quantified based on its importance scores. Finally, we integrated these functions into a desktop app: users can complete a 1-miute visual task and use the app to assess their risk level. The graphical user interface is designed for nonexpert users and provides fully automated processing with no need for manual parameter tuning, which supports convenient at-home use. All data processing, feature extraction, and model training were performed in Python using Detectron2 for segmentation and scikit-learn for ML analyses. The analysis pipeline ran on a Lenovo ThinkPad laptop (Intel i9-14900HX, 32 GB RAM, NVIDIA GeForce RTX 4060 Laptop GPU), achieving an end-to-end processing time of ~4 minutes per session, while segmentation models were trained on an NVIDIA A100 GPU server.

Data Analysis

The primary outcome measure was the presence of deteriorated asthenopia, identified by an increase of ≥3 points in the CVS-Q score following visual tasks. The sample size was calculated using G*Power 3.1 software [42], targeting a statistical power of 0.90 and a significance level (α) of .05, with an expected effect size (Cohen f=0.25). To account for a potential 20% dropout rate, the final sample size was adjusted to 38 participants. Data were presented as mean (SD) or mean (95% CI) for continuous variables with a normal distribution or as median (IQR) for nonnormally distributed variables. The Shapiro-Wilk test was used to assess data normality [43]. Paired *t* tests were used for normally distributed data [44]. Nonparametric tests, including the Mann-Whitney U test, McNemar's test, and Wilcoxon signed-rank test, were used to handle nonnormal or ordinal data [45]. The Wilcoxon signed-rank and McNemar's tests were used to measure within-participant changes in visual fatigue metrics over time points. The Mann-Whitney U test compared demographic characteristics, baseline characteristics, and changes in extracted objective metrics in subgroup analyses. All tests were two-tailed, with α=.05 considered statistically significant. The analysis was performed using Stata18.0 (StataCorp) [46].

Results

Participant Details

A total of 38 participants completed the study. Their ages ranged from 19 to 31 (mean 24.89, SD 3.11) years, and 19 (50%) were female. The mean TBUT was slightly shorter in the right eye than in the left eye (mean 6.48, SD 2.90, seconds vs mean 7.18, SD 2.72, seconds). The mean spherical equivalent was −2.23 (SD 2.30) diopters in the right eye and −1.93 (SD 2.32) diopters in the left eye. More than half of the participants (n=58%) had baseline asthenopia (CVS-Q score≥6). Participants reported a mean daily screen exposure of 9.45 (SD 3.37) hours. Their detailed baseline characteristics are summarized in Table 1.

XSL•FO
RenderX

Table 1. Baseline characteristics of participants (N=38).

Characteristics	Value
Age (years)	
Mean (SD)	24.89 (3.11)
Median (IQR)	26 (19-31)
Females, n (%)	19 (50)
TBUT[a] (seconds), mean (SD)	
Right eye	6.48 (2.90)
Left eye	7.18 (2.72)
Spherical equivalent (diopters), mean (SD)	
Right eye	–2.23 (2.30)
Left eye	–1.93 (2.32)
Asthenopia[b], n (%)	22 (58)
Screen exposure (hours/day), mean (SD)	9.45 (3.37)

[a]TBUT: tear film break-up time.

[b]Asthenopia was determined by a Computer Vision Syndrome Questionnaire (CVS-Q) score of ≥6.

Segmentation Performance of the EyeFatigue Tracker System

The model achieved an overall mean Dice of 93.3 (SD 0.4, 95% CI 92.9-93.7) and an overall mean IoU of 87.4 (SD 0.8, 95% CI 86.7-88.1). Among individual structures, the pupil showed the highest overlap, with a Dice of 94.0 (95% CI 93.7-94.4) and an IoU of 88.8 (95% CI 88.2-89.5), followed by the iris with a Dice of 86.6 (95% CI 85.1-88.0). The palpebral fissure was the most challenging, with a Dice of 75.0 (95% CI 71.4-78.6) and an IoU of 60.2 (95% CI 55.5-64.9). COCO metrics were strong at the overall level, with a mean AP@0.50 of 99.3 (SD 0.4), a mean AP@0.50-0.95 of 80.6 (SD 1.1), and a mean AR@0.50-0.95 of 84.7 (SD 1.0). At the structure level, the iris yielded the highest AP@0.50-0.95 of 87.4, and all structures maintained an AR@0.50-0.95 of >80%. The 95% CIs were narrow across metrics, indicating stable performance across folds. This pattern is consistent with the image characteristics: the pupil has a regular circular shape and strong contrast against the surrounding iris in IR videos, whereas the iris boundary and especially the palpebral fissure are less well defined, frequently affected by eyelashes and partial eyelid closure, and therefore inherently more difficult to delineate. Table 2 summarizes all objective metrics, and Figure 2 shows representative overlays for each structure and the final composite. Additional examples of segmentation performance under different eye-closure conditions are provided in Figure S2 in Multimedia Appendix 1.

Table 2. Segmentation performance by structure[a].

Structure	Dice[b], mean (SD)	IoU[c], mean (SD)	AP[d]@0.50, mean (SD)	AP@0.50-0.95, mean (SD)	AR[e]@0.50-0.95, mean (SD)
Pupil	94.0 (0.4)	88.8 (0.8)	99.2 (0.5)	75.9 (1.5)	82.1 (1.4)
Iris	86.6 (1.7)	76.4 (2.6)	99.7 (0.3)	87.4 (0.8)	90.7 (0.6)
Palpebral fissure	75.0 (4.1)	60.2 (5.3)	99.2 (1.0)	78.3 (1.3)	81.2 (1.4)
Overall[f]	93.3 (0.4)	87.4 (0.8)	99.3 (0.4)	80.6 (1.1)	84.7 (1.0)

Comparison of Differences in Objective Metrics Before and After Visual Tasks

In addition to objective ocular metrics, subjective CVS-Q scores also showed significant worsening after visual tasks. Specifically, participants' CVS-Q scores were higher after visual tasks compared to baseline values (mean 9.21, SD 4.57, vs mean 6.76, SD 3.76, $P<.001$). The prevalence of participants in the higher-severity group (CVS-Q scores=13-18) increased from 3 (8%) of 38 participants at baseline to 13 (34%) participants, while those without asthenopia (CVS-Q scores<6) decreased from 16 (42%) of 38 participants to 12 (32%) participants. In addition, SSS, KSS, and FAS levels all slightly increased after visual tasks (SSS: median 1, IQR 0-2; KSS: median 1, IQR 0-2; FAS: median 1, IQR 0-4). Notably, the number of participants reporting the most common complaint, dryness, rose by 4 (95% CI –6% to 27%), while those reporting excessive blinking saw a substantial increase of 15 (95% CI 21%-58%). Together, these results show that the task led to more pronounced short-term aggravation of visual fatigue during the protocol (Table S2 in Multimedia Appendix 1). Changes in these ocular metrics (ie, blink patterns, eye movement metrics, and pupil parameters) and CFF values before and after visual tasks are presented in Table 3. All differences were calculated as post- minus pretask values, so negative numbers indicated a decrease after visual tasks. The deteriorated asthenopia group exhibited a marked reduction in the average blink duration (median –4.76, IQR –49.44 to 6.74, ms). Moreover, the nondeteriorated asthenopia group demonstrated an increase in blink times (median 4, IQR 0-8). Notably, these differences were statistically significant between the two groups. Figure 3 illustrates the changes in the average pupil size and palpebral fissure length over an 1800-frame interval before and after visual tasks. The deteriorated asthenopia group showed an increase in both parameters, while these metrics remained relatively stable in the nondeteriorated asthenopia group.

XSL•FO
RenderX

Figure 3. Changes in palpebral fissure length and pupil size before and after visual tasks. The x axis represents 1800 fpsframes per minute, while the y axis shows the average difference in pupil size values (A) and fissure length (B) before and after visual tasks. The blue line represents participants with deteriorated asthenopia, and the orange line represents participants without deteriorated asthenopia. Values below 0 indicate that the posttask value is smaller than the pretask value. For each time point, values were first computed per participant and averaged within each group for the pre- and posttask recordings. The posttask-pretask difference was then calculated as the difference between the two group-averaged trajectories. These curves are provided for visualization only and were not used for statistical feature extraction or ML model input. fps: frames per minute; ML: machine learning.

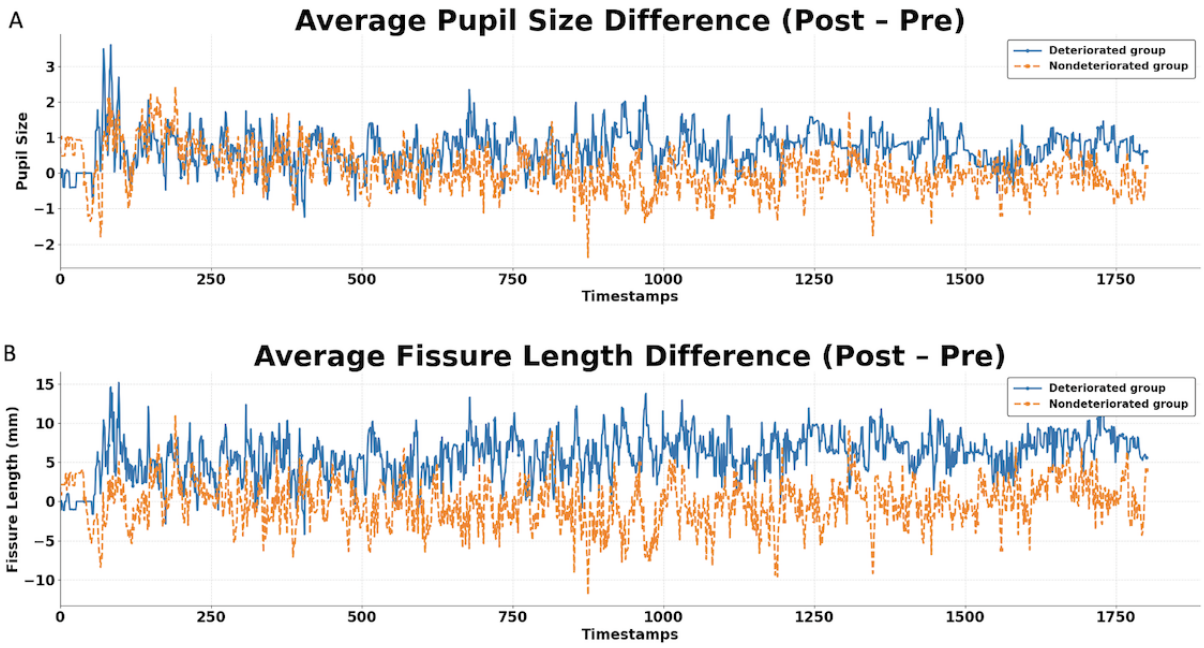

Table 3. Comparison of differences in blink patterns, eye movement metrics, pupil parameters, and CFF[a] values before and after visual tasks in participants with and without deteriorated asthenopia.[b]

Parameter difference	With deteriorated asthenopia	Without deteriorated asthenopia	*P* value
Blink times (per minute), median (IQR)	0 (–3 to 1)	4 (0 to 8)	.02
Average blink duration (ms), median (IQR)	–4.76 (–49.44 to 6.74)	12.21 (0 to 33.74)	.04
PERCLOS[c] (%), median (IQR)	–0.17 (–1.11 to 0.84)	0.56 (–0.83 to 2.78)	.10
Fixation number (per minute), median (IQR)	–5 (–14 to 10)	–7 (14 to 4)	.58
Average fixation duration (ms), median (IQR)	44.88 (–14.02 to 82.15)	–6.42 (–32.03 to 45.64)	.22
Average eye movement distance[d] (pixels), median (IQR)	36.49 (–21.60 to 75.03)	0.90 (–57.49 to 42.24)	.22
Average pupil diameter[d] (pixels), mean (95% CI)	0.15 (–0.15 to 0.45)	0.33 (–0.00 to 0.67)	.21
Maximum speed of pupil constriction[d] (pixels/second), median (IQR)	0.61 (–3.65 to 9.40)	0.77 (–8.27 to 9.23)	.71
Average speed of pupil constriction[d] (pixels/second), median (IQR)	–0.32 (–1.00 to 1.41)	0.14 (–0.96 to 0.54)	.53
CFF (Hz), mean (95% CI)	–2.97 (–3.96 to –1.98)	–2.14 (–2.96 to –1.32)	.09

[a]CFF: critical flicker fusion frequency.

[b]All values are expressed as post- minus pretask; negative values denote a reduction after visual tasks.

[c]PERCLOS: percentage of eyelid closure.

[d]Average value of both eyes.

Variability of Objective Metrics During the Reading Task

Tables 4-6 provide an overview of the changes in variability metrics, including pupil size, fissure length, blink duration, and blink interval, across the 1800-frame interval during the text-reading task in both groups, corresponding to the three increasing difficulty levels of the reading segments. Statistically significant differences were observed in several parameters. In the nondeteriorated asthenopia group, participants exhibited

significantly greater variability in pupil size across the 600-1200–frame interval, as indicated by a higher variance (median 0.64, IQR –0.27 to 1.81, vs median –0.22, IQR –1.25 to 0.68; *P*=.005) and coefficient of variation (median 3.77, IQR –3.78 to 10.48, vs median –3.31, IQR –9.62 to 0.61; *P*=.002). Similarly, fissure length variability was significantly higher in this frame interval in the nondeteriorated asthenopia group, with a higher SD (median 1.22, IQR –0.21 to 4.24, vs median –0.12, IQR –2.01 to 0.58; *P*=.007), variance (median 16.61, IQR –3.31 to 72.81, vs median –1.27, IQR –25.00 to 7.09; *P*=.003), and coefficient of variation (median 3.72, IQR 0.06-10.24, vs median –2.10, IQR –9.09 to 0.23; *P*<.001). In addition, across all frame intervals, the coefficient of variation for fissure length was significantly higher in the nondeteriorated asthenopia group (median –0.88, IQR –7.23 to 0.92, vs median 1.85, IQR –1.71 to 6.27; *P*=.006). No significant differences were found in blink duration or blink interval variability metrics (*P*>.05).

Table 4. Comparison of differences in variability metrics of pupil size before and after visual tasks in participants with and without deteriorated asthenopia.

Difference in variability metric and frame interval	With deteriorated asthenopia	Without deteriorated asthenopia	*P* value
SD, median (IQR)

Risk Prediction for Deteriorated Asthenopia

As shown in Table 7, model performance was evaluated using accuracy, AUROC, the F_1-score, and balanced accuracy on the independent test set. Four ML models were built using ten selected features: average blink duration, coefficient of variation of fissure length (600-1200 frames), coefficient of variation of fissure length (200-1800 frames), variance of fissure length (600-1200 frames), SD of fissure length (600-1200 frames), coefficient of variation of pupil size (600-1200 frames), blink times, SD of pupil size (600-1200 frames), variance of pupil size (600-1200 frames), and the CFF. Among the four models, the random forest demonstrated the best overall performance, achieving the highest mean AUROC of 0.850 (95% CI 0.830-0.860), together with the highest accuracy (mean 0.720, SD 0.035), F_1-score (mean 0.771, SD 0.032), and balanced accuracy (mean 0.698, SD 0.042). XGBoost also achieved a high mean AUROC of 0.820 (95% CI 0.800-0.830), whereas the decision tree showed moderate performance across all metrics. In contrast, the SVM exhibited limited discriminative ability, with a balanced accuracy close to the chance level. Table 8 presents the contributions of each feature to the prediction of deteriorated asthenopia using the random forest. The importance scores indicate the relative influence of each feature on the model's predictive performance, with the average blink duration (score=0.194) and coefficient of variation of fissure length (600-1200 frames, score=0.119) being the most impactful features. Other variability-related features of fissure length and pupil size also contributed nonnegligibly to the model's predictions, whereas blink times showed a relatively lower contribution. Figure 4 shows the risk report generated by the deployed system. It predicts the deteriorated risk level (high/low), together with the summary metrics and time-series plots of objective metrics. In the prototype, the predicted risk level (low/high) is intended as the main output for lay users, whereas the detailed numerical and time-series indices are primarily provided for clinicians and researchers; future versions will include more user-friendly explanations and simplified summaries of these metrics. Enlarged versions of the individual plots are provided in Figure S3 in Multimedia Appendix 1.

Table 7. Prediction performance for detecting deteriorated asthenopia using ML[a] models.

Model	Accuracy, mean (SD)	F_1-score, mean (SD)	Balanced accuracy, mean (SD)	Mean AUROC[b] (95% CI)
Decision tree	0.688 (0.046)	0.726 (0.039)	0.682 (0.051)	0.75 (0.73, 0.77)
Random forest	0.720 (0.035)	0.771 (0.032)	0.698 (0.042)	0.85 (0.83, 0.86)
SVM[c]	0.555 (0.039)	0.692 (0.037)	0.511 (0.031)	0.59 (0.56, 0.63)
XGBoost[d]	0.677 (0.048)	0.741 (0.041)	0.661 (0.051)	0.82 (0.80, 0.83)

Figure 4. Example report generated by the EyeFatigue Tracker system. The app summarizes changes in ocular parameters during a single 1-minute standardized reading task. The panel on the top shows the IR ocular video with segmentation overlays, and the panel on the right displays the predicted risk level for eye fatigue. The summary block lists key metrics: total time, blink count, mean blink duration, fixation count, mean fixation duration, mean square error of fixation duration, and PERCLOS. The plots depict blink status, blink duration and interval, palpebral fissure length, pupil size, and pupil trajectory for both eyes across the 1-minute task. Values are illustrative. IR: infrared; PERCLOS: percentage of eye closure.

Discussion

Principal Findings

In this study, we developed and validated EyeFatigue Tracker, an at-home system that classifies the short-term risk for asthenopia deterioration using a standardized 1-minute reading task. The segmentation module performed reliably (overall Dice=93.3% and IoU=87.4%), providing stable masks for downstream analysis. Using these masks, the device objectively quantified ocular metrics related to eye fatigue, including blink patterns, eye movements, and pupil variations. Features

XSL•FO
RenderX

reflecting the intratask variability of palpebral fissure length and pupil size, together with blink measures and the CFF, were most informative for prediction. Across the four ML models, the random forest demonstrated the most balanced and robust overall performance on the test split, achieving the highest F_1-score (mean 0.771, SD 0.032), with a mean accuracy of 0.720 (SD 0.035) and a mean AUROC of 0.85 (95% CI 0.830-0.86). Taken together, these results suggest that brief, home-collected ocular signals can support practical monitoring of asthenopia in daily digital use and may offer new insights into objective biomarkers of visual fatigue.

Blink Behavior as a Compensatory Mechanism

Previous studies have reported a significant association between blink patterns and asthenopia [47,48]. In this study, the average blink duration and blink times emerged as key predictors of deteriorated asthenopia in the random forest, exhibiting notable differences between the deteriorated and nondeteriorated asthenopia groups. Specifically, the average blink duration increased in the nondeteriorated asthenopia group but remained unchanged in the deteriorated asthenopia group, consistent with prior research suggesting that prolonged blink duration serves as a compensatory mechanism to alleviate visual discomfort [27,49]. This may indicate that individuals experiencing deteriorated asthenopia fail to exhibit an adaptive increase in blink duration, potentially leading to inadequate tear film replenishment and worsened eye strain. Additionally, blink times also contributed to the prediction of deteriorated asthenopia, further supporting the idea that increased blink frequency is often a compensatory response to increasing eye fatigue [50]. These findings indicate that individuals experiencing deteriorated asthenopia may be less able to implement compensatory blink behavior effectively, exacerbating their visual discomfort and strain.

Ocular Variability as a Biomarker of Deteriorated Asthenopia

Ocular instability, reflected in fluctuations of fissure length (fissure height) and pupil size, emerged as a key indicator of deteriorated asthenopia. Among all features, the coefficient of variation of fissure length (600-1200 frames) ranked among the most influential predictors (0.119), together with its coefficient of variation in a later interval (200-1800 frames; 0.101), as well as its variance (0.096) and SD (0.096). Similarly, the coefficient of variation of pupil size (600-1200 frames; 0.087) also played a notable role in the prediction model. Notably, variability changes were higher in the nondeteriorated asthenopia group, suggesting an active and functional neuromuscular response to counteract fatigue. In contrast, the deteriorated asthenopia group exhibited lower variability changes, which may indicate fatigue-induced rigidity, where the eyelid and pupillary muscles fail to adjust dynamically, leading to sustained strain and discomfort. This distinction supports the idea that fissure height and pupil size variability reflect an individual's ability to adapt to visual fatigue.

Previous research suggests that eyelid position influences tear film stability, which may contribute to asthenopia [51]. Additionally, a variability change of fissure length may reflect the orbicularis oculi muscle's response to visual fatigue [52]. Cen et al [53] introduced pupil size as the most significant feature for SVM-based visual comfort prediction. Hopkinson [54] suggested that measuring oscillations in pupillary diameter is one of the simplest methods for assessing visual fatigue. Similarly, Geacintov and Peavler [55] observed that oscillation patterns in pupil size increase with visual fatigue, further supporting its relevance as a fatigue indicator. The variability metrics of pupil size during the specified intervals may reflect underlying oscillatory patterns associated with fatigue, aligning with prior evidence of its sensitivity to fatigue-related changes. These findings suggest that these metrics may therefore serve as potential biomarkers for distinguishing between individuals prone to deteriorated asthenopia [56]. Interestingly, variability metrics within the 600-1200–frame interval were more predictive than those spanning the entire reading task (200-1800 frames). This can be attributed to the task design, which progressively increased in difficulty across three stages. In the first stage (200-600 frames), the task was relatively easy, minimizing visual strain and limiting fluctuations of fissure length and pupil size. In the final stage (1200-1800 frames), the task became highly demanding, potentially triggering compensatory fixation strategies that suppressed variability in both groups. In contrast, the middle stage (600-1200 frames) represented a transition from low-to-moderate difficulty, requiring sustained attention and accommodation. This highlights the 600-1200–frame interval as a critical window where ocular instability becomes most pronounced, making it a sensitive marker for detecting individuals prone to deteriorated asthenopia.

Role of CFF and Fixation Parameters

Although no statistically significant difference in the CFF was observed between the deteriorated and nondeteriorated asthenopia groups, its inclusion in the predictive model was based on its recognized role in assessing eye fatigue susceptibility [10]. The CFF has long been established as a psychophysical marker of visual fatigue, as it reflects temporal resolution thresholds in the visual system that deteriorate under asthenopia-inducing conditions [57,58]. Although its individual contribution to the model was lower than most other ocular variability metrics, the CFF remains a valuable input, complementing blink- and pupil-related parameters to improve prediction accuracy.

In contrast, fixation parameters showed limited utility in distinguishing between the two groups in this study. Although Wang et al [13] reported that the average fixation duration increases and fixation numbers decrease as eye fatigue worsens, our findings aligned with their observations in both groups. Nevertheless, these changes were not statistically significant enough to differentiate the deteriorated and nondeteriorated asthenopia groups. One possible explanation is that visual fatigue did not deteriorate considerably during the computer gameplay process, reducing the sensitivity of fixation parameters as discriminative indicators in this context.

Clinical and Practical Implications of the EyeFatigue Tracker

Building on these observations, our findings contribute to advancing the diagnostics and prediction of deteriorated

XSL•FO
RenderX

asthenopia by addressing key limitations in previous studies. Previous research has often relied on head-mounted devices to analyze single-eye metrics, such as pupil accommodation speed [14], blink frequency [15], and eye closure duration [14], or has relied on eye trackers to extract pupil size and eye movement parameters, which are typically unable to directly capture blink pattern data [13]. In contrast, our EyeFatigue Tracker captures binocular ocular videos and a segmentation-driven pipeline to derive an integrated set of metrics for at-home use. Its portability and cost-effectiveness further enhance its potential for pragmatic monitoring in daily digital use. From a health care perspective, this at-home, session-based assessment could help detect early worsening of visual fatigue in high-risk users and provide objective measures to evaluate simple interventions. In telemedicine, the automatically generated reports can be shared with eye care professionals to complement questionnaires and guide follow-up. It may also be applied in clinical settings for the detection and follow-up of asthenopia, providing objective metrics alongside subjective assessments. Moreover, by introducing within-task variability measures as candidate indicators of deterioration, this study suggests potential gains in predictive performance and diagnostic utility.

Limitations and Future Directions

This study has several limitations that require consideration. First, the relatively small sample size may increase the risk of false-negative results when comparing the objective metrics between the deteriorated and nondeteriorated asthenopia groups and limits the generalizability of our findings. Future studies should recruit larger and more diverse populations to enhance statistical power and broader applicability. In addition, statistical feature filtering ($P<.05$) was used to define candidate ocular biomarkers and was not re-estimated within each cross-validation fold; this design choice may introduce selection bias and lead to optimistic performance estimates. Moreover, performance showed nonnegligible variability across cross-validation folds, underscoring uncertainty under the limited sample size and the need for external validation in independent cohorts. Second, no severe asthenopia cases were observed during the experiment. Including participants with severe symptoms in future studies would provide deeper insights into the relationship between objective metrics and severe visual fatigue. Third, the cohort was studied at a single site under a standardized protocol; subsequent research could incorporate diverse clinical or real-world settings (eg, workplaces with prolonged screen use or clinical contexts involving pre- and postsurgical patients) to better validate the predictive value of objective metrics in broader contexts. Fourth, future technical work could aim to improve the segmentation of challenging structures, such as the palpebral fissure. In addition, although a simple overexposure suppression step improved segmentation stability in our dataset, future versions of the system could integrate more advanced illumination enhancement methods to further increase robustness under challenging at-home lighting conditions. Fifth, we did not systematically test different video frame rates or learning rate schedules; future studies should compare alternative frame rates and apply learning rate–scheduling strategies (eg, step decay or plateau-based reduction) to further optimize the balance between accuracy and computational cost.

Conclusion

This study developed an at-home system that estimates the short-term risk for asthenopia deterioration after computer use and highlights objective biomarkers that may support earlier detection and prevention. Our findings indicate that brief, home-collected signals can enable practical monitoring and add objective evidence to symptom-based assessment. These conclusions should be interpreted in the light of the methodological and study limitations, including the modest sample size, the single-site design, and the use of short-term changes in CVS-Q scores as the reference outcome. Future work should validate generalizability in larger and more diverse cohorts, assess longitudinal stability in routine use, and evaluate performance in clinically severe cases.

Acknowledgments

We thank the InnoHK, a major initiative of the Hong Kong Special Administrative Region Government, for providing valuable support. The research work described in this paper was conducted in the Jockey Club Science, Technology, Engineering, and Mathematics Lab of Innovative Light Therapy for Eye Diseases, one of the labs funded by the Hong Kong Jockey Club Charities Trust. We also acknowledge the support of the Hong Kong Polytechnic University–Rohto Centre of Research Excellence for Eye Care.

Funding

This study was supported by the Hong Kong Polytechnic University–Rohto Centre of Research Excellence for Eye Care (P0046333) and the Start-up Fund for Research Assistant Professors under the Strategic Hiring Scheme (P0048638), with the sponsor or funding organization not being involved in the study’s design or implementation.

Authors' Contributions

YC and MH conceived the study and edited and reviewed the paper. FS, ML, and ML collected data. GL and ZT built the deep learning model. FS and GL conducted the literature search. FS, GL, YC, and JZ analyzed the data. FS and YC contributed to key data interpretation. FS wrote the manuscript. All authors have critically revised the manuscript.

Abstract

Background: Approach bias modification (ApBM) aims to target maladaptive approach tendencies toward substance-related cues and has increasingly been examined as an adjunctive intervention for substance use disorders, including nicotine use. However, although participants' subjective experiences of ApBM are likely to influence both its effectiveness and successful implementation, they have rarely been systematically investigated.

Objective: This study aimed to explore both proximate and long-term subjective training experiences reported by participants from 2 previously conducted randomized controlled trials of ApBM for smoking cessation. Training experiences were explored across 2 delivery modalities (virtual reality and smartphone app) and compared with those reported in matched sham training conditions.

Methods: Participants were invited to provide open-ended feedback immediately following the intervention and up to 7 weeks after study entry (proximate feedback), as well as again 4 years later (long-term feedback). Thematic analysis was conducted to identify core themes, complemented by exploratory frequency and descriptive quantitative analyses comparing ApBM and sham conditions.

Results: In total, 87 (ApBM: n=45; sham: n=42) of the 178 participants included in the randomized controlled trials provided proximate (7-week follow-up) feedback, and 63 (ApBM: n=33; sham: n=30) provided long-term (4-year follow-up) feedback; 104 participants contributed feedback at least once. Four overarching themes were identified, with the fourth emerging only in long-term reflections: (1) perceived treatment effects, spanning beneficial changes and a perceived lack of effects; (2) mechanisms of action, including presumed working mechanisms and impeding factors; (3) feedback on the training and study experience; and (4) attribution of effects to training-specific or external factors. Overall, participants engaged extensively in reflecting on potential mechanisms underlying the training, their relation to therapeutic outcomes, and opportunities for improving future interventions. Exploratory frequency analyses indicated that participants in the ApBM group more often suggested improvements to the training, whereas participants in the sham condition more frequently reported impeding factors, particularly difficulties understanding the training rationale. Quantitative training evaluations were generally more favorable for ApBM than for sham training, as reflected in a significantly higher overall evaluation score. In particular, ApBM received higher ratings for its perceived effectiveness in reducing smoking and its applicability to everyday situations.

Conclusions: This study provides novel insights into how ApBM for smoking is experienced both shortly after training and years later. To our knowledge, this is the first study in the context of cognitive bias modification, including ApBM, to examine subjective experiences over a multiyear time frame. The findings highlight the importance of participants' understanding of the training rationale and underscore the value of incorporating participants' perspectives into the development and evaluation of ApBM interventions.

Introduction

Cigarette smoking is highly addictive and remains prevalent despite its well-documented health risks. Globally, 1.18 billion people report regular smoking [1], with approximately half meeting diagnostic criteria for nicotine dependence [2]. Although the majority of individuals who smoke express an intention to quit [3], access to smoking cessation treatment remains limited to a small proportion of those in need. According to the World Health Organization [4], only about 30% have access to comprehensive smoking cessation services. Moreover, even among individuals who receive treatment, relapse rates remain substantially high [5,6]. Consequently, the development of feasible and easily accessible interventions that can complement and improve existing treatments represents a key priority not only in nicotine and tobacco research but also in public health.

One promising approach in this regard is the integration of therapeutic interventions into digital formats. In the context of smoking cessation, a growing number of mobile and computerized interventions have been developed, with evidence suggesting that incorporating cognitive behavioral therapy principles, such as self-reflection and cognitive restructuring, can support smoking cessation compared with no or minimal support (see Chu et al [7] for a recent meta-analysis). However, given the persistently high relapse rates even following treatment [5,7], it is likely that, beyond reflective processes targeted in traditional psychotherapeutic approaches, more automatic, implicit cognitive processes contribute to the maintenance of smoking behavior.

Over the past 2 decades, a range of computer-based training interventions has been developed to modify such implicit processes implicated in maladaptive substance use (for reviews, see Kakoschke et al [8] and Vrijsen et al [9]). Collectively, these interventions are referred to as cognitive bias modification (CBM). Whereas cognitive bias assessment tasks require equally frequent responses to substance-related and substance-unrelated stimuli (eg, equally often approaching and avoiding smoking and nonsmoking pictures), CBM training paradigms use systematic stimulus-response contingencies (eg, always avoiding smoking and always approaching nonsmoking pictures) to counteract the bias (for a recent review, see Vrijsen et al [9]). Hence, unlike traditional psychotherapeutic approaches, which primarily target reflective processes to facilitate behavioral change, CBM aims to directly alter more automatic, implicit processes through repeated training. To date, several CBM variants have been developed that differ in the specific cognitive processes they aim to modify. For example, attention bias modification (ABM) aims to train attentional allocation away from substance-related cues and toward more adaptive alternatives, using paradigms such as spatial cueing or gaze-contingent training. CBM for interpretations (CBM-I) targets the tendency to interpret ambiguous stimuli in a disorder-congruent way by consistently reinforcing benign or substance-unrelated interpretations. Approach bias modification (ApBM), on the other hand, repeatedly trains individuals to make avoidance movements in response to substance-related cues and approach movements toward neutral or goal-consistent cues [9]. Indeed, the strongest evidence for CBM's clinical effectiveness comes from ApBM in alcohol use disorder (AUD), particularly when applied as an adjunct to psychological therapy in structured clinical settings (see Pan et al [10] for a recent meta-analysis and Wittekind et al [11] for a review). Several randomized controlled trials (RCTs) have demonstrated reductions in relapse rates of up to 10% at 1-year follow-up [12-16], which has led to the inclusion of ApBM in national treatment guidelines for AUD in Germany [17] as well as Australia [18].

Since then, this approach has been extended to other consumption-related behaviors, including nicotine use [19-23]. Although several studies have reported promising effects, such as increases in the number of abstinent days [19] or reductions in daily cigarette consumption following training [20,21], null findings have also been observed [23], and overall effect sizes remain modest (for a meta-analysis, see Boffo et al [24]). While multiple factors may contribute to this inconsistency, including differences in training design, participant characteristics, and outcome variables, participants' subjective experiences of the training are likely to play an important yet underexplored role in ApBM effectiveness. This is particularly relevant given that multiple training sessions are required to induce reliable and lasting changes in cognitive biases [12,25], which may place a considerable burden on participants and affect adherence. Consequently, training acceptance and motivation are critical determinants of successful CBM implementation [26]. Yet, systematic qualitative investigation of participant experiences with CBM, particularly ApBM for smoking, remains limited. Evidence from the few available studies suggests that CBM tasks are often experienced as monotonous and repetitive [27] and that participants frequently report difficulties in understanding the relevance of the training for their behavioral goals [28]. Such perceptions are likely to undermine training motivation and engagement and may therefore partially account for the inconsistent clinical outcomes observed in the literature.

This notion is supported by evidence from related CBM domains. For example, in the context of ABM for social anxiety, one study showed that patients' perceptions of the training predicted both bias reduction and subsequent symptom improvement [29]. Systematic research on subjective experiences with CBM in general, and ApBM in particular, remains scarce in the context of substance use, although a small number of studies suggest that participants' perceptions may be important in this domain as well. For example, in an implementation study on ApBM for AUD, Schenkel et al [30] assessed training evaluation among alcohol dependent inpatients and found that although the paradigm was rated predominantly positive, most patients (60%) did not believe that the training was effective in reducing relapse rates, and only a minority

XSL•FO
RenderX

(29%) perceived a transfer to everyday behavior. Extending these findings, a qualitative study investigating a combined ABM and ApBM intervention for problematic gaming behavior reported that negative training experiences, including perceptions of excessive duration and tediousness, might have accounted for extremely high attrition rates of up to 90% [31]. Thus, participants' perceptions of CBM procedures are likely to contribute to both training uptake and effectiveness, underscoring the need for more systematic investigation of these perceptions and for strategies to improve them.

In line with this objective, recent advances in training delivery have aimed to enhance training acceptance by embedding ApBM in novel digital formats, including virtual reality (VR) and smartphone apps (for a review, see Forman et al [26]). These approaches are assumed to increase engagement and perceived relevance, as training can be conducted in immersive or consumption-related contexts. Supporting this notion, 2 proof-of-principle trials in the context of anxiety translated the principles of ABM [32] and CBM-I [33] into VR environments and reported high levels of enjoyment, motivation, flow, and presence. However, both studies were limited by small sample sizes, single-session training designs, and relatively short follow-up periods of up to 6 weeks. Besides, a mixed methods study combining internet-based ApBM and CBM-I for hazardous alcohol use and social anxiety reported overall satisfaction, but a need for a more compelling training rationale [34]. Similarly, a feasibility study on an app-based ApBM intervention for problem drinking found that in addition to positive feedback regarding usability and intuitiveness of app design, participants criticized the intervention as repetitive and insufficiently personalized [35]. In the context of ApBM for smoking, 2 larger RCTs were recently conducted by our research group, both including multiple training sessions and follow-up assessments. These studies demonstrated that ApBM delivered via VR [36] or a smartphone app [37] led to greater smoking reduction compared to respective control conditions. To date, however, little is known about how these novel delivery formats are perceived by individuals motivated to quit smoking, and whether common challenges associated with CBM, such as perceived monotony or a lack of meaningfulness, remain an issue of concern. Moreover, there are no long-term studies examining how such novel training approaches are perceived over extended periods of time or the extent to which they are retrospectively regarded as useful in the longer-term process of behavior change. This is particularly important, as research on psychotherapy outcomes indicates that patients' perceptions of treatment may evolve over time, with important implications for sustained behavioral change and well-being. For example, Malkomsen et al [38] demonstrated that patients who were initially uncertain about the benefits of their psychotherapeutic treatment reported more positive views 3 years later. Such shifts may be particularly relevant given evidence that therapy perceptions influence whether learned skills are applied after treatment termination [39].

Against this background, this study examined subjective training experiences reported by participants from 2 RCTs that used VR-based [36] and app-based [37] ApBM for smoking cessation. The aims of the study were threefold: (1) to identify themes reflecting participants' experiences with the training, (2) to examine how participants evaluate novel delivery formats of ApBM for smoking, and (3) to explore whether and how training perceptions change or remain stable over the long term. More specifically, regarding the first aim, we explored the extent to which emergent themes correspond to those identified in previous qualitative studies on CBM and psychotherapy more broadly, as well as whether study-specific themes arise in the present context. Regarding the second aim, we examined whether digitally delivered ApBM are associated with engagement and motivation and/or whether these novel formats introduce distinct challenges (eg, technical issues). Regarding the third aim, we investigated whether long-term reflections become more general over time or whether participants report additional or qualitatively different insights compared to their immediate evaluations. To answer these research questions, participants were invited to provide open-ended feedback immediately following the intervention and again approximately 4 years after study completion. Thematic analysis was used to identify core themes associated with the training principles. To contextualize and complement participants' subjective accounts, descriptive information on smoking-related outcomes and quantitative training evaluations has been additionally assessed.

Methods

Ethical Considerations

This trial was approved by the local ethics committee of the University of Siegen (reference numbers ER_16_2018 and ER_18_2018) and was conducted in accordance with the Declaration of Helsinki and Good Clinical Practice guidelines. Participation was voluntary, and participants were able to withdraw their consent for participation at any time. Participants did not receive financial compensation for their involvement in the research.

To ensure privacy and confidentiality, all study data were stored on secure servers of the University of Siegen and were accessible only to authorized members of the study team. Participants were assigned a unique identification number, and all research data were stored and analyzed using these codes. A separate password-protected file linking participant names to identification numbers was maintained exclusively for study administration and follow-up purposes and was stored separately from the research data.

Trial Procedure

This study examines subjective experiences with either a VR-based or app-based ApBM for individuals motivated to quit smoking. Quantitative outcomes related to training effects and clinical efficacy of these interventions have been reported previously (see Machulska et al [36,37]). For all participants, a brief smoking cessation intervention constituted treatment as usual (TAU), followed by a 14-day training program delivered either in VR or via a smartphone app. Participants randomized to the experimental group (EG) were trained to respond to smoking-related cues with avoidance movements and to alternative cues with approach movements. Participants in the control group (CG) received a sham training in which no

XSL•FO
RenderX

systematic contingency between stimulus content and response movement was implemented.

In the app-based ApBM trial [37], an additional control condition was implemented, which received the TAU but was not given access to the training app during the main study period (baseline to short-term follow up). Consequently, feedback from this group is not presented in this analysis.

To explore participants' subjective experiences, open-ended feedback was collected immediately after the training period (posttest), 7 weeks after baseline (short-term follow-up), and approximately 4 years after baseline (long-term follow-up). Notably, the posttest and 7-week follow-up assessments were both conducted within the active study phase of the original RCTs. Accordingly, both time points are considered to reflect participants' proximate experiences and evaluations, rather than fully naturalistic, longer-term reflections. Based on this notion and to increase the amount of available qualitative data per time point, feedback from the posttest and short-term follow-up assessments was combined. Accordingly, these analyses distinguish between proximate feedback (posttest and 7-week follow-up) and long-term feedback (4-year follow-up).

Posttest and short-term follow-up assessments were conducted on-site at the laboratory. After completing the quantitative questionnaire battery, participants were invited to provide open-ended feedback in written form via the survey platform LimeSurvey. At the long-term follow-up, feedback was collected remotely. To maximize response rates, 2 complementary approaches were used. First, participants were contacted by telephone and, following a brief assessment of current smoking behavior, were invited to share open-ended feedback regarding the training and/or their overall study experience. In these cases, study assistants conducting the interviews documented participants' responses verbatim. Second, all participants received an email invitation to complete an online survey, which also included an open-ended response field to allow for more general reflections on study participation.

Participants

All participants took part in 1 of 2 RCTs investigating the effectiveness of a VR-based [36] or app-based [37] ApBM for smoking. Eligibility criteria for those RCTs included being at least 18 years of age, smoking a minimum of 6 cigarettes per day for at least 6 months prior to study entry, and reporting an intention to quit smoking within the subsequent 6 months. Exclusion criteria comprised a current substance use disorder other than nicotine, current psychiatric illness, insufficient proficiency in German, uncorrected visual or auditory impairments, or dyschromatopsia. In addition, participants who dropped out prior to the first training session or failed to become aware of the training contingencies in the EG were excluded from data analyses. This resulted in a total sample of 178 participants (n_{EG}=87; n_{CG}=91), of whom 96 received the VR-based training and 82 the app-based training. Overall, 104 of the 178 participants provided feedback at the proximate or long-term assessment. Of these, 54 had been randomized to ApBM training (n_{VR}=35; $n_{App=}$19) and 50 to sham training (n_{VR}=29; $n_{App=}$31). No differences were observed between participants who provided feedback and those who did not with regard to condition (χ^2_1=0.94; *P*=.34). However, participants in the VR trial were more likely to provide feedback than those in the app trial (χ^2_1=5.83; *P*=.02). The sample was evenly distributed by gender (52/104, 50% female), with age ranging from 22 to 67 years (mean 48.65, SD 11.73).

Interventions

The interventions used in the 2 initial RCTs are briefly described below. Please refer to the original studies [36,37] for more detailed information.

TAU: Brief Smoking Cessation Intervention

Prior to the baseline assessment, all participants took part in a brief smoking cessation intervention (TAU), administered by a trained psychologist. The session was conducted in small groups of up to 4 individuals and lasted about 90-120 minutes. The following topics were covered by the intervention: psychoeducation, including reflective and impulsive determinants of smoking maintenance vs cessation, motivational support for smoking cessation, instructions to self-monitor daily smoking, and bibliotherapy through the provision of a self-help book.

Approach Bias Training Paradigm

Overview

Each training variant was based on the traditional joystick training, in which different pictures are presented consecutively on a computer screen, and participants are required to perform push (avoidance) or pull (approach) movements by means of a joystick attached to the computer. Upon a push movement, images shrink in size, creating a sense of avoidance, whereas upon a pull movement, images grow, creating a sense of approaching (see Rinck and Becker [40], for a description of the original task). This training principle was translated into 2 novel delivery modalities: a VR format in the first RCT [36], where participants executed push and pull movements with their own arms that were visible in the virtual environment, and a smartphone app in the second RCT [37], where participants performed upward (avoidance) and downward (approach) swiping movements on a touchscreen. All participants received the same cover story stating that the training aimed to target automatic processes involved in smoking by strengthening more controlled responses to smoking-related stimuli. In addition, it was communicated that this approach was expected to enhance self-control over smoking behavior in everyday contexts.

VR Training

The virtual environment was situated within an office setting, in which smoking-related and smoking-unrelated objects consecutively appeared on a virtual desk. Objects were either blue- or red-bordered. An indirect task instruction was used as participants were instructed to ignore object content and respond to border color only (ie, push red-bordered objects and pull blue-bordered objects). In the EG, all smoking-related objects were bordered in red, which required an avoidance movement, whereas all smoking-unrelated objects were bordered in blue, which required an approach movement. Hence, a 100%-contingency between object content and response

XSL•FO
RenderX

movement was used. In the CG, participants performed a sham training version that closely resembled the VR-ApBM condition, except that there was no contingency between object content and response format. Each session took approximately 10-15 minutes to complete.

Smartphone App Training

Smoking-related and smoking-unrelated pictures appeared consequently at the center of a mobile screen. Pictures were either rotated 3° to the left or 3° to the right. An indirect task instruction was used as participants were instructed to ignore picture content and respond to image rotation only (ie, swipe-up pictures rotated to the right and swipe-down pictures rotated to the left). In the EG, all smoking-related pictures were rotated to the right and had to be swiped up (avoidance), whereas all smoking-unrelated pictures were rotated to the left and had to be swiped down (approach). As with the original ApBM training, a zooming feature was introduced to create a visual sense of avoiding vs approaching the image. In the CG, participants performed a sham training version that closely resembled the app-ApBM condition, except that no contingency between picture content and response format was introduced. Each session took approximately 5 minutes to complete.

Assessments

Qualitative Data

Participants were invited to provide open-ended feedback in response to the question: “Do you have any feedback or comments about the training?” Responses were assessed at 3 time points: online immediately after the training interval (posttest) and 7 weeks after baseline (short-term follow-up), which were combined to represent proximate feedback, as well as online and via telephone approximately 4 years after baseline (long-term follow-up), which was combined to represent long-term feedback.

Quantitative Data

Overview

To aid interpretation of the qualitative findings, basic smoking-related and training-specific variables assessed at proximate and long-term time points are summarized below. For a comprehensive description of all measures administered in the original trials, please refer to the published study protocols [41,42] and original reports [36,37].

Smoking-Related Data

In addition to demographic information (ie, age and sex), participants provided smoking-related information, including (1) the duration of nicotine use (in years), (2) 7-day point abstinence, (3) number of daily smoked cigarettes, and (4) degree of nicotine dependence as measured with the Fagerström Test for Nicotine Dependence (FTND) [43] (German version [44]), with scores ranging between 0 (no/very weak dependence) and 10 (very strong dependence).

Training-Related Data

The number of completed training sessions was recorded either by study assistants (VR-based training) or automatically within the training app (app-based training). At posttest, participants additionally completed a brief training evaluation questionnaire consisting of 9 dichotomous items (0=no, 1=yes) assessing perceived ease (“The training was easy to perform.”), motivation (“It was difficult to motivate myself to complete the training.” [reversely coded]), clarity (“The training setup was clear.”), and subjective efficacy (“The training is beneficial in reducing smoking.”) of the training. Item responses were summed to yield a total evaluation score ranging from 0 to 9, with higher values indicating more positive evaluations of the training.

Data Preparation and Planned Analyses

To explore participants’ perspectives and potential group differences in subjective training experience, we conducted a thematic analysis of the proximate and long-term open-ended responses. Three independent coders (AM, ES, and JB) followed an inductive, stepwise procedure for psychological thematic analysis according to Braun and Clarke [45,46]. All coders first reviewed the initial 20% of responses and generated codes from the data. They then met to compare codes, resolve discrepancies, and agree on a coding scheme. The remaining responses were coded using this scheme. Codes were subsequently grouped into higher-order subthemes and organized into overarching themes. Finally, the coding framework and theme assignments were reviewed by all coders and adjusted where necessary. Because the thematic analysis was exploratory, no a priori hypotheses were specified. Quotations presented in the Results were translated from German to English and checked for translation accuracy. To complement the qualitative analysis, we additionally quantified how often each theme and subtheme was mentioned and explored whether frequencies differed between the EG and CG using chi-square tests. Prior to quantification, the coders convened to ensure consistent application of the final coding framework across all participants. This procedure was undertaken to guarantee the reliability and validity of the theme assignment for the frequency-based analyses.

In addition, quantitative data regarding demographic variables, smoking-related behavior, and training-specific information are presented descriptively (means, SDs, and proportions) across conditions and time points to provide contextual information for the qualitative thematic analysis.

Results

Participants’ Characteristics

Participants’ characteristics with regard to demographic and smoking-related data are provided in Tables 1 and 2. As can be seen, the sample consisted of long-term smoking individuals who had been smoking for almost 30 years. The average consumption at baseline was approximately 19 (SD 6.59) cigarettes per day, with a moderate nicotine dependence (FTND score: mean 4.85, SD 2.12). Although descriptively, participants in the CG completed slightly more training sessions than those in the EG (CG: mean 9.1, SD 6.53 vs EG: mean 7.7, SD 5.27), short-term smoking-related outcomes improved to a similar extent in both groups. At the 4-year follow-up, descriptive differences between groups were observed for abstinence (30/48, 63% in the EG vs 13/38, 34% in the CG), daily cigarette consumption (EG: mean 6.19, SD 10.11 vs CG: mean 9.26, SD

XSL•FO
RenderX

9.36), and degree of nicotine dependence (EG: FTND: mean 1.29, SD 2.45 vs CG: mean 2.41, SD 2.80). Please note that these values are reported for contextual reasons only. Formal statistical analyses of smoking-related outcomes are presented in the primary RCT reports [36,37], with additional long-term analyses reported elsewhere [47].

Table 1. Sample sizes for overall participants and study groups across assessment time points.[a]

Variable	Overall (n=104), n	EG[b] (ApBM[c]; n=54), n	CG[d] (sham; n=50), n
Baseline	104	54	50
Posttest	100	51	49
Short-term (7-week) follow-up[e]	87	45	42
Long-term (4-year) follow-up	86	48	38

[a]Sample sizes were identical across outcome measures (abstinence and daily cigarette consumption).

[b]EG: experimental group.

[c]ApBM: approach bias modification.

[d]CG: control group.

[e]For nicotine dependence (Fagerström Test for Nicotine Dependence [43]) at the 7-week follow-up, data were available for 82 participants (EG=44 and CG=38) because scores could not be obtained from 5 participants.

Table 2. Demographic characteristics and smoking-related outcomes for the overall sample and study groups.

Variable	Overall	EG[a] (ApBM[b])	CG[c] (sham)
Demographic characteristics			
Age (years), mean (SD)	48.65 (11.73)	48.35 (12.98)	48.98 (10.33)
Gender (female), n (%)	52 (50)	26 (48)	26 (52)
Duration of nicotine use (years), mean (SD)	28.97 (12.08)	28.54 (12.85)	29.44 (11.29)
Number of training sessions, mean (SD)	8.36 (5.92)	7.70 (5.27)	9.06 (6.53)
Abstinence, n (%)			
Baseline	0 (0)	0 (0)	0 (0)
Posttest	20 (20)	12 (24)	8 (16)
Short-term (7-week) follow-up	21 (24)	11 (24)	10 (24)
Long-term (4-year) follow-up	43 (50)	30 (63)	13 (34)
Daily cigarette consumption, mean (SD)			
Baseline	18.93 (6.59)	19.69 (6.98)	18.11 (6.10)
Posttest	10.25 (7.82)	9.88 (8.45)	10.63 (7.17)
Short-term (7-week) follow-up	9.13 (6.86)	9.23 (6.98)	9.02 (6.81)
Long-term (4-year) follow-up	7.54 (9.85)	6.19 (10.11)	9.26 (9.36)
Nicotine dependence (FTND[d] score), mean (SD)			
Baseline	4.85 (2.12)	4.91 (2.33)	4.78 (1.89)
Posttest	3.04 (2.62)	3.00 (2.87)	3.08 (2.35)
Short-term (7-week) follow-up	2.45 (2.36)	2.52 (2.49)	2.37 (2.24)
Long-term (4-year) follow-up	1.78 (2.66)	1.29 (2.45)	2.41 (2.80)

[a]EG: experimental group.

[b]ApBM: approach bias modification.

[c]CG: control group.

[d]FTND: Fagerström Test for Nicotine Dependence [43]; scale: 0-10.

Quantitative Training Evaluation

Table 3 summarizes participants' quantitative responses to the training evaluation questionnaire at posttest. Overall, participants were satisfied with the training. The vast majority of participants reported that the training was clearly structured (97/99, 98%) and easy to perform (93/99, 94%), and most (83/99, 84%) indicated that they would recommend it for further use.

XSL•FO
RenderX

Approximately three-quarters of participants perceived the training as helpful in reducing cigarette smoking, and 68% (67/99) reported no difficulties in motivating themselves to complete the sessions. Lower levels of agreement were observed for items referring to broader effects: only 37% (37/99) of participants endorsed the view that the training may contribute to abstinence, and 47% (47/99) believed it can be applied to everyday situations.

Although the overall pattern was similar across conditions, participants in the EG evaluated the training more positively than those in the CG, as indicated in a significantly higher training evaluation sum score (t_{97}=3.08; *P*=.003). Specifically, participants in the EG indicated to have noticed more overall positive effects of the training (EG: 37/50, 74% vs CG: 24/49, 49%; χ^2_1=6.55; *P*=.01). In addition, a greater proportion of participants in the EG believed that the training was beneficial in reducing smoking (42/50, 84% vs 30/49, 61%; χ^2_1=6.47; *P*=.01) and could be transferred to everyday situations (30/50, 60% vs 17/49, 35%; χ^2_1=6.34; *P*=.01).

The training perceptions and between-group differences suggested by these quantitative findings are examined in greater depth in the qualitative analyses below.

Table 3. Training evaluations at posttest.[a]

Item	Overall	EG[b] (ApBM[c])	CG[d] (sham)	*P* value
The training setup was clear, n (%)	97 (98)	50 (100)	47 (96)	.15
The training was easy to perform, n (%)	93 (94)	47 (94)	46 (94)	.98
I have noticed positive effects from the training, n (%)	61 (62)	37 (74)	24 (49)	.01
I have made progress in my reaction times during the training, n (%)	65 (66)	36 (72)	29 (59)	.18
The training is beneficial in quitting smoking, n (%)	37 (37)	22 (44)	15 (31)	.17
The training is beneficial in reducing smoking, n (%)	72 (73)	42 (84)	30 (61)	.01
Training can be applied to everyday situations, n (%)	47 (47)	30 (60)	17 (35)	.01
It was difficult to motivate myself to complete the training, n (%)	32 (32)	14 (28)	18 (37)	.35
The training should continue to be used, n (%)	83 (84)	44 (88)	39 (80)	.26
Sum Score (0-9)[e], mean (SD)	6.28 (2.03)	6.88 (1.93)	5.67 (1.96)	.003

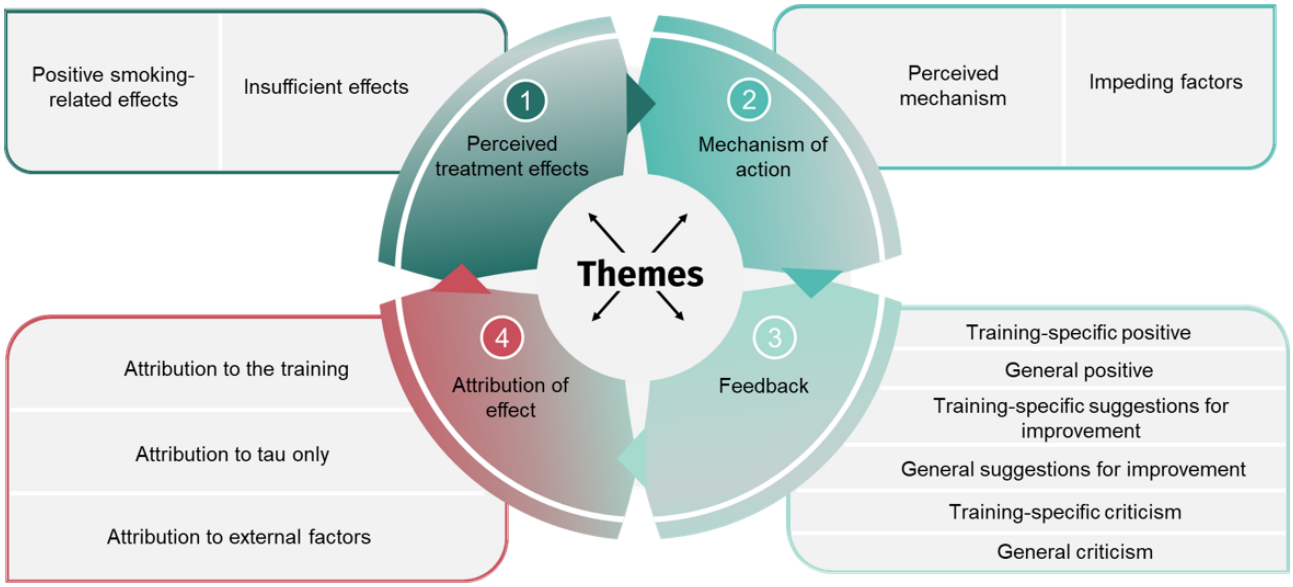
[a]Group differences regarding proportions were analyzed using chi-square tests; group differences in the sum score were analyzed using a 2-sample *t* tests. All *P* values are 2-tailed.

[b]EG: experimental group.

[c]ApBM: approach bias modification.

[d]CG: control group.

[e]This row indicates the sum score (0-9) for all items answered with "yes" (coded as 1), except for the item "It was difficult to motivate myself to complete the training," which was reversely coded.



Thematic Analysis of Participants' Feedback on the Training

Overview

Overall, the analysis yielded 4 overarching themes: *perceived treatment effects*, *mechanisms of action*, *feedback on the intervention*, and *attribution of effect*, each comprising several subthemes. Whereas the first 3 themes appeared at both time points, the fourth theme (attribution of effect) was only evident in the 4-year follow-up assessment. A comprehensive overview of all themes and subthemes is presented in Figure 1.

XSL•FO
RenderX

Figure 1. Overview of the thematic analysis.

Participants' Proximate Feedback

Overview

In total, 87 participants provided proximate feedback (posttest and/or 7-week follow-up). Of these, 45 were randomized to the EG, and 42 were in the CG. Example quotations are provided within the corresponding sections. In addition, each quote is accompanied by the participant ID, along with the intervention type (V=VR-based training; A=app-based training) and group assignment (1=EG; 0=CG). The analysis yielded the following overarching themes: *perceived treatment effects*, *mechanisms of action*, and *feedback on the intervention* (separate thematic analyses of the 4-year follow-up feedback yielded comparable results, with no meaningful differences in the thematic structure or content).

Theme 1: Perceived Treatment Effects

Overview

Participants described a broad range of perceived effects related to their participation, spanning positive smoking-related changes and reports of limited or absent effects.

Subtheme 1: Beneficial Smoking-Related Effects

Participants reported a variety of beneficial effects following the training. For instance, a notable number of participants described a reduced urge to smoke:

> *During the training, I did not feel any desire to smoke. I think that an intensive use of this training could indeed be beneficial and supportive.* [134V1; post]
>
> *This is great, I no longer have any desire to smoke.* [101V1; FU]

These subjective craving reductions were often accompanied by reports of a decreased daily cigarette consumption:

> *In general, I have noticed progress after training. I haven't completely cut down on smoking yet, but I have significantly reduced my consumption.* [89V1; post]
>
> *Everything is going well; it has helped me to reduce consumption by half so far.* [100V1; FU]

Moreover, some participants reported having ceased smoking following training:

> *I managed to quit smoking, certainly with the help of the VR training.* [7V1; post]

Others provided nonspecific accounts of beneficial training outcomes. These participants noted general improvements attributed to the training, for example:

> *So far, it has been helpful and enjoyable.* [100V1; post]

Subtheme 2: Insufficient Effects

Alongside the positive effects outlined above, not all participants consistently reported beneficial or sustained outcomes from the study or the training. For instance, some noted only temporary improvements:

> *After the second session, I experienced a temporarily reduction in my urge to smoke. Unfortunately, this effect did not persist in the following sessions. My urge to smoke and smoking behavior have not changed.* [50V1; FU]

Similarly, some participants noted that reductions observed during the training phase subsequently dissipated:

> *During the two weeks of training, smoking behavior changed significantly, but after the training program ended, the effect wore off, mainly due to stressors in the personal and professional environment.* [64A0; FU]

Moreover, a subset of participants reported experiencing no discernible effects:

> *Unfortunately, it had no effect whatsoever on my smoking habits.* [44V0; post]
>
> *I couldn't notice any change in myself.* [42V0; post]
>
> *Unfortunately, the training didn't do anything for me at all.* [129V0; post]

XSL•FO
RenderX

To summarize, participants experienced a diverse array of smoking-related outcomes in relation to their study participation. While some participants reported a reduction in cravings, smoking, or complete abstinence, others exhibited only transient changes or no change at all.

Theme 2: Mechanisms of Action

Overview

This overarching theme comprises participants' reflections on 2 distinct yet interconnected aspects of the training. First, it encompasses participants' insights into how the training may have exerted its effects on smoking behavior. Second, it addresses participants' perceptions of factors that may have limited or impeded the intended impact of the training.

Subtheme 1: Perceived Mechanisms of Action

Participants expressed a number of assumptions regarding the underlying mechanisms of action through which the training might have worked. Notably, some participants described processes that were closely aligned with the theoretical principles of ApBM. In particular, 1 participant attributed the training's effects to the contingency between smoking-related stimuli and the push movement, stating:

> *In my opinion, it helps you think about other things than SMOKING. It has already helped me, and in stressful situations I was able to simply push smoking away.* [53A1; post]

Consistently, several participants reported that the training helped them to engage in more reflective smoking behavior or that the training disrupted habitual patterns:

> *Through training and the reason for training, I perceive the topic of smoking and when to smoke differently.* [36V0; post]
>
> *I thought that it worked well to break routines, especially when used specifically during the urge to smoke a cigarette.* [25A1; post]

While the aforementioned participants alluded to mechanisms of action in close alignment with the theoretical underpinnings of ApBM, other participants referred to more general mechanisms of action. For instance, some described that the training provided a helpful distraction from smoking:

> *It's simply a good substitute for cigarettes at the beginning.* [53A0; FU]
>
> *The training is very helpful and shows me that I can become a non-smoker by 'distracting' myself from smoking objects or cravings.* [48V0; FU]

Moreover, for a subset of participants, simply dedicating time to the intervention was perceived as motivating. Notably, all of these participants took part in the VR-based training, where training sessions took place in a laboratory setting as opposed to the app-based training, which was conducted remotely.

> *Just going there had a positive effect on me.* [15V0; FU]
>
> *Overall, it was quite time-consuming to attend the 15-minute training sessions (travel time), but I also think that the considerable effort involved helped to motivate me to quit smoking. So, what seemed unpleasant and almost time-consuming at first was certainly what made it easier for me to quit in my case.* [91V1; post]

Lastly, some participants did not explicitly articulate assumptions about specific mechanisms of action, but expressed general confidence in the intervention:

> *The VR training certainly serves a purpose, even if I don't recognize it.* [53V0; post]
>
> *Since I am not qualified to assess it neurologically, I trust that it [the training] helps with smoking cessation and remain curious.* [3A0; post]

Subtheme 2: Impeding Factors

Concurrently, participants identified several factors that impeded the training's impact. These limiting factors refer to potential barriers to the implementation of ApBM within novel technological environments such as VR and app-based formats. Some factors perceived as limiting the training's effectiveness were directly related to the training design itself. For instance, a number of participants indicated that the absence of a contingency between smoking-related stimuli and push movements limited the training's impact on behavior. Notably, these participants were predominantly enrolled in the sham groups:

> *If I could just push all smoking-related objects away, the effect would perhaps be better?* [1A0; post]
>
> *I didn't understand why I had to pull almost all the smoking-related objects toward me during the app training. In my opinion, it would have been better if I had pushed all the objects related to smoking away from me.* [133A0; FU]

Similar concerns were reflected in notes from participants in the EG, who perceived the approach bias assessment at posttest to measure training-specific bias change as a barrier that limited the intervention's effectiveness:

> *After the last training session, the bias assessment from the pretest had to be repeated in order to evaluate reaction times. This involved pulling smoke objects towards me again. That ruined a lot of things. I found the effect very strong. In hindsight, I should have refused, following my first impulse.* [79V1; post]

In addition, many participants reported not fully understanding the purpose of the training, with some explicitly attributing this confusion to the lack of stimulus-response contingencies:

> *Since there was no need to consistently move smoke objects away from oneself or towards oneself, the purpose of the app was unclear.* [3A0; post]
>
> *Many images are pulled in one moment and pushed away the next. You'd think that makes little sense.* [136A0; post]
>
> *I didn't understand the point of the exercises, because I don't see how that's supposed to help.* [138A0; FU]

Likewise, some participants noted that the indirect instruction to respond to a content-irrelevant feature diverted their attention

XSL•FO
RenderX

from the stimulus content, which was associated with a lack of contingency awareness and, presumably, with a diminished training effect:

> *During the app training, I never saw the objects, only how the image was tilted.* [107A0; post]

> *I didn't care if they [the stimuli] were smoke objects... I only paid attention to red and blue [border color].* [86V0; post]

In addition to impeding factors that were directly related to the training design, some participants referred to barriers in relation to aspects of the training implementation. For instance, technical difficulties were frequently reported, with some participants also describing these issues as diminishing their motivation:

> *Unfortunately, my mobile phone freezes and the images cannot be swiped away quickly enough. This reduces my motivation.* [27A1; post]

Such technical difficulties may provide an explanation for the insufficient or inconsistent training effects experienced by some participants. Finally, a number of participants identified everyday life factors as barriers to training adherence. For instance, external stressors were reported to have an impact on the ability of participants to complete training sessions:

> *I work in a three-shift system. If I haven't done it [the training] in the morning before the afternoon shift, I tend to forget it.* [84V1; post]

> *Unfortunately, due to time constraints, I only completed the app training once. However, I noticed that my craving to smoke was suddenly reduced afterwards.* [135A0; post]

> *In my opinion, the planning/coordination was difficult for working people to implement due to the specified appointed times, etc.* [42V0; FU]

Closely related to this barrier, 1 participant observed that the training exhibited only limited transferability to everyday life:

> *In everyday life, "habits" still need to be broken.* [48V0; post]

In conclusion, participants indicated divergent assumptions regarding the mechanisms of action, spanning from more specific and theoretically grounded processes, such as actively pushing smoking-related cues away, to more general mechanisms, such as motivational effects and a general confidence in training effects. Notably, these specific assumptions were also reflected in perceived barriers, with participants in the sham condition reporting a desire to avoid smoking-related cues and some participants in the ApBM condition deploring reduced training effectiveness due to the posttest approach bias assessment, which removed the stimulus-response contingency. Moreover, technical problems and daily hassles were associated with limited training implementation and adherence to the training regimen. As accounts of factors impeding the training's efficacy were given frequently, participants' feedback on the intervention may provide insight into how to address such barriers in future applications of ApBM.

Theme 3: Feedback on the Intervention

Overview

This theme encompasses participants' feedback on both the study and the training. Subthemes comprise positive feedback, suggestions for improvement, and criticism, which were all divided into both training-specific reflections as well as general study experiences.

Subtheme 1: Training-Specific Positive Feedback

Participants reported training-specific positive feedback, including overall satisfaction with the training, enjoyment, favorable impressions of the stimuli, ease of use, and a desire to continue engaging with the training. Moreover, certain participants emphasized the efficacy of the training in conjunction with the TAU prior to randomization:

> *Certainly not sufficient on its own for immediate smoking cessation, but definitely useful as a supplement to the [self-help] book, for example.* [20A0; post]

In addition, some participants underscored the training's potential applicability to other domains:

> *The training is very helpful and shows me that I can become a non-smoker by 'distracting' myself from smoking objects or cravings. Yes, this training can also be applied to many other areas of life. Thank you very much for this.* [48V0; FU]

Subtheme 2: General Positive Feedback

Many participants additionally expressed satisfaction with the study, reporting gratitude and enjoyment. Furthermore, participants advocated for the continuation of the research:

> *Everything was perfect and very well organized. Thank you very much.* [101V1; post]

> *I really enjoyed it and it helped me reduce my cravings. Thank you very much!* [26V0; post]

Subtheme 3: Training-Specific Suggestions for Improvement

Beyond the positive feedback, participants provided ideas on several training-specific improvements. These included suggestions for technical enhancements, the use of direct instructions (ie, content-relevant feature training), and incorporating a larger variation in training scenarios and/or stimulus material:

> *Since the objects in the VR training are color-coded (red/blue), I find myself automatically looking only at the colors and not at the objects themselves. I think that if it were possible in terms of programming, I would stop assigning colors to the objects after the third training session so that you only have to focus on the object without the color dictating where the object has to go. I think that would be better for the effect of reacting and acting.* [34V1; post]

> *I would like to see more training sessions, possibly in different environments.* [4V1; FU]

XSL•FO
RenderX

Additionally, participants recommended decreasing the number of trials per session while increasing the number of training sessions:

> *The duration is a bit too long in some cases, but I would have liked to use it more often.* [95A0; FU]
>
> *Personally, I think the training with 200 images takes too long. [...]. I'd prefer the option of completing the training 2 times with 100 images instead.* [112A1; post]
>
> *I think 6 VR sessions are not enough.* [76V1; FU]

Consistently, participants also expressed a preference for an extended training interval:

> *The number of VR training sessions would have to take place at very regular intervals and over a longer period of time, then I would imagine it having an effect.* [65V0; FU]

Furthermore, participants consistently articulated the need for a better comprehension of the theoretical underpinnings of the training:

> *I would like to continue the app training and learn more about the background and scientific findings, ie, the specific goals and behavioral changes achieved through the training.* [145A1; FU]

Additionally, participants offered a plethora of recommendations regarding specific training application and/or implementation. For instance, some participants in the VR study assumed the training to be more effective when performed at home:

> *It would certainly be more effective if it took place more often, or if you could do it from the comfort of your own home.* [66V1; post]
>
> *VR training should be carried out daily, possibly programmed into an app.* [26V0; FU]

Other participants recommended integrating the training with additional interventions, such as:

> *I would also have liked to see more variety, eg, a stay in disgusting, dirty smoking rooms compared to a fresh flower meadow; [...]. Adding smells would certainly be successful.* [13V1; post]

Finally, participants put forth the notion of applying the training in specific situations and contexts. For instance, they noted its high use as a substitute for a cigarette:

> *It would be great if I could use the training more often to replace a cigarette; else, I tried to manage it without the app.* [95A0; post]

Subtheme 4: General Suggestions for Improvement

Participants additionally offered general suggestions to enhance the training's impact on behavior. For instance, they expressed a desire for greater interaction and exchange with both fellow training participants and therapists:

> *Possibly [introduce] more training sessions and also discussions about [smoking] cessation* [46V1; post]
>
> *I would have liked personal conversations.* [155A; FU]
>
> *It would be beneficial to introduce group sessions to the VR training so that participants can exchange ideas with others. This helps to motivate.* [49V1; FU]

Subtheme 5: Training-Specific Criticism

Some participants also reported training-specific criticisms, highlighting its monotony and questioning its effectiveness as a stand-alone intervention:

> *I have the impression that the exercises should be modified with each additional training session, as in some cases they simply become monotonous.* [27V1; post]
>
> *After an initial learning phase, boredom sets in. A little more additional information would be desirable. Perhaps something encouraging, such as a counter for different things that improve over the course of quitting smoking, eg, how much CO2/tar/nicotine you have not inhaled/absorbed. An anonymous chat with like-minded people would also be nice* [136A0; post]

Subtheme 6: General Criticism

In addition, some participants expressed general criticism:

> *I cannot imagine that a long-term smoker would be motivated to quit smoking through VR training. At least not me, so I stopped after the first session!* [33V1; post]

Taken together, participants offered both positive feedback, including enjoyment and ease of use, and recommendations for improving the training. These recommendations included a higher training dosage, the implementation of direct task instruction, and the adaptation of the training for different contexts and situations. Some participants also voiced critiques of the study and training, particularly with respect to the effectiveness of the training as a stand-alone intervention.

Differences in perceived outcomes attributed to the training may reflect variations in how participants understood and experienced the training's underlying mechanisms, as well as how these were shaped by training-specific features and individual or contextual factors. In particular, the stimulus-response contingency appears to play a central role in perceived meaningfulness and training efficacy, as several participants who experienced beneficial outcomes explicitly attributed these improvements to the stimulus-response contingency. Conversely, participants in the sham conditions linked insufficient effects to the absence of such a contingency. Furthermore, the mode of delivery also emerged as relevant: participants in the VR study described the training as motivating, enjoyable, and interesting, which aligns with the rationale for implementing ApBM in immersive environments. Likewise, participants in the app study appreciated the pictorial stimuli and expressed a wish to use the app more frequently in daily contexts. Building on this, participants' descriptions of impeding factors and their suggestions for improvement provide further insights into why some individuals did not experience beneficial outcomes. Several participants reported technical problems during training, indicating that the implementation of technically innovative ApBM still needs to be refined. Others advocated for direct task instructions as well as a higher training variety

XSL•FO
RenderX

and availability. The latter may be linked to reports of external stressors that diminished adherence to the training, thereby limiting its potential effectiveness. Finally, participants also recommended combining ApBM with other established interventions, assuming that they may benefit from multimodal approaches.

To complement the qualitative analysis, we quantified how often each theme was mentioned and explored whether frequencies differed between the EG and CG. These additional analyses are displayed in Table 4. Please note that due to the open response format, absence of mention does not indicate absence of experience. Inferential statistics should therefore be interpreted with caution and are used here only for exploratory purposes.

Table 4. Frequencies of reported themes and subthemes by group.[a]

[a]The number of mentions in relation to the virtual reality trial is shown in brackets. Differences between groups were analyzed using chi-square tests.

[b]EG: experimental group.

[c]ApBM: approach bias modification.

[d]CG: control group.

[e]N/A: not applicable.

[f]In cases where the expected cell frequencies fell below 5, no statistical tests were conducted.

As shown in Table 4, participants in the CG reported impeding factors significantly more often (χ^2_1=13.69; *P*<.001). A closer inspection of these comments indicated that most of these hindering factors centered on complaints about the lack of stimulus-response contingency and the perceived lack of meaningfulness of the training. Conversely, participants in the EG provided more suggestions for improving the training (χ^2_1=9.77; *P*=.002). Several interpretations may account for this pattern. For example, given that no group differences emerged in positive, training-specific feedback, the higher frequency of improvement suggestions in the ApBM groups may reflect a stronger cognitive engagement with the training procedures. Alternatively, it is possible that the more coherent and meaningful training experience in the EG facilitated participants' ability to generate concrete suggestions for refinement, whereas the relative opacity of the sham condition may have limited such reflections. However, these interpretations remain speculative, as the study was not designed to systematically probe the underlying reasons for this difference. No other group differences reached statistical significance.

Participants' Long-Term Feedback

Overview

In total, 63 participants provided open-ended comments at the final 4-year follow-up, of whom 33 were in the EG, and 30 were in the CG. The thematic structure largely mirrored the patterns observed for proximate feedback, encompassing *perceived treatment effects*, *mechanisms of action*, and *feedback on the intervention*. Each of these themes again comprised several subthemes comparable to those identified in the proximate feedback. Due to this substantial resemblance, detailed descriptions of the 3 recurring themes at the 4-year follow-up will not be presented here but are provided in the Multimedia Appendix 1. Notably, an additional overarching theme, *attribution of effects*, emerged uniquely at the 4-year follow-up, reflecting participants' retrospective reflections on what they believed to have contributed to long-term changes. A comprehensive overview of all themes, subthemes, and their interrelations is presented in Figure 1.

Theme 4: Attribution of Effect

Overview

Responses at the 4-year follow-up revealed an additional theme related to participants' attribution of treatment effects. Whereas earlier comments focused primarily on describing perceived changes, participants at the long-term follow-up engaged in a more elaborated meaning-making process by attributing their smoking-related outcomes—whether positive, limited, or absent—to specific causal sources. These attributions provide insight into how individuals retrospectively interpreted and contextualized their behavior change over an extended period.

Subtheme 1: Attribution to the Intervention

Several participants explicitly credited the training for their improvements, highlighting mechanisms or elements of the intervention they perceived as effective in supporting abstinence or reducing cigarette consumption:

> *Keep going. I am grateful for the app because it helped me to quit [smoking].* [53A1; online assessment]

> *Taking part in the study was very important for me, even though it took a long time until I finally managed to break away from nicotine. Taking part in the study also made me realize how harmful nicotine use is, which ultimately played a key role in my decision to quit smoking altogether. I would like to express my sincere thanks once again.* [133V1; online assessment]

While some participants referred broadly to the intervention as a whole, others explicitly attributed their outcomes to the combination of the training and TAU:

> *Everything was great; the book helped the most; the app was more of a supportive tool.* [133A0; telephone assessment]

Subtheme 2: Attribution to TAU Only

Some participants in the sham condition attributed their outcomes primarily to the support and guidance provided through TAU, namely, the bibliotherapy that was prescribed to all participants prior to randomization:

> *In retrospect, the book was very helpful; [I] only read it after the intervention had ended and then stopped.* [57A0; telephone assessment]

> *Because of the intervention, I succeeded in becoming a non-smoker. The book "Endlich Nichtraucher" [The Easy Way to Quit Smoking] contributed to this. The book was additionally handed out at the beginning of the study.* [68V0; online assessment]

Subtheme 3: Attribution to External Factors

A subset of participants attributed their smoking-related changes to factors outside the study context. These external attributions encompassed a range of factors that participants perceived as more decisive than the training itself. Medical issues were frequently cited as strong motivators for cessation:

> *[I had] a lung cancer surgery. Since then, I haven't touched a cigarette.* [115A0; telephone assessment]

> *It was a very good experience, which unfortunately did not work for me, but I still managed it without any aids, because a serious illness that was related to smoking was the reason; and it's just a matter of mindset and absolute willpower.* [100V1; online assessment]

In addition, some participants emphasized significant life circumstances such as the birth of a grandchild or the wishes of significant others as meaningful catalysts for change:

> *It didn't work because of that [the study], but only later due to an illness and the birth of my grandchild.* [63V0; telephone assessment]

Some participants reported relying on other interventions, including additional cessation aids or self-initiated strategies outside the study protocol:

> *I did not smoke during the study, but unfortunately, I started again two weeks later. I made another attempt in mid-2023 with Fumexan smoking cessation therapy (injections into the ear) and it has worked quite well so far.* [8V1; online assessment]

Finally, 1 participant pointed to reasons unrelated to the training, suggesting that personal decisions or timing were more influential in determining their outcome than the intervention:

> *[I have] quit independently of the study 1.5 years ago.* [93V0; telephone assessment]

In summary, participants expressed a wide range of attributions regarding their long-term smoking-related outcomes. While some linked beneficial effects to the training and/or TAU, others pointed to additional or different factors outside the study context. Such attribution patterns underscore the complexity of smoking cessation processes and the varied meaning-making practices through which participants explained change long after the intervention had ended.

To quantify how often each theme was mentioned across groups, counts of reported themes and subthemes for the 4-year follow-up are also presented in Table 4. Similar to the proximate

XSL•FO
RenderX

feedback, participants in the EG appeared to report more beneficial smoking-related outcomes; however, this difference did not reach statistical significance (χ^2=3.52; *P*=.06). No group differences emerged for the remaining themes, including effect attribution (P_s>.16).

Discussion

Principal Findings

Overview

This study sought to elucidate participants' subjective experiences with 2 newly developed ApBM programs for smoking cessation, delivered either via VR or a smartphone app. In addition, the study examined factors perceived to contribute to beneficial or insufficient training effects, as well as retrospective reflections on the training that were obtained 4 years after study inclusion, alongside proximate feedback collected up to 7 weeks after the intervention. The thematic analysis identified four overarching themes, with the fourth emerging only in the long-term follow-up: (1) *perceived treatment effects*, ranging from positive smoking-related changes to a perceived lack of effects; (2) *mechanisms of action*, encompassing reflections on presumed working mechanisms as well as factors perceived as impeding effectiveness; (3) *feedback* on the training and the broader study experience; and (4) *attribution of effect*, referring to participants' attempts to attribute behavioral change to training-specific or external influences.

Core Themes in Participants' Experiences: Links to Prior Research and Novel Insights

With regard to our first research question, the overarching themes identified in this study are broadly comparable to those reported in previous qualitative studies investigating participants' subjective perceptions of app-based psychotherapeutic interventions. For instance, Tudor-Sfetea et al [48] examined participants' perceptions of a smoking cessation app based on cognitive behavioral therapy principles and identified themes such as "*application effects*," comparable to the present theme of "*perceived treatment effects*," as well as "*application content*" related to style, quality, and engagement, which partially overlaps with the current theme of "*mechanisms of action*." At the same time, some themes appear to be specific to the present investigation, particularly "*attribution of effects*." This difference may be attributable to the short-term assessment focus (1 week) in Tudor-Sfetea et al [48], compared to the additional long-term follow-up in this study.

More specifically, in the context of CBM, Kuckertz et al [29] investigated participants' perceptions of 2 computer-based ABM interventions for anxiety and identified themes including "*perceived symptom change*," "*mechanisms of action*," "*acceptability and feedback*," and "*barriers and facilitators to engagement*." Similarly, Prior et al [34] asked adults with lived experience of hazardous alcohol use and social anxiety to evaluate a combined web-based ApBM and CBM-I intervention and revealed themes related to "anticipated clinical value," "motivation and engagement," and "perceived usefulness." Thus, it appears that similar aspects are reported across different CBM training programs, which are not solely specific to ApBM or the training delivery method used. Consistent with other studies, our findings indicate that participants engage in complex reflection on the intervention that is difficult to capture through quantitative assessment methods alone. In the context of psychotherapy research, such treatment expectancies and their perceived potential to contribute meaningfully to improvement constitute a well-established common factor to treatment efficacy [49] and have been proven to predict treatment outcome [50]. In this trial, this dynamic was most clearly reflected in Theme 1 (*perceived treatment effects*) and Theme 2 (*mechanisms of action*). Participants reported a range of perceived outcomes following the training, including reductions in craving, decreases in cigarette consumption, and complete abstinence. Importantly, these perceived outcomes were closely connected with reflections on how the training was thought to work. Anticipated mechanisms of action included the existence of a stimulus-response contingency (ie, smoke-push trials), the disruption of automated action tendencies, and the strengthening of reflective processes related to smoking behavior. While these reflections are broadly consistent with both dual-process accounts of addiction [51] and the theoretical rationale underlying ApBM [11,13], they should be interpreted as subjective explanations rather than evidence of actual mechanisms, as findings in this regard remain mixed. For example, training-specific bias change or mediation effects have not been consistently observed (for a review and a meta-analysis, see Boffo et al [24]), suggesting that additional processes, potentially not accessible to subjective reflection, may also contribute to ApBM effects and remain to be further elucidated in CBM research.

By contrast, a subset of participants in the sham training groups reported difficulties in making sense of the task, especially due to the absence of a clear stimulus-response contingency. This lack of perceived meaningfulness was often accompanied by frustration and, in some cases, explicitly linked to insufficient training effects. Such accounts may also help explain the group differences observed in quantitative training evaluation ratings.

Germane to this, several participants expressed a desire for a clearer and more coherent theoretical integration of the training rationale (see Theme 3: *feedback*). In this study, the brief smoking cessation intervention (TAU) explained the impact of reflective and impulsive processes on smoking behavior, thereby introducing the rationale underlying the training as a means to target the latter. In addition, a cover story was used to convey the basic logic of the training task. Thus, participants were provided with basic explanations of the training's purpose, which is consistent with recommendations emerging from prior qualitative research (eg, [34]). Nevertheless, these findings suggest that this level of explanation may not be sufficient and that a more sustained integration of the training rationale is warranted. In this instance, Kuckertz et al [29] compared a traditional, minimally explained ABM intervention with an "enriched" version that included more detailed explanations of the training's theoretical background. Contrary to expectations, however, qualitative analyses revealed that participants in both

XSL•FO
RenderX

conditions perceived the explanations as insufficient. Rather than receiving a single explanation at the outset, participants expressed a preference for repeated reminders of the training rationale and opportunities to discuss the training with clinicians during the program. This resembles established psychotherapeutic practices, in which treatment rationales are revisited and linked to patients' everyday experiences and goals, and suggests a potential avenue for enhancing the perceived credibility of CBM interventions.

Perceptions of Digital Delivery Formats

With regard to the second research question, another important issue emerging from this study concerns participants' perceptions of the novel delivery formats used for ApBM, namely VR and smartphone apps. While a few participants described the training as repetitive or suggested that it could be improved through greater stimulus variety, which is consistent with earlier reports on CBM task perceptions [27], others reported high levels of motivation and engagement. At the same time, several participants noted technical difficulties, which in some cases undermined motivation and disrupted training adherence. These findings highlight that the implementation of novel technologies may entail trade-offs, particularly when technological infrastructures are still under development. Importantly, prior CBM research suggests that more technologically advanced training approaches do not necessarily translate into better training perceptions. For instance, studies incorporating gamification elements [15], personalized stimuli [31], or adaptive designs [34] have reported mixed results with regard to user engagement and acceptability. Accordingly, efforts to enrich ApBM interventions should be undertaken cautiously, ensuring technical feasibility, and should not come at the expense of other critical factors such as participant support and the integration of the training into a broader theoretical or therapeutic framework (see the Core Themes in Participants' Experiences: Links to Prior Research and Novel Insights section above).

Correspondence Between Short- and Long-Term Feedback

Regarding the third research question, comparisons between proximate and long-term feedback indicated that participants' perceptions of the training were largely stable over time, as the 3 overarching themes identified at short-term follow-up were still evident 4 years later. Notably, a fourth theme emerged at the long-term follow-up concerning the *attribution* of beneficial outcomes, most commonly abstinence. Over time, participants appeared to develop a need to make sense of their behavior change, attributing it either to the training itself or to broader life circumstances. These attributions were almost evenly distributed, with approximately half of the participants explicitly emphasizing the training and/or the overall study experience as the primary reason for abstinence, while the other half referred to health- or family-related factors. Given that attribution was not explicitly probed, it is noteworthy that some participants spontaneously cited the training as causal even after such a prolonged period. As attributing change to internal or treatment-related rather than external factors is considered important for sustaining therapeutic gains [52,53], future research should systematically examine attribution processes in CBM and explore how training-related attributions can be fostered, for example, by providing and repeatedly reinforcing a theoretically and empirically grounded training rationale aligned with participants' goals (see the Core Themes in Participants' Experiences: Links to Prior Research and Novel Insights section above).

Principal Contributions

This study contributes to the literature in several ways. First, it expands prior qualitative work on CBM by examining participants' training experiences over an extended follow-up, spanning several years. Such a long time frame is rare in both CBM and psychotherapy research. Moreover, a relatively high response rate was achieved overall (104/178 participants provided feedback at least 1 assessment time point). In addition to the dual-contact approach used at follow-up (ie, telephone and online contact; see Methods), features of the original RCTs may have supported sustained engagement, including the predominantly in-person study procedures, which likely facilitated personal contact, rapport building, and peer interaction. The somewhat higher response rate in the VR-based ApBM condition further suggests that the immersive, on-site training format may have enhanced participant engagement. Moreover, the trials were explicitly framed as investigations of novel digital smoking cessation interventions, with an emphasis on both short- and long-term experiences communicated during the active study phase, which may have increased commitment to participate in the long-term follow-ups.

Second, although the overarching themes broadly align with prior qualitative work on CBM and related digital interventions, these findings provide additional insight into how different training conditions are experienced. Notably, participants in the sham condition frequently reported difficulties understanding the training rationale and, in some cases, explicitly criticized the absence of a stimulus-response contingency. This finding is particularly relevant for CBM research, as it suggests that blinding may be challenging when control conditions closely resemble the active training but lack its core mechanism. Such control conditions may not function as neutral comparators but could, in some cases, evoke frustration or reduced credibility, potentially influencing outcomes. At the same time, sham training was not consistently evaluated more negatively in this sample, and prior meta-analytic evidence indicates that sham interventions may still produce meaningful effects, particularly at higher training dosages [24]. Together, these findings highlight the ongoing challenge of identifying appropriate control conditions in CBM research and suggest that alternative comparator designs may warrant further investigation.

Third, these findings suggest that participants' perceptions of ApBM remain relatively stable over time, while also giving rise to retrospective processes of sense-making. In particular, participants reflected on whether sustained behavior change could be attributed to the intervention or to external factors. Due to the relatively small number of spontaneous attribution-related statements, it was not possible to examine predictors of attribution or their relationship with long-term

XSL•FO
RenderX

outcomes. This represents an important avenue for future research.

Limitations and Future Directions

Alongside notable strengths, several limitations warrant consideration, which highlight relevant directions for future CBM research. First, the relatively high overall response rate may reflect both sustained motivation for smoking cessation and a willingness to contribute to research in this area. Hence, findings may not fully generalize to less intrinsically motivated or less engaged populations. While ApBM is often assumed to be more effective in motivated individuals or clinical samples, systematic evidence on the role of motivation in CBM outcomes is still limited. Future work should, therefore, examine whether motivation moderates ApBM effects or whether motivational processes can themselves be targeted by CBM principles, an issue that remains largely unresolved in the current literature.

At the same time, perspectives from a notable subset of the sample remained unavailable, especially at the 4-year follow-up. Exploratory analyses comparing participants who provided feedback at any time point with those who did not on key demographic, intervention-related, and smoking-related variables indicated largely comparable groups. However, selective attrition and survivorship bias cannot be fully excluded. For example, it remains possible that participants who provided long-term feedback were those for whom the intervention was more salient (ie, who were particularly satisfied or dissatisfied), which may have influenced both the qualitative themes and the interpretation of descriptive outcome data. Relating to this, although participants were encouraged to provide both positive and negative feedback, and the thematic analysis identified a range of critical next to favorable perspectives, responses may still have been influenced by demand effects. Hence, incorporating multimodal assessments beyond self-report, such as behavioral indicators or momentary assessments, may be a fruitful direction for future research to reduce possible bias and enhance the validity of findings.

Third, the thematic analysis was based on unprompted, open-ended responses. As participants decided independently which aspects of their experience to report, the absence of a particular theme cannot be equated with the absence of the corresponding experience. This limitation may be particularly relevant for the theme of *attribution of effects*, which emerged only at the 4-year follow-up. Moreover, the open-ended question used to elicit feedback was phrased in broad terms. While some participants provided in-depth reflections on the training and its potential mechanisms, others offered more general evaluations, resulting in considerable variability in the specificity of responses. Future research could therefore benefit from targeted qualitative or mixed methods approaches—for instance, semistructured interviews—which would allow for a more systematic examination of attribution processes over time.

Implications for ApBM Task Design and Implementation

These findings offer important implications for the design and implementation of future CBM interventions. These relate primarily to (1) the communication of the training rationale and management of expectancy effects, (2) the optimal dosage and contextual embedding of the training, and (3) specific design features of the training tasks.

First, participants' requests for a stronger theoretical integration of the training, combined with greater therapeutic support, highlight the importance of how the training rationale is communicated. While many CBM trials deliberately minimize expectancy effects to enhance internal validity (ie, by providing limited information about the training's rationale or theoretical background), implementation-oriented studies aiming to maximize clinical benefit may need to adopt a different strategy [54]. In clinical and medical settings, it is well established that providing patients with clear information about an intervention, along with conveying confidence and therapeutic rationale, can meaningfully influence outcomes [55]. Accordingly, greater emphasis on external validity in CBM research, including ApBM, may be warranted, particularly when interventions are delivered to clinical or affected samples. Such an approach may not only enhance training efficacy but may also be in better accord with participants' expectations and preferences. Future work may, therefore, incorporate more transparent and evidence-informed rationales, for example, by referencing prior findings on ApBM effectiveness, to enhance engagement, perceived training relevance, and training-related effect attributions.

Second, participants frequently suggested increasing training dosage and embedding the intervention more strongly within supportive contexts, such as peer exchange. These suggestions are in line with both dual process accounts of addiction [51], which stress the importance of targeting both reflective and impulsive processes to contribute to sustained behavioral change, as well as empirical findings that show that multisession CBM as an add-on to regular treatment tends to be more effective than single-session or stand-alone trainings [24,25]. At the same time, the number and spacing of training sessions remain to be determined. In the context of ApBM for AUD, one study suggests that 6 training sessions may be optimal in terms of learning effects [25], which informed the design of the present interventions, particularly the VR-based training. However, further research is needed to establish optimal training dosage for ApBM in the context of smoking cessation. Furthermore, participant suggestions regarding context-sensitive training use (eg, during craving or before or after quitting attempts) align with ongoing developments in the field [22,56] and further highlight the potential value of involving participants in the iterative development of CBM interventions (see Prior et al [34], for an encouraging example of a participatory codevelopment approach for an ApBM + CBM-I online intervention). Taken together, task design decisions should integrate evidence-based mechanisms of ApBM with participants' experiential insights regarding how the intervention is perceived to work, as optimizing outcomes may depend on aligning these complementary perspectives.

Third, participants' feedback also pointed to specific design features of CBM tasks. In particular, some participants reported that the indirect task instruction (ie, react to a content-irrelevant feature) prevented them from paying attention to the stimulus content. As a result, they suggested that direct task instructions

XSL•FO
RenderX

(ie, approach-avoid movements explicitly based on stimulus content) might enhance training effectiveness. Traditionally, CBM paradigms rely on indirect instructions, requiring participants to ignore stimulus content and respond instead to content-irrelevant features. Empirical evidence directly comparing instruction types is limited. Yet, one study contrasted content-relevant (emotional) vs content-irrelevant (color-based) instructions and showed that emotional stimulus features were still processed when being task-irrelevant [57], underscoring the main assumptions of CBM [50,58] and suggesting that indirect instructions are not inherently inferior despite participants' reservations. Importantly, such findings also highlight that participant accounts can inform the refinement of intervention design, but that proposed adaptations require systematic empirical testing. At the same time, evidence suggests that training effects under indirect instructions may be enhanced by increasing participants' awareness of the stimulus content [57]. Such findings show that participant-informed design adaptations, such as increasing the salience of contingencies without abandoning indirect paradigms, may represent promising avenues for future task adjustments but require systematic testing.

Conclusions

To conclude, this trial demonstrates that participants' subjective experiences constitute a central dimension of how ApBM for smoking is perceived and engaged with. By assessing both proximate (up to 7-week follow-up) and long-term (4-year follow-up) perspectives, the findings highlight that behavior change is embedded in an ongoing process of meaning-making that extends beyond the duration of the training. Future research should continue to place emphasis on participants' perceptions and incorporate them into the development of ApBM protocols by adopting participatory and patient-centered approaches. Such efforts may help to enhance both the effectiveness and acceptability of the intervention by better aligning training procedures with participants' needs and experiences.

Acknowledgments

We thank Luka Koep, Sabine Stähler, Nik Hulsmans, Lukas Flöter, Verena Born, Carolin Kraus, Daphne Heidecke, and Nicole Nagy, who assisted with data collection. We would also like to express our sincere gratitude to all smoking individuals who have set themselves the goal of quitting smoking and participated in this extensive study. Machine tools were used for refinement and to improve the clarity of language.

Funding

This study receives funding from the German Ministry of Culture and Science of the Land of North Rhine-Westphalia (grant 005-1706-0006). The funding source was not involved in study design, the collection, analysis, and interpretation of data, the writing of the report, or the decision to submit the paper for publication.

Data Availability

The dataset used and analyzed during this study will be made available at Open Science Framework [59].

Abstract

Background: Rising global demand for mental health services strains traditional care models, a trend evident in New Zealand, where the Integrated Primary Mental Health and Addictions (IPMHA) model was introduced to improve access to care. While the IPMHA model shows promise, significant service-delivery challenges undermine its scalability. Digital mental health tools (DMHTs) present an opportunity for digital optimization, yet their effectiveness is often limited by low practitioner adoption, a persistent implementation barrier. To ensure these tools are impactful, a user- and context-centered DMHT design approach may help mitigate practitioner adoption barriers and create solutions that can be seamlessly integrated into clinical workflows.

Objective: Reporting on the Test stage of the 5-stage Design Thinking framework, this study aimed to evaluate the usability and acceptability of a DMHT software prototype intended to support health improvement practitioners working within New Zealand's IPMHA model.

Methods: Five health improvement practitioners from a single primary health organization participated in semistructured usability interviews. Data were collected using a think-aloud protocol during mock clinical sessions and analyzed using affinity diagramming to identify key software feature requirements necessary to promote usability, adoption, and workflow integration.

Results: Feedback was obtained for all software minimum viable product features. While practitioners found the clinical support features valuable, 2 system-level requirements were identified as prerequisites for adoption. The first was administrative optimization: the DMHT must reduce workload by automating tasks, such as clinical note entry, data reporting, and psychometric scoring. The second was seamless integration with existing clinic patient management software to eliminate double-handling of data and resolve IT-related workflow frustrations.

Conclusions: For a DMHT to be successfully adopted by IPMHA practitioners, it must primarily function to solve existing administrative and workflow inefficiencies. Clinical support features, such as the provision of therapeutic tools and exercises, though helpful, are secondary to the tool's ability to be a practical, efficient, and fully integrated component of daily practice. These findings underscore the value of user- and context-centered design in uncovering the pragmatic, systems-level needs of end users in a complex primary care service-delivery environment.

digital mental health; usability testing; technology adoption; primary health care; integrated care scalability; integrated primary mental health and addictions model; health care workflow optimization; human-centered design; more-than-human design; context-sensitive design; user-centered design

Introduction

Globally, the prevalence of mental illness is rising, with approximately 1 billion people living with some form of mental illness in 2019, most commonly depression or anxiety [1]. The COVID-19 pandemic had a significant and well-documented impact on global mental health, with initial estimates from the World Health Organization showing a 26% increase in anxiety disorders and a 28% increase in major depressive disorders in 2020 alone [2], placing additional strain on already overstretched mental health services. Despite growing demand, access to adequate care remains limited due to chronic underinvestment

XSL•FO
RenderX

in mental health services and ongoing workforce shortages [1]. For decades, international health bodies have highlighted the growing disparity between the demand for mental health support and the available resources, a crisis that has only worsened over time [3]. This treatment gap, reaching as high as 90% in some nations, underscores a persistent global failure to prioritize mental health, leaving public health systems overwhelmed and unable to provide necessary care for a substantial portion of the population [1].

This international trend is evident in New Zealand, where there has been a sharp increase in psychological distress across the population in recent years [4,5]. Demand for mental health services continues to grow, placing significant strain on an already underfunded and resource-limited public health system [6]. This issue is particularly acute among young people, women, Māori, and Pacific peoples, who are disproportionately affected and experience higher rates of psychological distress. Furthermore, socioeconomic status is a significant factor, with individuals in more deprived areas facing a greater likelihood of mental health challenges, compounded by unequal access to care [5].

To address this significant gap in service access, the New Zealand government introduced the Integrated Primary Mental Health and Addictions (IPMHA) model in 2017. This integrated care initiative, based on the primary care behavioral health approach [7], aims to provide accessible, publicly funded care for those with mild-to-moderate mental health and behavioral issues within primary care settings. Following a successful pilot, the IPMHA model was implemented nationwide and, as of mid-2024, was available to over 70% of the enrolled primary care population [8]. The service is delivered by clinicians known as health improvement practitioners (HIPs) who offer brief, 30-minute sessions using focused acceptance and commitment therapy (fACT) [9]. While designed to be delivered within a single session, the model allows for follow-up appointments as needed, with primary care physicians maintaining overall responsibility for patient care [9]. A step-by-step breakdown of a typical fACT session is available in Multimedia Appendix 1. Evaluations have shown that the IPMHA model has improved access to mental health support, particularly for underserved groups, by reducing wait times and minimizing financial barriers [9].

Despite these successes, the IPMHA model faces significant implementation challenges. Workforce shortages and inconsistent application across different regions can lead to unpredictable care quality and availability, and practitioners often struggle to maintain fidelity to the brief, single-session intervention model [9]. While the model has improved mental health service access in New Zealand, the operational efficiency and potential for scalability of the IPMHA model are undermined by these service-delivery challenges.

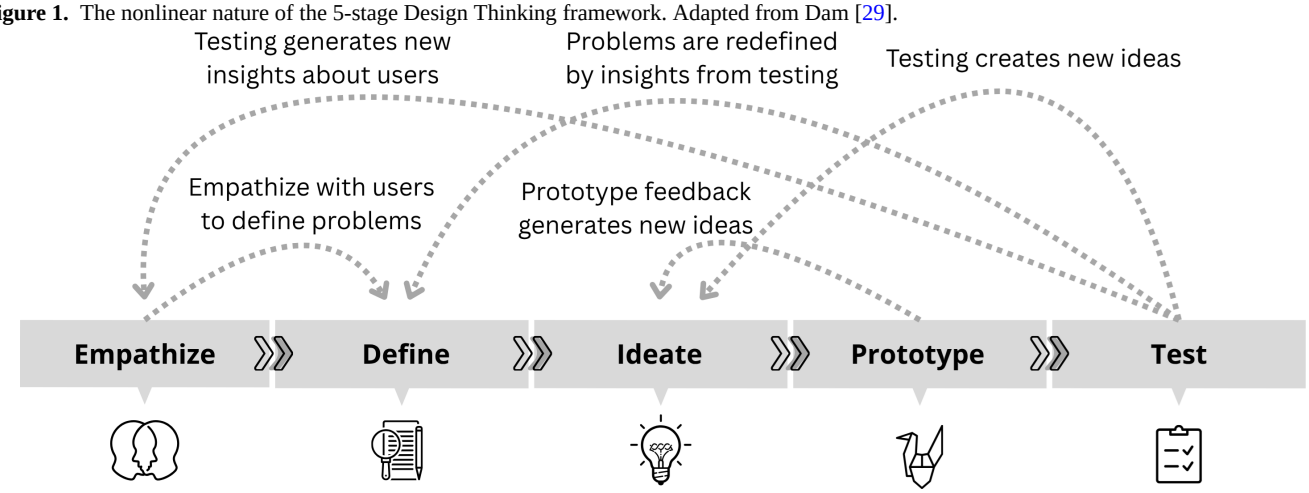
Digital mental health tools (DMHTs), from self-help apps to technologies that support practitioner-led care, are increasingly seen as a solution to the global mental health treatment gap [10,11]. Although commonly associated with self-guided therapy, the primary promise of these tools is their potential for integration into existing health care services [12-14]. Specifically, embedding a custom-designed digital tool within a service that faces delivery challenges, such as the IPMHA model, could enhance the service's effectiveness and scalability [9,10,15,16].

While digital tools can be effective alone, their impact is greatest when combined with practitioner support [10,11,14,17]. This suggests that digital mental health solutions should be viewed not only as a way to replace in-person services but also to augment them, thereby improving the efficiency and reach of existing, evidence-based, human-delivered care.

Despite the potential of digital mental health tools, real-world implementation is hindered by low adoption among practitioners [16,18-20]. Several recent systematic reviews show that clinicians are less likely to adopt tools that are difficult to use, increase workload, disrupt workflows, or are poorly integrated with existing organizational systems [18,20-23]. Rather than being conceptualized as stand-alone products, digital tools for integration into existing services should be designed as integral components of the service they are intended to support. Adopting a context-specific, user-centered software development methodology is necessary to ensure that these tools provide practical value while also integrating seamlessly into clinical workflows and organizational systems [10,13,15,16,24].

This study reports on the final phase of a larger research project that used the 5-stage Design Thinking framework [25,26] to develop a DMHT to enhance the IPMHA model. The Design Thinking methodology was selected for this project due to its iterative user-centered approach and proven efficacy in creating effective digital solutions for complex health care service-delivery problems [27,28].

The aim of this study was to evaluate the usability and acceptability of the software minimum viable product (MVP) developed through this process, with a focus on integration into existing primary care systems and workflows. Specifically, the study sought to evaluate the usefulness and usability of the software's features and to identify whether these features support practitioner adoption and effective integration into the IPMHA service-delivery context.



Methods

Research Design and Framework

This study reports on the Test stage of the 5-stage Design Thinking framework (Figure 1). The preceding 4 stages, described below, informed the development of the software MVP evaluated in this study.

XSL•FO
RenderX

Figure 1. The nonlinear nature of the 5-stage Design Thinking framework. Adapted from Dam [29].

1. Empathize: The project began with an exploration of HIPs' experiences working within the IPMHA model through interviews and a workforce survey. This process uncovered a variety of service-delivery challenges, many of which could be addressed by a purpose-built DMHT [30].
2. Define: Service delivery challenges identified during the Empathize stage were translated into user stories and problem statements, ensuring that the project remained focused on validated, contextually relevant, real-world problems.
3. Ideate: The research team generated a broad range of potential software solutions and features based on the problem statements synthesized during the Define stage.
4. Prototype: Software interface prototypes were developed from promising Ideate stage design concepts. Iterative feedback from HIPs and other IPMHA stakeholders shaped the evolution of low-fidelity pen-and-paper sketches into functional wireframe prototypes. The functional wireframes were created using the Figma software package [31]. The culmination of the Prototype stage was the development of a functional software MVP, built using the Flutter programming language [32] for use on an Android tablet.

The purpose of this software MVP was to address the various administrative and workflow challenges reported by HIPs and enhance the delivery of the brief fACT intervention package. To provide a general overview of the software MVP's functionality, Multimedia Appendices 2-4 present screenshots and interface flows for several key features. While this is not an exhaustive list of the software's functions, these examples highlight several core capabilities. Multimedia Appendix 2 depicts the user flow for starting a session, which includes selecting a client from the integrated electronic health record, reviewing prior session information, starting a new session, taking notes, and using a model fidelity support tool. Multimedia Appendix 3 details the creation of a wellness plan, and Multimedia Appendix 4 demonstrates the in-session experiential exercise feature.

Participants and Recruitment

Participants were HIPs working within the IPMHA model in New Zealand primary care clinics. All participants were employed by the same primary health organization (PHO) to ensure consistency in organizational systems and processes. HIPs were recruited through an electronic flyer distributed internally within the participating PHO. Detailed information outlining the study's purpose and procedures was provided to all prospective participants.

A total of 5 HIPs completed the usability interviews. Small-group user testing is considered appropriate for early-stage software evaluation with relatively homogeneous user groups, where the primary goal is to collect qualitative insights rather than achieve statistical validation. Feedback from 5 participants can uncover approximately 85% of major usability issues, as common problems typically become evident within the first few sessions, with additional participants offering diminishing returns [33-35]. Given the homogeneity of the target user group and the focused, deductive approach to data collection and analysis, small-group testing with 5 participants was deemed appropriate for this study.

Participants were eligible for inclusion in the study if they were aged 18 years or older, were able to provide informed consent, and were currently employed as an HIP within the participating PHO.

Data Collection

Data were collected through semistructured, one-on-one interviews designed to elicit in-depth feedback on the usability and perceived usefulness of the software MVP. All interviews were conducted in person by the primary investigator. Participants were informed that the interviews would take between 1 and 2 hours.

During the interview sessions, participants' interactions with the software MVP, running on a tablet device, were captured using the device's integrated screen recording functionality. This was synchronized with an audio recording of the interview to contextualize participants' comments about usability and usefulness in relation to their actions within the software. The average interview duration was 76 (SD 23.49) minutes, with sessions ranging from 49 to 117 minutes, meeting the recommended duration for a broad usability analysis [35].

Interview Procedure

The interview process was structured into 4 phases.

XSL•FO
RenderX

1. Preamble and software orientation: The interviewer introduced the participant to the overall software interface, guiding them through its key features. This phase aimed to familiarize participants with the software and to begin identifying any immediate usability issues. Participants were encouraged to verbalize their thoughts and observations while interacting with the software, following the think-aloud [36] data collection method.
2. Mock fACT session: Participants engaged in a role-play exercise in which they assumed the role of a clinician delivering a typical fACT session using the software. The interviewer acted as the client. Both parties were encouraged to remain "in character" as much as possible to simulate the intended clinical use of the software. Throughout the session, participants continued to verbalize their thoughts and critically reflect on the real-world usability and relevance of different software features.
3. Final think-aloud exploration: Following the mock session, participants were invited to freely navigate the software, revisit specific features, and reflect on their experiences. They were encouraged to comment on the ease of use, functionality, and integration of the software within their existing workflow and organizational processes.
4. Blue-sky brainstorming: The interview concluded with an open-ended brainstorming session, during which participants were invited to share any additional thoughts or suggestions about the software. They were encouraged to propose ideas for new features, suggest modifications to existing features, explore how various features could be integrated within their workflows, and reflect on which features would be essential for addressing service delivery challenges and leading to sustainable engagement with the software.

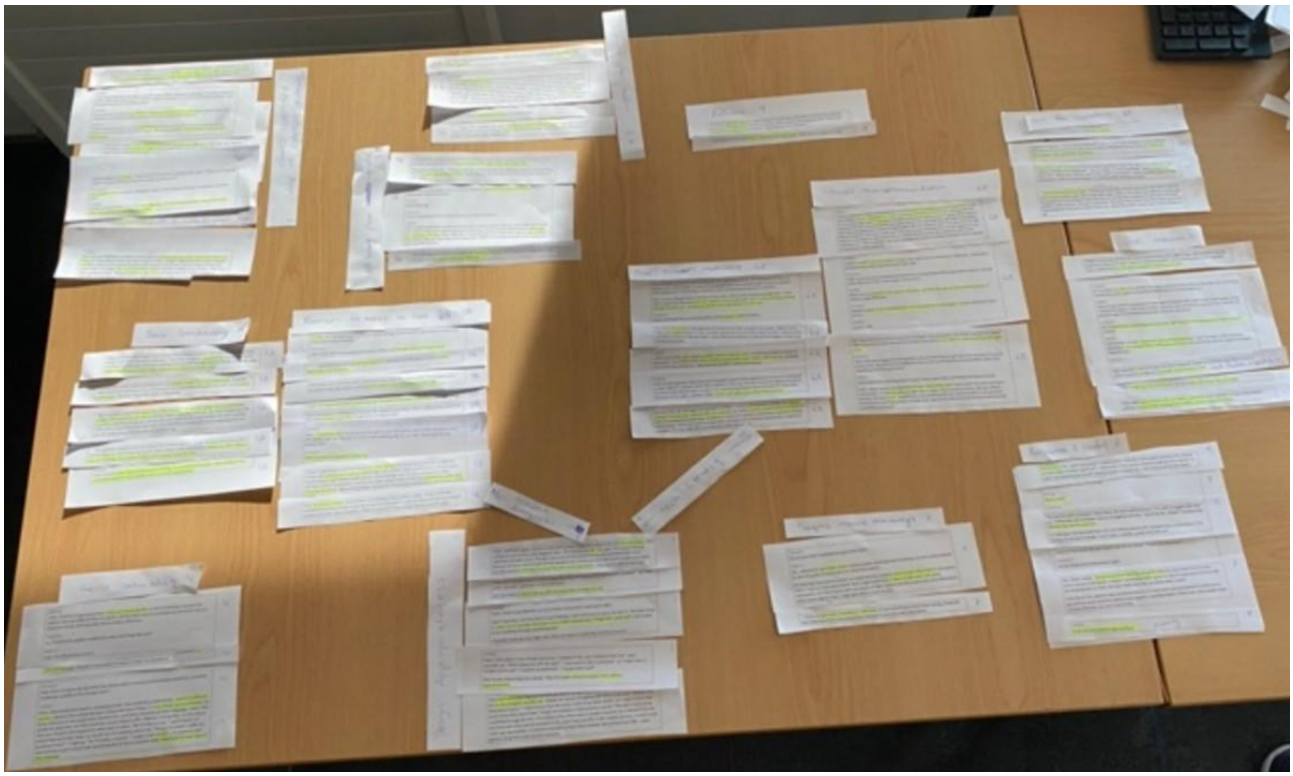
Figure 2 shows the setting for the usability interviews. The participant (substituted here with an actor) is engaging with the software via a tablet and keyboard. The interviewer, who also acted as the "client" during the mock fACT session, sat across from the participant to simulate the clinical context of how the software would likely be used.

During the mock fACT session portion of the interview, participants were instructed to conduct a typical session as they would with a regular client, using the software MVP where appropriate to supplement their standard workflow. This involved the participant using the software to load a client (played by the interviewer) from a simulated clinic database, review client data, take clinical notes, use experiential exercises, create a wellness plan, and commit all notes and session data to a simulated integrated electronic health record upon conclusion.

Figure 2. Recreation of the interview setting, showing how the participant engaged with the software minimum viable product (MVP) in a simulated clinical context.

Data Analysis

The data analysis methodology chosen for this study was affinity diagramming [37], a qualitative technique commonly used in software development and user experience design [38]. This approach allowed for the systematic exploration of participant feedback concerning the usability and acceptability of the software MVP, particularly in relation to the usefulness, importance, and workflow integration potential of the various software features. The analysis began with a thorough reading of the interview transcripts to gain a high-level overview of the dataset. Each transcript was reviewed alongside the



XSL•FO
RenderX

synchronized screen recordings showing participant engagement with the software. Viewing the screen capture alongside participant feedback facilitated a deep understanding of the context surrounding participants' comments, linking their verbal feedback directly to their interactions with the software.

The data collection process was structured to elicit feedback on specific features of the software, and the software feature set was used as the initial deductive framework for organizing the data. This iterative process involved sorting the interview data into different feature categories and coding relevant interview excerpts (codes) within each category. This included the creation of new categories for any emergent feature-related themes that were identified through the initial reading of the transcripts.

Once the data were categorized and coded, each feature category within the framework was independently analyzed using affinity diagramming to visually organize and group related codes (Figure 3). Related interview excerpts, now represented by these codes, were clustered together into "affinities" These clusters represented overarching themes related to that specific feature. After clustering the codes, each cluster was examined to identify the underlying theme or key message, providing a higher-level summary of user feedback for each feature.

Figure 3. Collaborative affinity diagramming using interview transcript excerpts.

Following the initial feature-driven analysis, an additional analysis of the entire dataset was conducted using the same affinity diagramming methodology. The objective was to identify which features or overall functionalities of the software HIPs identified as being the most important for facilitating effective implementation into workflows and supporting sustained long-term engagement with the software.

The construction of the feature-driven framework, refinement of that framework, transcript coding, and subsequent theme identification were conducted collaboratively by the principal researcher (VA) and a trained research assistant. The Nvivo-14 software package assisted with data organization and tracking, whereas printed copies of the transcripts were used for performing the collaborative affinity diagramming activities.

Collectively, these analyses sought to answer key questions regarding the usefulness of specific features and functionalities, the perceived importance of those features and functionalities, and the potential for integration into the HIP workflows and broader organizational systems. The findings are detailed in the *Results* section, providing a comprehensive understanding of the software MVP's usability and acceptability from the perspective of its intended users.

Ethical Considerations

This study was approved by the Auckland Health Research Ethics Committee (reference AH21908). Informed consent was obtained from all participants. Participants received a voucher valued at $50 NZD (US $29.50) for each hour of interview time. During the transcription process, any information relating to participant identity was removed, with a unique participant identifier code assigned to each interview script to ensure confidentiality.

Results

Critical Features and Functionalities to Support Practitioner Adoption and Workflow Integration

A primary goal of this research was to identify which software features HIPs deemed most important for successfully integrating the tool into their workflows. This subject was a central focus during the usability interviews. The functionalities

XSL•FO
RenderX

that HIPs specified as necessary to support the adoption and effective implementation of the software MVP are detailed in Textbox 1 and elaborated upon in the description that follows.

Participants indicated that their willingness to adopt the software is contingent on its ability to solve existing service-delivery problems and demonstrably reduce their workload. If the tool fails to do this, it will likely be treated as an optional accessory rather than an integral part of their workflow.

The most critical area identified for workflow improvement was the reduction in administrative burden. Key areas included reducing double-handling of data, automating psychometric collection and scoring, and streamlining the process for sharing resources with clients. HIPs reported that these administrative frustrations were compounded by broader IT issues. They described frustrations in dealing with workflow friction caused by software incompatibilities, the need to switch between different devices, and managing multiple logins for various systems. A key benefit of the new software, they emphasized, is its ability to eliminate these technical hurdles.

Textbox 1. Features and functionalities necessary to support implementation of the software.

1. Administrative optimization and time-saving
2. Seamless integration with existing practice management software
3. Solving IT and workflow frustrations
4. Must solve problems and reduce workload, not add tasks to an already busy workflow

To solve these interconnected issues, participants consistently stated that seamless integration with existing clinic patient management software was essential. They expressed a strong need for the software to automatically synchronize data, which would minimize manual data entry and ensure a smooth, unified workflow. This was seen as particularly important for practitioners who work across different clinics and PHOs. Ultimately, HIPs indicated that without a high level of systems integration to solve their core administrative and IT problems, they would be unlikely to use the software.

Usability and Usefulness of Specific Software Features

Participant feedback on specific features is presented in Table 1, organized by software feature or functionality. Feedback included feature validation, constructive critiques, and suggestions for modification. The summary in Table 1 is elaborated upon in the subsequent descriptions, and a detailed point-by-point breakdown is available in Multimedia Appendix 5.

XSL•FO
RenderX

Table . Practitioner feedback on specific features and overarching functionalities of the software minimum viable product (MVP).

Software feature	Feature validation	Critique and change requests
Experiential exercises and recordings.	• Useful for early career and fatigued HIPs[a]. • They are well suited for brief sessions. • Easy to integrate into existing workflow.	• Additional customizability for different client needs. • Adding visual elements may improve engagement with recordings.
Love Work Play Health tool.	• Enhances model fidelity. • Provides a useful reminder for early career HIPs.	• The design should encourage flexible use.
Model fidelity checklist.	• Enhances model fidelity. • Useful for both novice and experienced HIPs.	• Would benefit from key information being more accessible. • Would benefit from better integration into workflow.
Session history review.	• Improved efficiency compared to clinic electronic health record. • Provides easy access to patient-specific information and reminders.	—[b]
Automation of external data reporting.	• Reduces double-handling of data. • Automating psychometric scoring and reporting. • Structuring notes to align with reporting needs.	—
Psychometric recording and analysis.	• Expanding psychometric options for clinical use. • Enhancing psychometric administration in session. • Improving workflow and integration with note-taking.	—
Psychometric review.	• Visualizing change over time. • Supporting client conversations.	—
Session timer.	• Time management and session flow.	—
Values elicitation and recording.	—	• Efficiency and collaboration. • Language and accessibility issues. • Integration with contextual interview and note-taking.
Wellness plan creation.	—	• Wellness plan creation should be flexible. • Terminology concerns. • Usability and interface design. • Inclusion of a support person.
Clinical note and session data recording.	• Reducing administrative burden.	• Integrating note-taking with model fidelity tools and overall session flow. • Improving access to notes and supporting personal reflections. • Automating data recording and reporting.
Integration of the software with existing clinic IT systems.	• Integration with clinic patient management software is essential. • Reducing administrative burden and double-handling of data. • IT simplification across clinics and PHOs[c]. • Supporting model fidelity and reliable data collection.	• Securely and efficiently sharing resources with clients. • Ensuring data security and clinic buy-in.

XSL•FO
RenderX

Software feature	Feature validation	Critique and change requests
Postsession support for clients.	• Providing clients with session takeaways. • Collecting postsession outcome data.	• Balance between ongoing support and managing HIP workload. • Personalizing and adding value to session summaries. • Overcoming administrative challenges. • Format of takeaway resources must be flexible around client needs.

[a]HIP: health improvement practitioner.

[b]Not applicable.

[c]PHO: primary health organization.

Experiential Exercises and Recordings

Participants felt that having a library of prerecorded experiential exercises was a valuable asset, particularly for early-career or fatigued HIPs who might need support in delivering them consistently. The shorter exercises, such as mindful breathing, were seen as especially well suited for the brief intervention model. HIPs appreciated that having these resources integrated directly into the software was more efficient than searching for content online. Furthermore, the ability to use editable scripts allowed for customization in pacing and duration to better meet individual client needs, such as during moments of panic. To further improve client engagement, participants suggested adding visual elements or animations to the recordings and valued the ability to send recommended exercises to clients as part of a session summary.

Love Work Play Health Tool

The Love Work Play Health tool was seen as a valuable feature for enhancing fidelity to the fACT model. Participants reported that it provides a structured guide to ensure a thorough contextual interview is conducted, prompting HIPs to explore key life domains and client values. This was considered particularly useful as a reminder for newer practitioners. However, HIPs stressed the importance of flexibility, noting that it would be impractical to ask every prompt in a single session. They recommended including guidance that clarifies the tool is a flexible aid rather than a rigid script to be followed verbatim.

Model Fidelity Checklist

Participants indicated that a digital Model Fidelity Checklist was a practical tool for ensuring correct fACT delivery, serving as a step-by-step guide for novices and a helpful refresher for more experienced HIPs. Many practitioners already use printed reference materials, so integrating a digital checklist directly into the session workflow, for instance, within a note-taking template, was seen as a significant improvement. To enhance usability, participants suggested making key information more accessible through on-screen prompts or expandable info buttons. They also proposed that embedding the checklist directly into the session notes would encourage its active use and could even help streamline external data reporting.

Session History Review

The ability to easily review a client's session history was highlighted as a significant efficiency gain. Participants described the current process of reviewing past notes in clinic patient management software as slow and cumbersome. The proposed feature, which collates previous session notes, allowed HIPs to quickly prepare for appointments, access important client-specific information, and recall personal details that aid in building rapport. Moreover, HIPs often leave themselves reminders in session notes, and easy access to this history would ensure important follow-up tasks are not overlooked.

Automation of External Data Reporting

Automating external data reporting was considered an essential time-saving feature by participants. They expressed significant frustration with the "double-handling" of data, where they must reenter the same information for both clinical notes and separate reporting systems. The software's ability to capture information once and automatically transmit it was seen as a key function that would significantly reduce administrative workload. Likewise, automating the scoring and reporting of psychometric measures would not only save time but also improve model fidelity. Participants suggested that structuring note-taking templates to align with reporting requirements would further streamline this process.

Psychometric Recording and Analysis

Participants appreciated the software's flexibility in offering a range of psychometric tools beyond the 2 mandated ones, noting that practitioners often use other measures, such as the 10-item Kessler Psychological Distress Scale Kessler-10 or 9-item Patient Health Questionnaire, which are more familiar to referring physicians. The ability to administer these assessments collaboratively, either by reading them aloud or having clients complete them, was valued, and the automatic scoring feature was seen as a major time-saver that allows for the immediate discussion of results in-session. HIPs also stressed the need for a seamless workflow, allowing them to pause an assessment to explore a client's response and skip questions if necessary.

Psychometric Review

The ability to visually track a client's psychometric scores over time was viewed as a highly valuable feature. Participants explained that seeing these changes at a glance helps them monitor progress and identify areas needing further attention. They also noted that presenting these data visually on a single

XSL•FO
RenderX

screen would significantly improve their workflow when reviewing results with clients. This direct comparison of past and present scores facilitates meaningful conversations about progress and helps collaboratively identify new goals.

Session Timer

A session timer was seen as a simple but effective tool for managing session flow and adhering to tight schedules. Participants noted that having a visible timer benefits both the practitioner and the client. For the HIP, it ensures all components of the fACT model can be covered without feeling rushed. For the client, being able to view the remaining session time during collaborative tasks could help maintain focus.

Values Elicitation and Recording

Participants highlighted the need for a more efficient and accessible way to elicit client values, as traditional methods, such as card sorts, can be time-consuming. They suggested that the term "values" can be confusing for clients and recommended using simpler, more relatable language, such as asking, "What is important to you?" While values often emerge naturally during the contextual interview, HIPs expressed a desire for a designated, collaborative space within the software to seamlessly record them as they are identified.

Wellness Plan Creation

Flexibility was the key theme for feedback on the wellness plan feature. Participants emphasized that creating a plan should accommodate diverse client needs, with optional fields for elements, such as start dates or reminders. They also raised concerns about terminology, suggesting that words such as "likeliness" or "confidence" are more suitable than "willingness," and "support person" is preferable to the informal term "buddy." From a usability perspective, they recommended a more user-friendly interface for setting dates and frequencies. The ability to include a support person was seen as beneficial for client accountability, but it was stressed that clear information about data privacy is essential. Finally, providing a printable summary is crucial for clients who may not engage with digital resources.

Clinical Note and Session Data Recording

The primary value of this feature lies in its potential to significantly reduce administrative burden. Participants emphasized that eliminating the "double-handling" of data by entering notes once and having them automatically sync with the clinic's patient management software was a critical function. They also desired a workflow where fidelity tools are integrated directly into the note-taking process, using structured templates that mirror the natural progression of a session. Quick access to past notes, a separate space for personal reflections, and the ability to attach nontext materials were also identified as valuable enhancements. To ensure proper data management, participants suggested reminders for obtaining client consent and automatic submission of draft notes after a set period to prevent lost records.

Integration of the Software With Existing Clinic IT Systems

Across all interviews, seamless integration with existing clinic IT systems, particularly with patient management software, was identified as an essential, nonnegotiable requirement for adoption. Participants stated that the software must solve current administrative problems, not create new ones. By automating data entry, synchronizing notes and psychometrics, and reducing the "IT friction" of multiple logins and incompatible systems, the software would significantly reduce workload and improve job satisfaction. This integration is key to ensuring consistent data collection and allowing HIPs to securely and efficiently share resources with clients.

Postsession Support for Clients

Participants valued the software's ability to extend support beyond the session. They highlighted the importance of providing clients with tangible takeaways, such as wellness plans and experiential exercises, in a format that suits their needs, whether digitally via email or as a printed hard copy. The ability to personalize these summaries with key insights or links to external resources was seen as a way to enhance client engagement. While collecting postsession outcome data via a client-facing app was considered useful, HIPs cautioned that a balance must be struck to avoid overwhelming clients with excessive notifications. Streamlining the process of sending these resources was seen as a key benefit that could overcome common administrative challenges within clinic settings.

Discussion

Principal Results

The key objectives of this study were to evaluate the usability and acceptability of the software MVP and identify which features and functionalities were critical for facilitating effective integration into the IPMHA service-delivery context. The analysis revealed 2 nonnegotiable prerequisites for the software's adoption into HIP workflows: significant administrative optimization and seamless integration with existing IT systems. Participants' willingness to use the tool was primarily contingent on its ability to reduce their workload by automating tasks, such as note-taking, data reporting, and psychometric scoring. This need for efficiency was directly linked to the second prerequisite: robust integration with existing patient management software to synchronize data, eliminate duplicate entry, and resolve workflow friction. Without these foundational capabilities, participants indicated the software would likely be viewed as a workload-increasing add-on rather than an integral component of their clinical practice.

Beyond the overarching need for efficiency and integration, several individual features were highlighted for their potential benefits. The inclusion of experiential exercise recordings was seen as a valuable resource, particularly for newer or fatigued HIPs. The Love Work Play Health and model fidelity checklist tools were acknowledged for their potential to support HIPs with in-session training, promote adherence to the fACT model, and reinforce best practices in session delivery. The session history review feature was praised for offering a more efficient

XSL•FO
RenderX

way to access information from previous client interactions. Finally, the psychometric recording and analysis tools were appreciated for expanding the available assessment options and streamlining their administration within sessions.

These findings highlight that a successful digital tool designed to support HIPs working within the IPMHA model must not only offer features to assist with clinical practice but also seamlessly integrate with existing systems and significantly reduce the administrative burden for HIPs. Effectively addressing these administrative optimization challenges will likely be the primary determinant of practitioner engagement, sustained use, and the tool's impact on IPMHA model scalability.

Implications for Design

The feedback from HIPs regarding the importance of administrative optimization and seamless workflow integration led to a redesign of the software's backend as well as several interface changes. These changes were informed by specific usability feedback. For instance, the call for better integration of clinical note-taking with other in-session tools prompted the redesign of the note-taking tool to create a more unified workflow that matched the clinical note format typically used in primary care services. Other notable changes included a dedicated resource upload feature to facilitate sending PDFs and worksheets to clients. HIPs also stressed that they needed to retain the ability to easily print resources for less-tech-capable clients, which prompted the integration of one-click print functionality for the experiential exercise scripts, wellness plan summaries, and session summaries. Most of the model fidelity and fACT support tools were retained in the same format, with minor changes in response to feedback—for example, the addition of a "support person summary screen" in the wellness plan to enhance transparency regarding what information would be shared.

It is important to view these design changes not as a final step but as part of the ongoing iterative Design Thinking process. Our team is now applying feedback from the usability study to refine the software for clinical implementation. Most of the requested features involve backend modifications to ensure seamless integration with existing clinical systems, requiring only minor changes to the user interface. These backend updates will be incorporated into our next MVP, which will then be tested in a clinical implementation trial to validate its effectiveness and acceptability in a real-world primary care setting.

Strengths and Limitations

This study has several key strengths. The methodological approach, combining semistructured interviews with a think-aloud protocol and a mock fACT session, yielded rich, in-depth qualitative data. This captured both high-level reflections on the software's features and direct, in-the-moment usability feedback. A particular strength of this study was its use of a simulated clinical environment. Having the participant actively use the software MVP in a realistic service-delivery context helped uncover usability issues that are often missed by less hands-on methods, such as simple feature walkthrough interviews or focus groups. Furthermore, this study demonstrates the usefulness of rapid, small-sample usability testing in generating rich and actionable insights, highlighting the efficiency of this low-resource approach for iterative development cycles.

By focusing on a homogeneous user group (HIPs from a single PHO), we controlled for organizational variables. This approach provided a clearer understanding of the software's usability in a specific service context and generated actionable data to guide the MVP's iterative development for use with this specific group of prospective users.

However, the study also has notable limitations. The most significant limitation is that the usability analysis was not based on real-world clinical usage of the software. Consequently, the findings reflect practitioners' perceived usability and anticipated usefulness based on a simulated clinical environment, which may not fully correspond to their experiences during actual, day-to-day clinical practice. The small sample size of 5, while appropriate for uncovering major usability issues, limits the generalizability of these findings. Similarly, the recruitment of participants from a single PHO implies that the results may not be generalizable to HIPs working in different organizational or geographical contexts. Finally, there is a potential for social desirability bias, as participants may have been inclined to provide positive feedback to the interviewer, who was also the primary investigator involved in the development of the software.

Comparisons With Prior Research

To situate the findings of this study within the broader academic literature, we compared the software features and functionalities prioritized by HIPs against the key barriers to practitioner digital adoption identified in prior research. A comprehensive synthesis of 6 major systematic reviews [10,18,19,21-23] reveals a variety of common practitioner digital adoption barriers. Across different health care contexts, a core set of three challenges consistently emerges: (1) the fear that digital tools will increase practitioner workload and disrupt workflows; (2) inadequate training and support with digital tools; and (3) concerns regarding data privacy and security.

The most significant theme to emerge from our study, the demand for administrative optimization, strongly validates what the literature identifies as the most significant adoption barrier: the fear that digital tools will increase practitioner workload [10,18,23,24]. HIPs stated that their adoption of the software hinges on its ability to "solve problems and reduce workload, not add tasks to an already busy workflow." Specifically, participants valued features that automate clinical notes and data reporting to eliminate the "double-handling" of data, as well as those that automate psychometric scoring to save time. These findings confirm that for IPMHA practitioners, like many other health care professionals, adoption depends on a digital tool demonstrably reducing, rather than increasing, their existing administrative burden.

A common workload-related adoption barrier identified in the literature is system interoperability [10,16,18,19,22,24]. Our second key finding, the necessity of seamless integration with

XSL•FO
RenderX

existing practice management software, directly addresses the well-documented barrier of poor system interoperability. HIPs were unequivocal that without robust integration, the software would likely remain unused because it would create, rather than solve, administrative problems. This desire for a high level of interoperability was also reflected in their wish for the DMHT to solve common "IT and workflow frustrations," such as managing multiple logins and system incompatibilities. These findings confirm that, similar to other digital tools designed for health care implementation [39,40], a DMHT's value is contingent not on its clinical features alone, but on its ability to integrate seamlessly into existing workflows and organizational systems.

Beyond these primary themes, participants' concerns also echoed other established barriers. The frustrations HIPs expressed with workflow issues are symptomatic of an environment lacking integrated support systems, aligning with the consensus that effective adoption requires continuous, context-specific training and readily available technical support. Furthermore, the core barrier of privacy and security was also present in our findings. HIPs stressed the importance of "ensuring data security and clinic buy-in" and designing the system with low-risk data handling as a primary consideration. This concern extended to client-facing features, with HIPs noting the importance of clarifying what information a "support person" could access. This confirms that even when a tool offers clear workflow benefits, adoption will be hindered if it does not first establish a foundation of trust and security for both practitioners and the clients they serve.

Interestingly, whereas prior research focusing on mental health tools has highlighted a fear that technology could depersonalize the therapeutic relationship [10,18], our findings reveal a more nuanced perspective from the IPMHA workforce. Participants identified several ways the software could enhance rather than detract from relational aspects of care. For instance, the Session History Review feature was valued for enabling HIPs to recall personal client details to build rapport in subsequent sessions. Likewise, psychometric tools were seen not as impersonal data collection exercises but as a way to facilitate collaborative conversations with clients about their progress. This suggests that for this workforce, when a tool is designed to support, rather than replace, clinical judgment and interaction, it can be perceived as an asset to the therapeutic alliance.

In conclusion, the findings from this study strongly validate well-established evidence from the broader literature. The primary concerns voiced by HIPs—the fear of increased administrative burden and the absolute necessity of seamless workflow and patient management software integration—directly mirror the complex, sociotechnical barriers to digital tool adoption consistently reported across various other health care contexts. This underscores a crucial takeaway: the path to successful implementation of DMHTs is paved by solving the pragmatic, operational challenges that practitioners face. For a digital tool to be adopted by the IPMHA workforce, its value must be demonstrated through its ability to function as a trusted, efficient, and well-integrated component of the complex clinical environment it seeks to support.

Conclusions and Implications for Future Research

The central message from this study is that, for a digital tool to be adopted by HIPs, its clinical use is secondary to its ability to solve their most pressing administrative and workflow challenges. While clinical support features were valued, they are not the drivers of adoption. Instead, practitioners require a tool that functions as a practical and efficient component of their daily practice, capable of reducing their administrative load through task automation and seamless integration with existing patient management software. These findings suggest that the successful implementation of any DMHT in this context is contingent on its capacity to address the foundational, operational realities of primary care service delivery.

These findings illustrate the value of collaborative and user-centered research methodologies for DMHT development. By grounding the overarching research project in the lived experience of HIPs through a user- and context-centered design framework, this study was able to uncover the true determinants of digital adoption for this group of practitioners. A traditional, top-down, researcher-led approach to digital tool development, which might prioritize theoretical clinical advancements or novel functionalities, would have been at high risk of missing the pragmatic, foundational needs of the end users. Without this direct engagement with end users, the importance of the DMHT in solving administrative and workflow frustrations could have easily been overlooked, leading to the development of a tool that, while perhaps innovative, would ultimately fail to gain traction in the demanding environment of primary care. This underscores that for digital mental health tools to be effective and engaging, their development must be driven by the actual, expressed needs of the people who will be using them.

The findings of this study provide valuable early-stage validation of the required software features and functionalities that a DMHT must possess to effectively support IPMHA practitioners operating within New Zealand primary care. Now that the proposed feature set has been validated, future research will focus on further refinement of the software MVP into a clinically implementable DMHT. This development will prioritize the core administrative and workflow features that were validated in this study, with a particular focus on robust patient management software integration and the automation of practitioner data management tasks. A clinical implementation trial will be conducted in which IPMHA practitioners use the DMHT in their daily practice. The purpose of this trial will be to investigate the tool's impact on administrative efficiency, assess its usability and feasibility in a live clinical environment, and determine its efficacy in improving client outcomes and enhancing the overall scalability of the IPMHA model.

Funding

This work was supported by the Ember Korowai Takitini Mental Health and Addiction Innovation Grant and the Health Research Council New Zealand Health Delivery Research Activation Grant. No generative artificial intelligence tools were used in the preparation of this manuscript.

Data Availability

The qualitative interview data are not publicly available to protect participant privacy. Aggregated data supporting the findings are available from the corresponding author upon reasonable request.

Authors' Contributions

Conceptualization: VA, KS, DL
Data curation: VA
Formal analysis: VA
Investigation: VA
Project administration: VA
Resources: VA
Supervision: KS, DL
Writing – original draft: VA
Writing – review and editing: VA, KS, DL
All authors have read and agreed to the published version of the manuscript.
KS and DL contributed equally to this work as senior authors.

Conflicts of Interest

VA has a financial interest in Lighthouse Healthtech (a social enterprise company) created to develop and implement the digital tool referenced in this research paper. The other authors declare no conflicts of interest.

Multimedia Appendix 1
Structure of a focused acceptance and commitment therapy (fACT) session.
[DOCX File, 16 KB - humanfactors_v13i1e84412_app1.docx]

Multimedia Appendix 2
Screenshots of the software minimum viable product (MVP) interface showing electronic health record integration and client selection, session and psychometric review, session start, focused acceptance and commitment therapy (fACT)–specific clinical conversation prompts, and the clinical notepad.
[PNG File, 1159 KB - humanfactors_v13i1e84412_app2.png]

Multimedia Appendix 3
Screenshots of the software minimum viable product (MVP) interface showing wellness plan creation, including setting automated plan reminders for the client.
[PNG File, 1155 KB - humanfactors_v13i1e84412_app3.png]

Multimedia Appendix 4
Screenshots of the software minimum viable product (MVP) interface showing in-session experiential exercise feature, including voice actor selection, and the exercise script view.
[PNG File, 1129 KB - humanfactors_v13i1e84412_app4.png]

Multimedia Appendix 5
Detailed feature-specific user feedback.
[DOCX File, 3780 KB - humanfactors_v13i1e84412_app5.docx]
